therefore income reported at the top. Hence, the increase in inequality may be due to a reduction in tax avoidance because of lower tax rates for richer groups.[50] Indeed, Figure 8.21 shows how the top marginal tax rates changed over time for the sample of countries under investigation, highlighting a clear overall reduction in tax progressivity over time.

However, several researchers have devoted substantial attention to this aspect and pointed out that differences in levels across countries and the upward trend in income inequality observed in many countries are substantially robust, real phenomena rather than spurious results merely driven by tax avoidance and tax evasion (Alvaredo, 2010; Alvaredo and Saez, 2009; Banerjee and Piketty, 2005; Leigh, 2009; Leigh and van der Eng, 2009; Moriguchi and Saez, 2008; Roine and Waldenström, 2008).

First, as reported by Leigh (2009), the evidence suggests that income underreporting (the size of the tax gap) does not substantially vary across countries, whereas tax regimes vary dramatically. In addition, the extent of tax avoidance (and the scope for evasion) at the very top of the income distribution may not necessarily be higher than that for the rest of the distribution given the public visibility of their sources of income and the efficient enforcement efforts of tax authorities (Alvaredo, 2010; Alvaredo and Saez, 2009; Leigh and van der Eng, 2009).

Second, despite the reduction in tax progressivity, one can argue that there is little evidence to suggest that the extent of tax avoidance among the richest households has changed substantially over time, at least for countries with relatively high tax compliance[51] (see Internal Revenue Service, 1996, 2006 for evidence on the United States; Roine and Waldenström, 2008[52] for Sweden). In addition, even if this was not the case, the extent of avoidance (and evasion) at the top should have decreased much more than that of the rest of the population to exert an overall positive influence on the top shares.[53]

Third, the country-specific top wage shares often closely follow the evolution of the overall top income shares. These results are inconsistent with the assumption that the evolution of inequality is entirely captured by the time-varying tax avoidance and evasion. Indeed, the tax on wages and salaries—compared with farm income or business income—is usually withheld at the source so that it is almost impossible to escape the tax authorities' purview (Alvaredo, 2010; Banerjee and Piketty, 2005; Moriguchi and Saez, 2008).

[50] This case is made by Reynolds (2007) for the United States.

[51] This might be because government and tax authorities already had strong incentive and capability to enforce tax regulations in place when overall marginal rates at the top began to be reduced. Nonetheless, no evidence is available for countries outside the United States and Sweden, and any further generalization is not prudent.

[52] The authors suggest that it is possible that both the incentive of top individuals to underreport and the benefit and ability to monitor tax compliance by tax administration went up contemporaneously.

[53] A similar argument is used by Williamson and Lindert (1980).

Finally, Piketty et al. (2012) developed and tested a model linking the increase in top income shares to reduced tax progressivity, mainly through three motivations: increase in hours of work supplied (e.g., supply-side theory), increased rent-seeking activity (e.g., a top executive has control of salaries has more incentive to influence remuneration and seize a greater share of the firm profits), and decreased tax avoidance. However, the elasticity of reported income to change in tax rates due to tax avoidance is considered the least important factor. Indeed, Piketty et al. also point out that there are countries (such as Italy, Japan, Sweden, and the Netherlands) that experienced only modest increases in top shares despite significant top rate tax cuts of similar magnitude to those implemented in Norway, Finland, and all advanced English-speaking countries.

In sum, there is little evidence to suggest that tax avoidance in relation to decreases in top marginal tax rates is a particularly relevant explanatory factor of the long-run surge in top income shares. Nonetheless, other types of changes in taxation regulations may well have a substantial impact on top shares. Below, we differentiate between those changes bringing about permanent shifts in income or temporary behavioral responses.

Both theory and empirical evidence highlight how tax avoidance (especially income shifting over time or across the tax base) can be of great relevance for short-term changes in reported income to exploit tax opportunities (Saez et al., 2012 provide a comprehensive survey of this literature as well as interesting empirical findings). The classic example discussed within the top incomes literature is the Tax Reform Act (TRA) of 1986, which, among other things, dramatically decreased the top marginal tax rate on personal income, increased the capital gains tax rate, and, while lowering it, set the corporate income tax rate at a level higher than the top personal income tax rate. These policy changes provided strong incentive for agents to realize capital gains in the short term and to shift income from corporate to personal income (Gordon and Slemrod, 2000; Slemrod, 1996). It is worth noting that the shifting of business income from the corporate tax base to the individual tax base has brought about a permanent level shift for the top income shares in the United States (if excluding capital gains). Following these legal changes, the highest fractile share in total U.S. income (top 0.01%) increased by 30% from 1986 to 1987 (a year of a stock market crash) and by 53% from 1987 to 1988 (when a systemic banking crisis hit). However, as argued by Atkinson et al. (2011), the taxation policy change did not affect the series including capital gains[54] because "before TRA 1986, small corporations retained earnings and profits accrued to shareholders as capital gains eventually realized and reported on individual tax returns. Therefore, income including capital gains does not display a discontinuity around TRA 1986" (note to Figure 8.5). Similarly, the changes in taxation do not seem to have influenced the long-run trend of the shares.

[54] The only documented effect was an artificial spike in capital gains realizations in 1986 in anticipation of the announced increase in tax rate that took place in 1987.

There are also other less-discussed examples that may illustrate the full range of changes (and their complexity) in tax statistics and that we ought to take into account. For example, a substantial reduction of marginal tax rates on dividends was obtained in Australia in 1987 through the introduction of the full-imputation system (before the income from dividends was subjected to both corporate and income taxation).[55] Atkinson and Leigh (2007) note that "the effect of the introduction of imputation in Australia in 1987 is evident in the statistics." Indeed, the taxation regime change was announced in 1985 and had a short-term impact on dividend distribution once the law was passed in 1987, consistent with optimal retiming of income reporting. Moreover, it is also possible that the substantial reduction of the marginal tax rate on dividends may have induced more firms to distribute a greater share of their profits (changing the level of the shares).[56]

A switch to a full-imputation system in 1993 had a long-lasting impact on the composition of top income shares in Finland (as documented by Jäntti et al., 2010).[57] A similar change was documented for New Zealand in 1989. However, in the same year, a tax cut to take place in 1990 was announced (the top individual rate would have been reduced to the company tax rate), causing companies to postpone their payment to top executives. Moreover, "similar anticipation of tax changes is likely to have caused the sharp spike in top income shares is observed in 1998–99, and may have caused the 2000 figure to be depressed," as discussed by Atkinson and Leigh (2005).[58] Similarly, in 2005 Norway announced a permanent increase in dividend tax (to be increased in 2006); this marked

[55] The Australian dividends tax reform in 1987 increased the corporate profits tax rate from 46% to 49%, equalizing it to the top income marginal tax rate. However, as noted by Burkhauser et al. (2013), "under the new 100 per cent imputation tax system contained in the reform legislation, these company taxes effectively became withholding taxes. This was the case since their payment could be used to offset personal income tax on dividends as well as other taxes."

[56] It is nonetheless important to note that, as argued in recent work by Burkhauser et al. (2013), the changes in taxation regime also have brought about substantial permanent effects on reported income within top income brackets, although not through taxation avoidance. The previous section discussed how the taxation reform expanded the personal income tax base through the inclusion of dividends and capital gains (possibly more gradually), which were previously unreported. Once these issues are appropriately taken into account, the real increasing trend of Australian top shares is slightly downsized, especially using the series including capital gains. Indeed, as discussed earlier, it may be possible that the inclusion of capital gains within the personal tax base was only gradually increasing over time given the specific prescriptions of the taxation reform.

[57] The introduction of a dual taxation system that favored capital income promoted the surge of dividends income at the expense of entrepreneurial income.

[58] The authors go on to state that when the government announced in 1998 that "the marginal tax rate on earnings over $60,000 would be raised from 33 percent to 39 percent in the 2000 tax year, many taxpayers took the opportunity to realise business earnings in the 1999 tax year, significantly boosting top income shares in that year, and perhaps to a lesser extent also in the 1998 tax year."

a notable peak in top income shares as individuals and corporations shifted income over time to avoid the impending rate increase (Aaberge and Atkinson, 2008).[59]

8.4.2.2.5 Definition of Tax Units

Different country-specific series are based on different definitions of tax units. In some countries the unit of reference is the family (e.g., typically spouses with dependents or singles with no dependents). This is the case for the United States and most continental European countries. Other countries define their tax units based on individuals. This is the case, for example, for Australia, Canada, New Zealand, Japan, India, Italy, and Spain.[60]

Most important, some countries have experienced a change in the tax base as the taxation system moved from a family to an individual base. Fortunately, however, only the United Kingdom experienced such a shift within the period under analysis (the shift occurred in 1990).[61] Such a change in tax units can create comparison problems for at least two reasons.[62]

First, the level of top shares is affected and the direction and magnitude of such a change depends respectively on the joint distribution of income within families populating the top income brackets and on the actual proportional difference between the number of individuals and the number of tax units as well as on the specific assumption about the Pareto coefficient.[63] As discussed by Atkinson et al. (2011), if the income for the richest families is unequally distributed (e.g., the head of the family concentrates most of the family income), we expect, under specific assumptions, the shift from family to individual unit to have a positive impact on the measured top income share series. The impact on the shares becomes negative if income is equally distributed within the top tax units. In the United Kingdom, for instance, the tax units increased from 33,000 to 46,000 in 1990 because of the change from family units to individual units, and the top 1% series experienced an approximate positive jump of 1 percentage point as a result.

[59] Aaberge and Atkinson (2008) also proposed a new set of estimates of Norwegian top shares by estimating the capital income from stock holding using a "Hicksian" approach. In other words, they impute the returns from stocks by multiplying the "estimated market value of the households' stocks and the long-run average rate of return (8.9 per cent) on the Oslo Stock Exchange (OSE)" (p. 13). Moreover, they argue that "The 'Hicksian' measurement of the stock returns is less sensitive to changes in income reporting behavior than the conventional income definition and may thus provide a better basis for analyzing the trend in top incomes during the pre- and post-reform period."

[60] The unit of analysis in New Zealand was based on family before 1953.

[61] Also, Spain changed from family to individual taxation in 1988, but this was corrected within the original calculations of the series. See Alvaredo and Saez (2009). Other cases of changes in tax units occurred in the pre-1970 period are discussed within Chapter 7. In particular, the authors discuss the "borderline" case of Sweden, in which, "the family was the tax unit before 1967 when a choice of filing individually was introduced. This was then the rule until individual taxation finally became compulsory in 1971" (p. 17).

[62] We do not discuss explicitly the change in the control total for the population that has to change accordingly to the definition of the tax units.

[63] Atkinson and Harrison (1978, in particular, Chapter 9).

Second, and most important, a change in the composition of tax units may also affect the trend of the series, not just its level. Indeed, this happens if the factors influencing the level of the shares discussed above also vary over time. This is not implausible; for example, income may have become more evenly distributed within the richest families and the growth rate of tax units could have well exceeded population growth over the past decades. Also, the change in the distribution of income at the top over time (formalized as the change of the Pareto coefficient) has been thoroughly documented and discussed by Atkinson et al. (2011). Nonetheless, the available country-specific evidence (for Canada) shows that the use of different unit bases may affect only the level of shares (see Saez and Veall, 2005).

8.4.2.2.6 Gross and Disposable Top Income Shares

Gross income data can be complemented by information on government transfers and taxation to obtain measures of disparity in disposable incomes or spendable income, ultimately a preferable income definition for individuals. Indeed, the pretax top share can show a different picture than the post-tax share, depending on the degree of progressivity of the tax system and the extent of redistribution. As discussed earlier, tax systems in most of the countries discussed here have changed a great deal over time and have reduced their progressivity. These tax policy changes can influence both the perception of economic inequality and comparisons of inequality over time and across countries. Indeed, the incidence of taxation on net top income shares may vary across countries, affecting the extent of comparability of top shares trends across countries.

Data on disposable top income share are available only for a handful of countries. In this section we describe the evidence for the Netherlands and the United Kingdom (Atkinson and Salverda, 2005), Canada (Veall, 2012), the United States, and France (Piketty and Saez, 2006).

Although one should bear in mind that methodologies adopted by these authors are not homogenous and income definitions are not directly comparable, it is interesting to obtain a measure of the direct impact of taxation on top shares.

Following the work by Atkinson and Salverda (2005), we divide the pretax income shares by the after-tax shares to measure the so-called relative implicit tax rate. We define the latter as the "arithmetic impact of taxation" on top shares, calculated as 1 − (pretax share)/(post-tax share), which in turn is equal to 1 − (1 − average tax rate at the top)/(1 − average tax rate for the overall population). Figure 8.22 depicts the "implicit tax rate" for Canada, the Netherlands, the United States, and the United Kingdom,[64]

[64] France has only two observations, one in 1970 and one in 2005, which are not shown in the graph. The implicit tax rate calculated for the French top 1% share is relatively mild and it marginally increased over time—from 0.08 in 1970 to 0.1 in 2005 (results are based on calculations of data taken from Piketty and Saez, 2006). In other words, the net of taxes top 1% share is approximately 8% and 10% lower than the gross share in 1970 and 2005, respectively). We remind the reader here that the calculated implicit tax rates are not directly comparable across countries.

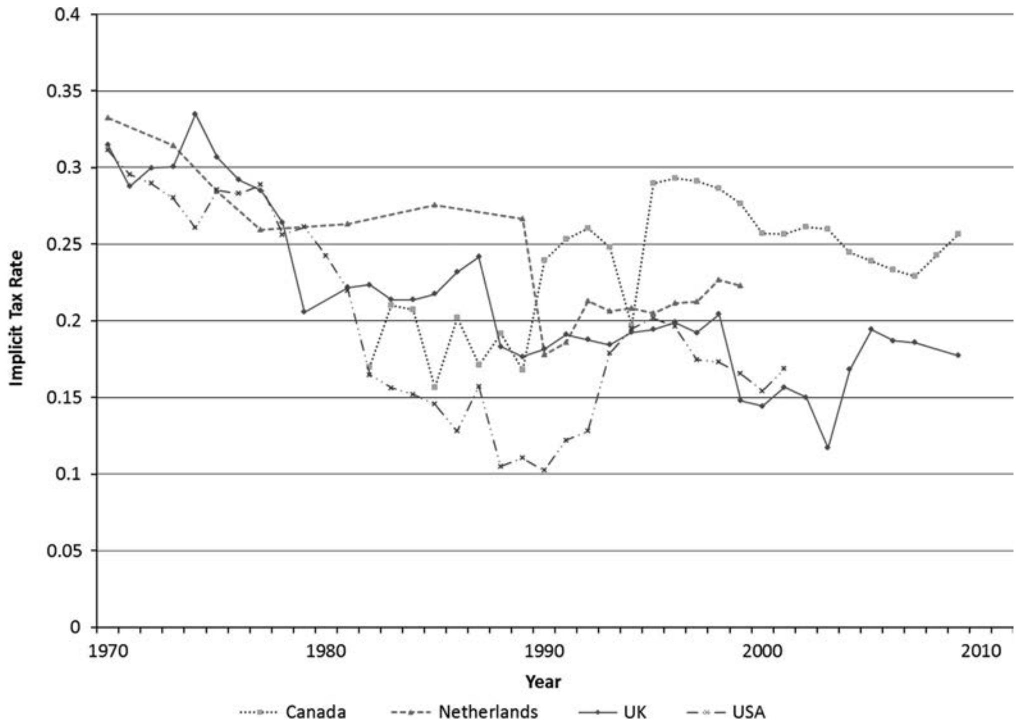

Figure 8.22 Implicit tax rates for a selected group of countries. The graph shows the dynamics of the "relative implicit tax rate" from 1970 for the United States, United Kingdom, Canada, and New Zealand. The implicit tax rate represents the "arithmetic impact of taxation" on top shares, and it is calculated as [1 − (pretax share)/(post-tax share)], which in turn is equal to [1 − (1 − average tax rate at the top)/(1 − average tax rate for the overall population)]. *Sources: Calculation of the authors based on data from country-specific literature for the United Kingdom and New Zealand (Atkinson and Salverda, 2005), Canada (Veall, 2012), and the United States and France (Piketty and Saez, 2006).*

showing that, with the exception of Canada, the tax system reduced its progressivity in these countries. For the United Kingdom, United States, and the Netherlands, the inversed implicit tax rate for the top 1% went from around 35% in 1970 to around 20% in 2000. However, the implicit tax rate in United States decreased more during the 1980s, reaching the value of 10% in 1990 before rebounding to around 20%. In Canada the pattern was nearly reversed. The Canadian implicit tax rate was, on average, lower than 20% during the 1980s; it then increased by 10 percentage points during the 1990s and finally declined gradually to a value of around 25%. This is why net top income share would show an attenuated increase in inequality in Canada, as shown in Figure 8.23. In the United States and the United Kingdom, however, pre- and post-tax trends in the top 1% share are essentially indistinguishable.

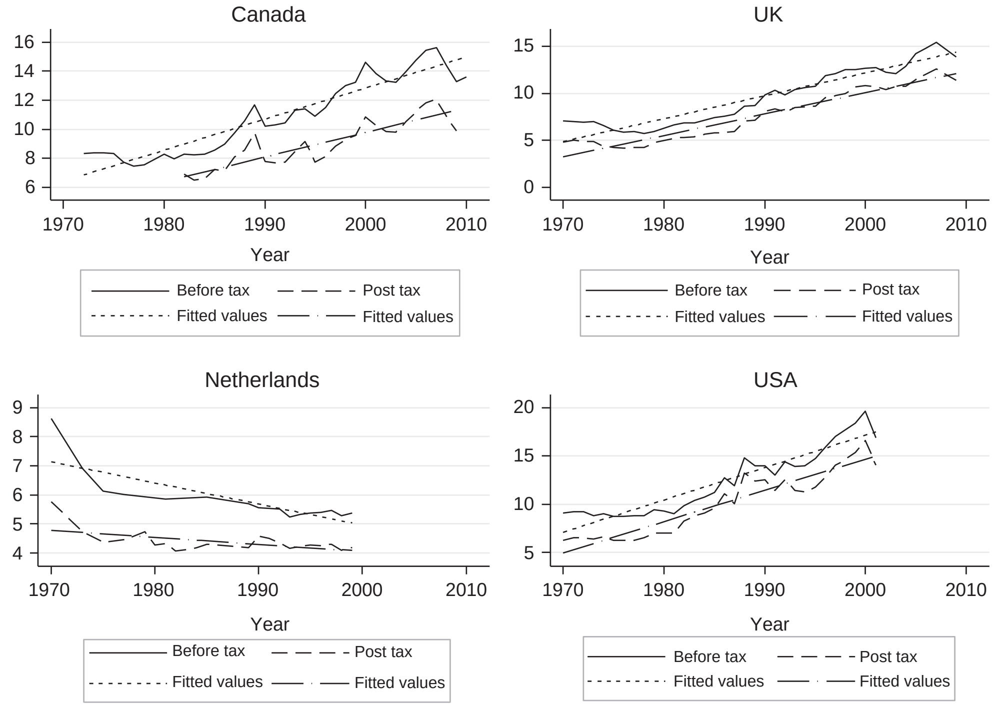

Figure 8.23 Pre- and post-tax top 1% shares for selected countries. The graphs show both the top 1% based on gross income (net of taxes and of transfers) as well as on net income. *Sources: Elaboration of the authors based on data from country-specific literature for the United Kingdom and New Zealand (Atkinson and Salverda, 2005), Canada (Veall, 2012), and the United States and France (Piketty and Saez, 2006).*

8.4.2.3 Top Shares in the Late 2000s

The WTID contains information for top income shares in 25 countries. In addition to all of the caveats described above, making comparisons across countries is limited to the years of data that are available. Nineteen of those countries, though, do have data during the "late 2000s" (2009, 2010, or 2011), and several more have at least some data for the period of the "mid-2000s" (2003–2008). Such data for the top 1% shares in the mid-2000s and late 2000s are represented in Figure 8.24. Comparisons of the level of inequality using these top share figures across countries may be problematic for all of the reasons discussed above. Differences in definitions of income and income reporting units, as well as tax treatment of different types of income and potential differences in tax reporting, avoidance, and evasion, can all influence differences in the levels of top income shares over time.

These caveats notwithstanding, it is interesting to notice that the ranking of countries based on top income shares remains similar to what was observed using the inequality

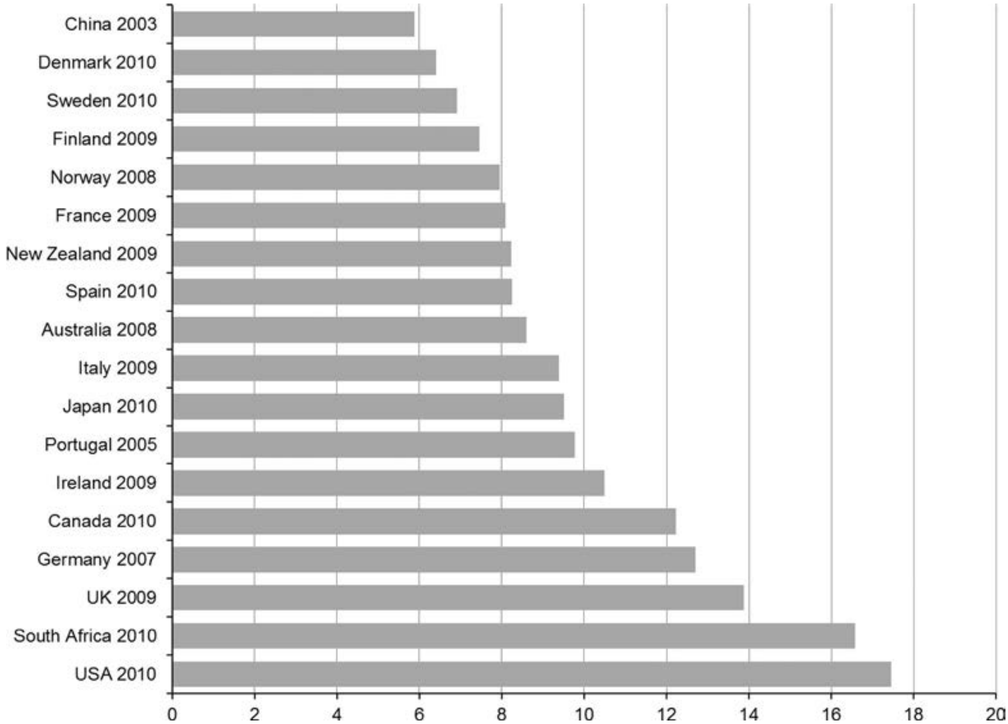

Figure 8.24 Top 1% shares in the late 2000s. *Source: Data from the World Top Income Database (accessed September 2013).*

measures across in the entire distribution (based on data comparable across countries) in Section 8.4.1. Among rich countries, the English-speaking countries have higher measured inequality than the Nordic counties. In 2010 the top 1% share was nearly 18% in the United States and less than 7% in Sweden and Denmark. Among the MICs and developing countries under investigation within the chapter and for which we have data, South Africa has the highest levels of inequality.

8.4.2.4 Comparison of Trends Across Country Groups

The primary goal of this section is to explore commonalities and differences in data trends across countries from 1970 to 2010. Previous sections emphasized how different sources, methods, and definitions of income tax may affect the estimated top shares across countries. However, we have showed that not all changes in methodology or breaks in data series create comparability problems.

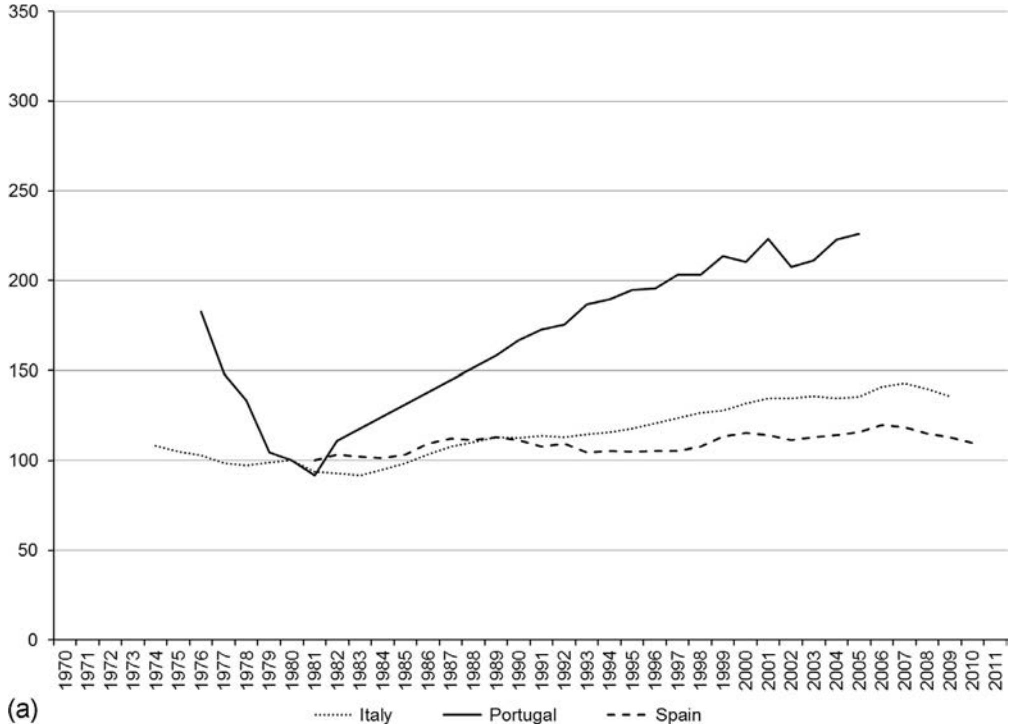
As noted by Gottschalk and Smeeding (2000), the time-varying and time-invariant factors specific to the shares need to be the same across countries to have meaningful cross-country comparisons. To ease the exploration of differences in trends, we ignore factors that are country-specific and time invariant, namely the differences in levels. More precisely, we standardize the values of the shares to be equal to 100 in 1980. Because of data availability, the standardization to 100 is done for the year 1990 for emerging countries. This takes care of measurement errors and heterogeneity of methodology of calculation of top shares across countries that are constant over time.

We group the countries in our data set into the following clusters: Nordic European (Denmark, Finland, Norway, and Sweden); southern European (Italy, Portugal, and Spain); western English-speaking (Australia, Canada, Ireland, New Zealand, the United Kingdom, and the United States); and continental European countries (France, Germany, the Netherlands, and Switzerland) together with Japan. The remaining countries—China, India, and South Africa—are labeled as emerging or MICs. These clusters differ somewhat from the previous section discussing inequality across the entire distribution but are consistent with the groupings used by Atkinson et al. (2011). According to Atkinson et al. (2011), these groupings are "made not only on cultural or geographical proximity but also on proximity of the historical evolution of top income shares" (p. 40).

The various panels in Figure 8.25 show that top income shares are growing in many countries; increasing inequality is not limited to a small number of countries or any obvious subset of countries. Indeed, a common pattern observed across most of the countries in the WTID shows declining top shares for one or two decades since 1970, followed by steadily rising top shares through 2010. The precise timing and extent of the "U turn" in top shares varies across countries, and we provide below a description of the main features of the dynamics of top shares over time across different country groups.

All of the southern European countries have seen an increasing top 1% share since 1980, but the increase has been much sharper in Portugal, where the top share more than doubled between 1980 and 2010 compared with an increase of "only" 40% in Italy and approximately 15% in Spain (Figure 8.25a). Trends in the top shares of Continental European countries (Figure 8.25b) fluctuate more with business cycle patterns than the southern European countries. Nonetheless, the pattern of top shares series remains broadly consistent with a mild U shape; the top 1% share fell between 1970 and the early 1980s and remained more or less stable until the mid-1990s, when it mildly rebounded until the onset of the 2007–2008 financial crisis. In fact, most of the Continental European countries lack top share data over the past decade, making a complete analysis of this period impossible at present. France and Japan are the two countries in this group with data over the full period, and they both follow this pattern closely. Between the mid-1990s and mid-2000s, the top share increased approximately 30% in Japan and 15% in France. Between 2007 and 2010 top shares held steady in Japan but declined sharply in France.

Top shares in the English-speaking countries also fluctuated with the business cycles but exhibit a clearer upward trend since the early or mid-1980s than the Continental European countries (Figure 8.25c). Moreover, with the exception of New Zealand,



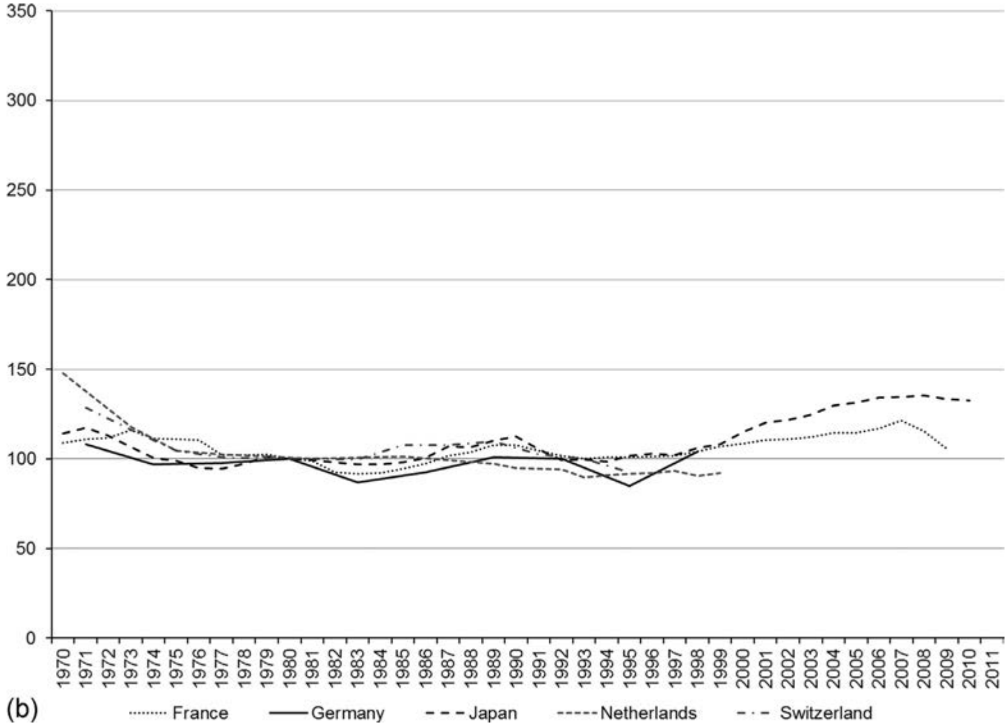


Figure 8.25 Top 1% share trends between 1970 and 2011 by country group: Southern Europe (1980 = 100) (a). Continental Europe and Japan (1980 = 100) (b), English-speaking countries (1980 = 100)

Continued

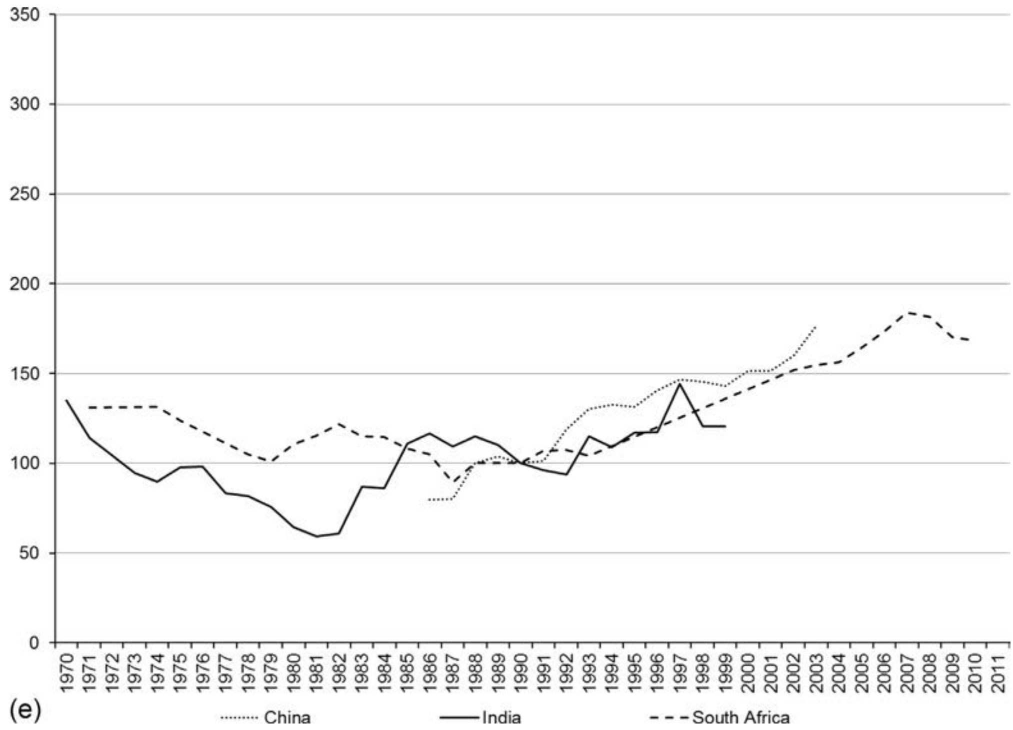

Figure 8.25, cont'd (e). In (a)–(d), 1980 was calculated as 100. In (e), 1990 was calculated as 100. *Source: World Top Income Database, accessed September 2013. Elaboration by the authors.*

all English-speaking countries[65] experienced a similar trend since the end of the 1980s.[66] Between 1990 and the onset of the 2007 financial crisis, the top 1% share increased between 60% and 70% (in Australia, Canada, the United Kingdom, and the United States) and around 90% (in Ireland). Trends in the English-speaking countries show some evidence of the impact of the economic crisis, with top shares decreasing between 2007 and 2010–2011.

[65] Evidence for New Zealand suggests that the top 1% share increased by 50% from 1980 to the onset of the recent crisis, accounting for only the change in reported income driven by the switch to the full imputation system in 1989, as detailed earlier. Once we ignore this permanent jump in reported income (and the subsequent temporary spike in 1998–1999 due to income shifting over time), the trend for New Zealand's top share is almost flat. This was already noted by Atkinson and Leigh (2005).

[66] This allows netting out some of the structural effect induced by changes in the taxation system, as discussed earlier.

In the Nordic countries, top shares were mostly flat during the 1980s and did not start increasing until 1990 or later (Figure 8.25d). This is particularly clear in the case of Norway, where the top 1% share was unchanged between 1980 and 1990 but doubled between 1990 and 2000. Increases after 1990 were smaller in the other Nordic countries, especially Denmark, where the top income share only rose 15% between the late 1980s and the late 1990s before sliding back down in the late 1990s and early 2000s. The post-1990 trend in rising top shares appears to have been halted or reversed by 2000 in Finland and by the mid-2000s in Norway, although in Sweden the increase in top shares continued. As discussed earlier, the unusually large spike Norway's top 1% share in 2005 is attributable to dividends paid out in anticipation of tax policy changes in 2006.

In developing countries in the WTID, the trends in top shares seem to resemble most closely those in the English-speaking countries. Top shares started increasing in the early 1980s in India and in the late 1980s in China and South Africa (Figure 8.25e). After the 1990s, these three developing countries appear to experience a long-term increasing trend in the top 1% share of income.

Between 1980 and 2009–2011, top shares more than doubled in the United States and the United Kingdom and were on track to double in Australia and Ireland before falling sharply in the global economic downturn that hit most developed countries beginning in 2007/2008. The English-speaking countries stand out as experiencing the largest increases in top shares over the entire post-1980 period, and they account for three of the top five countries with the largest cumulative changes in top 1% share between 1980 and the average after 2000 (Figure 8.26a). However, much of the run-up in top shares in English-speaking countries occurred in the 1980s. Focusing on changes in top shares since 1990, a different set of countries stands out as having large increases. The four countries with the largest cumulative changes in the top 1% share since 1990 include two Nordic countries (Finland and Norway) and two developing countries (China and South Africa) (Figure 8.26b). After 1990, cumulative increases in top shares were roughly equal between English-speaking and developing countries. It is important to note that the results are invariant to the exclusion of the abnormal spike in the top income share that occurred in Norway largely as a result of the anticipated change in taxes on dividends.[67]

The various graphs in Figure 8.25 track the decrease in top income shares in the decade or two after 1970, depending on the country, followed by increasing top shares starting around 1980 or 1990, again depending on the country. Whether these long-term

[67] As mentioned before, in 2005 Norway announced a permanent increase in dividend tax (to be increased in 2006); this marked a notable peak in top income shares as individuals and corporations shifted income over time to avoid the impending rate increase (Aaberge and Atkinson, 2008).

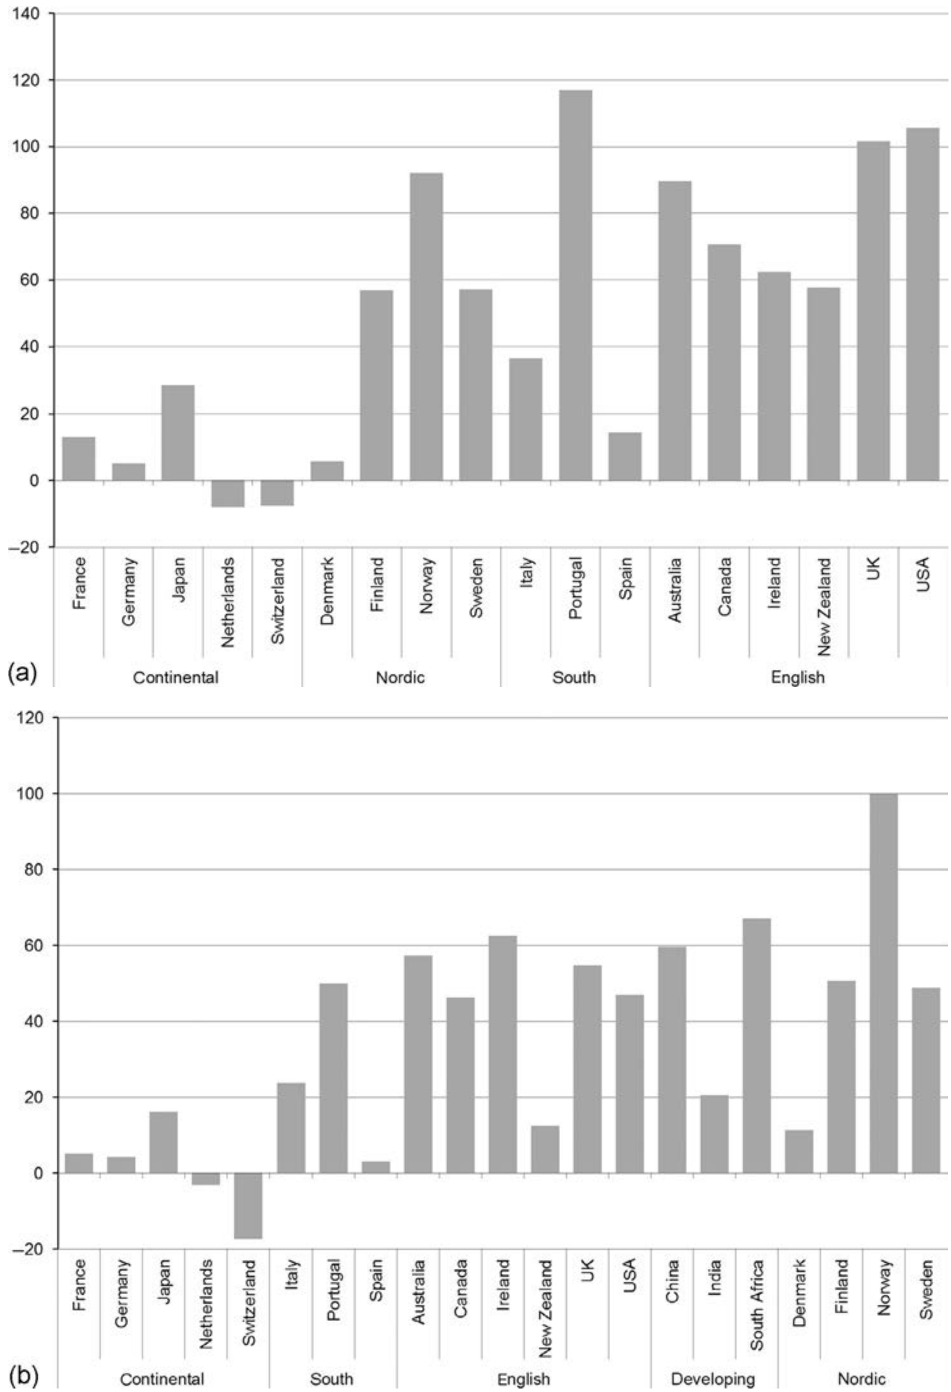

Figure 8.26 Cumulative changes in top income shares by country and country group. (a) Average cumulated change from 1980 to after 2000. (b) Average cumulated change from 1990 to after 2000. Data are sorted by the average cumulative change in top 1% by country groups. In the case of Germany, we draw information from the top share including capital gains. The cumulated change is computed since 1990 for the developing countries. Because of a lack of information the period after 2000 is equivalent to 1995 for Switzerland and to 1999 for India and the Netherlands. Results obtained exclude Norway's top 1% peak in 2004 and 2005. *Source: World Top Income Database, accessed September 2013. Elaboration by the authors.*

trends will persist into the future is an open question. Most of the countries in the WTID did witness decreasing top shares between 2007 and 2010, but many of the countries lack data during these years. Have long-term trends toward rising inequality been reversed by this period of financial turmoil and recession? Or, can they be expected to revert to their pre-2007 trends? Morelli (2014) uses the US top income shares data to answer this question by estimating impulse response functions of top shares to the occurrence of banking shocks. The main findings of this paper suggest that the short-term impact of systemic banking crises on the upper-income brackets of the income distribution is negative at the very top of the income distribution (e.g., above the 99th percentile) and positive at the bottom of the top decile (e.g., between the 90th and 99th percentiles). In other words, the relative response to systemic banking shocks differs across top income groups given their heterogeneous nature.

However, and most importantly, systemic banking crises do not seem to substantially affect top income shares; their estimated dynamic responses are found to be relatively small in magnitude.[68] Moreover, the findings of the paper are also suggesting that the impact of crises may also be temporary in nature since top income shares may quickly return to their predicted path in the absence of a crisis.

Consistent with what was informally documented and suggested by Atkinson et al. (2011), Saez (2013), and Piketty and Saez (2012), these results suggest that even major disruptive crises such as the financial turmoil in 2007/2008 do not represent a structural break for top shares series, and we should not expect a reversal of the increasing trend in income concentration unless some strong change in the political and institutional framework is expected (e.g., a change in taxation regime, remuneration practices, regulation policies).

8.4.2.5 Income Decomposition

In the sections above we described the increasing trends of top income shares for most of the countries. What is driving these trends? To better understand the mechanisms that led to an increase in inequality in most of the countries under investigation, we can use composition data from income tax statistics. However, income decomposition by sources is available for only a few countries. Ideally, we would like to understand how both marginal distributions of each source of income as well as their joint distribution affect the dynamics of the right tail of the income distribution. This is discussed by Atkinson et al. (2011) and subsequently by Alvaredo et al. (2013) in the case of the United States for two sources of income, namely wage and capital. Their results suggest an increasing

[68] Indeed, the estimated impacts of crisis are generally found to be substantially below one standard deviation, irrespective of the specific top share or country group under investigation.

association between the two sources of income for individuals within top brackets. However, understanding this important issue (which requires the availability of microdata for every country and year) goes well beyond the scope of this chapter. A less rigorous approach is to simply decompose the top income into, say, two main sources (wage and capital income) to understand their incidence in total income accruing to the top.

Below we depict the share of capital income (including rental income from buildings, interest income, and dividends but excluding realized capital gains where possible) and employment income (wages, salaries, bonuses, allowances, and pensions) for those eight countries where these calculations are possible (Australia, Canada, France, Japan, Italy, the Netherlands, Spain, and the United States). On balance, wage income weighs substantially more within the total top income above the 99th percentile (top 1%). This holds true with the exception of Italy and Australia, where wage income has a relatively lower incidence on the total (Figure 8.26).[69] The picture is reversed if we look at richer top income brackets above the 99.99th percentile (top 0.01%). Here, the incidence of capital income is generally higher than earned income (the only exceptions are Canada and the United States).[70] Results are shown in Figure 8.27.

The relative shares of different sources of income accruing to the top also have changed over time, and the experience has been heterogeneous across countries. In the case of top 1% shares, on balance, there is evidence of a slight increase over time in the labor-type income share for the countries for which income composition data are available (Figure 8.27a). The main exceptions are Spain and Australia, which exhibited decreasing wage shares from the late 1990s until the mid-2000s.[71] In Japan and the United States, wage shares increased slightly before 1990, but they have remained roughly constant since. In other countries, including France and Italy, there is little evidence of any trend

[69] Australian data can only be decomposed as wage and nonwage income. The latter represents our definition of "capital" income and includes realized capital gains as well as business income (self-employed income, profits from unincorporated businesses, and farm income).

[70] Recall that realized capital gains are not included in the standard top income shares under analysis.

[71] It is important to note that Spanish data include capital gains within the definition of capital income. This explains the more acyclical nature of wage shares, which recovered substantially in Spain in the late 2000s; a similar but milder trend seems to have occurred in Australia. It is also important to notice that Australia remains the only country where the incidence of capital income within the top 1% group is higher than the wage share. This is due to two main reasons. First, business income is entirely included within the "nonwage" income. Second, Australian data incorporate capital gains to the extent that they are taxable (at varying degrees over time). Indeed, as recalled by Burkhauser et al. (2013), "Prior to 1985, Australia had no general tax on capital gains. Hence, almost no capital gains were captured in tax record data, since most capital gains were excluded from the personal income tax base. It was not until 1972 that realized capital gains on most assets were included in the tax base under Section 26AAA of the tax law, but only for short-term capital gains (those on assets held less than one year), and excluding owner-occupied housing. While a tax on realized capital gains on assets based on speculation existed as far back as the 1920s, it was not systematically enforced and it generated little revenue" (p. 8).

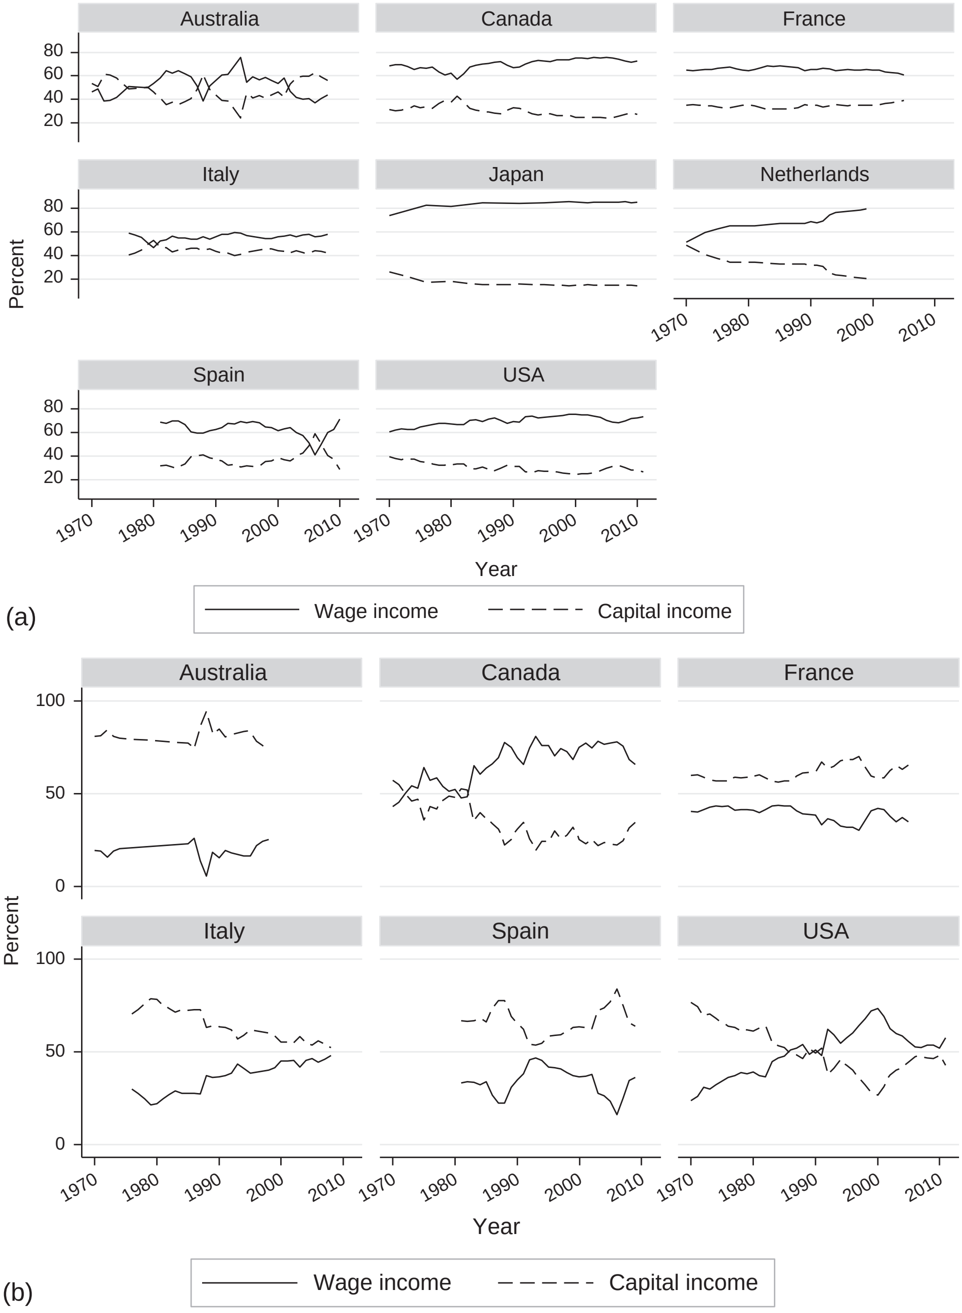

Figure 8.27 Labor and capital compositions of top incomes. (a) Income composition of the top 1% group. (b) Income composition of top 0.01% group. The graphs depict the incidence of different sources on total income accruing to the top 1%. In particular, the graphs show the share of capital income (including rental income, interest income, and dividends but excluding realized capital gains, where possible) and employment income (wages, salaries, bonuses, allowances, and pensions) for the eight countries where these calculations are possible (Australia, Canada, France, Japan, Italy, Netherlands, Spain, and the United States). Note that Australian and Spanish data include realized capital gains to the extent they are taxable. Moreover, Australian data can only be decomposed in wage and nonwage income ("capital" income includes realized capital gains as well as business income, self-employed income, profits from unincorporated businesses, and farm income). *Source: World Top Income Database, accessed September 2013. Elaboration by the authors.*

in wage shares. The clearest cases with increasing wage shares are the Netherlands after 1990 and Canada after 1980.

The evidence of an increase in top wages income is less clear cut for the top 0.01% shares (Figure 8.27b). Wage income visibly increased over time for Italy, Canada, and the United States (until around 2000, after which there was a marked reversal). The wage income share was relatively stable in Australia and France.

It is nonetheless important to bear in mind that definitions of income sources are not necessarily comparable across countries and that different tax systems within different countries may incentivize the reporting of a specific income source with greater fiscal convenience (see section 8.4.2.2.4 concerned with fiscal avoidance). It is therefore not always clear how one should interpret the documented percentage incidence of wage and capital incomes within top brackets. The results discussed within this section do not take these important issues into account.

8.4.2.6 Bridging the Gap Between Tax Statistics and Survey Data: Gini Versus Top Share

In the second section of this chapter we explored the dynamics of overall income inequality using a variety of summary statistics, including Gini coefficients, decile ratios, and others. These variables are usually constructed from household surveys. Some countries are, however, increasingly resorting to register data (such as the Scandinavian countries) or to a combination of both survey and register data (such as the United Kingdom and France since 2008) in an attempt to overcome standard household survey limitations.

Indeed, household surveys are not typically stratified by income, and, in part, as a result suffer limitations that are particularly pernicious for top income groups (measurement errors, nonresponse, or incomplete response); these surveys often adopt a top-coding methodology that by construction limits the information on the right tail of the income distribution.[72] These limitations frequently make it impossible to get robust quantitative evidence about the incomes of individuals at the very top of the distribution.[73]

[72] There are usually two levels of top-coding. The first level guarantees the secrecy of data, whereas the second (present even within the data exclusively available internally to statistical agencies) serves to avoid outliers having an influence on the aggregate statistics.

[73] This has been pointed out by Brewer et al. (2008) for the case of the United Kingdom, where the statistical office usually adjusts the measure of income accruing to the very rich individuals detected within the Family Resources Survey using the data provided within the Survey of Personal Income. In turn, the latter samples information on income from the tax administrative data of the HMRC and by design oversamples the information on rich individuals. Similarly, Moriguchi and Saez (2008) discuss the limitation of the National Survey of Family income and Expenditure (NSFIE), which collects a representative sample of about 10,000 households and, because it "contains few observations at the high end of income distribution, it is difficult to provide precise estimates for the top 0.5% income group and above using NSFIE data."

On the other hand, top income shares are constructed from tax administrative microdata or grouped tabulations and are particularly suitable to estimate the right tail of the income distribution. Nonetheless, they provide less compelling information about the bottom of the distribution.

Do these two different sources provide substitutable or complementary information? In other words, are top income shares to be combined with survey data to have a more complete picture of economic inequality within a country? Or, do top shares embed sufficient information to proxy the distribution of income as a whole? In what follows we discuss these important questions individually.

8.4.2.7 Are Top Income Shares Complementary to Household Survey Data?

Work by Burkhauser et al. (2012a) compared the evolution of the top income shares in the United States calculated in survey data (Current Population Survey (CPS) data from internal sources) with that provided by Piketty and Saez (2006) using administrative tax data (from the Internal Revenue Service).[74] Burkhauser et al. (2012a) suggest that CPS-based top shares track closely with the tax-based top shares up to the 99th percentile. Importantly, the comparison takes into account the same unit of reference (tax units) and a definition of income similar to that adopted in Piketty and Saez (2006). However, the U.S. top 1%, as estimated by Burkhauser et al. (2012a), does not track the top 1% obtained by Piketty and Saez (2006) with the same precision. This is even more evident once capital gains are included within the income definition,[75] as noted by Atkinson et al. (2011). Indeed, as shown before, capital gains are an important component of income at the top and could influence substantially both the level and the trend of income inequality. In addition, including capital gains arguably provides a more economically meaningful measure of income dispersion.[76]

Atkinson et al. (2011) also provide a tentative adjustment of official CPS Gini coefficients, taking into consideration the differentials in top 1% shares between survey-based and tax-based estimates (including capital gains). The result suggests that the official CPS data on Gini (household equalized gross income) fail to capture about half of the increase in overall inequality in the United States as measured by the adjusted Gini index.

[74] The internal CPS files contain better coverage of top incomes, specifically nontop-coded income levels, than the publicly available CPS.

[75] The CPS does not record capital gains. In addition, CPS data also exclude information on stock option gains, which are instead recorded within IRS taxation data.

[76] Moreover, the series including capital gains is less sensitive to changes in tax avoidance around TRA 1986. Indeed, as we discussed previously, the TRA 1986 mostly incentivized "a shift from corporate income toward individual business income." However, as noted by Atkinson et al. (2011), it is also true that "Before TRA 1986, small corporations retained earnings and profits accrued to shareholders as capital gains eventually realized and reported on individual tax returns. Therefore, income including capital gains does not display a discontinuity around TRA 1986 (1986 is artificially high due to high capital gains realizations before capital gains tax rates went up in 1987)."

These findings seem to indicate that taxation data are able to capture additional information that is not recorded within statistical surveys. Yet it is also important to stress here that the extent to which estimates based on survey data can be adjusted using tax statistics is not yet fully understood or investigated. Moreover, the required "adjustments" may well be different across countries. Such adjustments are increasingly implemented within the literature.

Atkinson (2007) provides the intuitive formal *approximate* relationship between the top share and the Gini coefficient, $G=(1-S)G^*+S$, where G represents the overall Gini coefficient, S is the top share, and G^* is the Gini coefficient for the rest of the population excluding the top individuals. However, the above-mentioned derivation requires the assumption that the top income group refers to an infinitesimal share of the population (say top 1%, top 0.1%, or top 0.01%). Alvaredo (2011) subsequently obtains the more general derivation valid for noninfinitesimal top groups as well: $G=(1-S)(1-P)G^*+S-P+G^{**}PS$, where P is the population share of the top group under investigation and G^{**} is the Gini relative to the distribution of income within the top group (G^{**} can be further simplified to $1/(2-\alpha)$, assuming that the right tail is Pareto distributed with coefficient α).

Under the presumption that the observed Gini coefficient (obtained from standard survey data) is a better representation of inequality within the bottom group (G^*), we can use the above results to obtain estimates of the adjusted Gini for the whole population (G). This could be considered to be the first approximate attempt to correct the overall measure of inequality using the available additional information about the top income share (for instance, this was illustrated for the case of Argentina by Alvaredo, 2011). From the discussion above one can already expect the actual value of the adjusted measure of Gini to depend on the choice of top shares to be used.

Assuming that the top percentile is excluded from the national household survey, we can illustrate the adjustment of the official Gini coefficient of gross equalized household income (including cash transfers) from the CPS data in the case of the United States. Using Atkinson's (2007) original formula illustrated above and the top 1% share from the WTID, including capital gains, the adjustment is worth 5 percentage points in 1970 and more than 10 percentage points in 2006 (Figure 8.28). The adjustment is approximately 1 percentage point lower if we use the top 1% excluding capital gains. Furthermore, using Alvaredo's (2011) more general formula, the adjustment is further reduced by one additional percentage point.

Such adjustments, however, depend on the strong assumption (not necessarily true) about the exact share of national income thought to be excluded from the household survey statistics. Such an assumption has to be carefully assessed before carrying out any corrections to the shares. Indeed, one could obtain adjusted Gini measures in a slightly more sophisticated way by estimating the top shares using both the survey and the

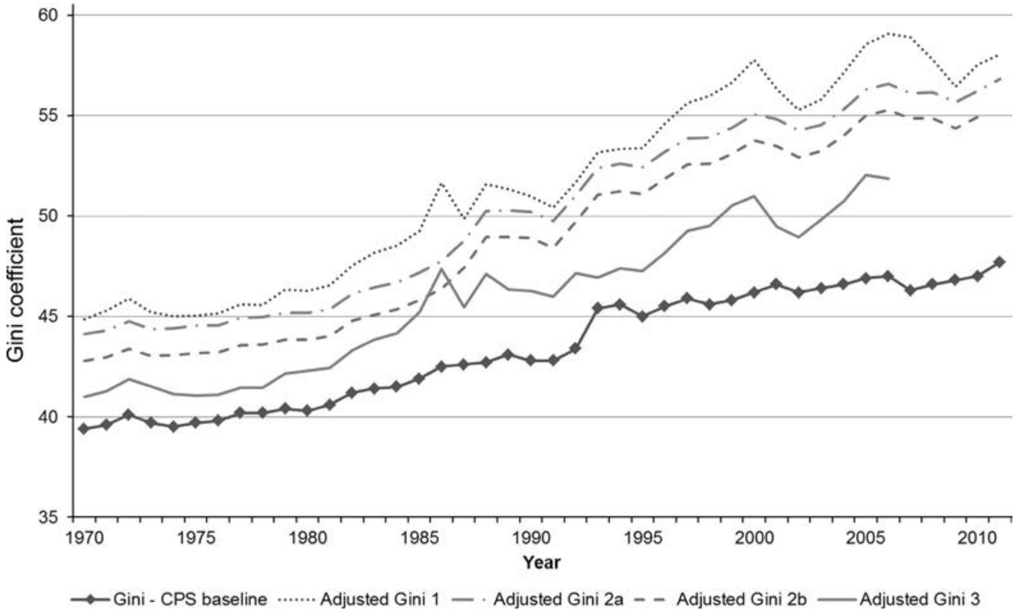

Figure 8.28 Adjusting the U.S. Gini coefficient using the top income shares. The baseline Gini coefficient represents the headline series of the U.S. Current Population Survey (CPS) based on household equivalized gross income. Top income shares estimated by Piketty and Saez (2003), Saez (2013), and Burkhauser et al. (2009) then are used to calculate adjusted measures of Gini coefficient. We carried out four different adjustments. Adjustment 1 assumes that the top 1% (including capital gains) is not captured at all within the household survey statistics, and we use the formula described by Atkinson (2007) to derive the "true" Gini coefficient: $G=(1-S)G^{*}+S$, where G represents the overall Gini coefficient, and S is the top share, and G^{*} is the Gini coefficient for the rest of the population excluding the top individuals. Adjustment 2a uses the same formula above but the top 1% excluding capital gains. Adjustment 2b makes use of the more general specification highlighted by Alvaredo (2011): $G=(1-S)(1-P)G^{*}+S-P+G^{**}PS$, where P is the population share of the top group under investigation and G^{**} is the Gini relative to the distribution of income within the top group (G^{**} can be further simplified to $1/(2-\alpha)$, assuming that the right tail is Pareto distributed with coefficient α). Finally, adjustment 3 assumes that the top 1% share is partially captured within the national survey. The difference D represents the estimates of top shares using taxation statistics (and including capital gains) from those using survey data; the following correction is then used to apply the following adjustment: $G=(1-D)G^{*}+D$. *Sources: Burkhauser et al. (2012), Atkinson et al. (2011), and calculations of the authors.*

taxation administrative data, adopting a homogeneous methodology (e.g., unit of analysis, income definition, control totals). The formulas mentioned above will then serve to adjust the available Gini from the survey data using the difference D of the estimates of top shares using different sources: $G=(1-D)G^{*}+D$. A similar adjustment was carried out in the case of the United States (discussed above) and illustrated by Atkinson et al. (2011).[77] This adjustment, using top income shares including capital gains, is represented in Figure 8.28 and represents a substantially smaller adjustment to the Gini coefficient than the ones discussed above (an approximate change of 1.5 percentage points in 1970 and 5 points in 2006 with respect to the actual baseline Gini coefficient based on gross income). This suggests that more than half of the increase in inequality from 1970 to 2006 is not captured by the inequality measure (based on household surveys), which excludes a sizeable part of the top 1% share of national income, as estimated with taxation data.[78]

Finally, one could go beyond the first approximation adjustments we discussed above by matching the individual information within surveys using administrative data with full coverage of the population. Not much research has been carried out yet at this stage, and this remains an important open issue that will attract the attention of economists and statisticians in the coming years.

To conclude, top income shares tend to be underestimated within household surveys (especially above the 99th percentile), and we have shown that taxation data can, in some cases, provide additional and complementary information that could not be otherwise recorded. Given the relentless increase in top income shares in many advanced and developing countries, it is possible that the official indicators of income inequality might substantially and increasingly underestimate the extent of the change in the actual dispersion of income distribution. However, data on reported income for taxation purposes are not without caveats, as we extensively discussed in this chapter, and caution is prudent when applying any kind of approximate correction to a Gini coefficient that is heavily dependent on arbitrary choices.

8.4.2.8 Changes in Top Income Shares as Proxies for the Overall Income Distribution

We discussed above how top income shares, as measured using tax statistics, may not be fully represented within household survey data. However, changes in top shares may still be informative about the dynamics of the income distribution as a whole, especially if much of the action is at the top, as suggested by the burgeoning literature on top incomes.

The analysis of data in this chapter highlighted how different measures of inequality generally result in similar impressions of how inequality has changed and which countries have the most unequal distributions of income, whether based on the entire distribution or only on top-income households. For instance, it is true that countries with larger top 1% shares also tend to have higher Gini coefficients, S80/S20 ratios, and P90/P10 ratios, although the correlation coefficient is substantially less than 1. The top 1% share (using

[77] However, the measure of the Gini used for the correction by Atkinson et al. (2011) and here is not computed from the survey using a methodology comparable with that of tax statistics. On the contrary, for illustrative purposes, they merely took the baseline Gini from the official publication of the CPS data.

[78] This was also recalled by Atkinson et al. (2011).

pretax income of tax units) and the Gini coefficient (using DHI) have a correlation coefficient of 0.65; using the S80/S20 ratio the correlation is also 0.65, and using the P90/P10 ratio, it is 0.72.[79]

Consistent with this evidence, an important study by Leigh (2007) found that the correlation between top shares and Gini coefficients[80] is not only strong in the cross section but also after controlling for country fixed effects and common time effects. This suggests that within-country changes of top income shares and Gini coefficients also are strongly correlated.

Given the importance of the work by Leigh (2007), and similar to what was done in Chapter 7, we extend here his analysis by making use of updated data on both top income shares and Gini coefficients made available since Leigh has published his work.[81] However, we further extend the work in several respects. First, we used two additional series of Gini coefficients. Specifically, we use the Gini series (related to equivalized DHI) assembled by Atkinson and Morelli (2012, 2014) within the *Chartbook of Economic Inequality*,[82] and we make use of series of Gini coefficients of gross/market income,[83] which is more directly comparable with the series of top income shares. Although Leigh's analysis stretches back to the early years of twentieth century, we focus here on the post-1970 period only.

Second, and most important, we acknowledge here that Leigh's (2007) original specification treats top income shares as the dependent variable. To the extent that we need to analyze the informative content of top shares for the overall income distribution measures, this is not necessarily the preferred approach.[84] Thus we reverse the order of the regression variables by regressing the log of Gini on the log of top shares to obtain more direct information about the elasticity of the Gini coefficient as it relates to changes in top share. This is shown in Table 8.7, where the elasticity of Gini to changes in top

[79] The simple pairwise correlations between the different inequality measures were calculated using the figures from Table 8.2 and Figure 8.24.

[80] The study by Leigh (2007) made use of Gini coefficients of DHI from the LIS and from the World Income Inequality Database (WIID).

[81] For evidence of the relationship between Gini coefficients and top income shares for developing countries we direct the reader to Chapter 9.

[82] The *Chartbook of Economic Inequality* covers the more than 100-year period since 1900 for 25 different countries, accounting for more than a third of the world population. The database collects information on five different annual measures of "economic inequality," among which is the Gini index on equivalized DHI (the remaining measures are top income shares, income- or consumption-based poverty measures, earnings dispersion measures, and top wealth shares). The underlying figures are available for download at: www.chartbookofeconomicinequality.com.

[83] These series, with few exceptions, are mostly retrieved from the OECD inequality database, accessed on October 1, 2013.

[84] The regression order of two variables is irrelevant only if the variables under investigation are standardized. Furthermore, the choice of the order of regression is essentially a scientific one and reflects the nature of the theory underlying the empirical specification.

shares is estimated to be in the range of 10–40%, with strong statistical significance if we consider the whole post-1970 period.

As a third step, we also estimate the elasticity of Gini coefficients to changes in the top 1% across three different subperiods: 1970–1985, 1986–2000, and 2001–2012. This allows us to study the evolution of the elasticity of the Gini to change in the top 1% over time.[85] The findings show that the relationship between changes in top shares and changes in the Gini coefficient tends to disappear during the latest period (Table 8.8).[86] This seems consistent with the facts observed within previous sections, where top shares show no sign of having "peaked," whereas Gini coefficients have increased at a slower pace in many countries since the 1980s or the 1990s. One reason, as discussed before, may be that household income surveys poorly measure the top share.[87]

[85] Different from Leigh (2007), we also focus exclusively on the top 1% and not on the top 10%. Moreover, we check the relationship between top 1% shares and Gini coefficients only, excluding other types of inequality measures, such as Atkinson's indices and interfractile ratios.

[86] It is worth noting that the relationship between the top 1% and Gini is generally more robust over time using data from the *Chartbook of Economic Inequality*. For simplicity, Table 8.8 exclusively represents the evidence about Gini based on gross income from the OECD and Gini based on net income from LIS data.

[87] For instance, Kenworthy and Smeeding (2013) show that, in the United States, once the top centile is removed from survey data, income inequality has increased much more modestly since the mid-1990s. These findings suggest that, viewed cross-sectionally, the increase in the top end has driven much of the distribution in the United States.

Finally, we also replicate[88] here the original specification (regressing log of top shares on the log of Gini) by Leigh (2007). Results are represented in Table 8.9, where the original results by Leigh (panel A) are compared with those making use of more up-to-date data (panel B) as well as with the results based on two different series of Gini coefficients (panel C).

It is worth noting that the use of up-to-date and adjusted inequality series, together with the restriction to the post-1970 period, does not seem to affect the validity of Leigh's (2007) findings (panel B). Similarly, the use of the two additional series of Gini coefficients (panel C) substantially confirms the Leigh's findings.[89] The latter result is relevant because Gini coefficients based on pretax and pretransfer income are more appropriate data series to compare with top income shares (based on gross income).[90]

To summarize, the relationship between changes in the top shares and Gini coefficients documented by Leigh (2007) remains strong and robust to the controls for updated information, restricted period sample, and different Gini indicators, including that based on pretax and pretransfer income. Hence, changes in top income shares remain, on average, a good proxy for overall income distribution despite the misrepresentation of top income brackets within the statistical survey data documented above. However, there is evidence suggesting that the relationship between Gini and top shares became weaker during the first decade of the twenty-first century, suggesting that household surveys may not entirely capture the dynamics of income at the top. This suggests that greater

[88] We thank Andrew Leigh for kindly providing the original code, which eased the replication of the findings.

[89] The strong association between changes in top 1% shares and Gini coefficients is only weakened once the analysis is restricted to the use the Gini coefficients based on the definition of gross income, and we use the time and fixed effects specification. Indeed, the elasticity coefficient based on the two-way fixed effects regressions between the top 1% and gross Gini is no longer statistically different from zero.

[90] Results are broadly consistent using the top 10% share, although results are not tabulated. The findings are available upon request.

prudence is called for when extrapolating the validity of any results based on the analysis of top income shares directly to the overall income distribution.[91]

8.5. SUMMARY AND CONCLUSIONS

This chapter focused on a wealth of new inequality data that has grown in detail, form, and importance since 2000. In addition to LIS, which was the bedrock of work by

[91] This conclusion seems to differ from what was discussed in Chapter 7, where the focus on the long-run relationship between top shares and Gini coefficients does not allow the weakening of such a relationship to be identified for the first decade of the twenty-first century.

Gottschalk and Smeeding (2000), OECD, EU-SILC, and a series of country trend data, maintained in part by Atkinson and Morelli (2012, 2014) and Brandolini and Smeeding (2008, 2009), have made a tremendous difference in what we know about levels and trends in inequality and poverty over the past 30 years. Importantly, a whole new set of WTID data has proliferated and offers long-term trends in inequality for tax units at the top of the distribution. All of these new data come with new complications and caveats, which were discussed in the previous sections. Despite these caveats, these data do allow us to make a few overall summarizing observations about levels and trends in poverty and inequality over the past 30 years.

The modest conclusions we draw here include the following:

1. Of 28 rich and MIC nations in the late 2000s, 17 nations successfully reached single-digit poverty rates (where between 5% and 10% of the country's population are poor by the half-median relative poverty measure). But the range of poverty rates in rich nations alone varies by a factor of almost 4 and, when adding MICs, by a factor of 5. Hence one experiences a wide range of relative poverty rates in these nations. Our trend data suggest that progress against poverty was uneven and rare in rich nations over the past 20–30 years. Other than Mexico, relative poverty rates did not consistently decrease over the past 15–20 years in any of the nations we examine here.
2. We conclude that while there was little progress in reducing relative poverty in almost all the rich countries examined here over the past two or three decades (up to 2010), real living standards for the poor have changed over this same period. Anchored poverty is an increasingly useful concept to establish how upward and downward changes in real median incomes affect poverty differently from a solely relative measure. Anchored poverty decreased in almost all rich nations from the 1990s to 2007 because of rising living standards in most of the rich world up to that point. However, since the GR, increases in anchored poverty up to 2010 reduced some of the progress in real living standards that low-income households experienced over the preceding 15 years.
3. Inequality increased (almost) everywhere over the 1970–2010 period, with some flattening during the GR, although the longer-term rising trend continued. Small changes year to year may produce strong trends over a 20–30-year period. Long-term increases in the Gini coefficients, P90/P10 ratios, and S80/S20 ratios are evident for DHI calculated using household surveys and with top income shares calculated with tax data.
4. The cyclicality of some measures of inequality—particularly for top income shares—is demonstrated clearly in the trends calculated with the WTID. Recessions have depressed the incomes of the rich especially, but these incomes bounced back even stronger after the recessions of the last decades of the twentieth century. Preliminary evidence suggests the same pattern will likely hold for the GR.

5. The 1950–1980 period stands out as the "golden age" for labor and decreasing or stable inequality in the rich western nations. Several additional nations now show a U-shaped pattern of inequality, with inequality increasing even more since the last look at this phenomenon 14 years ago (Gottschalk and Smeeding, 1997, 2000; OECD, 2011). The longer time series of the WTID shows an even stronger U shape in inequality trends in these data.
6. Cross-national inequality rankings in the most recent data largely look similar to how they appeared 15 or even 30 years ago. The English-speaking countries (led by the United States and the United Kingdom) are the most unequal, by most measures, and the Nordic countries are the least unequal. There have been some important changes to note as well. New data allow us to add Israel and South Africa to the list of the most unequal. Also, the distance between the most and least unequal among rich countries has diminished as inequality growth surged in some of the least unequal.
7. Increasingly, one has to examine capital income as well as earned income. Increasing income from capital is more concentrated at the top of the distribution, as seen in the WTID in many nations since the 1990s and through the GR.
8. Broad-based distribution measures increased most in the 1970s, 1980s, or 1990s (depending on the country) but rose less, and were sometimes stable, in the 2000s. Using top income shares, however, inequality seems to still be rising and shows no sign of having "peaked." How long this pattern can continue is an open question.
9. The relentless increase in top income shares poses new challenges to the informative content of different indicators of income inequality. On the one hand, intrinsic limitations of existing household surveys do not capture the entirety of income accruing to the top income brackets. This suggests that conventional measures such as the Gini coefficient may be increasingly missing the actual extent of the change in income inequality. On the other hand, there is evidence suggesting that the relationship between Gini and top shares became weaker over the past decade, pointing to greater prudence in extrapolating any results based on the analysis of top income shares directly to the overall income distribution.

The future research agenda for empirical studies of inequality and poverty is quite rich and may provide the answers to many questions that are not clear at this point. Additional research on the relationship of inequality and economic growth, as well as who receives the growth dividends, is called for. In a rich and aging world, how will changes in the age distribution affect inequality? In addition, and perhaps most important, the increasing availability and usefulness of data from MICs will provide us with comparisons to the living standards in these and poorer countries. Suffice it to say that with inequality increasing in most rich nations and with increased coverage of the top 1% of income earners, and of MICs, we still have much to learn about inequality, its sources, its origins, and its effects on social and economic outcomes. It is indeed time to bring inequality back into the fold of mainstream economics, as Atkinson (1997) suggested.

ACKNOWLEDGMENTS

The authors thank their organizations for support of this work. In particular, the authors especially thank David Chancellor and Dawn Duren of IRP for their assistance with graphs and manuscript preparation and Peter Frase for research assistance. The authors also thank Tony Atkinson, Francois Bourguignon, Michael Forster, Andrew Leigh, Max Roser, Stephen Jenkins, and the editors for helpful comments on an earlier draft and Andrea Brandolini for providing helpful inequality trend data. The authors, not their organizations, are responsible for all opinions in this chapter, as well as all errors of omission and commission.

Abstract

This chapter reviews the empirical evidence on the levels and trends in income/consumption inequality and poverty in developing countries. It includes a discussion of data sources and measurement issues, evidence on the levels of inequality and poverty across countries and regions, an assessment of trends in these variables since the early 1980s, and a general discussion of their determinants. There has been tremendous progress in the measurement of inequality and poverty in the developing world, although serious problems of consistency and comparability still remain. The available evidence suggests that on average the levels of national income inequality in the developing world increased in the 1980s and 1990s and declined in the 2000s. There has been a remarkable fall in income poverty since the early 1980s, driven by the exceptional performance of China over the whole period and the generalized improvement in living standards in all the regions of the developing world in the 2000s.

9.1. INTRODUCTION

Poverty and inequality are certainly among the main concerns in the developing world. A typical developing country is characterized by high levels of material deprivation and large dispersion in individual well-being, at least when compared to a typical high-income economy. Fighting poverty and minimizing the unjust inequalities are top priorities in the developing world. The United Nations, in the famous declaration of the Millennium Development Goals (MDGs), proposed as target number 1 to halve income poverty from 1990 to 2015. The reduction of inequality does not occupy the same privileged position in the agenda, but few would not list it as a central social concern.

Whereas Chapter 8 of this Handbook deals with poverty and inequality in advanced economies, this chapter documents patterns and changes in the developing countries.

There is no need to argue about the relevance of including a separate chapter in the Handbook: The developing world is home of 85% of total world population and bears levels of poverty and inequality far higher than in the rich nations. Whereas in a typical developing economy the share of people striving to survive with less than $2 a day is more than 30%, that share is close to zero in the industrialized countries. In fact, on this basis poverty is an issue exclusively of the developing world. The differences in income inequality are presumably also large, although the comparisons are hindered by the fact that national household surveys typically capture income in developed countries and consumption expenditures in developing ones.

High poverty and inequality are pervasive characteristics of the developing world; however, they are not immutable features of these economies. There is convincing evidence pointing to a robust decline in the levels of absolute income poverty over the last decades and substantial progress in the reduction of deprivation in various nonmonetary dimensions—education, health, sanitation, and access to infrastructure. Changes in income inequality have been much less clear, as relative inequality has risen in some countries and fallen in others. In fact, the evidence suggests that on average the developing countries are today (2014) somewhat more unequal than three decades ago.

This chapter reviews the empirical evidence on the levels and trends in income inequality and poverty in developing countries. We focus the analysis on the income/consumption approximations to welfare; in particular the chapter deals mainly with relative inequality across individuals in household consumption expenditures per capita, and with absolute poverty defined over that welfare variable, and considering alternative international lines defined in U.S. dollars adjusted for purchasing power parity (PPP). This choice is restricted by space limitations and does not imply ignoring that a general assessment of poverty and inequality should also include other nonmonetary dimensions (e.g., health, education) and other monetary variables (e.g., wealth). Other chapters in the Handbook contribute to fill those gaps.

The analysis in this chapter is mostly focused on inequality and poverty within countries and not within supranational regions or in the world.[1] Although issues of global inequality are increasingly relevant, inequality is still primarily a national concern. People are generally worried about inequality mainly in their countries, and public policies are typically aimed at reducing disparities among individuals within national boundaries.

The empirical evidence shown in this chapter is drawn from the academic literature, regional and country papers, and open-access databases, in particular the PovcalNet project developed in the World Bank. Although most of the evidence is based on statistics obtained from national household surveys, we also report results from tax records (the World Top Incomes Database, WTID) and international surveys (the Gallup World Poll) to illustrate some issues. Even though the main purpose of the chapter is to present basic

[1] Global inequality is analyzed in Chapter 11 of this volume.

evidence on levels and trends, we also briefly review the main discussions on determinants of recent changes in inequality and poverty.

The rest of the chapter is organized as follows. In Section 9.2 we briefly characterize the economies in the developing world and discuss the data sources and some measurement issues. The following two sections are assigned to the main topic in this volume—inequality. In Section 9.3 we document the levels of income inequality in the developing world, and in Section 9.4 we summarize the evidence on trends since the early 1980s. The next two sections repeat the sequence for poverty: Section 9.5 compares levels across countries, and Section 9.6 summarizes trends and discusses the evidence at the regional level.[2] Section 9.7 closes with a summary and some final remarks.

9.2. THE DEVELOPING WORLD: CHARACTERIZATION AND DATA

In this section we briefly characterize the economies of the developing world and review the sources of data to measure and analyze income poverty and inequality.

9.2.1 Developing Countries

The division between developed and developing countries is a helpful simplification that can be done in different arbitrary ways. In this chapter we follow the World Bank's main criterion based on gross national income (GNI) per capita: Developing countries are those with per capita GNI below a certain nominal threshold (US$ 12,276 in 2011). These nations are usually classified into six geographical regions: East Asia and Pacific (EAP), Eastern Europe and Central Asia (ECA), Latin America and the Caribbean (LAC), Middle East and North Africa (MENA), South Asia (SA), and sub-Saharan Africa (SSA). The Appendix includes a list of all the developing countries in each region with their populations.[3] The developing countries cover almost 75% of the total land area in the world and represent 85% of the total population. Table 9.1 summarizes some basic demographic and economic statistics.

According to these indicators Eastern Europe and Central Asia is the most developed region in the group: per capita GNI is almost twice the mean for the developing world, and the Human Development Index (HDI) is significantly higher. Latin American and the Caribbean ranks second, and Middle East and North Africa third. Although economic growth in Asia has been remarkable in the last decades, per capita GNI and other development indicators are on average still below the mean of the developing world.

[2] The separate treatment of inequality and poverty is somewhat artificial, as they are just two characteristics of the same income distribution. However, and despite some possible overlapping and duplications, we prefer to follow most of the literature and discuss both concepts separately.

[3] In this chapter we include emerging economies as part of the developing world, a decision that implies some overlapping with Chapter 8. In the period under analysis, some countries graduated from the set of developing countries; to avoid selection bias we do not drop them from the analysis.

Table 9.1 Population, GNI per capita and Human Development Index, 2010
Developing countries, by region

			GNI per capita		
	Countries	Population (millions)	PPP	Atlas method	HDI
Developing countries	153	5,840	7,023	4,291	0.608
East Asia and Pacific	24	1,961	4,911	2,992	0.619
Eastern Europe and Central Asia	30	478	12,558	7,815	0.751
Latin America and the Caribbean	31	584	9,789	6,433	0.706
Middle East and North Africa	13	331	6,462	3,647	0.636
South Asia	8	1,633	3,429	1,704	0.535
Sub-Saharan Africa	47	853	3,288	1,798	0.450
Developed countries	62	1,055	37,303	38,818	0.857
Total	216	6,894	15,682	14,181	0.663

Source: Population is taken from the United Nations Demographic Yearbook. Gross National Income (GNI) per capita in international dollars adjusted for purchasing power parity (PPP), and in current US$ (Atlas method) are taken from World Development Indicators. The Human Development Index (HDI) is from the UNDP Human Development Report. GNI and HDI are unweighted averages across countries.

South Asia is significantly less developed than East Asia and the Pacific. Sub-Saharan Africa is the poorest and least developed region of the world. The mean of the national per capita GNIs in that region is less than 50% of the developing world mean and less than 10% of the mean of the industrialized economies.

9.2.2 Data Sources

National household surveys are the main source of information for distributive analysis. Because one of the central goals of these surveys is measuring living standards, they typically include questions to construct a monetary proxy for well-being: income and/or expenditures on consumption goods. Although some developing countries started to implement national household surveys after World War II, it is only recently that governments engaged in programs of regularly collecting information through household surveys, often with the help of some international organization. Distributive statistics for the developing world are rare before the 1970s and reasonably robust only from the 1990s on. There has been a remarkable increase in the availability of national household surveys over the last decades. A chapter like this one, that includes a broad assessment of income inequality and poverty in developing countries, could hardly have been written two decades ago and is a sign of the huge progress made on data collection. However, as we discuss later, data limitations are still stringent and allow only a still blurred picture of inequality and poverty.

The databases for international distributive analysis can be classified into two groups: those that produce statistics with microdata from surveys or administrative records, and those that collect, organize, and report summary measures. The former group includes the World Bank's PovcalNet, the Luxembourg Income Study, the World Income Distribution database, the World Top Incomes Database, and some regional initiatives. The second one includes the seminal work by Deininger and Squire (1996) and its follow-up—the WIDER's World Income Inequality Database, the *All the Ginis* database, and some other projects.

The main source of information for poverty and inequality analysis at a large international scale in the developing world is the World Bank's PovcalNet, a compilation of distributive data built up from national household surveys, generally fielded by national statistical offices. PovcalNet, used for the World Bank's World Development Indicators, includes statistics constructed mostly from household survey microdata and in some few countries from grouped tabulations. At the moment of writing this database includes more than 850 surveys from almost 130 countries, representing more than 90% of the population of the developing world, spanning the period 1979–2011. The website of PovcalNet provides public access to data to generate estimates for selected countries and alternative poverty lines from grouped data.[4] Martin Ravallion and Shaohua Chen, the developers of PovcalNet, have produced several papers exploiting the data set (Chen and Ravallion, 2001, 2010, 2012; Ravallion and Chen, 1997). This project has been increasingly influential in shaping the assessment of inequality, and in particular poverty, in the developing world by researchers and policy practitioners. It is, for instance, the source used to monitor the poverty-reduction goal of the MDGs. This chapter draws heavily on statistics computed in the PovcalNet project.

Some regional initiatives aimed at estimating social statistics from harmonized household survey microdata are useful to study distributive issues in specific geographic areas and as sources of information for world databases. For instance, the *Socioeconomic Database for Latin America and the Caribbean* (SEDLAC), jointly developed by CEDLAS at Universidad Nacional de La Plata (Argentina) and the World Bank's LAC poverty unit, includes distributive and labor statistics for LAC constructed using consistent criteria across countries and years. *BADEINSO*, developed by the United Nations´ ECLAC, is also a large and good-quality database on social variables in LAC. In Eastern and Central Europe the *World Bank ECA database* includes statistics for 28 countries since 1990 computed from direct access to household surveys. The *Household Expenditure and Income Data for Transitional Economies* developed by Branko Milanovic at the World Bank is the predecessor of that database. Milanovic has also built the *World Income Distribution* (WYD) database, which includes data for five benchmark years (1988, 1993, 1998, 2002, and 2005) for 146 countries, 75% obtained from direct access to household surveys. The data set has

[4] Statistics are derived from the estimation of a general quadratic and a beta Lorenz curves from grouped data. Shorrocks and Wan (2008) propose an algorithm that reproduces individual data from grouped statistics with a higher degree of accuracy.

been used in several studies to compute global inequality (Milanovic, 2002, 2005, 2012). The *Luxembourg Income Study* (LIS), described in Chapter 8 of this volume, includes distributive information computed from household survey microdata for developed countries. LIS also reports statistics for several transitional economies in Eastern Europe and recently has added some developing countries in Latin America (Brazil, Colombia, Guatemala, Mexico, Peru, and Uruguay).

The growth in the availability of distributive statistics stimulated efforts to gather and organize them. Deininger and Squire (1996) put together a large data set of quintile shares and Gini coefficients for most countries since World War II taken from different studies and national reports.[5] This panel database, which greatly promoted the empirical study of the links between inequality and other economic variables, was updated and extended by the UNU/WIDER-UNDP *World Income Inequality Database* (WIID; WIDER, 2008).[6] The WIID database includes Gini coefficients, quintile and decile shares, and the income shares of the top 5% and bottom 5%. The information is drawn from very different sources, which raises comparability concerns.[7] To provide guidance in the use of the database, ratings are given to the observations, based on the survey quality, the coverage, and the quality of the information provided by the original source. The *SWIID* is an effort to identify reasonably comparable information in WIID (Solt, 2009).[8]

The *All the Ginis* database, assembled also by Branko Milanovic, is a compilation and adaptation of Gini coefficients retrieved from five data sets: LIS, SEDLAC, WYD, the World Bank ECA database, and WIID. Besides gathering all the information in a single file, the *All the Ginis* database is useful as it provides information on the welfare concept and recipient unit to which the reported Gini refers, facilitating the comparisons.

The *Chartbook of Economic Inequality*, assembled by Atkinson and Morelli (2012), presents a summary of evidence about changes in economic inequality (income/consumption, earnings, and wealth) in the period from 1911 to 2010 for 25 countries. The information drawn from household surveys for the seven countries in the developing world included in the database (Argentina, Brazil, India, Indonesia, Malaysia, Mauritius, and South Africa) starts in the 1950s.

[5] The Deininger and Squire data set was preceded by several earlier collections by the United Nations agencies, the World Bank, ILO, and others. See, for example, Paukert (1973), Jain (1975), and the references in Atkinson and Brandolini (2001).

[6] WIID was initially compiled over 1997–1999 for the UNU/WIDER-UNDP project "Rising Income Inequality and Poverty Reduction: Are They Compatible?" directed by Giovanni Andrea Cornia.

[7] Analyzing the Deininger and Squire data set, Atkinson and Brandolini (2001) conclude that "users could be seriously misled if they simply download the *accept* series (i.e., the 'high-quality' subset)". Although WIID implies a significant improvement from the original DS data set, a similar word of caution applies.

[8] SWIID should also be reviewed critically. In many cases it requires a case-by-case analysis, which is simply a sign that much effort is still needed in putting together comparable statistics. As it is based on secondary data sets, external problems are inadvertently incorporated.

All the data sets mentioned earlier are based on data from national household surveys.[9] Even when they are the best available source of information for distributive analysis, household surveys are plagued with problems for international comparative studies because, among other reasons, the questionnaires and the procedures to compute income/consumption variables differ among countries and frequently also within a country over time.[10] Some surveys inquire about income and others about consumption, some capture net income and some gross income, in some cases variables are reported on a weekly basis and in others on a monthly basis, items as the imputed rent for owner-occupied housing are included in some surveys and ignored in others.[11] Even in those projects that make explicit efforts to reduce these differences, comparability issues persist, as problems rooted in differences in questionnaires are difficult to be completely overcome. These limitations are well recognized in the literature. Chen and Ravallion (2012) state that "... there are problems that we cannot deal with. For example, it is known that differences in survey methods (such as questionnaire design) can create non-negligible differences in the estimates obtained for consumption or income." In a survey of global income inequality, Anand and Segal (2008) share those concerns.

There are some alternatives to reduce the comparability problems, although they all come at a price. Gallup conducts a survey in nearly all nations in the world with almost exactly the same questionnaire. The *Gallup World Poll* is particularly rich in self-reported measures of quality of life, opinions, and perceptions, but it also includes basic questions on demographics, education, and employment, and a question on household income. In principle, the Gallup World Poll allows a distributive analysis in nearly all the countries in the world based on the same income question. The downside is that measurement errors may be very large when reported income is based only on one question and with sample sizes of just around 1000 observations per country.[12]

The *Estimated Household Income Inequality* (EHII) data set produced by the University of Texas Inequality Project is based on UTIP-UNIDO, a global data set that calculates industrial pay-inequality measures for 156 countries from 1963 to 2003, using the between-groups component of a Theil index, measured across industrial categories in the manufacturing sector (Galbraith and Kum, 2005). Specifically, EHII consists on

[9] The exception is the Chartbook of Economic Inequality, which uses a range of sources, including tax data, that in some cases allows the analysis to go back much further than with household survey data.

[10] Some of these issues are also addressed in Chapter 11 of this Handbook.

[11] In addition, the typical problems of underreporting and selective compliance are negligible in some cases and endemic in others. See Deaton (2003, 2005) and Korinek et al. (2006).

[12] Gasparini and Gluzmann (2012) compare basic statistics drawn from the Gallup Poll with those computed from the national household surveys of the LAC countries for year 2006 and conclude that in most countries statistics from the Gallup Poll, including income poverty and inequality, are roughly consistent with those from national household surveys.

estimates of gross household income inequality computed from an OLS regression between the Deininger and Squire (DS) inequality measures and the UTIP-UNIDO manufacturing pay-inequality measures.[13] Although in principle the use of industrial pay information could lend some homogeneity into the comparisons, it should be stressed that because the underlying data do not refer to individuals and then have no distributive content, the methodology could be seen just as an extension of DS.

9.3. INEQUALITY: LEVELS

In this section we present results regarding the level of inequality in the developing countries, deferring to the next section the discussion of the trends. In most of the section we measure inequality computed over the distribution of household consumption per capita, using data from PovcalNet.[14] Consumption is usually regarded as a better measure of current welfare than income on both theoretical and practical grounds, especially in developing countries (Deaton and Zaidi, 2002). As it is usual in this literature, we frequently refer to *income inequality*, despite the fact that statistics are constructed over the distribution of consumption expenditures.

As discussed earlier, this chapter is mainly focused on within-country inequality, so welfare disparities are measured among individuals living within national boundaries. Although globalization is increasingly raising global inequality concerns, inequality remains mainly a national matter. This view also leads us to mostly document *unweighted* statistics of inequality measures across countries, a practice that is consistent with the typical cross-country approach in the development literature. Weighting by population would imply an assessment of inequality in a region or in the world strongly affected by some highly populated countries, such as China, India, and Indonesia in Asia, or Brazil and Mexico in Latin America, and almost ignoring the situation in other less-populated nations. Having said that, because the decision of taking each political entity as a unit in the analysis is certainly debatable, we show some results using both unweighted and population-weighted statistics.[15]

[13] The regression typically includes controls for the source of information in the inequality data (income/expenditure, gross/net, and household/per capita measures) and for the share of manufacturing employment in total employment.

[14] The drawbacks of computing inequality in the distribution of consumption or income per capita to measure distributive justice have been widely acknowledged. Among other limitations, it is a one-dimensional approach, it is focused on results not opportunities, it ignores the value of publicly provided goods such as education and health services, and it adopts a simple adjustment for demographics ignoring intrahousehold inequality, economies of scale, and differences in needs (Ferreira and Ravallion, 2009). However, extending inequality measurement to alleviate these limitations in a way that keeps international comparisons feasible has been proved difficult.

[15] See some arguments on this debate in Bourguignon et al. (2004).

9.3.1 Inequality in the Developing Countries

We start by comparing inequality levels across developing countries based on the Gini coefficient for the distribution of household consumption per capita for year 2010, computed in PovcalNet mostly from household survey microdata. Other inequality measures are highly correlated with the Gini coefficient. For instance, in PovcalNet and WIID data sets the Pearson and Spearman correlations of the Gini and several extreme inequality measures (e.g., the 90/10 and 80/20 income-share ratios) exceed 0.9.

PovcalNet includes information for the distribution of per capita consumption expenditures, except in almost all Latin American and a few Caribbean countries, for which income inequality statistics are reported. In the analysis that follows, we adjust the income Gini coefficients in that region to reflect the gap between income and consumption inequality estimates. Specifically, we selected seven Latin American countries with household surveys that include reasonably good consumption and income data in several years[16]: On average the ratio of the consumption/income Ginis is 0.861 (standard deviation of 0.046). We apply that coefficient to the 22 Latin American and Caribbean countries with income data to approximate their consumption Ginis.[17,18]

In most cases the observations correspond to year 2010, or adjacent years. However, some countries are lacking a recent household survey (or it was dropped due to quality concerns). In fact, in 24 countries the survey used to estimate inequality in 2010 was carried out between 2000 and 2005, whereas in 6 cases (5 of them in the Caribbean) the observation corresponds to the 1990s. With that caveat in mind, the PovcalNet data set has relatively recent distributive information for 82% of the countries in the developing world, representing 97% of its total population (see Table A.1 in the appendix). The country coverage across regions is heterogeneous. In East Asia and Pacific PovcalNet includes 12 out of the 24 developing countries, which nonetheless represent 96% of the total population of the area. The coverage in Eastern Europe and Central Asia is almost complete, lacking information only for Kosovo. In LAC the coverage is complete in continental Latin America, but weak in the Caribbean. Anyway, countries with information represent 98% of the total population in LAC (the main missing country in terms of population is Cuba). The data set in Middle East and North Africa does not include information for Lebanon and Libya, which represent only 3% of the MENA population. In South Asia the only country missing is Afghanistan, whereas in sub-Saharan Africa

[16] The countries are Argentina, Costa Rica, Ecuador, Mexico, Nicaragua, Panama, and Peru.

[17] We decided to apply the same coefficient to all LAC countries after failing to find significant regularities between the ratio consumption/income Ginis and other observable variables for the seven countries in the sample. World Bank (2006a) reports consumption and income Ginis in four Latin American countries; the mean ratio of the Ginis is 0.81. The value is somewhat lower (0.77) for the eight non-LA countries in the sample.

[18] We also tried an additive adjustment, instead of a multiplicative one, with no significant changes in the results.

there is information for 42 out of the 47 countries, representing 95% of the population, although in some cases the information is rather old.

Figure 9.1 displays the range of Gini coefficients for 122 countries around year 2010, ranking from the least unequal (Ukraine, 25.6) to the most unequal economy (South Africa, 63.1).[19] The mean value is 39.8, and the median is 39.2. More than half of the observations are in the range [35, 45]. Only seven Eastern Europe countries have Ginis below 30, and five sub-Saharan African countries have Ginis higher than 55. The population-weighted mean is less than one point lower than the simple mean (39.1), a result affected by the relatively low level of inequality in populous India and Indonesia (China has a Gini somewhat higher than the world mean). Figure 9.1 shows the position of some of the most populated countries: Brazil has high inequality levels, China and Russia intermediate values, and India and Indonesia relatively low levels in the context of the developing world.

The variability of Gini coefficients across countries is large compared to the changes within countries over time, at least for the period for which we have more robust information (since the early 1980s). Li et al. (1998) find in the Deininger and Squire data set that 90% of the total variance in the Gini coefficient is explained by variation across

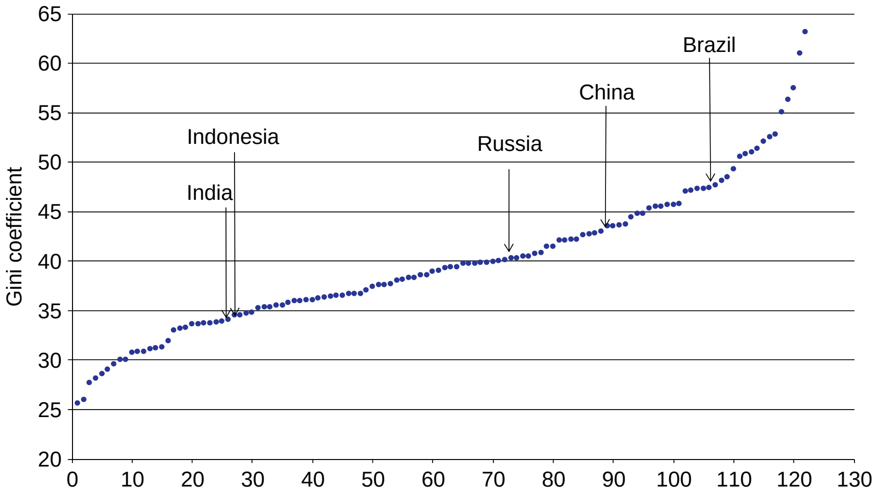

Figure 9.1 Gini coefficients for the distribution of household consumption per capita. Developing countries, 2010. *Note: Countries sorted by their Gini coefficients. Source: Own calculations based on PovcalNet (2013).*

[19] PovcalNet reports Ginis above 63.1 for Comoros and Seychelles, two small island countries in the Indian Ocean. However, the results are not well established. For instance, the reported Gini in Seychelles was 42.7 in 2000 and 65.8 in 2007, a highly implausible change in just 7 years.

countries, whereas only a small percentage is accounted for by variation over time. From this observation Li et al. (1998) conclude that inequality should be mainly determined by factors that differ substantially across countries, but tend to be relatively stable within countries over time. We find a similar result in a panel of developing countries from 1981 to 2010 (PovcalNet data): 88.5% of the variance in that panel is accounted for by variation across countries.

The inequality rankings are relatively stable over time. The Spearman-rank correlation coefficient for the Ginis in 1981 and 2010 is 0.68, whereas it rises to 0.74 for 1990 and 2010, both significant at 1%. The last decades witnessed enormous economic, social, and political changes in the developing world, but, although the income distributions have been affected with various intensities, the world inequality ranking has not changed much, a fact that suggests the existence of some underlying factors that are stronger determinants of the level of inequality.

In Figure 9.2 developing countries are grouped in regions. Sub-Saharan Africa is the geographic area that includes countries with the highest inequality levels, but it is also the region with the highest dispersion, possibly in part due to measurement errors (Table 9.2). Although eight out of the 10 highest Gini coefficients belong to sub-Saharan African countries, and the arithmetic mean of the Gini coefficient is the highest in the world, the median is lower than in Latin America.

Latin America and the Caribbean has been typically pointed out as the most unequal region in the world. Deininger and Squire (1996), for instance, stated that their data set confirm the "familiar fact that inequality in Latin America is considerably higher than in

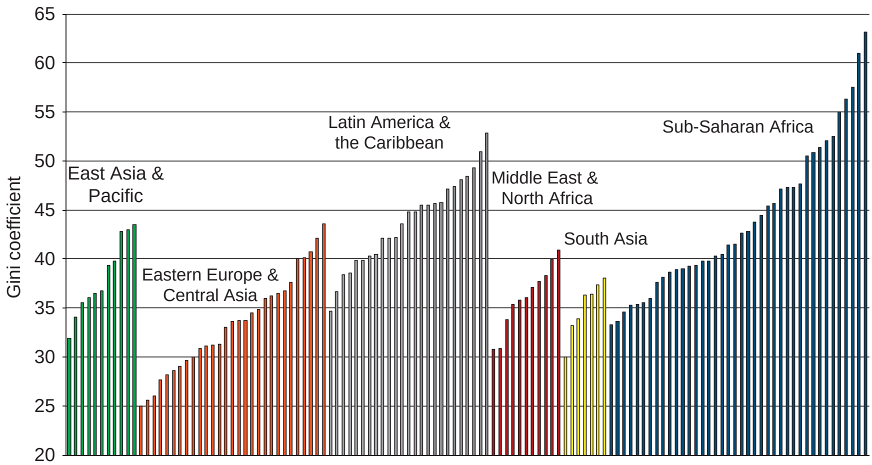

Figure 9.2 Gini coefficients for the distribution of household consumption per capita. Developing countries, 2010. *Note: Each bar represents a country in a given geographic region of the developing world. Source: Own calculations based on PovcalNet (2013).*

Table 9.2 Gini coefficients for the distribution of household consumption per capita
Developing countries, 2010

	Mean	Median	Coef. Var.	Min.	Max.
East Asia and Pacific	38.1	36.7	0.101	31.9	43.5
Eastern Europe and Central Asia	33.6	33.7	0.144	25.6	43.6
Latin America and the Caribbean	43.8	44.8	0.104	34.7	52.8
Middle East and North Africa	36.0	36.1	0.091	30.8	40.9
South Asia	35.0	36.3	0.081	30.0	38.1
Sub-Saharan Africa	44.4	42.1	0.175	33.3	63.1
Developing countries	39.8	39.2	0.181	25.6	63.1

Note: Unweighted statistics.

the rest of the world."[20] This type of assessment, however, is usually made combining income Ginis for LAC with consumption Ginis for other regions and/or ignoring sub-Saharan Africa. With the adjustment mentioned earlier to take the consumption/income gap into consideration (factor 0.861), we find that the mean Gini for LAC is 43.8, slightly lower than in SSA (44.4), but the median is higher (44.8 in LAC and 42.1 in SSA). To reach the result of a higher mean Gini in LAC than in SSA, we would need an adjustment parameter higher than 0.92; such value is larger than what we estimated in all LA countries in the sample, except Mexico.

The rest of the regions in the developing world have Ginis mostly below 40. The arithmetic mean is 38.1 in East Asia and Pacific, 36.0 in Middle East and North Africa, and 35.0 in South Asia. Inequality is likely to be higher in MENA because several oil-producing countries are excluded for being high-income economies (and also for lack of information).[21] Eastern Europe and Central Asia is the region with the lowest inequality levels, with a mean Gini coefficient of 33.6. Interestingly, the dispersion measured by the coefficient of variation is higher than in the rest of the regions, except SSA.

Almost all very highly unequal countries (Gini coefficients above 50) are in sub-Saharan Africa (Table 9.3). This region, however, has a similar share of countries in the high and middle categories. In contrast, in LAC most countries have high levels of inequality, whereas in EAP, MENA, and SA most countries are in the middle-inequality group. Only ECA has economies with low inequality (Gini coefficients below 30).

The *All the Ginis* data set (ATG) includes Gini coefficients from LIS, SEDLAC, WYD, the World Bank ECA database, and WIID. We selected consumption Ginis from ATG for year 2005 or close and applied a similar adjustment as described earlier for those countries in LAC with only income Ginis. The basic results are similar to the ones

[20] See also López Calva and Lustig (2010) and Chen and Ravallion (2012).
[21] Bahrain, Kuwait, Oman, Qatar, Saudi Arabia, and United Arab Emirates are in that group. Malta and Israel are also ignored for being developed, and Lebanon and Libya are excluded for lack of information.

Table 9.3 Classification of countries by level of inequality and by region
Developing countries, 2010

	Inequality				
	Very high [50–70]	High [40–50]	Middle [30–40]	Low [20–30]	Total
East Asia and Pacific	0	3	8	0	11
Eastern Europe and Central Asia	0	5	16	7	28
Latin America and the Caribbean	2	17	6	0	25
Middle East and North Africa	0	1	10	0	11
South Asia	0	0	7	0	7
Sub-Saharan Africa	10	14	16	0	40
Total	12	40	63	7	122

Note: Countries are classified according to the value of the Gini coefficient for the distribution of household consumption per capita.
Source: Own calculations based on PovcalNet (2013).

obtained with PovcalNet data. The linear correlation coefficient for the Gini between both data sources is 0.763, whereas the Spearman rank correlation is 0.771, both significant at 1%. The Gini coefficients in ATG go from 23.1 (Czech Republic) to 62.9 (Comoros). The mean and median coincide in 40.1. Again, more than half of the observations are in the range [35, 45]. Only several Eastern European countries have Ginis below 30, whereas only four sub-Saharan African countries have Ginis higher than 55.

The evidence on inequality levels in the developing world drawn from WIID is similar. For instance, based on a sample of income Ginis for around 2005, Gasparini et al. (2013) find that the mean Gini for the six sub-Saharan African countries in the data set is 56.5, followed by Latin America (52.9), Asia (44.7), and Eastern Europe and Central Asia (34.7).[22] The linear correlation coefficient for year 2005 for the Gini coefficient in PovcalNet and WIID is 0.871, and the Spearman coefficient is 0.820.

The Luxembourg Income Study database (see Chapter 8 of this volume) covers 36 countries, including 6 in Latin America, which occupy the top places in all the income inequality rankings.[23] The mean Gini for the Eastern European countries in LIS is slightly higher than the mean for the high-income economies. Data from the World Development Indicators also suggest that inequality in the developing world is significantly higher than in the OECD high-income countries. The mean income Gini for the latter group is 32.2, which is lower than in any other region in the world.

[22] The OECD high-income countries rank as the least unequal in the world with a mean income Gini of 32.8.

[23] The LA Ginis go from 50.6 in Colombia to 43.9 in Uruguay; the most unequal non-LA country is Russia with a value of 40.8, whereas the rest of the countries in LIS go from 37 (USA) to 22.8 (Denmark).

The EHII database confirms the high inequality levels of sub-Saharan Africa and Latin America, but perhaps surprisingly, it records similar levels in South Asia and Middle East and North Africa (Gini of around 47).[24] According to this data set, inequality is relatively lower in East Asia and Pacific and Eastern Europe and Central Asia. The estimated level of the Gini coefficient is substantially lower in the developed economies; the mean is equal to 36.5.[25] The Pearson (Spearman) correlation coefficient between EHII and PovcalNet Ginis is 0.642 (0.603), lower than the resulting value when comparing PovcalNet with WIID or ATG, but still significant at 1%.

Most international databases do not provide confidence intervals for the point estimates of the distributive measures, making impossible the assessment of the statistical significance of the differences in inequality among countries. However, given that the indicators are calculated from large national household surveys, the confidence intervals are typically relatively narrow. SEDLAC provides the confidence intervals for all the Gini coefficients in Latin America. For instance, the 95% confidence interval for the income Gini was [43.9, 44.7] in Argentina 2010, [53.5, 54.0] in Brazil 2009, and [47.0, 47.9] in Mexico 2010. Differences in the point estimates of more than 1 Gini point are always statistically significant (Figure 9.3).

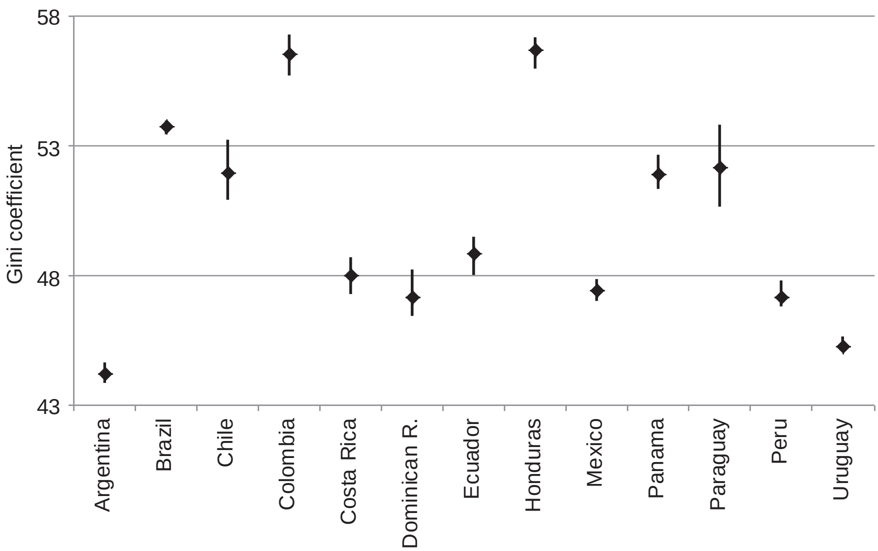

Figure 9.3 Gini coefficient and confidence intervals (95%). Distribution of household income per capita. Latin American countries, 2010. *Source: Own calculations based on SEDLAC (CEDLAS and the World Bank).*

[24] See also Galbraith and Kum (2005).

[25] This mean excludes the oil-rich Arab countries. When including these countries in the sample, the mean Gini jumps to 39.

9.3.2 Inequality Beyond the Gini Coefficient

The international databases usually allow a closer look at the distributions in the world beyond a single parameter, such as the Gini coefficient. Table 9.4 reports some basic statistics of the decile shares in 120 countries around 2010.[26] On average (unweighted) the poorest 10% of the population in a country accrues 2.6% of total consumption reported in the survey; that share climbs to 31.5% for the top 10%. In a typical developing country the aggregate consumption of the poorest 60% of the population is similar than the consumption of the top 10%.

It is interesting to notice that the coefficient of variation of the decile consumption shares across countries is decreasing up to the top decile, when it strongly rises. Countries in the world seem substantially different in the consumption share of the poor and the rich, but not in the share of the middle strata, in particular the upper-middle strata.[27]

The aggregate consumption share of deciles 5–9 is on average around 50%, and it is very stable across countries. Palma (2011) has labeled this phenomenon the *homogeneous middle*. Variability across countries is actually smaller in the upper-middle deciles (deciles 7–9). The proportion of total consumption accruing to that group is quite similar in all geographic regions of the world; it ranges from 35.9% in SSA to 37.3% in ECA. The main difference across regions lies in the share of the bottom 60% compared to those

Table 9.4 Deciles shares, distribution of household consumption per capita
Developing countries, 2010

Deciles	Mean	Std. Dev.	Coef. Var.	Min.	Max.
1	2.6	0.81	0.31	1.0	4.4
2	3.8	0.86	0.23	1.5	5.8
3	4.8	0.90	0.19	2.0	6.8
4	5.8	0.92	0.16	2.6	7.8
5	6.8	0.92	0.13	3.5	8.8
6	8.1	0.87	0.11	4.7	9.9
7	9.6	0.80	0.08	6.6	11.0
8	11.7	0.65	0.06	9.0	12.7
9	15.3	0.84	0.05	12.7	17.6
10	31.5	6.12	0.19	19.5	51.7

Note: Unweighted statistics.
Source: Own calculations based on PovcalNet (2013).

[26] Again, figures for Latin American and a few Caribbean countries are estimated based on the comparison of income and consumption microdata of seven countries in that region.

[27] This observation could be simply linked to the fact that the cumulative distribution functions of two income distributions most often cross around the middle (e.g., in a mean preserving spread) rather than at the ends of the distributions.

in the upper 10%. For example, whereas the share of deciles 7–9 in total consumption is almost the same in ECA (37.3%) and LAC (37.1%), the share of the bottom 60% is more than 7 points higher in the former (36.4% and 29.1%, respectively).

The correlation coefficients for the decile shares in total consumption provide information about the structure of the distributions across countries (Table 9.5). In a cross-country perspective, gains are highly positively correlated in the first 8 deciles; on the other hand, for decile 10 correlations are all negative and large, except with decile 9, for which the correlation is non-significant. Gains in the participation of the richest 10% are tightly linked to losses in the share of the poorest 80% of the population. The table suggests that when we move up in the ladder of countries according to the share of the bottom deciles, we expect to see gains in the lowest strata obtained mostly against the share of the upper 20% of the population (and not, for instance, against the middle strata, and in alliance with the most affluent).

9.3.3 Inequality in the Gallup World Poll

The Gallup World Poll provides new evidence on the international comparisons of income inequality, as it includes identical income and demographic questions applied to national samples in 132 countries. Of course, the reliability of the national inequality estimates in Gallup is lower than those obtained with household surveys because only one income question is used to approximate well-being, and the sample sizes are considerably smaller. However, Gluzmann (2012) finds that the correlation coefficient between the Gini coefficients computed with Gallup microdata and those reported in the World Development Indicators (WDI) that are based on per capita income is high (0.85).[28] International surveys with similar questionnaires across countries, such as the Gallup World Poll, could hardly be a substitute for household surveys as the main source for distributive analysis at the country level, but they may have a great potential for international comparisons of social variables. Future improvements in the quality of these surveys could turn them into a very valuable source for comparative international research.

Gasparini and Gluzmann (2012) use microdata from the Gallup World Poll 2006 to compute inequality in each region of the world. According to the unweighted mean of the national income Gini coefficients, Latin America is the most unequal region in the world (excluding Africa, which is not in the sample). The mean Gini in Latin America is 49.9, slightly larger than in South Asia (48.9) and Eastern Asia and Pacific (47.1). Countries in Eastern Europe and Central Asia (41.8), North America (39.2), and especially Western Europe (34.0) are the least unequal. Alternatively, regional inequality can be measured by considering each region as a single unit and computing inequality among

[28] Interestingly, the relationship between the income Ginis in Gallup and the consumption Ginis in WDI is much weaker; the linear correlation coefficient is 0.21, non-significant at 10%.

all individuals in that unit, after translating their incomes to a common currency—a concept usually labeled *global inequality* (see Chapter 11 of this Handbook). The global Gini in Latin America is 52.5, a value higher than in Western Europe (40.2), North America (43.8), and Eastern Europe and Central Asia (49.8), but lower than in South Asia (53.2) and Eastern Asia and Pacific (59.4). The change in the rankings between the two concepts of inequality is driven by the differences across regions in the heterogeneity among countries in terms of mean income. Gasparini and Gluzmann (2012) report that the between component in a Theil decomposition accounts for 8% of total regional inequality in Latin America and 32.4% in East Asia and Pacific.

9.3.4 Top Incomes

Until the recent developments in the literature of top incomes from tax records (Atkinson and Piketty, 2007, 2010; see also Chapter 8 in this volume), inequality research has been mostly based on household surveys, which suffer from several limitations when focusing on the upper end of the distribution. Household surveys are all but ideal for studying top shares: The rich are usually missing from surveys, either for sampling reasons or because they refuse to cooperate with the time-consuming task of completing or answering a long form. Because extreme observations are sometimes regarded as data "contamination," the rich may be intentionally excluded or top coded so as to minimize bias problems generated by presumably less-reliable outliers or to preserve anonymity. In addition, survey data present severe underreporting at the top; the richest individuals are more reluctant to disclose their incomes or have diversified portfolios with income flows that are difficult to value.

Székely and Hilgert (1999) look at surveys from eighteen Latin American household surveys and confirmed that the ten highest incomes reported are often not much larger than the salary of an average manager in the given country at the time of the survey. In general, the profile of the average individual in the top 10% of the distribution is closer to the prototype of highly educated professionals earning labor incomes, rather than capital owners. On this specific issue, the quality of statistical information coming from surveys has not improved in the last years. Consequently, the inequality that we are able to measure with household surveys can be severely affected, regarding both levels and dynamics, in those cases or periods in which an important part of the story takes place at the top.

Tax and register data are being increasingly preferred over surveys in studying distributive issues at the top. In fact, under certain conditions registry data can provide valuable information to improve survey-based estimates. Typically, incomes reported to the surveys are checked against the registers, or incomes are directly taken from administrative sources for the individuals in the sample. Even if the combination of survey and administrative data can be seen as an improvement, there remains the issue of the sampling framework for the top of the distribution.[29] In any case, statistics offices in the developing world are not exploiting register data to complement surveys yet.

The use of tax statistics is not without drawbacks. First, because only a fraction of the population files a tax return, studies using tax data are restricted to measuring top shares, which are silent about changes in the lower and middle part of the distribution. Second, tax data are collected as part of an administrative process and do not seek to address research needs; both income and tax units are defined by the tax laws and vary considerably across time and countries. Third and most important, estimates are affected by tax avoidance and tax evasion; the rich, in particular, have a strong incentive to understate their taxable incomes. These elements, which are common to all countries, become critical in the developing world, characterized by tax systems with low enforcement and multiple legal ways to avoid the tax.[30]

A number of researchers have addressed the differences in the ability of tax and survey data to represent income inequality, trying to reconcile the evidence using the two sources (see Alvaredo, 2011; Burkhauser et al., 2012 for the United States). Unfortunately, at the moment of writing only a few developing countries have made available microdata from the income tax (namely Colombia, Ecuador, and Uruguay). Alvaredo and Londoño (2013), and Alvaredo and Cano (forthcoming) show that, in contrast to survey-based results, high-income individuals are, in essence, rentiers and capital owners. This feature differs from the pattern found in several developed countries in recent decades, where it has been shown that the large increase in the share of income going to the top groups has been mainly due to spectacular increases in executive compensation and high salaries, and to a lesser extent to a partial restoration of capital incomes. Although the working rich have joined capital owners at the top of the income hierarchy in the United States and other English-speaking countries, Colombia and Ecuador remain more traditional societies where the top-income recipients are still the owners of the capital stock.

Results, even if fragmentary, confirm that incomes reported to the tax authorities are considerably higher than those captured by the surveys at the top. For instance, the share of income accrued by the top 1% in Argentina in 2007 was 8.8% using household survey data (PovcalNet) and 13.4% using income tax data (WTID). In Uruguay 2010 the shares were 8.2% and 14.3%, and in Colombia 2010 13.9% and 20.4%, respectively. Even if those numbers are not directly comparable (surveys incomes are before tax), they show

[29] If high-income individuals are not properly identified in the sample framework, comparing the incomes reported to the surveys against those in the registers one by one is only a partial improvement. In the UK, for example, the ONS scales up the surveys' incomes so that the surveys' averages match the average income in tax data.

[30] The reasons for which the rich and wealthy may be particularly dissuaded from disclosing their fortunes and incomes to authorities in the developing world may go beyond tax concerns, lest the information revealed fall into the wrong hands. Alvaredo and Londoño (2013) report that in Colombia, until recently plagued by high insecurity, anecdotal evidence suggests that during the intense political violence of the 1990s, leaked personal tax returns were used by criminal groups to target victims and kidnap for ransom.

that synthetic measures of inequality, if presented in an isolated way, hide survey-based shares that may be unrealistically low. In this sense, it could be a good practice to systematically show the inequality indexes together with the shares of the underlying top percentiles to let users judge the quality of the estimates.[31]

A natural question, which has received much attention lately, is the extent to which tax data can complement household surveys in examining the level of inequality in developing countries. Alvaredo and Londoño (2013) compare the Colombian household survey with the tax micro-data over the years 2007–2010. The total household income from the survey is 60–65% of the NAS measure of disposable income.[32] Such gap cannot be seen as an accurate measure of the total missing income in household surveys because both sources are different, but a partial explanation may well be at the top of the distribution. As a simple exercise, these authors replace all the incomes above the percentile 99 in the survey with those from tax data (net of taxes and social security contributions to render both sources comparable), under the assumption that the top 1% is poorly captured in the survey. Two elements are worth mentioning. First, the gap between the NAS figure and the survey's incomes of the bottom 99% plus the net-of-tax incomes from tax data above the percentile 99 goes down from 35–40% to 20–25%. Second, the Gini coefficient of individual incomes goes up from 55 to 61 in 2010.[33]

These findings challenge the general skepticism regarding the use of tax data from developing countries to study inequality. Such estimates should be regarded as a lower bound, to take into account the effects of evasion and underreporting. Nevertheless, they show that incomes reported to tax authorities can be a valuable source of information, under certain conditions that require a case-by-case analysis.

9.3.5 Inequality and Development

Is the level of inequality in a country associated to its development stage? In this section we take advantage of a cross section of national Gini coefficients for year 2010 to take a look at this issue. Of course, this topic is related to the long-lasting debate initiated with the seminal contributions by Lewis (1954) and Kuznets (1955), who argued that the process of industrialization would imply an inverse U pattern for inequality. However, the empirical test for the Kuznets curve requires time-series or panel data, and not just a cross

[31] Povcalnet follows this practice by providing estimates of the Lorenz curve, with varying degrees of detail depending on the country.

[32] The National Accounts-based measure of household disposable income has been defined as: balance of households' primary incomes + social benefits other than social transfers in kind − employers' actual social contributions − imputed social contributions − attributed property income of insurance policyholders − imputed rentals for owner occupied housing − fixed capital consumption − employees' social security contributions − taxes on income and wealth paid by households.

[33] These results are still approximations, as defining individual actual incomes from the Colombian tax records is not always straightforward.

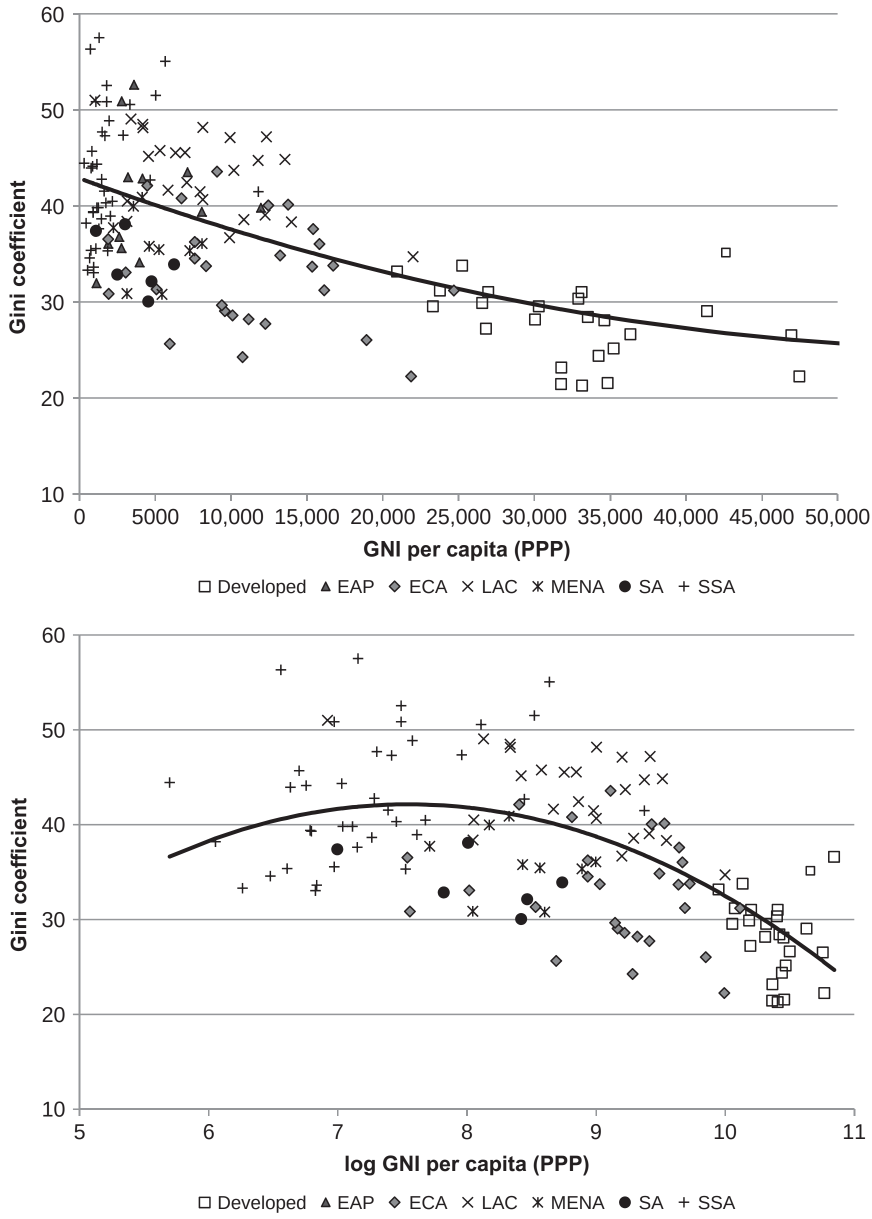

Figure 9.4 Inequality and development. Per capita gross national income (GNI) and Gini coefficient, 2010. *Source: Own calculations based on WDI and PovcalNet (2013).*

section, because it is a hypothesis about the dynamics of an economy over its development process. The causal relationship between development and inequality is the subject of a large literature that has to face numerous empirical challenges, and hence it is far from settled (see Anand and Kanbur, 1993; Banerjee and Duflo, 2003; Fields, 2002; Voitchovsky, 2009, for assessments). In this section we simply document the empirical relationship between these two variables across countries in a recent point in time without exploring the difficult issue of causality.

The first panel in Figure 9.4 plots the Gini coefficient for the distribution of consumption per capita against per capita gross national income (GNI).[34] The figure seems to

[34] The Gini for the developed countries is computed over the distribution of income per capita, and not consumption per capita, a fact that probably underestimates the slope of the curve.

reveal a decreasing relationship between inequality and development. The linear correlation coefficient between the Gini coefficient and per capita GNI is −0.56 (statistically significant at the 1% level). An inverse-U shape shows up in the second panel of Figure 9.4, when per capita GNI is presented in logs. However, the increasing segment of the curve covers only very poor sub-Saharan African countries. The relationship Gini-GNI is decreasing in the range of GNI of most countries in the world.

The results of the regressions in Table 9.6 and the Lind and Mehlum (2010) test confirm an inverse U shape for the relationship between the Gini coefficient and log GNI per capita in a cross section of countries.[35] The result seems also valid, although it becomes considerable weaker when restricting the sample to developing economies. It should be stressed that the turning points implicit in the regressions correspond to around US$ 1800, a value that is lower than the per capita GNI of most developing countries, except for some economies in sub-Saharan Africa.[36] The inclusion of regional dummies reveals that East Asian, and especially Latin American and sub-Saharan African, countries are particularly unequal, even when controlling for their levels of economic development.[37]

9.4. INEQUALITY: TRENDS

In this section we report the recent trends in income inequality in the developing countries. We start laying out the general patterns, and then dig deep into the evidence for each region. Although most of the section deals with relative inequality, we devote a section to explore patterns for absolute inequality and a section to document aggregate welfare changes.[38] We end with a brief summary of the methodologies and main issues in the debate on inequality determinants in the developing world.

9.4.1 General Changes

The available evidence suggests that on average the levels of national income inequality in the developing world increased in the 1980s and 1990s and declined in the 2000s. Using data from PovcalNet, the mean Gini for the distribution of per capita consumption

[35] It is also confirmed estimating GDP with the Atlas method and using the *All the Ginis* database.

[36] Larger measurement errors in the SSA countries may also account for the increasing segment of the curve. Also, it is possible that the econometric model is picking up the concavity of the relationship at higher income levels.

[37] The Latin American "excess inequality" is documented in Londoño and Székely (2000); Gasparini, Cruces and Tornarolli (2011a), and others.

[38] Although relative inequality measures are scale invariant, absolute measures are translation invariant. Accordingly, a general increase of x% in all incomes in the population will leave relative inequality unchanged, but imply an increase in absolute inequality.

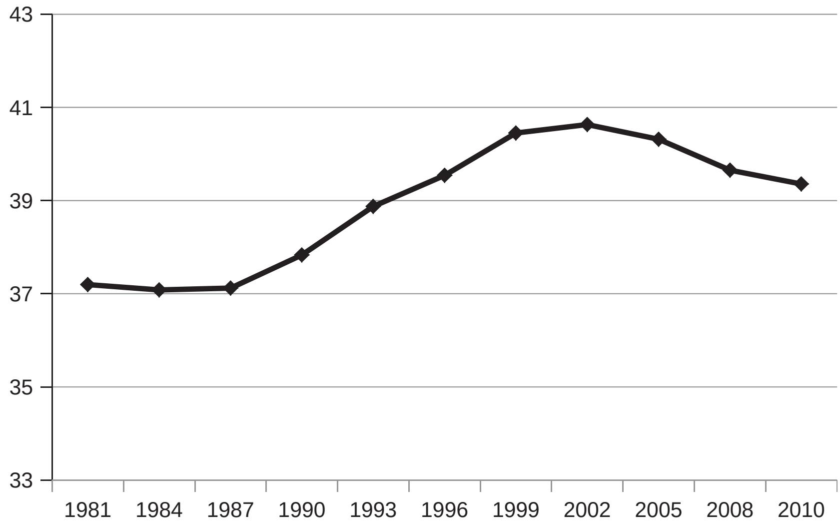

Figure 9.5 Gini coefficient. Unweighted mean for developing countries, 1981–2010. *Note: The national Gini coefficients are computed over the distribution of household consumption per capita. Source: Own calculations based on PovcalNet (2013).*

expenditures increased from 37.2 in 1981 to 39.4 in 2010 (Figure 9.5).[39] The mean was basically unchanged between 1981 and 1987,[40] then increased more than three points to reach a value of 40.5 in 1999, and from 2002 it started to fall, although slowly (from 40.6 in 2002 to 39.4 in 2010).[41]

Figure 9.6 adds to the picture the changes at different percentiles of the distribution of national Ginis. The figure makes clear that on average the changes in the last decades have not been large compared to the range over which the Gini varies across countries.[42] The picture also reveals that the growth in the mean Gini in the late 1980s and 1990s

[39] To compute changes we discard countries in PovcalNet with less than four observations over the period 1981–2010, or with observations concentrated in a narrow time-period. The sample we use for the calculations on trends include 76 countries that represent 88% of the developing world population. To build a sample in which the country composition is held constant in a few cases, Gini coefficients are imputed assuming constant inequality. Income Ginis in LAC are adjusted as explained in the previous section.

[40] This result is in part driven by the lack of information on changes in inequality over this period for several countries in the developing world. See below.

[41] The assessment of the economic salience of inequality changes over time is controversial as it involves both issues regarding the accuracy of the data and considerations on the purpose for which the inequality statistics are used. In the context of the OECD countries, Atkinson and Marlier (2010) propose applying a 2% points criterion to assess the salience of the change in the Gini. On this basis, the increase in inequality in the developing world from 1981 to 2010 is just salient.

[42] This observation does not imply that changes were of little social relevance; an increase in inequality in a given country could be small in relation to the difference with other countries, but still a major cause of concern.

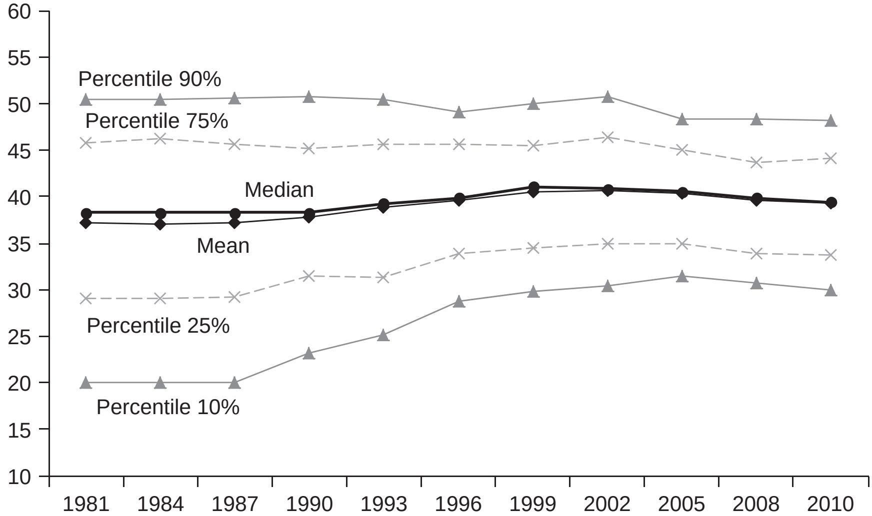

Figure 9.6 Distribution of Gini coefficients. Unweighted statistics for developing countries, 1981–2010. *Note: The national Gini coefficients are computed over the distribution of household consumption per capita. Source: Own calculations based on PovcalNet (2013).*

was mainly due to the substantial increase in the low-inequality countries, in particular Eastern Europe and Central Asia economies after the fall of communism, and also some Asian economies in the early stage of economic takeoff. Instead, the fall in the 2000s was widespread, although more intense in those countries above the median, such as those in Latin America. This observation suggests convergence in the levels of inequality in the developing economies. In fact, the standard deviation for the distribution of Gini coefficients substantially fell over time: 11.2 in 1981, 10.1 in 1990, 7.4 in 1999, and 7.2 in 2010. Countries in the developing world are still very different in terms of income inequality, but differences have become considerably smaller over the last three decades (more on convergence below).

A closer inspection of the data reveals that the result of a stable mean Gini in most of the 1980s is driven by the lack of information for several countries and by a substantial heterogeneity in the changes of those with information (Table 9.7).[43] The strong rise in the mean Gini in the 1990s is associated with a large proportion of countries with growing inequality in a framework of much improved information. The tide seems to have turned in the 2000s, when most of the countries in the sample experienced a fall in

[43] We classify countries in groups according to whether the Gini went up or down by more or less than 2.5% in a period. A change of 2.5% applied to the mean Gini in the developing world—which is around 40—represents 1 Gini point. A change of 1 point in the Gini coefficient is typically statistically significant, given the sample sizes of the national household surveys.

Table 9.7 Proportion of countries classified in groups according to the change in the Gini coefficient

	1981–1990	1990–2002	2002–2010
Fall	14.7	22.7	65.3
No change	21.3	16.0	14.7
Increase	34.7	60.0	20.0
No information	29.3	1.3	0.0
Total	100.0	100.0	100.0

Note: "Fall" includes countries where the Gini fell more than 2.5% in the period; "Increase" includes countries where the Gini rose more than 2.5%; "No change" includes countries where the Gini changed less than 2.5%; "No information" includes countries without two independent observations in each period.
Source: Own calculations based on PovcalNet (2013).

inequality. But even in this decade of widespread social improvement, the country performances in terms of inequality reduction were quite heterogeneous. In fact, in 20% of the economies of the developing world the Gini coefficient increased between 2002 and 2010, whereas in 15% of the countries the changes were smaller than 2.5%.

We find that the bulk of the countries in the sample (62%) experienced a change in the pattern of inequality around the turn of the century, from nonfalling to decreasing inequality, whereas only a few experienced a pattern of continuous increasing (15%) or decreasing (12%) disparities. In fact, an inverse-U shape for the inequality pattern is observed for many economies (45% of the sample), a fact that could be consistent with the Kuznets story of economic growth for countries located close to the curve turning point. However, we fail to find any significant correlation between the type of the inequality pattern and different measures of development and growth. The inverse-U pattern in the period 1981–2010 appears to have been common to a wide range of economies.

The growth in the population-weighted mean of the Gini coefficient across developing countries was stronger than the increase in the unweighted mean (Figure 9.7). Although the latter increased 2.2 points in the period 1981–2010, the former jumped 7.5 points. The gap between the two means shrunk from 5.4 points in the early 1980s to almost zero in the late 2000s. This pattern is mainly accounted for by the dramatic surge in income inequality in China over the period. Interestingly, the fall in the unweighted mean Gini in the 2000s does not show up in the weighted mean; although the Gini coefficient for a typical developing country significantly decreased in the 2000s, the national Gini for a typical person in the developing world did not fall.

In the rest of this section we go beyond the Gini coefficient and track changes along the distribution. In Figure 9.8 each point in a growth-incidence curve (GIC) indicates the unweighted mean across countries in the annual rate of growth of real consumption per capita (in PPP US$) for a given decile of the national distributions.[44] There is a stark

[44] The GIC depicted in Figure 9.8 is not the world growth-incidence curve, where, for instance, decile 1 would include the poorest 10% of the world population.

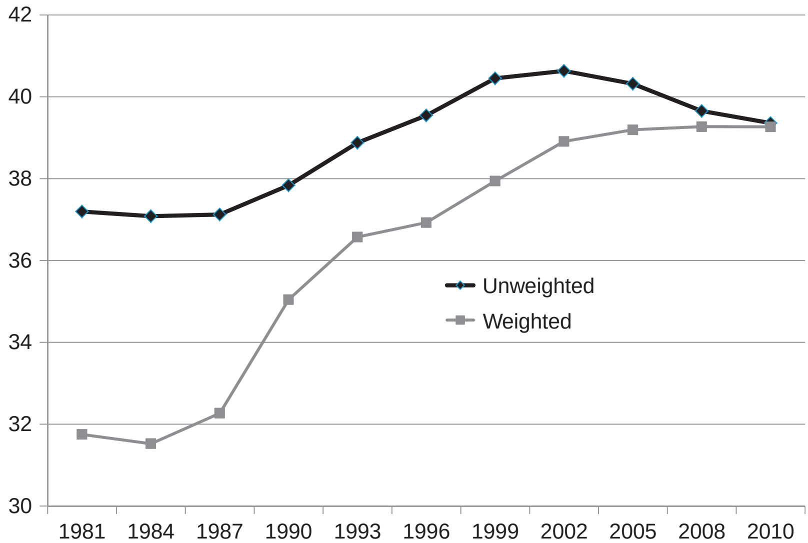

Figure 9.7 Gini coefficient. Weighted and unweighted means. Developing countries, 1981–2010. *Note: The Gini coefficients are computed over the distribution of household consumption per capita. Source: Own calculations based on PovcalNet (2013).*

contrast in the GIC corresponding to the 1990s and the 2000s. The first one is clearly increasing, suggesting growing inequalities, whereas the second is decreasing (and flatter), indicating a fall in well-being disparities in the 2000s. On average, in that decade consumption per capita grew by more than annual 4% in the three bottom deciles of the national distributions and by 3% in the top decile.

Naturally, the contrast between decades is also evident when looking at income shares. The results are summarized in Figure 9.9: whereas the share of the bottom 60% fell 2 points in the 1990s and increased 0.9 points in the 2000s, the performance of the top 10% was almost the exact mirror. The share of the "middle" (deciles 7–9) has remained quite stable over the two last decades (36.9 in 1990, 36.5 in 1999, and 36.6 in 2010). This stratum seems not only quite homogeneous across countries but also over time (Palma, 2011).

9.4.2 Changes by Region

Changes in inequality have been heterogeneous across the six geographical regions of the developing world (Figure 9.10).[45] The mean Gini coefficient in Latin America increased more than two points in the 1990s and then dropped in the 2000s by a larger amount. The data reveals almost no change in inequality in sub-Saharan Africa over the two last

[45] We prefer not to report the regional patterns before 1990 because the number of observations is small in several regions. The numbers of countries by region in the sample we use to assess inequality trends are 8 in EAP, 20 in ECA, 19 in LAC (all in Latin America, none from the Caribbean), 5 in MENA, 4 in SA, and 20 in SSA.

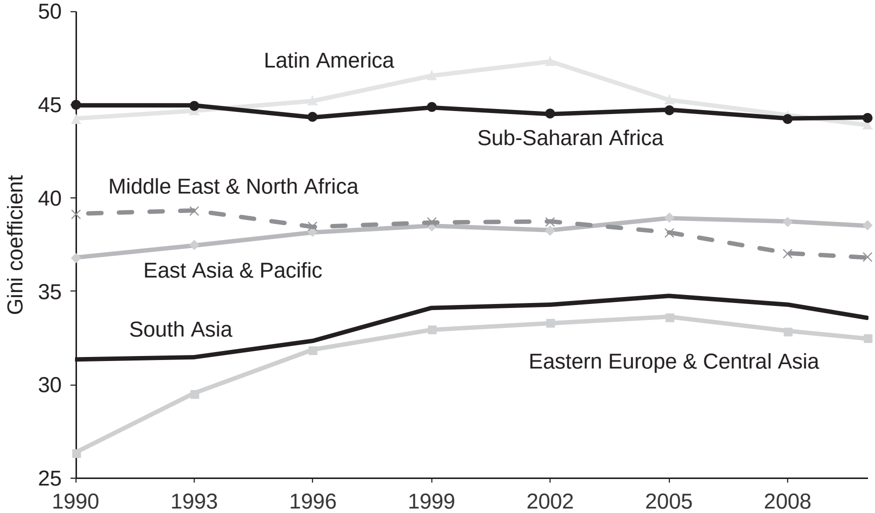

Figure 9.10 Gini coefficients. Unweighted means by region, 1990–2010. *Note: The Gini coefficients are computed over the distribution of household consumption per capita. Source: Own estimates based on PovcalNet (2013).*

decades and some decline in the five MENA countries included in the sample. Instead, the Gini coefficient increased more than two points in Asia and more than six points in Eastern Europe and Central Asia. Figure 9.10 suggests again some pattern toward convergence; the gaps in inequality among regions in the developing world are smaller now than two decades ago. For instance, whereas the gap in the Gini coefficient between Latin America and ECA was 18 points in the early 1990s, it shrank to 11 points in the late 2000s.

In all the regions the share of countries with falling inequality rose in the 2000s, as compared to the 1990s. The two most remarkable changes in the pattern occurred in Latin America and in Eastern Europe and Central Asia. Whereas the Gini went down in 26% of the LA economies in the 1990s, that share increased to 95% in the 2000s. In ECA, whereas the growth in inequality was generalized in the 1990s, more than half of the countries experienced reductions in the 2000s.

Using data from PovcalNet, Chen and Ravallion (2012) report changes in the within component of the global mean-log deviation between 1981 and 2008. This within component is a population-weighted measure of the national inequalities. They find substantial increases in East Asia and Pacific (from 0.125 to 0.256) and Eastern Europe and Central Asia (from 0.128 to 0.225), smaller increases in South Asia (from 0.156 to 0.181), Latin America and the Caribbean (from 0.541 to 0.561), and sub-Saharan Africa (from 0.338 to 0.347) and a fall in MENA (from 0.256 to 0.215). Bastagli et al. (2012) report similar patterns using data from PovcalNet, SEDLAC, and LIS.

The picture of national inequalities in the developing world is similar when using other databases. For instance, the unweighted mean Gini in the *All the Ginis* database assembled by Milanovic grew from 36.2 in 1990 to 40.7 in 1999 and then dropped to 39.7 by 2005. Whereas in the 1990s inequality rose in 63% of the economies in the ATG database, that share dropped to 35% in the 2000s. The recorded increase in the 1990s was generalized across regions, but especially intense in Eastern Europe and Central Asia (9 Gini points), whereas the fall in the 2000s was larger in MENA and Latin America. Cornia and Kiiski (2001), Cornia (2011), and Dhongde and Miao (2013) document similar results using WIID data. We find that the linear (rank) correlation coefficient for the change in the Gini coefficient between 1990 and 2005 recorded in PovcalNet and WIID is 0.776 (0.868), significant at 1%. The corresponding values for the comparison between PovcalNet and ATG are 0.721 and 0.765.

The evidence drawn from the EHII database is also roughly consistent with the patterns discussed earlier. The mean Gini for the developing world remained almost unchanged in the 1980s, increased in the 1990s from 42.5 in 1990 to 47.0 in 1999, and dropped to 46.5 in 2002 (the latest available date).[46] Whereas in 62% of the countries inequality increased in the early 1990s, that share dropped to 55% between 1993 and 1999 and to 49% between 1999 and 2002. The regional patterns are roughly consistent with those described earlier. The main difference is that EHII reveals a dramatic increase in inequality in the Middle East and North Africa (7 Gini points) that is not present in the evidence drawn from household surveys.

In the rest of this section we briefly review the literature on inequality changes in each geographic region of the developing world, while we take a closer look to the story of some particular cases: Brazil, China, India, Indonesia, and South Africa.

9.4.2.1 East Asia and Pacific

The inequality patterns in East Asia and Pacific can be traced based on information from only 8 out of the 24 countries in the region, which nonetheless represent 96% of its total population. This set includes Cambodia, China, Indonesia, Lao PDR, Malaysia, Philippines, Thailand, and Vietnam. There is scattered evidence for Fiji, Micronesia, Mongolia, and Timor-Leste, but information is either lacking or too scarce for American Samoa, Kiribati, Korea, Dem. Rep., Marshall Islands, Myanmar, Palau, Papua New Guinea, Samoa, Solomon Islands, Tonga, Tuvalu, and Vanuatu.

The slightly increasing pattern showed in Figure 9.10 for the unweighted mean of the consumption Gini in EAP hides important differences across countries (ADB, 2012; Chusseau and Hellier, 2012; Ravallion and Chen, 2007; Sharma et al., 2011; Solt, 2009; Zin, 2005). Consumption inequality increased in most economies in the region during the 1990s, with the exception of Thailand and Malaysia. The increase was

[46] These estimates are computed dropping countries with few observations in the period.

particularly strong in China, where the consumption Gini climbed around seven points in that decade. The performance in the 2000s was more heterogeneous; inequality continued increasing in China, Lao PDR, and Indonesia and also went up in Malaysia, but there is evidence pointing to a fall in consumption inequality in Cambodia, Philippines, Thailand, and Vietnam.

Overall, considering the two decades, EAP combines countries with systematic increases in inequality (China, Indonesia, Lao PDR), several cases in which inequality had a cyclical pattern, ending in 2010 at similar levels than in 1990 (Cambodia, Malaysia, Philippines, and Vietnam), and only one successful story of consistent reduction in consumption inequality: Thailand, for which the estimated reduction in the Gini coefficient exceeded five points; from 45.3 to 39.4 over the last two decades. Universal social policies, including basic education and health, have been stressed by many authors as significant drivers of that fall (Jomo and Baudot, 2007).

Probably the most striking phenomenon regarding inequality in EAP was the strong rise that took place in the two most populous countries of the region, China and Indonesia: the Gini coefficient went up around 5 points in Indonesia and more than 10 points in China over the last two decades. Such dynamics happened in a context of high growth and falling poverty, most notably in China. Sharma et al. (2011) summarize the main factors behind these changes: (i) the realignment of activity away from agriculture and toward industry and services; (ii) the skill premium increase due to the unmatched growing demand for skills, and even the emigration of skilled workers; (iii) increasing inequalities in educational attainment in secondary and tertiary schooling; and (iv) a lack of infrastructure linking urban areas with rural areas and other barriers to labor mobility.

China

Since 1978, when China started pro-market reforms, GDP has increased at an average rate close to 10%, and household per capita income has grown more than 7% per year. Such remarkable economic transformation has been accompanied by important changes in inequality and poverty. China is a successful story of reduction in absolute poverty (Minoiu and Reddy, 2008; Ravallion and Chen, 2007, 2008; World Bank, 2009). However, it is argued that it will be harder for China to maintain its past rate of progress against absolute poverty without addressing the problem of rising inequality.

The increase in income inequality in China over the last three decades has been widely documented. Ravallion and Chen (2007) and World Bank (2009) show that income inequality rose from the mid-1980s through 1994, dipping a bit in the late 1990s, and then edging upward thereafter. Li et al. (2013), among others, document the increase in the 2000s, a pattern explained by the widening of the rural–urban income gap, and the increase in income from property and assets, driven by the development of urban residential real-estate markets, the expansion of stock and capital markets, the growth of private enterprises, and other property rights.

A significant share of income inequality in China is now accounted for by rural–urban differences in income levels. The concentration of growth in urban areas is creating a rural–urban divide in employment and earning possibilities, exacerbated by the much more rapid development that occurred in coastal areas. Interestingly, in marked contrast to most developing countries, relative inequality is higher in China's rural areas than in urban areas. However, there has been convergence over time with a steeper increase in inequality in cities.

Indonesia

During the 30 years before the Asian crisis of 1997–1998, which coincided with the New Order under Suharto's dictatorship, Indonesia GDP grew at an average rate of 7% per year. The process was not smooth and went through different phases that implied immense structural change. Despite problems with the data, scholars agree in that there was a systematic drop in poverty rates between 1976 and 1997. At the same time, overall consumption inequality in Indonesia did not change markedly with development until the late 1980s, when inequality started to rise, driven by increasing income disparities in urban areas. Alatas and Bourguignon (2000) decompose the inequality increase between components associated with changes in the structure of earnings, changes in occupational choice, and changes in the sociodemographic structure of the population. They find as main explanations the migration from rural to urban areas and the increase in nonfarm self-employed work. The increase in inequality was partly offset by shrinking income gaps in rural areas (Cameron, 2002). Alatas and Bourguignon (2000) find that the returns to land size decreased between 1980 and 1996; opportunities for off-farm earnings for rural households also contributed to falling rural inequality.

Indonesia was severely hit by a financial crisis: In 1997–1998 GDP dropped by 15%. This turned into a sharp decrease in inequality and an increase in poverty. Skoufias and Suryahadi (2000) find that this pattern seems to have arisen from a decrease in regional inequality. Urban areas (which tend to be wealthier than neighboring rural areas) were hit harder, and the urban middle class, who lost their formal sector jobs, was harshly affected. As the crisis reduced the per capita expenditure of households, the percentage reduction was probably less among the poorer population than among the less poor population. Since 2001, and along with the process of decentralization of powers to local authorities, a general pattern of rising consumption inequality has been observed. Miranti et al. (2013) suggest that the recent increases in inequality may be linked to the higher share of workers employed in the informal sector (70%), hence not covered by minimum wage legislation or employment protections.

9.4.2.2 Eastern Europe and Central Asia

The transition from central planning to market system in the countries of Eastern Europe (EE) and those belonging to the former Soviet Union (FSU) had profound socioeconomic impacts, which could be better documented (compared to the situation in previous decades) due to the improvements in the production and release of information by the new administrations (Milanovic, 1998).[47] The fall of the communist regimes was followed by a substantial increase in inequality in almost all countries.[48] According to PovcalNet data the mean Gini for the distribution of per capita consumption expenditures grew from 26.4 in 1990 to 31.9 in 1996. The increase in the first half of the 1990s was particularly strong in those countries belonging to the FSU and in Southeast Europe and somewhat milder in those economies that joined the European Union. Such developments have been linked to the process of privatization, which implied an increase in earnings dispersion in comparison to the more compressed wage structure of the state-owned firms. One key characteristic of the planned economies was the imposition of wage "grids" that forced a wage compression; the fast transition from wage setting under the wage grids toward a less-regulated labor market provoked a rise in the returns to education, and hence a surge in inequality.[49,50] The economic liberalization also triggered changes in the sectorial structure of the economy; in particular the ensuing de-industrialization during the transition is linked to an increase in inequality (Birdsall and Nellis, 2003; Ferreira, 1999; Ivaschenko, 2002; Milanovic, 1999). Milanovic and Ersado (2010) highlight the role played by the inception or increase of tariffs for utilities, whereas Standing and Vaughan-Whitehead (1995) point to the weakening of the minimum wage as key factors behind the increase in inequality.

After the initial surge in the early 1990s, inequality continued growing in the region in the second half of the 1990s although at slower rates. The patterns were more heterogeneous in the 2000s; inequality increased in some economies, but went down in most countries, especially those in the FSU (World Bank, 2005). The mean Gini for Eastern Europe and Central Asia in the late 2000s was lower than in the late 1990s but still significantly higher (around 7 Gini points) than before the transition.[51]

9.4.2.3 Latin America and the Caribbean

All Latin American countries regularly carry out national household surveys that include income questions, and in some of them also questions on consumption expenditures.[52]

[47] Much information also existed about pre-1990 earnings and household incomes in (former) Czechoslovakia, Hungary, and Poland (Atkinson and Micklewright, 1992).

[48] Milanovic and Ersado (2010); Ivaschenko (2002); Ferreira (1999); Milanovic (1998); Cornia (1996); Cornia and Reddy (2001); Mitra and Yemtsov (2006).

[49] See Fleisher et al. (2005) for a study of 10 transition economies and Gorodnichenko and Sabirianova (2005) for the cases of Russia and Ukraine.

[50] In Hungary, for instance, the income share accrued by the top 1% almost doubled between 1992 and 2009, from 6–7% to 12%. Half of the increase was due to capital income, whereas the other half was due to increased earnings (Mosberger, 2014).

[51] The reader is referred to Chapter 19 for a survey of cross-country studies on the multiple causes of inequality in OECD, including many countries in Eastern Europe.

[52] The increasing availability of surveys in Latin America allowed the creation of databases that make efforts to standardize the generation of poverty and inequality statistics, favoring a close monitoring of the social and labor situation in the region (SEDLAC by CEDLAS and the World Bank, and BADEINSO by UN´s ECLAC).

In contrast, the situation in the Caribbean is much less favorable, as surveys are sporadic, and information is not easy to access. In fact, trends shown in the literature and in this section are restricted to Latin America, which represents 94% of total LAC population.

Latin America experienced two distinct distributive patterns in the last three decades (De Ferranti et al., 2004; Gasparini et al., 2011a,b; IDB, 1999; López Calva and Lustig, 2010). During the 1980s, 1990s, and the crises at the turn of the century, income inequality soared in most countries for which comparable data are available. The mean Gini for the distribution of household per capita income crawled from 50.1 in 1980 to 51.5 in 1986, 51.9 in 1992, 53.0 in 1998, and 53.4 in 2002 (Gasparini et al., 2013). The frequent macroeconomic crises that hit the region in that period were unequalizing because the poor were less able to protect themselves from high and runaway inflation, and adjustments programs frequently hurt the poor and the middle-class disproportionately (Lustig, 1995). The market-oriented reforms that started in Chile in the 1970s and became widespread in the region in the 1990s were associated with rising inequality, although this pattern had a notable exception in the case of Brazil (López Calva and Lustig, 2010). In most countries employment reallocations brought about by trade liberalization and the skilled-biased technical change associated to the modernization of the economy implied a sizeable reduction in the demand for unskilled labor, which led to higher inequality. In some countries adjustments that led to a contraction in the demand for labor affected unskilled workers disproportionately. All these changes took place in a framework of weak labor institutions and safety nets, and hence their consequences made a full impact on the social situation (Gasparini and Lustig, 2011).

Starting in the late 1990s in a few countries and in the early 2000s for the rest, inequality began to decline. The mean Gini for the distribution of household per capita income dropped from 53.4 in 2002 to 50.9 in 2008 (Gasparini et al., 2013). Updated SEDLAC and BADEINSO statistics suggest that the downward trend continued. The evidence, in fact, indicates that between 2002 and 2013 income inequality went down in all Latin American economies. This remarkable decline appears to be driven by a large set of factors, including the improved macroeconomic conditions that fostered employment, the petering out of the unequalizing effects of the reforms in the 1990s, the expansion of coverage in basic education, stronger labor institutions, the recovery of some countries from severe unequalizing crises, and a more progressive allocation of government spending, in particular monetary transfers. The empirical evidence on the driving factors of the recent fall in inequality is, however, still scarce and fragmentary (Cornia, 2011; Gasparini and Lustig, 2011; López Calva and Lustig, 2010).

Brazil

For decades Brazil was singled out as the most unequal economy in Latin America, and in some rankings even the most unequal in the world. In the late 1980s the Gini coefficient for the distribution of household per capita income reached values higher than 60. But

Continued

from that point on inequality started to decrease, first slowly in the 1990s, and then more dramatically in the 2000s.[53] By 2011 the Gini reached an unprecedented low value of 52.7, several points below the level of some other Latin American economies (e.g., Honduras, Colombia, Bolivia).[54] Brazil—the fifth most populous nation in the world—is still a high-inequality country, but it stands out as a successful case of consistent reduction of income disparities.

Data from the Brazil´s national household survey (PNAD) reveals a drop in the Gini of 2 points in the late 1970s and no systematic changes for most of the 1980s, until a deep macroeconomic crisis hit the country, pulling inequality to unprecedented levels. The Gini went up from 59.2 in 1986 to 62.8 in 1989 and returned to 59.9 in 1993. During the 1990s the Gini moved down very slowly, decreasing by just 1 point between 1993 and 2001. That pace drastically increased in the 2000s: the Gini went down from 58.8 in 2001 to 52.7 in 2011, averaging a fall of 0.6 points a year. During 10 years per capita income of the poorest 10% of the Brazilian population grew at an average annual rate of 7%, almost three times the national average.

In an in-depth study of the determinants of inequality changes in Brazil, Barros et al. (2010) highlight the role played by the sharp fall in earnings inequality and the substantial increase in public transfers as the two main direct determinants of the decline in income disparities since the early 2000s.[55] They find that half of the reduction of inequality in labor incomes was associated to the educational progress that took place over the previous decade, which significantly increased the ratio between skilled and unskilled workers. The average years of education for the adult population grew 22% in the 2000s, and the Gini coefficient computed over the distribution of that variable fell 23%, values well above the mean for Latin America (Cruces et al., 2014). Using different decomposition techniques, Barros et al. (2010) and Azevedo et al. (2011) find a sizeable impact of the fall in the returns to education on earnings inequality. Several authors have also found a reduction in spatial and sectorial labor market segmentation. The substantial increase in the minimum wage—68% in real terms between 2002 and 2010—is also underlined as one important force behind the fall in household income inequality, given that the minimum wage sets the floor for both unskilled workers earnings and for social security benefits.

The strong expansion of public transfers accounts to a large share of the fall in income inequality in Brazil (Azevedo et al., 2011; Barros et al., 2010; Alejo et al., 2013; Lustig et al., 2012). The main force was the rapid expansion in the coverage of government cash transfers targeted to the poor, mainly a transfer to the elderly and disabled (*Benefício de Prestação Continuada*) and Brazil's signature conditional cash transfer program *Bolsa Família*.[56]

9.4.2.4 Middle East and North Africa

Data constraints are particularly limiting when analyzing distributive issues in Middle East and North Africa. The lack of accessible and comparable household surveys makes it difficult even to identify the extent of poverty and inequality in most MENA countries. The oil-rich economies (Bahrain, Kuwait, Oman, Qatar, United Arab Emirates, and Saudi Arabia) enjoy high levels of per capita income and are usually not included in the analysis of the developing world. In any case, distributive data is rarely available for these economies. A second group, by far the largest in terms of population, consists of middle-income countries. Within this group there is no public accessible information for Lebanon and Libya, just one data point for Djibouti, Iraq, Syrian Arab Republic, West Bank, and Gaza, and only a few for Algeria and Yemen. In sum, the only MENA countries for which it is possible to track changes in poverty and inequality over time are Egypt, Iran, Jordan, Morocco, and Tunisia, but even in these cases data is scattered and often of low quality. MENA has a long way to go to build a reliable, comparable, and sustainable system of household surveys and distributive statistics.

Despite this constraint, several studies shed some light on the trends in inequality in this region.[57] Authors coincide in dividing the last four decades into three periods. The first one, spanning until 1985, was characterized by rapid economic growth. Page (2007) reports a substantial reduction in income inequality between the mid-1970s and the early 1990s.[58] Data from PovcalNet confirms that fall, although the magnitude is more modest. "Middle Eastern economies entered their rapid growth period with income distributions that were becoming more egalitarian, reflecting the political ideology and policies of post-colonial governments" (Page, 2007). The second period covers the late 1980s and most of the 1990s and is characterized by low economic growth and meager or no social gains; real per capita incomes increased by less than 1.5% per year, whereas income distributions were rather stable. The downward pattern in inequality appeared to have resumed in the 2000s, although at a slow pace. According to our estimates based on PovcalNet, the mean Gini fell from 38.7 in 2002 to 36.8 in 2010. These values place MENA as a region of moderate inequality within the developing world, a fact that has puzzled some authors, that would predict higher income disparities given the political process and the balance of political power in those societies.[59]

Alvaredo and Piketty (2014) analyze the issue from a regional perspective and show that, irrespective of the uncertainties on within-country disparities, income inequality is extremely large at the level of the Middle East taken as a whole, simply because regional

[57] See Acar and Dogruel (2012), Adams and Page (2003), Bibi and Nabli (2010), Iqbal (2006), Page (2007), and Salehi-Isfahani (2010).

[58] According to Iqbal (2006) reliable pre-1985 household surveys are only available for Tunisia and Egypt.

[59] "In many MENA countries, from the Maghreb to the Arabian peninsula, power is wielded by rather narrow groups.... Seen from this perspective, the most puzzling thing about inequality in the Middle East is how low it is" (Robinson, 2009).

inequality in per capita GNP is particularly large. Under plausible assumptions, the top 10% income share could be well over 60%, and the top 1% share might exceed 25% (vs. 20% in the United States, 9% in Western Europe, and 18% in South Africa). The authors conclude that the popular discontent that contributed to the Arab spring revolt might reflect the fact that perceptions about inequality and the (un)fairness of the distribution are determined by regional (and/or global) inequality, and not only on national inequality.

9.4.2.5 South Asia

South Asia has been a region of low inequality for developing world standards, though rising since the early 1990s. In India, further discussed in a separate box, the consumption Gini moved from 30.8 in 1993 to 33.9 in 2010. Bangladesh displayed relatively low inequality throughout the 1980s (Gini equal to 26.1 in 1984), but the situation worsened since the beginning of the 1990s: the Gini climbed to 32.1 by 2010. Khan (2008) argues that incomes from nonfarm sources and the high concentration of land tenure have all been disequalizing forces, whereas the positive effects of the more-evenly distributed farm income were offset partly by its declining share in total income.

Scholars do not always agree about the distributive changes in Pakistan; PovcalNet helps defining the picture by providing consumption Ginis of 33.2 for 1990, 28.7 for 1996 and 30.0 for 2008. The high economic growth during the 1980s contributed to a sharp decline in poverty, but it was accompanied by a mild increase in inequality. The fall in economic growth during the 1990s resulted in a rise in poverty, whereas inequality decreased modestly. According to Hussain (2008) in Pakistan there is an institutional structure that excludes a large proportion of the population from the process of economic growth as well as governance.

Sri Lanka experienced rising inequalities between 1985 (Gini of 32.5) and 2007 (Gini 40.3)—among the highest increase in the region during the period of free market reforms, integration to the world markets and high growth—with a reversal of the trend toward 2010 (Gini of 38.3) and persistent regional disparities due to conflict. Nepal presents similar dynamics. Gosh (2012) notes that rising inequality reflects two components: first, growing vertical inequality within the modern industrial sector driven by the returns to skill, and second, increasing disparities between the industrial fast-growing sector and the traditional agricultural activities.

India

Chakravarty (1987) argues that even if policymakers in India adopted a development strategy based on central planning over the 40 years following independence, "there was a tolerance towards income inequality, provided it was not excessive and could be seen to result in a higher rate of growth than would be possible otherwise." One of the explicit goals of the socialist program was to limit the economic power of the elite in the context of a mixed economy. From the mid-1980s, however, India gradually adopted market-oriented economic reforms. Initially, these were accompanied by an expansionist fiscal policy involving allocations to rural areas, to counterbalance the negative redistributive effects of the liberalization. The speed of reforms accelerated during the early 1990s, and the focus shifted away from state intervention toward liberalization, privatization, and globalization.

Most analysis on inequality in India over the last three decades are based on the observations from the expenditure surveys conducted in 1983, 1987/8, 1993/94, 2004/05, and 2009/10 for urban and rural areas, which have allowed for an analysis pre- and postreforms. Inequality increased significantly in the postliberalization years, especially in urban areas; on the contrary, estimates of absolute poverty measures have systematically fallen since 1983. Mazundar (2012) summarize the main drivers of these changes: (i) the lead in employment and output growth has been taken not by manufacturing but by the tertiary sector, which displays higher inequality in pay; (ii) much of the labor reallocated from agriculture is absorbed in the informal sector, where earnings are only slightly higher than the poverty line; (iii) although numerous social insurance schemes have been established, their actual impact has been limited and regressive as they have disproportionately benefited workers in the small formal sector; (iv) the modest and selective increase in social sector spending is constantly threatened by the budget deficit; (v) the education polices implemented over the years have been biased toward the promotion of tertiary education and have neglected basic primary and lower secondary education.

From a different perspective, Banerjee and Piketty (2010) look at the tax-based shares of top incomes. Their results suggest that the gradual liberalization of the Indian economy made it possible for the top 1% to substantially increase their share of total income, from 4.7% in 1980 to 8.9% in 1999. Although in the 1980s the gains were shared by everyone in the top percentile, in the 1990s it was those in the top 0.1% who benefited the most.[60]

9.4.2.6 Sub-Saharan Africa

Although recently there have been many improvements, the lack of a consistent body of household surveys undermines the assessment of income inequality in sub-Saharan Africa. Time series data on inequality is severely lacking in most SSA countries, hindering the inferences about trends in the region. For example, in PovcalNet some

[60] The authors stress that these results could be linked to the debate around the Indian growth paradox of the 1990s. According to the household expenditure survey conducted by the National Sample Survey (NSS), real per capita growth during the 1990s was fairly limited, in sharp contrast with the fast growth measured by national accounts. It was suggested that much of such growth could have gone to the rich, absent from surveys. Banerjee and Piketty (2010) conclude that top incomes could explain between 20% and 40% of the puzzle, which still leaves the bulk of the difference unaccounted for.

SSA countries are missing (Equatorial Guinea, Eritrea, Mauritius, Somalia, Zimbabwe), whereas for 13 of them there is only one observation in the database for the whole period 1981–2010. In fact, very few countries have reliable surveys in the 1980s, and it was not until the mid-1990s when inequality could be really traced with some confidence in the region.

Regional studies typically report a mixed picture, with both increases and decreases in inequality, a fact that could reflect the heterogeneity in the region, but also could be caused by noise in the country estimations (Christiansen et al., 2002; Okojie and Shimeles, 2006). Bigsten and Shimeles (2003), for instance, report that for 17 African countries the trend in inequality shows significant variations over short periods, causing concern about measurement problems.

The available evidence seems to support some few broad facts about consumption inequality in the sub-Saharan African countries. First, inequality is very high on average, possibly the highest in the world. This result is in stark contrast with the presumption of low inequality in SSA, held for a long time based on the predictions of Kuznets-like models and the absence of reliable data.[61] Second, on average inequality does not seem to have changed much in the 1990s and 2000s. Data from PovcalNet and other sources suggest a slow downward pattern; but in any case the evidence is mixed and weak. Third, the heterogeneity among countries in terms of inequality levels and patterns is large, partly possibly due to various measurement errors. It is hard to identify a prototype of an inequality pattern in SSA, as in other regions such as LAC or ECA. The scarce literature on inequality in SSA is consistent with these observations. Go et al. (2007) report that high income inequality levels in SSA have remained more or less constant over the last four decades. Okojie and Shimeles (2006) underline the fact that SSA is one of the most unequal regions in the world, and that disparities have remained persistent over time. In contrast, Sala-i-Martin and Pinkovskiy (2010) picture a more optimistic scenario, reporting a significant downward pattern for inequality during the period of growth (1995–2006).

South Africa

Over the last 30 years there have been important studies of inequality and poverty in South Africa, and a heated debate about trends in post-apartheid transition.[62] South Africa has long been regarded as having one of the most unequal societies in the world. Consistent

[61] Several studies have sought to explain the unexpected result of high inequality in sub-Saharan Africa (Milanovic, 2003; Moradi and Baten, 2005; Okojie and Shimeles, 2006; and Van de Walle, 2008).

[62] See, for example, McGrath (1983), McGrath and Whiteford (1994), Klasen (1997, 2005), Nattrass and Seekings (1997), Terreblanche (2002), Dollery (2003), van der Berg and Louw (2004), Leibbrandt et al. (2009), Leibbrandt et al. (2010a, 2010b), and Aron et al. (2009).

with this view, the country has the highest Gini coefficient of household consumption per capita (63.1 in 2010). During the early 1970s, the previously constant racial shares of income started to change in favor of the blacks, at the expense of the whites, in a context of declining per capita incomes (McGrath, 1983; McGrath and Whiteford, 1994). But while interracial inequality fell throughout the eighties and nineties, inequality within race groups increased (Simkins, 1991; Whiteford and Van Seventer, 2000). Leibbrandt et al. (2010a, 2010b) provide evidence from comparable households' surveys conducted in 1993, 2000, and 2008. These authors find that since the fall of apartheid, inequality continued to increase steadily, both for the whole population and within each racial group. The high level of overall income inequality accentuated between 1993 and 2008, incomes becoming increasingly concentrated in the top decile. van der Berg and Louw (2004) also conclude that rising black per capita incomes over the past three decades have narrowed the interracial income gap, although increasing inequality within the black and Asian/Indian population seems to have prevented any decline in aggregate inequality.

In explaining these changes scholars agree in that the labor market played a dominant role, where a rise in the number of blacks employed in skilled jobs (including civil service and other high-paying government positions) coupled with increasing mean wages for this group of workers. Leibbrandt et al. (2010a, 2010b) indicate that in the initial post-apartheid period participation rates increased faster than absorption rates with a consequent increase in unemployment across all deciles. Since 2000 the aggregate unemployment rate declined, but the in the lower deciles the early post-apartheid trend continued to 2008. State transfers have increased their importance as an income source but not in a way that has substantially narrowed the income gaps. They have, however, compensated for the decreasing share of remittance income.

Increasing inequality and stable poverty are consistent with the rising trend in top income shares recorded between 2002 and 2010 by Alvaredo and Atkinson (2010), which could be associated with the favorable conditions in the world market for agricultural commodities, the increase in the value of minerals other than gold, and the developments in the financial sector.

9.4.3 Inequality Convergence

As suggested earlier, there are signs of inequality convergence among countries in the developing world. As an example, the mean Gini coefficient for the 20 most unequal countries in our PovcalNet sample in 1981 fell 11% in the following three decades, while it increased 58% for the 20 most egalitarian economies. Bénabou (1996) was the first to present empirical evidence for cross-country convergence in income inequality with data from 1970 to 1990 drawn from the Deininger and Squire data set. He found evidence consistent with the predictions of a neoclassical growth model that yields convergence of the entire income distribution and not just the first moment.[63] Evidence on inequality convergence was also found in studies that used improved data: Ravallion (2003) based on PovcalNet, Bleaney and Nishiyama (2003) based on WIID, and Dhongde and Miao (2013) using both data sets. With variations, a typical inequality convergence study estimates

$$G_{it} - G_{i1} = (\alpha + \beta G_{i1})(t-1) + e_{it} \quad \text{for} \quad t = 2, \ldots, T; \quad i = 1, \ldots, N,$$

where G_{it} is the Gini coefficient for country i in year t, and e_{it} is an heteroscedastic error term. The parameter β measures the link between the change and the initial Gini, and therefore $\beta < 0$ indicates inequality convergence. Models could be estimated with the Gini coefficient in levels or logs. In his early study Bénabou (1996) found a β coefficient of -0.039 for a small sample of around 30 countries. Naturally, estimates of β vary according to the data used, the period covered, the time horizons considered, and the regression model applied. Ravallion (2003) estimated a value of -0.028 in the 1990s, Bleany and Nishiyama (2003) a value of -0.0125 between 1965 and 1990, and Dhongde and Miao (2013) a value of -0.022 from 1980 to 2005. This literature has also found that the impact of the initial Gini coefficient on the inequality change diminishes over longer time horizons, and that the speed of inequality convergence is higher than the speed of convergence in per capita income.

We add to this literature our own estimates, taking advantage of the PovcalNet panel of 76 countries from 1981 to 2010 used in this section. Table 9.8 shows the OLS and IVE estimates of α and β for different initial years.[64] The parameter β is negative and significant in all the specifications, suggesting evidence for inequality convergence. The estimated coefficients are in the range of those estimated in the literature.

Although the evidence for inequality convergence in the last decades seems well established, the reasons driving that pattern are not clear. As mentioned before, Bénabou (1996) finds the evidence on convergence consistent within the framework of a growth model. In contrast, the evidence for unconditional inequality convergence is interpreted by Ravallion (2003) as the result of policy and institutional convergence since around 1990, when socialist planned economies became more market-oriented, and non-socialist economies adopted market reforms.

[63] The Benabou model may not be considered strictly neoclassical because it involves market imperfections and endogenous redistributions (see Chapter 14 in this Handbook for an extensive discussion of these issues).

[64] Caselli et al. (1996) and Dhongde and Miao (2013) discuss biases that may arise in an OLS model. However, in the IVE model the instrument used to correct for measurement error may include as much measurement error itself.

Table 9.8 Inequality Convergence
Models of the change in the Gini coefficient

	Initial year 1981			Initial year 1990		
	Intercept (α)	**Slope (β)**	R^2	**Intercept (α)**	**Slope (β)**	R^2
Gini Index						
OLS	1.098 (18.90)***	−0.026 (20.38)***	0.49	0.908 (11.20)***	−0.023 (10.97)***	0.35

Note: Robust *t* statistics in parentheses; **significant at 5%; ***significant at 1%; the heteroskedasticity-consistent covariance matrix estimator is used (HC1). IVE estimates use the initial value as the instrument for the inequality measure in the second survey. The number of observations is 456 in the first panel and 281 in the second.

9.4.4 Absolute Inequality

Although relative inequality has been the preferred concept in empirical work in development economics, absolute views of inequality certainly have some intuitive appeal (Amiel and Cowell, 1999; Atkinson and Brandolini, 2004). Interestingly, the trends in the two concepts over the last decades have been different in the developing world.[65] The fact that most countries experienced economic growth, while at the same time relative inequality did not fall, implied widening absolute income differences. On average, the absolute difference in monthly consumption per capita between the top and bottom 10% of each country increased over the two decades from US$ 415 (PPP adjusted) in 1990, to US$ 497 in 2002, and US$ 646 in 2010. In more than 90% of the countries in the sample that absolute difference was higher in 2010 than in 1990.

The contrast between the recent trends in absolute and relative inequality in the developing countries is illustrated in Figure 9.11. Whereas relative inequality rose in the late 1980s and early 1990s, absolute inequality declined, driven by a reduction in

[65] See, as an example, the analysis of Atkinson and Lugo (2010) for Tanzania.

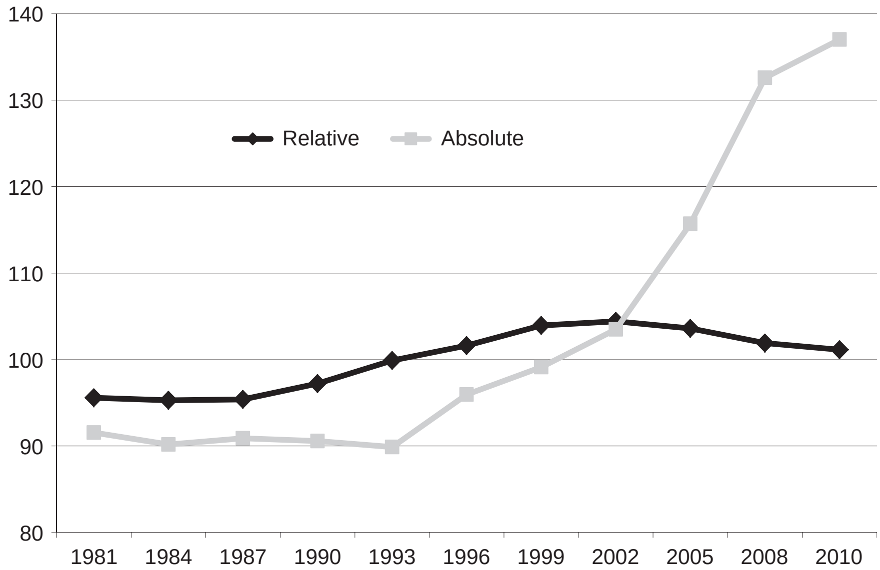

Figure 9.11 Absolute and relative Gini coefficients. Unweighted means, developing countries, 1981–2010. *Note: Normalized to 100 = mean over the period 1981–2010. The Gini coefficients are computed over the distribution of household consumption per capita. Source: Own estimates based on PovcalNet (2013).*

mean income. The strong growth in the developing world since mid-1990s is reflected in the substantial hike in the degree of absolute inequality. Although some equalizing forces operated in the 2000s that reduced the relative gaps, they were not enough to narrow the absolute gaps in a context of economic growth. Based on these facts, Ravallion (2004) argues that the disagreements over whether inequality in the world has gone up or down may partly be due to differing views about the importance of absolute versus relative conceptions of inequality.

9.4.5 Aggregate Welfare

The typical way of assessing the economic performance of a country is by means of its per capita income or output. However, this practice is valid only when the evaluator's welfare function is utilitarian. Except in this extreme case, measuring aggregate welfare involves not only knowing the mean but also other elements of the income distribution, in particular the degree of inequality. Although social welfare functions are naturally arbitrary, because they depend on the analyst's value judgments, it is common in the literature to work with anonymous, Paretian, symmetric, and quasiconcave functions. For

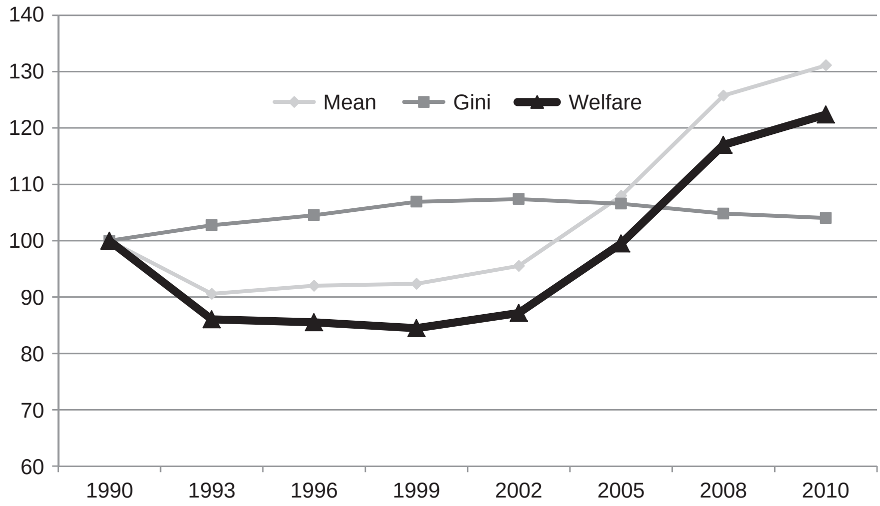

Figure 9.12 Aggregate welfare. Sen welfare function, unweighted mean, developing countries, 1990–2010. *Note: Normalized to 100 = value in 1990. Source: Own estimates based on PovcalNet (2013).*

simplicity, here we consider the abbreviated welfare function proposed by Sen (1976), $W_S = \mu(1 - G)$, where μ is the mean of the distribution and G is the Gini coefficient. Figure 9.12 shows the unweighted mean of W_S for the developing countries in the period 1990–2010 computed from household survey data. In general, aggregate welfare has followed changes in per capita consumption. The fall in mean consumption in the early 1990s (mostly due to the negative performance in ECA) was reinforced by the increase in inequality, driving welfare down by around 15%. Between 1993 and 2002 mean consumption went up, but the change was counterbalanced by a similar increase in the Gini, keeping welfare roughly constant. The 2000s witnessed a robust increase in mean consumption, along with some fall in inequality, implying a 40% increase in aggregate welfare between 2002 and 2010. According to these calculations, the mean aggregate welfare in the developing countries was 22% higher in 2010 than in 1990, implying an annual growth rate of around 1%.

To calculate welfare, it is necessary to have estimates of the mean income and some inequality measure. Ideally, both parameters should be estimated from the same source, typically a household survey, as we have done so far. Some authors have taken a different approach, anchoring the mean to a variable from National Accounts, such as per capita GDP or aggregate household consumption expenditures. For several reasons changes in mean income from household surveys tend to differ significantly from changes in per capita GDP (Anand and Segal, 2008; Deaton, 2003, 2005). Some of these differences are natural because per capita income and GDP are different concepts, but some are

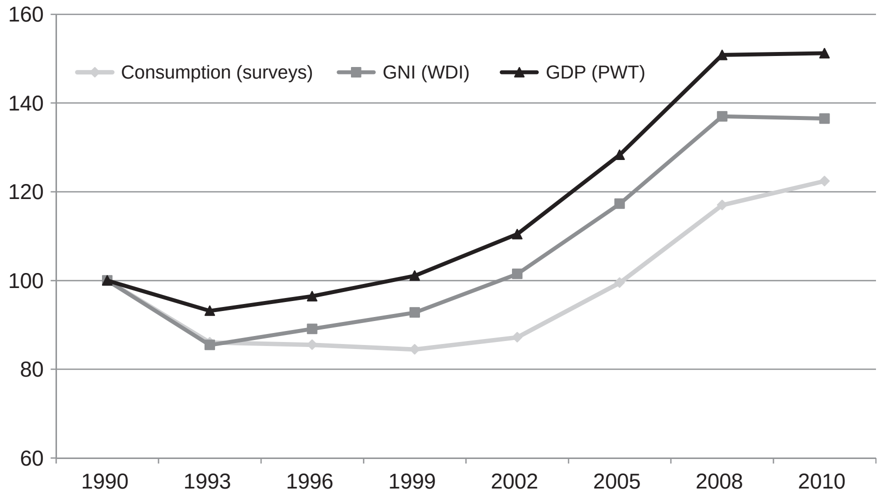

Figure 9.13 Aggregate welfare for alternative mean variables. Sen welfare function, unweighted mean, developing countries, 1990–2010. *Note: Mean anchored to per capita consumption (PovcalNet), GNI per capita (WDI), and GDP per capita (PWT). Normalized to 100 = value in 1990. Source: Own estimates based on PovcalNet (2013), WDI, and PWT.*

rooted in measurement errors both in household surveys and in National Accounts. Some authors pay the price of the potential inconsistency of using two different data sources (i) in order to avoid departing from the typical growth and development literature that is based on National Accounts data, (ii) as a way to alleviate the underreporting issue in household surveys, and (iii) to avoid problems related to the unavailability of surveys for many years in several countries (Ahluwalia et al., 1979; Bhalla, 2002; Bourguignon and Morrison, 2002; Sala-i-Martin, 2006).

In Figure 9.13 we report the results of computing the unweighted average of aggregate welfare across developing countries using alternative mean income variables. According to these estimates, mean welfare in the developing world grew at an annual 1% from 1990 to 2010 using mean consumption per capita from household surveys, 1.6% using per capita GNI from WDI, and 2.1% using per capita GDP from Penn World Tables (PWT; Heston et al., 2012).[66] These discrepancies are worrying and call for increasing efforts to understand and reduce the gaps among data sources.

[66] In fact, this difference comes from the combination of higher growth recorded in the National Accounts in the 1990s compared to household surveys and the opposite result in the 2000s. For instance, although mean per capita GDP slightly fell between 2008 and 2010, mean consumption in household surveys increased at an annual 2%.

The population-weighted mean of the welfare measure grew at a much higher rate, due to the positive performance of several large countries.[67] The growth rate between 1990 and 2010 was 2.3% using household survey data, 3% anchoring mean income to per capita GNI from WDI, and 3.3% when using the Penn World Tables.

9.4.6 Trends from Tax Records

At the moment of writing (2014), the WTID offers estimates of the tax-based shares of top incomes for a small number of developing countries: Argentina, Colombia, India, Malaysia, Mauritius, Uruguay, and South Africa.[68] Ongoing research analyzes the cases of Brazil, Chile, and Ecuador over the last decades. Results for the former colonial territories—being prepared by Atkinson (British colonies), and Alvaredo, Cogneau and Piketty (French colonies)—will be available soon.[69] Consequently, evidence in this respect is still fragmentary, not only because this particular research program is rather recent in what concerns the developing world, but also because of the unavailability of tax data.

The results for the top 1% income share are presented in Figure 9.14, together with survey-based Gini coefficients for six developing countries. Several elements are worth mentioning. First, both sources are not directly comparable for the reasons discussed in Section 9.3. The top share estimates are in general before taxes, while survey Ginis are net of taxes; in addition the units of analysis usually do not match. Second, there is substantial heterogeneity in this group, both in levels and dynamics, compared to the evidence discussed in Chapter 8 for developed countries. It should be borne in mind that the differences in the tax systems across countries imply different income concepts, so that top share levels should be read with this caveat in mind. Third, Leigh (2007), who analyzes 13 developed countries and finds a strong and significant relationship between top income shares and broader inequality measures, concludes that "panel data on top income shares may be a useful substitute for other measures of inequality over periods when alternative income distribution measures are of low quality, or unavailable."

[67] Some authors have computed global welfare, ignoring the division of the world in countries. The evidence suggests an increase in aggregate welfare in the developing world in the last decades (Atkinson and Brandolini, 2010; Pinkovskiy, 2013; Pinkovskiy and Sala-i-Martin, 2009).

[68] The results for China (1986–2003) and Indonesia (1982–2004) available in the WTID are based on household surveys and not on tax records. The fact that top income share estimates are lower than in the most egalitarian developed countries shows that they are likely to be underestimated. In the case of China, the rising trend is robust and can be taken as an indicator of the true dynamics of concentration at the top. Piketty and Qian (2010) show that top income shares increased at a very high rate during the period, which is consistent with the evidence discussed in Section 9.4. The top decile share rose from about 17% in 1986 to almost 28% in 2003—that is, by more than 60%. The top 1% income share more than doubled between 1986 and 2001, from slightly more than 2.6% in 1986 to 5.9% in 2003.

[69] This project has assembled data for some 40 colonies covering the periods before and after independence. Unfortunately, the series stop before 1970 in most cases due to unavailability of recent data.

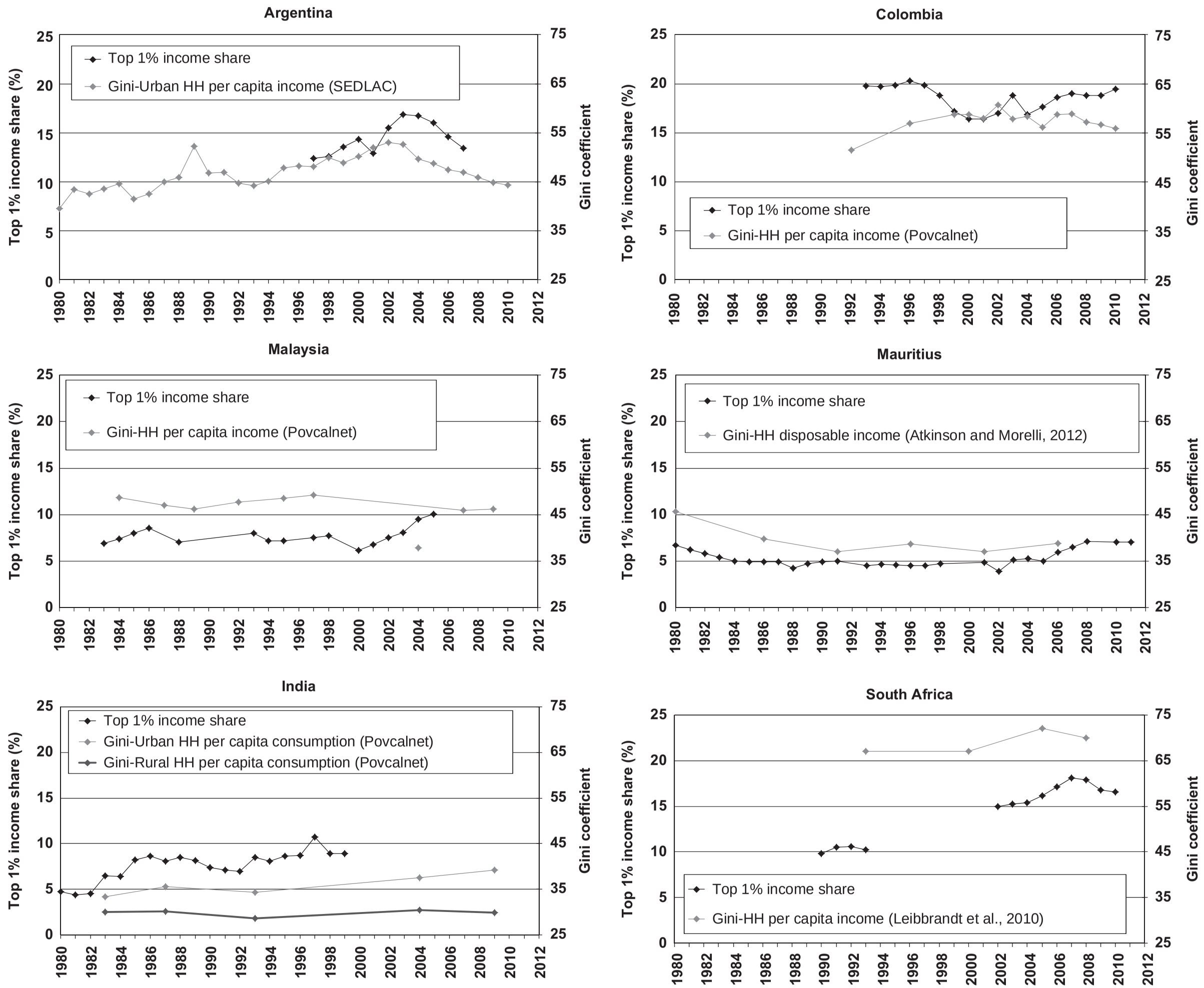

Figure 9.14 Top 1% income share and Gini coefficients. Argentina, Colombia, Malaysia, Mauritius, India, and South Africa. *Note: Gini coefficient for Malaysia 2004 identified as outlier. Source: Own estimates based on WTID and Povcalnet.*

Figure 9.14 seems to agree with the results in Leigh (2007) in some cases but not in others. For example, the trends in the Gini coefficient and the top 1% share in Colombia are particularly diverging, whereas the dynamics in Mauritius are remarkably similar. Top shares and broader, synthetic inequality measures can very well display different trends. The problem arises when the top group plays a major role in the changes in inequality and survey data fail to capture high incomes.

9.4.7 Exploring Inequality Changes

Explaining changes in income distribution is a very difficult and challenging task that lies well beyond the objectives of this chapter. In this section we briefly review some methodologies to study the determinants of the income distribution changes and lay out some of the main results regarding developing countries.[70] Certainly, there has been sustained progress in our understanding of the factors that shape income distributions, but yet the image that emerges from reviewing the literature is still that of a patchwork of numerous hypotheses without conclusive empirical support. In addition, countries may be very heterogeneous in terms of the importance of the various causal factors and their actual effects.

Decompositions are one of the most widely used techniques to characterize income distribution changes. Typically, an income model is estimated, and a counterfactual distribution is simulated modifying some elements of the estimated income model (e.g., parameters or the distribution of observable factors), while keeping the rest fixed. The difference between the actual and the simulated distribution captures the first-round partial-equilibrium effect of the change under study.[71] The method generates entire counterfactual distributions and hence can capture the heterogeneity of impacts throughout the distribution. The decompositions have been typically used to shed light on the impact of changes in the returns to education; in the demographic, sectorial, occupational and educational composition of the population; and in labor and social policies. The decompositions do not allow for the identification of causal effects and suffer from the usual problems of equilibrium-inconsistency and path dependence. Nevertheless, these types of exercises are informative about the relative strength of several direct determinants that may be driving the distributive changes, and therefore could be useful in identifying areas in which to focus the research efforts.

[70] Bourguignon et al. (2008a, 2008b) and Ferreira (2010) are excellent references for methodological issues in recent research on inequality determinants.

[71] See Bourguignon et al. (2005), Barros et al. (2006), and Bourguignon et al. (2008a, 2008b) for methodological proposals; Bourguignon et al. (2005) for applications to Asia and Latin America; and Inchauste et al. (2012) for a recent application to poverty reduction in Bangladesh, Peru, and Thailand. Fortin et al. (2011) and Essama-Nssah (2012) are useful surveys of the economic literature on decompositions.

Ideally, income distribution changes should be studied in a general equilibrium framework because they are the result of complex processes that involve all sorts of effects and interactions throughout the economy. Computable general equilibrium (CGE) models have been applied to study changes in the income distributions around the developing world. These exercises, however, depend critically on parameters and functions that are difficult to estimate and rely on many simplifying assumptions. The more recent macro-micro approach combines a CGE model (the macro component) with a microsimulation (the micro component). CGE models provide a framework to assess consistency of policy alternatives, but lack the necessary disaggregation for the analysis of distributive issues, which is provided by the microsimulations. The macro and micro components of this methodology communicate through aggregate variables such as employment levels and wage rates that are generated by the CGE model and used as inputs in the microsimulations (Bourguignon and Bussolo, 2012; Bourguignon et al., 2008a,b). In a related approach, rather than building a full general equilibrium model of the economy, researchers rely on a reduced-form relationship between a set of observed exogenous variables (such as changes in tariff rates) and a set of sector-level variables (such as industry-skill wage premia), that serve as inputs in the microsimulations.[72]

A very different strand of the literature involves the estimation of cross-country regressions, typically with panel data, where an aggregate measure of overall inequality, such as the Gini coefficient, is linked to various potential causal factors (e.g., Anderson, 2005; Li et al., 1998). Naturally, endogeneity problems are endemic to this approach, which is useful to characterize the structure of correlations among variables, but less successful in identifying causal links.

Most of the literature takes a less ambitious but probably more productive road and focuses on the partial-equilibrium impact of specific shocks and policy changes, using different identification strategies depending on the characteristics of the shock/policy and the data available. Examples of these methodologies include (i) a typical supply and demand approach, where the impact of indicators of trade, technology, or other factors on the relative wage between skilled and unskilled workers is estimated, controlling for relative supply; (ii) the cost function approach, where the impact of several indicators on the share of skilled wages in the total wage bill is estimated, using flexible cost functions (usually a translog cost production function); and (iii) mandated wage regressions.[73] When experiments with random assignment are available, causal links are more clearly identified. For instance, the conditional cash transfer program *Progresa* in Mexico was initially implemented with a random assignment of treated and control rural villages, which allowed a rigorous impact evaluation. Taking advantage of that design, Todd and Wolpin

[72] Ferreira et al. (2010) use this approach to estimate the effect of a trade liberalization episode on the distributions of wages and household incomes in Brazil.

[73] See Anderson (2005).

(2006) estimate a full structural model of behavior, including education, fertility, and labor supply decisions, a model that can be used to simulate the distributive impact of policies and shocks.[74]

The bulk of the distributive analysis in developing countries has focused mainly on the labor market and on public and private transfers, while largely setting aside the role played by other sources of income, such as capital, land rents, and business profits. The neglect of these other factors is essentially due to the fact that household surveys fail to capture these income sources properly.[75] This shortcoming has, for instance, severely limited the study of the impact of the natural resources exploitation on inequality, a relevant topic in several developing countries.[76] Most studies narrow the analysis to particular indicators of the labor market, such as the wage gap between skilled and unskilled labor (the wage premium) or the returns to education. For instance, Bourguignon et al. (2005) show that increases in returns to schooling were large contributors to increasing inequality in East Asia and Latin America in the 1990s.

In what follows we review some general debates on the determinants of recent inequality changes.

Growth and development. As shown in Section 9.3.5, there is a significant negative relationship between inequality and measures of development, such as GNI per capita, in a cross section of countries. From this evidence Ferreira and Ravallion (2009) conclude that "high inequality is a feature of underdevelopment." However, the short- or medium-run relationship between inequality and development has proved to be elusive. There appears to be no evidence in the last decades of a significant correlation between the growth rate of an economy and the change in the inequality level (Dollar and Kraay, 2002; Ferreira and Ravallion, 2009; Ravallion, 2001; Ravallion and Chen, 1997).[77] Ravallion (2007), for example, analyzes 290 episodes in 80 countries in 1980–2000 and finds a correlation coefficient non-significant at the 10% level between the changes in the log of the Gini coefficient and changes in the log of mean income in real terms between successive household surveys. The analysis of more recent data from PovcalNet leads to the same conclusion. Using 473 spells in the period 1981–2010 we find a non-significant coefficient of –0.0094. A similar result applies when restricting the sample to

[74] See also Parker and Skoufias (2001) and Gertler (2004) for impact evaluations studies of the Mexican conditional cash transfer program.

[75] For instance, according to SEDLAC data, on average in Latin America in 2010 the share of labor income in total household income was 82.3%, the share of transfers (including pensions) 13.9%, and the rest of the sources just 3.8%.

[76] See Caselli and Michaels (2013).

[77] A related literature finds no support for a Kuznets curve with longitudinal data (Fields, 2002; Hellier and Lambrecht, 2012).

observations after 1990 or 2000, or when considering longer spells.[78] The data suggests that among both growing and contracting economies, inequality increased about as often as it fell. In the last decades economic growth has been distribution-neutral on average in the developing countries.[79]

Globalization. Much of the recent public and academic debate on inequality changes has been related to the rise in globalization. In the latest decades most developing countries have experienced increasing openness to international trade, capital markets flows, and foreign direct investment. The theoretical channels linking these changes to inequality are multiple and complex, which accounts for the lack of conclusive empirical results (Anderson, 2005; Goldberg and Pavcnik, 2007; Harrison et al., 2011; Rama, 2003; Winters et al., 2004; Wood, 1997). Although studies in cross sections of developing countries are inconclusive in relation to the impact of globalization on inequality, several longitudinal estimates concerning countries taken separately or in small groups reveal a positive correlation between openness and the relative demand for skilled labor (Anderson, 2005; Chusseau and Hellier, 2012; Goldberg and Pavcnik, 2007; Harrison et al., 2011). Trade openness may affect the income distribution through various channels. The traditional Stolper-Samuelson effect predicts a reduction in the skill premium in unskilled-labor-abundant developing countries, a prediction that does not appear to be confirmed by the facts (Feenstra, 2008; Goldberg and Pavcnik, 2007). Although some of the research has pointed then to non-trade factors—such as skill-biased technological change and labor institutions—to explain rising wage gaps, in recent years new mechanisms have been explored through which trade can increase income inequality. These mechanisms include heterogeneous firms and bargaining, trade in tasks, labor frictions, and incomplete contracts (Harrison et al., 2011). In addition, competition among developing countries may increase inequality in middle-income countries (e.g., Latin America) competing with low-income economies.[80] Also, the growing size of the developing world, as new countries enter the world markets, may foster inequality by augmenting the world endowment of unskilled labor. The literature finds that the mechanisms through which globalization affects income distribution are country, time, and case specific, and therefore the impacts of trade liberalization need to be examined in conjunction with other concurrent policy reforms (Goldberg and Pavcnik, 2007). In addition, and due to various limitations, the literature is mostly focused on the static link

[78] The relationship becomes negative, although just slightly significant, when using the change in log real per capita GDP (Penn World Tables) or per capita GNI (WDI) as measures of growth.

[79] Ravallion (2004) argues that, on average, growth is not associated with increases in relative inequality but absolute inequality, and it is these higher absolute gaps between "rich" and "poor" that generate the perception of an unequal growth processes.

[80] The increase in inequality in Latin America has also been explained arguing that it is a region relatively abundant in natural resources, whereas in the onset of liberalization Asian countries were relatively abundant in unskilled labor (Wood, 1997).

between globalization and income distribution that typically operates through changes in relative prices and wages, rather than on the dynamic, more indirect link from trade to growth, and then to poverty and inequality.

Technology and education. Skill-biased technological change has been a popular explanation for the rise in inequality in the developed countries. Changes in technology, such as the use of computers, increase the relative demand for skilled workers driving the skill premium up. This hypothesis is also plausible in the developing world, where globalization increased the transfers of more skill-intensive technologies from the North and fostered imports of capital goods, typically complementary of skilled labor. Several studies find that openness-driven technological transfers tend to increase inequality in emerging countries (Conte and Vivarelli, 2007). The increase in the wage skill premium may be temporary, as the introduction of new technologies requires a transitional period during which skilled workers are employed to adapt the firm to the new technology (Helpman and Trajtenberg, 1998; Pissarides, 1997). The empirical applications usually show evidence on the short- and medium-run effects of the reforms, failing to capture the long-run impact. The generalized fall in inequality in the 2000s in the developing world might be in part attributed to the petering out of the unequalizing initial impact of the liberalizing reforms and technological shocks experienced by many countries in the 1990s.

The increase in education may counteract the effect of skill-biased technological change in the Tinbergen´s race between education and technology.[81] In fact, education has expanded in the developing world at high rates during the last decades, mitigating the impact of other factors that tend to increase the wage premium.[82] However, the link between education and income inequality may not be that straightforward. Given the convexities in the returns to education, even an equalizing increase in schooling may generate an unequalizing change in the distribution of earnings. Bourguignon et al. (2005) have labeled this phenomenon "the paradox of progress," a situation in which an educational expansion is associated with higher inequality.[83]

Market reforms. Several developing countries have implemented market-oriented reforms in the last decades, reducing regulations and privatizing firms. The paradigmatic case includes the former socialist planned economies in ECA, but the transition from centrally planned to market-oriented economies was also experienced by several African and Asian countries, including China. The evidence suggests a significant increase in inequality over the transition period. That surge has been linked to the process of privatization, that implied an increase in the earnings dispersion in comparison to the more compressed

[81] According to Tinbergen (1975) changes in earnings inequality are the outcome of a "race" between technological progress raising the demand for skills, and the expansion of education raising the supply of skills.

[82] See Gasparini et al. (2011a, 2011b) for Latin America.

[83] Inequality may also increase after an education expansion, given that wage dispersion is larger at higher educational levels (Alejo, 2012).

wage structure of the state-own firms, and the institutional and regulatory reforms that have increased competition in product and factor markets and decreased the bargaining power of labor.[84] Other non-socialist economies also adopted market-friendly reforms; Ravallion (2003) argues that in some cases (e.g., Brazil) pre-reform controls benefited the rich and kept inequality high, and then reforms help lowering inequality, while in some others (e.g., India) the controls (and the reforms) had the opposite effect.

Fiscal and social policy. Developing countries are characterized by relatively low levels of taxation, heavy reliance on regressive revenue instruments, and low coverage and benefit levels of transfer programs (World Bank, 2006a,b). This structure limits the redistributive potential of fiscal policy and in some cases even exacerbates the market income disparities.[85] Although average tax ratios for advanced economies exceed 30% of GDP, ratios in developing economies (excluding emerging Europe) generally fall in the range of 15–20% of GDP (Bastagli et al., 2012). Tax collection is not only lower but also more regressive than in developed countries. The difficulties in collecting more progressive taxes are related to the high levels of self-employment and sizeable informal sectors, which limit the capacity of the tax authorities to verified taxpayers´ income and assets. On the spending side, in most developing economies social spending is relatively low, and participation in social insurance schemes is restricted to high-income workers in the formal sector and to public-sector employees.[86] All these factors combine for a low redistributive impact of the fiscal policy. For instance, Goñi et al. (2008) and Lustig (2012) finds that the tax and transfer system in Latin America decreased the market Gini by only 2 points, a meager impact compared to the 20-points impact estimated in 15 European economies.

Since the mid-1990s there have been some encouraging signs of improvement, especially in terms of increasing coverage and better targeting of social policies. The recent expansion of conditional cash transfer programs (CCTs) implies a promising approach for enhancing the distributive impact of public spending in developing economies. CCTs typically transfer income to poor households, conditional on households making certain investments on their children's human capital—education, health, and nutrition. Such programs have been adopted in many developing economies, including some sub-Saharan African countries, although on a smaller scale (Fiszbein and Schady, 2009; Garcia and Moore, 2012). CCTs became particularly popular in LAC: by 2010 there were 18 countries in Latin America and the Caribbean applying CCTs, covering

[84] See Cornia (1996), Milanovic (1998), Ferreira (1999), Cornia and Reddy (2001), and Milanovic and Ersado (2010).

[85] For instance, Lustig (2012) finds that in some Latin American countries when indirect taxes are taken into account, the net income of the poor and the near poor can be lower than before taxes and cash transfers.

[86] ILO (2010) reports that in the early 2000s the share of the population above the legal retirement age receiving a pension in developing economies was, on average, around 40%, as compared to 90% in European economies.

20% of total LAC population, and spending on average 0.40% of GDP (Cruces and Gasparini, 2012). Soares et al. (2009) estimated that the CCTs in Brazil and Mexico reduced the Gini for disposable income by 2.7 points, accounting for about a fifth of the decrease in that index between the mid-1990s and the mid-2000s.

Macroeconomic crises. The scale of the recent crisis has placed the distributive impact of macroeconomic shocks back on the agenda. Banking crises, crashes in stock and real estate markets, and GDP collapses are events with potential large effects on the income distribution. Atkinson and Morelli (2011) is the first paper in addressing this issue from an empirical, historical and global perspective. They investigate the effect of crises on inequality as well as the impact of inequality on the probability of economic crises, by analyzing the history of banking, consumption, and GDP collapses over a 100-year period in 25 countries, out of which only 6 are developing economies. These authors observe the variation in distributive variables taking a 5-year window before and after the crisis date, and classify each one according to whether inequality was increasing, constant, or decreasing before and afterward.[87] Table 9.9, panel A, reproduces their results specifically regarding GDP collapses.[88] They identify 103 crises, but for only one-third is information available on inequality changes. The shadowed diagonal shows combinations where the trajectory was unchanged; above the diagonal are cases where the trajectory "bent" downward; below the diagonal are cases where the trajectory "bent" upward. As it is readily apparent, one cannot draw firm conclusions: (i) the raw totals show that most crisis did not involve changes in inequality ex-post; (ii) the number of cases above the diagonal is low and not very different from the cases below the diagonal, which means that GDP crises are not necessarily associated with a specific direction in the change of inequality; and (iii) the inverted V shape (inequality increasing and then decreasing) is not prevalent. Atkinson and Morelli (2011) conclude that "economic crises differ a great deal in whether or not they were preceded by rising inequality, and, in any case, where there was such a rise, causality is not easy to establish." When banking crisis are analyzed instead of GDP drops, the cases in which inequality tend to increase following a crisis are in the majority.

We replicate their methodology for the years 1980–2010 to take into account the set of developing countries and show the results in panel B of Table 9.9.[89] Even if our list is not exhaustive and could be considerably improved, we identify at least 67 crises

[87] In the case of the Gini coefficient, a change is considered significant when it is higher than 0.7% points (that is, 1/3 of 2 Gini points).

[88] A collapse is identified as a cumulative percentage drop in per capita GDP (from peak to trough) of at least 9.5% for 1911 to 1950 and of 5% for the post-1950 period. Their results are somewhat different when they look at banking crises and consumption collapses, but not more conclusive.

[89] Given the higher volatility of per capita GDP in developing countries, we have kept the threshold of a 9.5% drop to identify a crisis for 1980–2010. The data come from the World Bank Development Indicators. Changes in Gini coefficient are taken from PovcalNet.

Table 9.9 Inequality and GDP collapses

Panel A (Atkinson and Morelli, 2011)

		After crisis				
		Decreasing	No change	Increasing	Unknown/ excluded	Totals
Before crisis	Increasing	1	3	2	3	9
	No change	1	4	1	9	15
	Decreasing	1	1	0	1	3
	Unknown/ excluded	1	8	3	64	76
	Totals	4	16	6	77	103

Panel B (developing countries, 1980–2010)

		After crisis				
		Decreasing	No change	Increasing	Unknown/ excluded	Totals
Before crisis	Increasing	0	2	1	0	3
	No change	0	0	1	0	1
	Decreasing	0	1	0	0	1
	Unknown/ excluded	3	3	10	46	62
	Totals	3	6	12	46	67

Source: Own calculations based on PovcalNet (2013) and WDI.

episodes. As in general they occurred during the 1980s or early 1990s, it is not surprising that in most cases inequality changes before the crises remain unknown due to data unavailability. There is a tendency for inequality to rise after a GDP collapse (10 cases), but again the numbers are too small to draw conclusions, and this could just be the continuation of a previous tendency. This is not necessarily in contradiction with Atkinson and Morelli (2011) due to at least two reasons: (i) GDP crises may well be more correlated with financial crises in the developing world, and (ii) such conclusion is highly influenced by the experience of the transition economies after the fall of the Berlin Wall. It should also be noted that several of the canonical Latin American exchange rate crises of the 1980s and 1990s, with the exception of Argentina and Brazil (included in Atkinson and Morelli, 2011), do not fall within our classification of a collapse. In this sense, there is much work to be done about the magnitude of a crisis and its sensitivity on the two-way relationship with inequality. In any case, the pattern in Latin America points to an increase in inequality before the crashes (regressive inflation tax, rise in unemployment due to openness to trade, and loss of competitiveness from exchange rate mismanagement), then followed by short-term reductions after stabilization programs.[90]

Others. Of course this brief review does not exhaust the multiple factors behind distributive changes in the developing world; in fact, arguably any shock or policy could affect the income distribution. For instance, demographic factors, such as the decline in fertility, the rise in life expectancy, and the growing importance of assortative mating and single-parent households have been identified as relevant sources of inequality changes. Labor policies are a key target for research, as well. Several studies find that the weakening of labor institutions such as unions and the declining real value of minimum wages were responsible for the increase in earnings inequality in several developing countries, especially in the 1990s, whereas more ambitious labor policies contributed to the reduction in inequality in the 2000s. Migration and sector changes are also determinants of inequality changes, studied at least since the seminal contributions by Lewis (1954) and Kuznets (1955). Changes in inequality are associated with the geographic and sectorial pattern of growth (Loayza and Raddatz, 2010). Ferreira and Ravallion (2009), for instance, report that in Indonesia a large share of the increase in inequality was associated with migration from wage employment in agriculture to urban self-employment.[91]

9.5. POVERTY: LEVELS

The vast literature on poverty measurement suggests that there are neither normative nor objective arguments to set an unambiguous threshold below which everybody is poor and above which everyone is nonpoor (Deaton, 1997). Despite this central conceptual

[90] The case studies are numerous; see, for example, Forbes (2011) and Lustig (1990).
[91] The role of migration has been particularly relevant regarding global inequality (Milanovic, 2012).

ambiguity, reducing poverty is a deliberate policy objective for governments around the world. The international community has embraced this goal as reflected in the first Millennium Development Goal of halving poverty by 2015. In this section we focus on measures of poverty in the income/consumption space using international poverty lines in terms of U.S. dollars adjusted for purchasing power parity (PPP). This choice implies taking a one-dimensional, monetary, static, absolute view of poverty, that certainly has many limitations and drawbacks, but it is still the best available paradigm to summarize deprivations in the world.

The $1-a-day per person at PPP is a poverty standard meant to define an international norm to gauge the inability to pay for food needs. The $1 line, proposed in Ravallion et al. (1991) and used in World Bank (1990), was chosen as being representative of the national poverty lines found among low-income countries. The line was recalculated in 1993 PPP terms at $1.0763 a day (Chen and Ravallion, 2001), and more recently in 2005 PPP at $1.25 a day (Ravallion et al., 2009).

To make international comparisons of economic aggregates researchers have long favored the use of PPP conversion rates, instead of market exchange rates, with the aim of ensuring parity in terms of purchasing power over both internationally traded and non-traded goods. The simplicity of the PPP adjustment, however, entails several potential drawbacks for the international comparison of poverty measures, that have been extensively discussed in the literature.[92] For instance, a concern is that the weights attached to different commodities in the conventional PPP rate may not be appropriate for the poor.[93] The main data sources for estimating PPPs are the price surveys carried out within countries for the International Comparison Program (ICP) (World Bank, 2008). Although the estimation of PPP conversion rates has substantially improved in the last decades, it still has many limitations, including high variability; the switch from 1993 to 2005 PPP figures led to significant changes in absolute poverty measures in some countries.[94]

The $1.25 line is usually deemed too low for middle-income countries; for that reason it is typical to compute poverty with the $2-a-day standard, which is close to the median of the official poverty lines chosen by developing countries. Although these international lines have been criticized, their simplicity and the lack of reasonable and easy-to-implement alternatives have made them the standard for international poverty comparisons.[95] Although the measurement of poverty with national lines takes into consideration that societies differ in the criteria used to identify the poor, the international

[92] See Anand and Segal (2008), Deaton and Dupriez (2008), Deaton and Heston (2010), Ravallion (2010), and Chen and Ravallion (2001).

[93] Deaton and Dupriez (2008) estimate PPPs for the poor for a subset of countries; the results do not suggest that the reweighting has much impact on the conversion rates.

[94] Likely, the next round of PPP indicators (2011) will be affected by the same type of problems.

[95] For the debate on the international measurement of poverty, see Reddy and Pogge (2010), Deaton (2010), and Chapter 11 in this volume. Gentilini and Sumner (2012) compute global poverty using the national poverty lines officially set in each country instead of using international poverty standards.

lines are unavoidable instruments to compare absolute poverty levels and trends across countries and provide regional and world poverty counts.

The World Bank is the main institution that regularly produces information on poverty measurement in the developing world drawn from original microdata from household surveys.[96] In 2013, the World Bank released an update of the developing world's poverty estimates for 1981–2010. The new poverty estimates combine the PPP exchange rates for household consumption from the 2005 International Comparison Program with data from more than 850 household surveys across 127 developing countries. In this section we rely heavily on that data set (PovcalNet).

The problem of the choice of the welfare variable discussed for inequality in Section 9.3 applies to the measurement of poverty, as well. Although poverty estimates in PovcalNet refer to consumption deprivation, in most countries in Latin America and a few others in the rest of the world, they are constructed from income data. After computing consumption and income poverty in 22 household surveys of 7 Latin American countries using the \$2 standard, we find that on average the ratio of consumption/income poverty is 0.97 with only small differences across countries. Given this piece of evidence we decided not to perform an adjustment for income poverty figures in the analysis that follows.

9.5.1 Income Poverty in the Developing World

Although poverty is a ubiquitous characteristic of the developing economies, its severity widely varies across countries. Figure 9.15 shows the poverty headcount ratio in most of the developing countries in the world, using the \$2-a-day poverty line. The figure reveals the enormous differences among developing nations in terms of monetary deprivation. Although there are economies where the proportion of the population living with less than \$2 a day is below 2%, in several countries that proportion exceeds 80%. The problem of absolute income poverty has a radically different scale in some countries compared to others, even within the developing world.

In 2010, 41% of the population in the developing world lived with less than \$2 a day. The unweighted mean headcount ratio was significantly lower: In a typical developing country 33% of the population was poor according to that criterion. The difference between the weighted and unweighted mean is not determined by China, as the incidence of poverty in that country is similar to the developing world mean, but by India (and to a lesser extent Indonesia and Pakistan), where the deprivation measures are substantially higher. In fact, when ignoring India both the weighted and unweighted headcount ratios become very close (33.3 and 32.7). The median poverty rate is also lower than the mean (23.5 for the \$2 line). Table 9.10 reports these results for other indices and poverty lines. Interestingly, when using the \$1.25 line the weighted mean is

[96] Ahluwalia et al. (1979) was an early attempt to measure poverty in the developing countries.

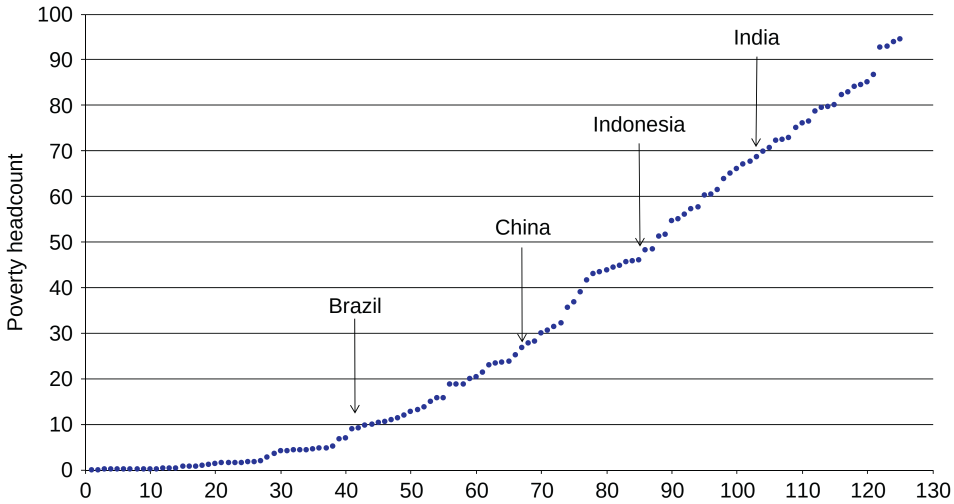

Figure 9.15 Poverty headcount ratio. Developing countries, 2010. *Note: Poverty computed over the distribution of consumption/income per capita with the PPP-adjusted \$2-a-day line. Source: Own calculations based on PovcalNet (2013).*

Table 9.10 Poverty measures
Developing countries, 2010

	Weighted mean	Unweighted Mean	Unweighted Std. dev	Unweighted Median
\$1.25 poverty line				
Headcount	21.4	19.6	22.9	9.3
Poverty gap	6.5	7.5	10.7	2.9
Squared poverty gap	3.0	4.0	6.5	1.0
\$2 poverty line				
Headcount	41.0	33.0	30.1	23.5
Poverty gap	15.8	14.5	16.4	7.1
Squared poverty gap	8.1	8.3	10.9	4.0
\$4 poverty line				
Headcount	66.7	54.8	33.6	59.3
Poverty gap	35.9	29.6	24.0	25.4
Squared poverty gap	22.9	19.5	18.5	13.2

Note: Poverty computed over the distribution of consumption/income per capita.

lower than the unweighted mean for the poverty gap and the squared poverty gap, a result driven by the relatively low value of these indicators in China and Indonesia.

The picture of poverty in the developing world is not significantly affected by changing the poverty indicator or the poverty line. The correlations across countries when using alternatively the headcount (H), the poverty gap (PG) and the squared poverty gap (SPG) with a given poverty line are all higher than 0.9.[97] For a fixed indicator the correlations are higher than 0.95 when changing the poverty line. The correlations are only slightly lower when changing both the indicator and the line (e.g., 0.85 for SPG with the $1.25 line and H with the $2 line).

The top 10 steps in the poverty ladder, using the headcount ratio with the $2 line, are all occupied by sub-Saharan African countries.[98] The following 10 features also eight SSA economies, in addition to a Caribbean country (Haiti) and a South Asian nation (Bangladesh). However, given its size, India is the country with the largest number of poor people. Although around 840 million people in that country live with less than $2 a day, the number in the second nation in that ranking, China, is less than a half (359). Both countries are home of 52% of the poor in the world, whereas the following four countries—Nigeria, Bangladesh, Indonesia, and Pakistan—represent 19%. Of course, these exact figures are valid only for a specific definition of income poverty, but the main results are robust to changes in indices and poverty lines.[99]

As expected, the relationship between mean consumption and poverty is very tight (Figure 9.16, panel a). A simple model of the headcount ratio ($2 line) on log mean consumption per capita estimated in a cross section of developing countries for 2010 accounts for more than 70% of the variation in the data. The cross-country relationship between poverty and inequality is much looser (panel b) see previous comment. The correlation coefficient between the headcount ($2 line) and the Gini is 0.17 (barely significant at 5%). The relationship is somewhat tighter with other poverty indices, but still in all cases the correlation coefficients are lower than 0.3. The magnitude of the correlations is similar when considering different income shares as measures of inequality.

Table 9.11 shows some simple regressions aimed at characterizing the relationship between poverty, mean income, and inequality in a cross section of developing countries. The results of course do not have any causal implication, and they are not helpful to orient policy, but nonetheless are illustrative of the empirical relationship among these three variables. An increase (cross-country) of 1% in mean consumption is associated to a fall

[97] The results are also robust to other poverty measures that do not belong to the FGT family, such as the Sen and Watts indices.

[98] Rwanda, Mozambique, Malawi, Nigeria, Tanzania, Zambia, Madagascar, Burundi, Congo Dem. Rep., and Liberia.

[99] The share of India and China in the world poor is 47% with the $1.25 line, 52% with the $2 line and 51% with the $4 line.

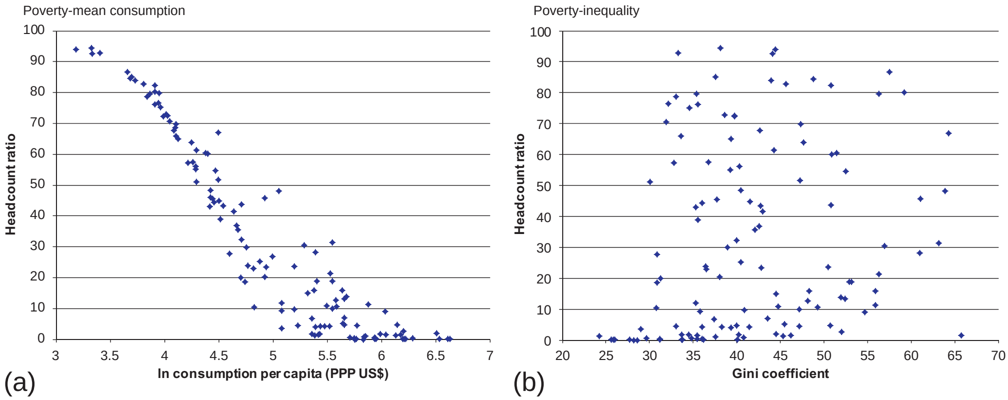

Figure 9.16 Poverty, mean consumption, and inequality. Developing countries, 2010. *Note: Poverty computed over the distribution of consumption/income per capita with the PPP-adjusted 2\$-a-day line. Source: Own calculations based on PovcalNet (2013).*

of around 2% in the headcount ratio, whereas a drop of 1% in the Gini coefficient is associated to a reduction of around 3.3% in poverty measured by the headcount. The results are similar when measuring deprivation with the squared poverty gap.

9.5.2 Poverty by Region

Poverty has a clear regional component: Table 9.12 reveals that Eastern Europe and Central Asia is always the region with the lowest income poverty, followed by Middle East and North Africa and Latin America and the Caribbean. Poverty in South Asia is substantially larger than in Eastern Asia when weighting by population, but roughly similar when ignoring weights. All income poverty measures are substantially higher in sub-Saharan Africa than in the rest of the developing world.

Figure 9.17 unveils the considerable heterogeneity within each geographic region. When using the \$2 line, the poverty headcount ratio ranges in EAP from 1.4 (Malaysia) to 70.6 (Timor-Leste), in ECA from 0.1 (Slovenia) to 35.6 (Georgia), in LAC from 1.2 (Uruguay) to 80.1 (Haiti), in MENA from 1.6 (Jordan) to 45.6 (Yemen), in SA from 6.8 (Maldives) to 76.5 (Bangladesh), and in SSA from 1.5 (Seychelles) to 94.5 (Liberia). Figure A.1 in the appendix displays a map of the poverty levels in the world that illustrates the regional differences, as well as the within-region heterogeneities.

There is a considerable degree of spatial correlation of poverty measures across countries. The Moran scatterplot is a way to illustrate that spatial correlation (Figure 9.18). The horizontal axis shows the normalized headcount ratio of a country (\$2 line), whereas the vertical axis depicts a weighted average of its neighbors´ normalized poverty rates, where neighborhood is defined in terms of geographical proximity. The graph suggests a strong positive correlation between a country poverty incidence rate and that of its neighbors (the Moran correlation coefficient is 0.507, significant at 1%). Almost 80%

of the countries are either in the HH cells (high poverty for the country and its neighbors) or in the LL cells.

The poverty gap indicator has an intuitive-appealing interpretation: when normalized by the poverty line and the total population of a country, it gives the total cost needed to end poverty, in the particular case in which cash transfers could be perfectly targeted to poor people in the amount just needed to reach the poverty line, and no changes in behavior take place. Table 9.13 shows the unweighted mean across countries of the cost of eliminating poverty as percentage of GDP under this scenario in each region. Although the context is clearly unrealistic, the figures give a rough idea of the magnitude of the task of fighting poverty in each region of the developing world in relation to the available economic resources. Although eliminating poverty with the $2 line in this scenario would require on average less than 1 GDP point in the economies of ECA and

between 1 and 2 points in MENA and LAC, the size of the effort is larger in Asia and orders of magnitude greater in sub-Saharan Africa.

International surveys, such as the Gallup Poll, provide an opportunity to alleviate some of the typical comparability problems of household surveys because survey design and questionnaires are identical across countries. However, as discussed earlier, these surveys have still small samples, and measurement errors are presumably large, given that only one income question is included. The correlation between headcount ratios computed with the Gallup Poll and PovcalNet is 0.32, significant at 2%, whereas the rank Spearman correlation is 0.61, significant at 1%.

Figure 9.19 shows the cumulative density function in some regions of the world, based on Gallup data. There is first-order stochastic dominance of the Western Europe distribution over the rest, whereas the South Asian distribution is dominated by the rest.[100] The curves of ECA and EAP cross each other, although they do so at high-income levels.

9.6. POVERTY: TRENDS

In the last decades the developing world has made undeniable progress toward the goal of ending absolute poverty. The evidence suggests that the first goal of the Millennium Development Goals—to halve extreme poverty from 1990 to 2015—was already met in 2010 for the aggregate of developing countries. However, the strong decline in global absolute poverty hides substantial heterogeneities across economies and over time. In this section we document and characterize trends in income poverty in the countries of the developing world since the early 1980s to 2010 and trace those changes to economic growth and distributive changes.[101]

The literature on international poverty trends can be divided into two main strands. The first one makes comparisons based exclusively on household survey microdata. This ambitious road that requires access to surveys for many countries over time has been taken by several initiatives at the regional level and by the World Bank at a global scale, mainly through the work of Martin Ravallion and Shaohua Chen. The second strand combines estimates of the national income distributions with GDP or aggregate consumption data drawn from National Accounts to anchor the mean. Bourguignon and Morrison (2002), Bhalla (2002), Karshenas (2003), and Sala-i-Martin (2006) are examples of this literature. In this section we mainly document the results of the first approach.

9.6.1 Trends in Income Poverty

Data from PovcalNet reveal a widespread fall in absolute income poverty in the developing countries over the last three decades (Figure 9.20). Only for a few nations poverty in 2010 was not lower than in 1981; that set includes some economies in Eastern Europe,

[100] First-order stochastic dominance ensures that the result of lower poverty in Western Europe is robust to the choice of poverty line and valid for a broad class of poverty measures (Atkinson, 1987).

[101] Chapter 11 in this volume also covers the issue of global poverty in the developing world. In our chapter the interest is more focused on the country trends, and then we make more use of unweighted statistics.

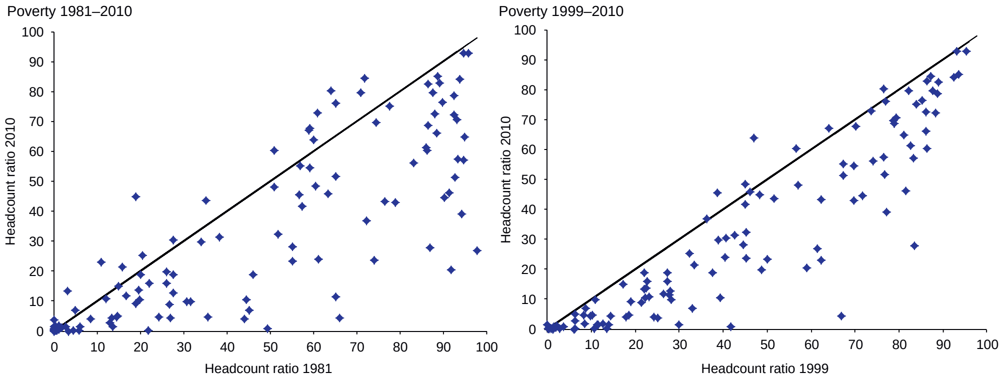

Figure 9.20 Poverty headcount ratio. Developing countries. *Note: Poverty computed over the distribution of consumption/income per capita with the PPP-adjusted \$2-a-day line. Source: Own calculations based on PovcalNet (2013).*

Central Asia, and sub-Saharan Africa and only a few in Latin America and the Caribbean. The poverty decline in the 2000s was even more generalized: in only 8 out of 121 countries did poverty increase between 1999 and 2010 (5 in sub-Saharan Africa).

The proportion of the population in the developing world living with less than \$1.25 per day decreased from 52% in 1981 to 20.8% in 2010, which implies a trend decline of around one point per year (Figure 9.21).[102] This is a remarkable achievement that should not be overlooked. It would be hard to find other episodes in history where the extent of extreme poverty was reduced so massively in such a short period of time.

However, this extraordinary result should be put in perspective. First, even after this global social improvement one of every five persons in the developing world still lives in extremely deprived conditions (less than \$1.25 a day), whereas four out of 10 people have household per capita consumption levels lower than a frugal \$2 per day.

Second, the positive performance of China is key for the global result. Ignoring China, the poverty decline is less impressive: the headcount ratio fell 16 instead of 31 points in three decades (Table 9.14).[103] In fact, when ignoring China, it is not clear that the developing world could meet the MDG for poverty reduction in 2015. Although the population-weighted mean of the poverty rate dropped 31 points between

[102] The cumulative distribution function of 2010 lies always below the functions corresponding to all previous years (first-order stochastic dominance).

[103] When ignoring China the distribution of 2010 still dominates (first-order stochastic dominance) 1981, although the distance between the two cumulative distributions is smaller. The curve for 1999 lies below 1981 and 1990 but only for poverty lines lower than \$3 a day.

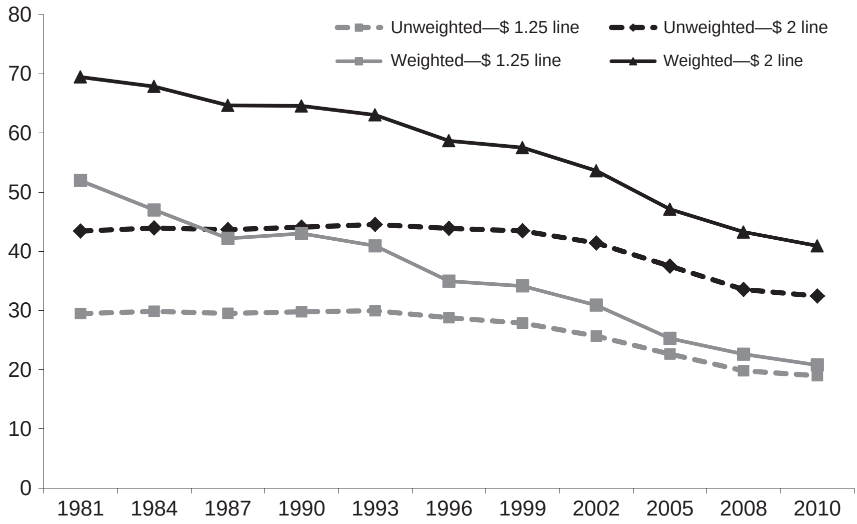

Figure 9.21 Poverty headcount ratio. Weighted and unweighted means, developing countries, 1981–2010. *Note: Poverty computed over the distribution of consumption/income per capita. Source: Own calculations based on PovcalNet (2013).*

1981 and 2010, the unweighted mean declined about 10 points, and the median went down just 8 points. The extreme poverty rate ($1.25) of a typical developing country was reduced from 29.5% in 1981 to 19% in 2010, which represents a fall of around a third of a point per year, a figure less impressive than the corresponding one for the global poverty rate (one point a year). In fact, this decline took place only since the late-1990s. A typical developing country did not experience any improvement for almost two decades: the unweighted poverty rate for the developing world was 29.5% in 1981, 29.8% in 1990, and 28.8% in 1996. From then on poverty declined more consistently, especially between 2002 and 2008, when for a typical developing economy the rate of poverty reduction was almost one point a year.

The fall in poverty appears less startling when using higher poverty lines. Whereas the headcount ratio with the $1.25 line fell 60% from 1981 to 2010, it declined 41% when measured with the $2 line and 20% with the $4 line. In fact, although the MDG goal of halving $1.25-a-day poverty from the value in 1990 was already met in 2010, the assessment is different when using the $2 line: the headcount ratio in 2010 was about two-thirds of the value in 1990.

The performance of the developing world in terms of poverty reduction also looks much less spectacular when considering poverty counts, instead of the typical measures that are invariant to the size of the population. In fact, for the majority of the developing countries (63%) the number of poor people was higher in 2010 than in 1981. Even during the booming 2000s the poverty count increased in 30% of the nations. The number

of poor people was in the late 2000s only slightly lower than in the early 1980s (2585 million in 1981 and 2394 million in 2010 with the $2 line); ignoring China, the poverty count actually increased in 422 million (from 1613 to 2035). Some authors have suggested that the difference in the assessment of world poverty when alternatively using the headcount ratio or the number of poor people may be behind some of the controversies in the public debate about globalization and the social performance of the world in the last decades.[104]

Because the calculation of global poverty with microdata is very cumbersome and requires having a large number of comparable household surveys, some authors estimate the changes in poverty with National Accounts data, anchoring the mean of the income distribution to output or domestic consumption taken from National Accounts, using secondary distributive data and making assumptions about the functional form of the income distribution, typically the lognormal parameterization (Ahluwalia et al., 1979; Bhalla, 2002; Chotikapanich et al., 1997; Pinkovskiy and Sala-i-Martin, 2009; Sala-i-Martin, 2006).[105] This methodology allows ambitious calculations in terms of coverage, but it faces some obvious caveats as changes in National Accounts aggregates may be misleading proxies for changes in household per capita income, and the secondary distributive data in which the estimates are usually based are mined with several comparability problems.[106]

According to the estimates by Pinkovskiy and Sala-i-Martin (2009) (PSM) using a sample of 191 countries, and distributive data from the WIID, world poverty rates ($2 line) went down from 45.2% in 1970 to 37.8% in 1981, 24.9% in 1990, 16.8% in 1999, and 13% in 2006. That pattern implies a fall substantially faster than what is estimated with household surveys data alone in the 1980s and 1990s, but slower in the 2000s.[107] For instance, although for 2008 the magnitude of the poverty rates in PSM for the $3 line is similar than in PovcalNet with the $1.25 line, the declines have been different. In PSM the headcount ratio fell at annual 2.6% and 3.5% in the 1980s and 1990s, respectively, whereas the rates were 2.1% and 2.5% with PovcalNet data. Instead, in the 2000s poverty fell at annual 3.1% in PSM and at annual 4.4% in PovcalNet.

[104] See Reddy and Pogge (2010), Chen and Ravallion (2012), and Cockburn et al. (2012).

[105] It should be noticed that the World Bank poverty estimates also use National Accounts (NAS) data, although to a limited extent. For instance, for countries with only one household survey, poverty is estimated by applying the NAS consumption estimates to the available distribution data, assuming the Lorenz curve remains fixed.

[106] An intermediate alternative was proposed by Karshenas (2003), who calibrated survey means using National Accounts statistics. Calibrated survey means are read off the fitted curve for the mean of household survey consumption conditional on the NAS mean.

[107] Dhongde and Minoui (2010) explore several factors behind the different results in Chen and Ravallion (2010) and Pinkovskiy and Sala-i-Martin (2009).

9.6.2 Decomposing Poverty Changes

Researchers frequently use decompositions of changes in poverty into growth and redistribution effects to characterize poverty trends.[108] The growth effect refers to the poverty change between two years that would have occurred if the mean income had changed as it did, but the shape of the distribution had stayed fixed. On the other hand, the redistribution effect records the poverty change between two years that would have occurred if the shape of the distribution had changed in the way it did, but the mean had remained fixed. Of course, this is just a mechanical exercise, as indicators of economic growth and changes in inequality and poverty are just three different ways of aggregate information on income dynamics, and therefore they are all jointly determined by the general equilibrium of the economy. In that sense the decompositions are helpful to illustrate the way incomes have changed and affected poverty, but they are silent on the fundamental factors underlying poverty changes and on the policies recommended to reduce deprivations more effectively.

The change in the growth-inequality-poverty triangle was very different in the 2000s compared to the previous decade. Table 9.15 illustrates this difference showing the unweighted mean of the growth and redistribution effects of changes in poverty for a sample of 76 developing countries with information on deciles shares in PovcalNet.[109] The mild fall in the poverty headcount ratio ($2 line) in the 1990s can be decomposed into a poverty-decreasing growth effect that outweighed a poverty-increasing redistribution effect. On average (unweighted) mean consumption grew at an annual 0.2%, and the Gini increased about 0.3 points per year, implying a very modest decline in poverty. In contrast, in the 2000s both effects contributed to a falling poverty. A robust increase of mean consumption (more than 3% a year) and a slow fall in inequality (around 0.1 Gini

Table 9.15 Decomposition of poverty changes
Developing countries, 1990–2010

		Effects	
	Actual change	**Growth**	**Redistribution**
1990–1999	−0.3	−1.5	1.2

1990–2010	−10.5	−10.4	−0.1

Note: The columns show unweighted means across a sample of 76 developing countries of the change in poverty headcount ratio ($2 line), and the growth and redistribution effects from the poverty change decomposition.
Source: Own calculations based on data from PovcalNet.

[108] See Datt and Ravallion (1992), Kakwani and Subbarao (1990), Kakwani (2000), and Mahmoudi (2001) for different proposals.

[109] Because the decompositions could be carried out changing the base year, the table shows the averages over the two exercises. To obtain the results we use lineal approximations to the Pen curve based on information on mean consumption per capita by decile from PovcalNet.

points a year) combined to yield a substantial reduction in indicators of material deprivation. The growth effect was particularly large, accounting for 90% of the fall in the headcount ratio ($2 line). This result does not mean that distributive changes are not important, but instead that they have not been the main drivers of poverty reduction in the past.

9.6.3 The Cost of Closing the Poverty gap

Although still a challenging problem, eliminating absolute extreme income poverty is an increasingly affordable target. Based on PovcalNet data, we computed the population-weighted poverty gap index in the developing world as a share of global GDP. This fraction, which indicates the fiscal effort required to end poverty in a scenario of perfect targeting, absent behavioral responses, has been substantially falling over time as poverty decreased and global GDP went up. The resources needed to close the poverty gap with the $1.25 line as a share of global GDP declined from 1.3% in 1981 to 0.2% in 2010 (the corresponding values for the $2 line are 3.6% and 1%).[110] As a share of the GDP in the developing world the cost of closing the poverty gap fell from 1.9% in 1981 to 0.4% in 2010 (5.4% and 1.8% for the $2 line).

Kanbur and Sumner (2011) highlight the fact that although in 1990 over 90% of the world's extremely poor people ($1.25) lived in countries classified as low-income countries (LICs), by the late 2000s this share dropped to less than 30%. From the fact that most of the world's poor live in middle-income countries with the domestic financial capacity to end at least extreme poverty, Sumner (2012) concludes that poverty reduction is increasingly becoming a domestic issue of national distribution and domestic political economy, rather than primarily an aid and international issue. Table 9.16 suggests than on average (unweighted) across developing countries the redistributive national effort to end extreme poverty under perfect targeting fell from 8.2% of GDP in 1981 to 4% in 2010. The median value is much lower and has fallen from 1.9% in 1981 to 0.5% in 2010. The third column shows the share of countries where the cost of eliminating extreme income poverty is less than 1 GDP point. That share substantially increased in the 2000s, from 41.3% in 1999 to 55.4% in 2010. Similarly, the share of countries for which closing the poverty gap is fiscally very burdensome (in the table more than three GDP points) fell from more than 50% in 1990 to about 30% in 2010. Sumner (2012) reports similar trends, although a lower proportion of countries with poverty gap/GDP less than 1%. Ravallion (2010) also notes that most middle-income countries would require very small additional taxation to end poverty.

[110] This computation assumes zero poverty in the high-income countries, when deprivation is measured with the international lines.

9.6.4 Regional Trends

The patterns in income poverty over time have been heterogeneous across the geographic regions of the developing world (Table 9.17). At least three facts are worth stressing: (i) the remarkable decline in poverty in Asia over the last three decades, (ii) the lack of significant progress in the rest of the regions in the 1980s and 1990s, and (iii) the generalized fall in poverty in the 2000s.

Arguably, the main fact about poverty dynamics in the last three decades has been the noteworthy decline in Asia. The share of people living with less than $2 a day went down from 92.4% to 29.7% between 1981 and 2010 in East Asia and Pacific, and from 87.2% to 66.7% in South Asia. The performance of EAP is enhanced by the presence of China, but also the unweighted mean dramatically fell in this region (from 70.4% in 1981 to 38.4% in 2010). The fall in the unweighted mean was similar in South Asia (from 80.3% to 43.5%). Almost all countries in Asia experienced drops in income poverty over the period 1981–2010. The reductions were on average larger in the 2000s than in the previous decades. For instance, in South Asia the unweighted mean fell 5.6 points in the 1980s, 10.9 in the 1990s, and 20.4 in the 2000s.

In the rest of the developing world the performance was weak and even negative in the 1980s and 1990s. Income poverty rose in Latin America in the 1980s, in Eastern Europe and Central Asia in the 1990s, and in sub-Saharan Africa in both decades. In contrast, all regions experienced falling poverty in the 2000s. The reductions were large and in general outweighed the weak performance of the previous decades. For instance, on

average (unweighted) income poverty ($2 line) went down 72% in ECA, 43% in MENA, 34% in LAC, and 12% in SSA. The proportion of countries where the headcount ratio fell more than 5% in the 2000s is above 90% in all these regions, with the exception of SSA, where the corresponding proportion is 66%.

The contrast between Asia and the rest of the developing world in terms of poverty reduction is even more dramatic when the calculations are carried out anchoring the mean of the income distribution to GDP from National Accounts. Figure 9.22 shows regional estimates taken from Pinkovskiy and Sala-i-Martin (2009), where the sharp

declines in poverty in East and South Asia stand out. According to these estimates there would be poverty convergence across the regions of the developing world, with the exception of sub-Saharan Africa.

Regions have been different in terms of the growth-inequality-poverty triangle (Table 9.18). The growth effect was strong in Asia dwarfing a much smaller (and sometimes poverty-increasing) redistribution effect. The increase in poverty in ECA in the 1990s is associated with both negative growth and inequality rise, whereas the fall in poverty in the following decade is mostly accounted for by neutral positive growth. In Latin America growth contributed in both decades, but only in the 2000s did the redistribution effect become poverty-reducing. Finally, in Africa (MENA and SSA) the growth effect in the 2000s was the major contributing factor to the fall in poverty.

In the rest of this section we take a closer look at the changes in poverty reported by the literature in each geographic region of the developing world.

9.6.4.1 *East Asia and Pacific*

As mentioned earlier, East Asia and Pacific has achieved an impressive record in terms of poverty reduction. The fall in the indicators of material deprivation has been strong, sustained over the two last decades and widespread across countries.[111] The poverty headcount ratio with the $2 line fell from 92.4% in 1981 to 81% in 1990, 61.7% in 1999, and 29.7% in 2010.

[111] See Ahuja et al. (1997) and Nissanke and Thorbecke (2010) as examples of a vast literature.

China's progress against absolute poverty was a key factor behind this dynamic (Minoiu and Reddy, 2008; Ravallion and Chen, 2007; World Bank, 2009). Rural areas accounted for the bulk of the gains to the poor, although migration to urban areas helped; agriculture played a far more important role than the secondary or tertiary sources of GDP, mainly from the efficiency gains after the decollectivization process. Ravallion and Chen (2007) claim that "the halving of the national poverty rate in the first few years of the 1980s was largely attributable to picking these low-lying fruits of agrarian reform." Provinces starting with relatively high inequality saw slower progress against poverty, due both to lower growth and a lower growth elasticity of poverty reduction. In 1990 the incidence of poverty in China was roughly 25 points higher than in the rest of the developing world, but by the end of the 2000s, it had fallen more than 10 points below the average.[112]

Between 1990 and 2010 the headcount ratio fell from 60% to 12% in China ($1.25 line), and from 54% to 18% in Indonesia, the two most populated countries in the region.

[112] During the early and mid-1990s poverty declined substantially, but then in the late 1990s to the early 2000s the downward trend stalled. Li et al. (2013) argue that further reductions in poverty became more challenging due to several factors, for example, the fact that a high proportion of the remaining poverty was geographically dispersed and transient and also because poverty had become less responsive to macroeconomic growth (World Bank, 2009). Policies adopted after 2002, such as the minimum living guarantee program, the new rural cooperative medical system, and the new rural pension system, have addressed some of these factors.

The rest of the East Asian economies experienced similar patterns. The headcount ratio dropped from 58% to 15% in Cambodia, from 12% to 0.4% in Thailand, and from 73% to 14% in Vietnam. The reductions were less spectacular, but anyway significant in the Pacific countries (Micronesia, Philippines, Papua New Guinea, Timor-Leste). According to the Asian Development Bank (2012a, 2012b), and using the national lines, poverty declined in all EAP economies except Mongolia, Micronesia, Samoa, Timor-Leste, Tonga, and Tuvalu. With respect to the poverty reduction target of the Millennium Development Goals, of the 10 economies for which data are available, six have achieved the poverty target, and Cambodia is very close to reaching it by 2015. Lao PDR, Philippines, and Timor-Leste are progressing more slowly toward that goal.

9.6.4.2 Eastern Europe and Central Asia

The evidence clearly suggests that poverty in Eastern Europe and Central Asia increased during the 1990s and decreased during the 2000s. The collapse of output in many of these countries following the dismantling of the Soviet Union, along with hyperinflation that wiped out savings, resulted in a dramatic drop in living standards for the majority of people and the emergence of poverty as a major issue.[113] However, according to Simai (2006), poverty in the region was not a new phenomenon; most of the countries began their transformation with extensive hidden unemployment and at least one-tenth of its population below the subsistence level. The transition also involved setbacks in non-monetary dimensions of well-being. Past achievements in social welfare came under pressure, the most striking being the reduction in life expectancy: In 1995, life expectancy for males in the Russian Federation was just 58 years, 10 years less than that of men in China.

Table 9.17 reminds the reader that poverty rates in these countries have always been much lower than in the other developing regions, irrespective of the line considered and of the weighted or unweighted averages, and despite the fact that low-income CIS (Georgia, Uzbekistan, Moldova, Armenia, Kygryz Republic, Tajikistan) display figures well above the regional mean. When growth resumed after the Russian crisis in 1998, poverty started to fall.[114] It was not until 2004 that the region as a whole returned to the level of GDP recorded in 1990 (World Bank, 2005). Much of the poverty reduction initially occurred in the populous middle-income countries (Kazakhstan, Russian Federation, Ukraine), but eventually it spread almost everywhere. Scholars have identified four main (nonindependent) explanations for the poverty dynamics: (i) the positive growth in output and wages; (ii) the decline in inequality, with incomes of poorer households increasing faster than average in some countries (CIS) but not in others (Poland,

[113] Poverty in Eastern Europe and the Soviet republics pre-1990 is discussed at some length in Atkinson and Micklewright (1992).

[114] For an analysis of the growth elasticities of poverty reduction, see World Bank (2005), Chapter 1.

Romania); (iii) the increasing role of public transfers, with benefits improving in coverage and adequacy; and (iv) private remittances, which in many cases far exceeded public funding.

9.6.4.3 Latin America and the Caribbean

Poverty estimates in Latin America, available since the 1970s, were always mostly based on income, not consumption.[115] Despite the fact that statistics were initially weak, there is agreement among researchers that during the 1970s economic growth pushed poverty down in the region (Altimir, 1979, 1996). In contrast, the "lost decade" of the 1980s was characterized by recurrent crises and output stagnation, which brought about a weak social performance. Latin American economic growth resumed in the 1990s, but in the context of growing inequalities, a combination that resulted in a modest decline in poverty (Londoño and Székely, 2000). The exceptional economic conditions in the 2000s and the consolidation of more ambitious social policies implied a sharp drop in poverty indicators in that decade. Gasparini et al. (2013) estimate that the income poverty headcount ratio ($2.5 line) fell from 36% in the early 1970s to 27.3% in 1980, slowly increased to reach 27.8% in 1992, mildly decreased to 24.9% in 2003, and was reduced dramatically to 16.3% by 2009.[116] The number of poor people in the region is estimated to have fallen from 119 million in 1992 to 89 million in 2009 (Gasparini et al., 2013). Other indicators of income poverty and of various types of material deprivation are consistent with these results. Data from SEDLAC confirms that the reduction in poverty continued in the period 2009–2013, despite a deceleration in the GDP growth rates. The improvements in social indicators in the 2000s have been linked to at least two factors: on the one hand, most of the region's economies experienced robust growth together with upswings in employment and labor income; on the other, all countries boosted social spending and put ambitious social protection systems into place or expanded the scope of their existing systems (Cruces and Gasparini, 2012; López Calva and Lustig, 2010).

The performance in terms of poverty reduction has been heterogeneous across the regions in Latin America. Although Central America experienced a slow decline in income deprivation over the last two decades, in the rest of the regions the rapid poverty fall of the 2000s contrasts with the sluggish or even negative performance of the 1990s.[117]

[115] In the Caribbean poverty is estimated based on consumption expenditures, but surveys are still scarce, so poverty changes are difficult to monitor.

[116] Estimates are based on SEDLAC statistics, Londoño and Székely (2000), Wodon et al. (2001), and official poverty estimates from all countries in Latin America.

[117] SEDLAC data indicate that using the international poverty line of $2.5, the average (unweighted) poverty rate in Southern South America increased from 17.7% in 1992 to 18.5% in 2003, and then dropped to 9.1% by 2010. In the same period the average poverty rate in the Andean region first rose from 30.2% to 33%, and then declined to 17.5%. In contrast, poverty in Central America fell more uniformly over the two decades: 33.3% in 1992, 28.6% in 2003, and 23.1% in 2010.

More than half of the population in Latin America lives in Brazil or Mexico. After a decline in the early 1990s, income poverty in Brazil remained stable for about a decade; the poverty rate with the $2.5 line was 27.8% in 1995 and 27.1% in 2003. After that plateau, the country experienced a fast and sustained reduction in income poverty, reaching 13.9% in 2010. The Mexican economy was hit by a serious crisis in the mid-1990s (the so-called Tequila crisis) that raised income poverty from 17.8% in 1992 to 43.4% in 1995 (SEDLAC data, $2.5 line). From that peak, income poverty initiated a consistent decline to reach a value of 12% in 2006, with no gains in the second half of the 2000s.

9.6.4.4 Middle East and North Africa

As discussed in Section 9.4, it is useful to divide the last four decades in MENA into three periods. The first one, spanning until the mid-1980s, was characterized by strong economic growth: the average per capita income growth for the region between 1975 and 1984 was over 4.5%. Adams and Page (2003) argue that given MENA´s relatively equal income distribution, this economic growth had a powerful impact on reducing poverty in the region. However, assessing that progress is difficult becaused pre-1985 household surveys are only available for Tunisia and Egypt. Iqbal (2006) reports that in Tunisia poverty fell from 51% in 1965 to 16% in 1985, while Egypt's achievement was also impressive, with poverty declining from 82% to 53% between 1975 and 1985. Page (2007) estimates a fall in the incidence of poverty ($2 line) in the region from 57% in the late 1970s to 22% in the early 1990s.

The second period, covering the late 1980s and most of the 1990s, was characterized by a sluggish economic performance, in part due to low prices for hydrocarbons, declining remittances and aid flows, as well as a low payoff to the reforms that were implemented. On average for the developing MENA countries, real per capita incomes went up by less than 1.5% per year. The proportion of those living with less than $2 per day stayed roughly unchanged at around 22% for a decade (PovcalNet). Iqbal (2006) reports that "by 2001, approximately 52 million people were poor, an increase in absolute numbers of approximately 11.5 million people, compared with the situation in 1987." The 1990s were a lost decade for economic growth and poverty reduction in the developing economies of the MENA region (Page, 2007).

The downward pattern in poverty appeared to have resumed in the 2000s. The incidence of poverty ($2 line) fell from 22% in 1999 to 12% in 2010. According to PovcalNet data the number of people living with less than $2 a day increased by 7 million in the 1990s and then was reduced by 20 million in the 2000s (from 60 to 40 million). In the 1990s poverty went down in a third of the MENA countries, but in the 2000s it went down in all economies, with the possible exception of Yemen.

9.6.4.5 South Asia

South Asia achieved impressive economic growth in the past 15 years. Since 1996 until the recent global crisis, GDP growth in the region exceeded 5% per year. As a consequence, poverty rates were considerably reduced. In Bangladesh, India, and Nepal, absolute poverty (headcount ratio, $1.25 line) fell by 18, 15, and 43 points, respectively, between 1996 and 2010. In Pakistan, it fell by 22 points between 2002 and 2010. Devarajan and Nabi (2006) optimistically expect the region to have single-digit poverty rates in 2015 if growth rates accelerated to 10% per year. This has indeed happened already in Sri Lanka (where poverty dropped from 17 in 1996 to 4 in 2010) as well as in Maldives (where, according to the 2006 census, about 1 of the population was living on less than $1 a day).

Growth has been instrumental in reducing poverty rates, but as Ghani (2010) points out from a gloomier perspective, poverty rates were not falling fast enough to reduce the total number of poor people. Those living on less than $1.25 a day increased from 549 million in 1981 to 595 million in 2005. In India, where around three-quarters of these poor live, the number increased from 420 million in 1981 to 455 million in 2005 (Ravallion et al., 2009). The situation seems to have slightly improved according to the most recent observations.

9.6.4.6 Sub-Saharan Africa

The economic and social performance of sub-Saharan African countries has been frustrating. Five decades after most nations gained independence, poverty is still at very high levels in SSA, in fact the highest in the world. Fortunately, it seems that finally, after years of impoverished economic performance, the last decade shows some signs of improvement. Based on figures from PovcalNet, the incidence of poverty increased between 1981 and 1999 from 51% to 58% for the $1.25 per day line and from 72% to 77% for the $2 line (the unweighted statistics are not very different).[118] Because of the increase in population the number of people living with less than $1.25 a day almost doubled in sub-Saharan Africa during those years, from 205 million to 377 million. These results are even more disappointing when compared to the rest of the developing world. The share of the world's poor living in sub-Saharan Africa rose from 11% in 1981 to 22% in 1999. Artadi and Sala-i-Martin (2003) find that the SSA poverty rate was stable in the 1970s, around a value of 49%, and soared in the 1980s and early 1990s, reaching 60% in 1995, following the deterioration of aggregate per capita income in the region. They report a nearly 50% reduction in the worldwide poverty rate between 1980 and 2000, which contrasts with a 27% increase in SSA.

Following the dismal performance of the 1980s and early 1990s, SSA witnessed some economic and social progress. Poverty declined considerably from their heights of the

[118] According to the $4 line, more than 90% of the SSA population is actually considered poor.

mid-1990s; in fact the reduction in extreme poverty from that date to the late 2000s was similar than in the rest of the developing world, excluding China. Chen and Ravallion (2012) stressed the fact that for the first time since 1981 the share of people in sub-Saharan Africa living below \$1.25 a day was less than 50%. Changes in poverty have been closely linked to economic growth. According to Fosu (2010), poverty has declined in SSA by about 0.5 points per year since the mid-1990s, quite comparable with South Asia's record. Sala-i-Martin and Pinkovskiy (2010) estimate that African poverty has been falling steadily since 1995. According to these authors the African poverty rate in 2006 was 31.8%, 30% lower than in 1995, and 28% lower than in 1990. The decline in poverty in the 2000s was quite extended: As reported earlier, two-thirds of the SSA countries in PovcalNet experienced reductions larger than 5%. Sala-i-Martin and Pinkovskiy (2010) find that "poverty fell for both landlocked as well as coastal countries; for mineral-rich as well as mineral-poor countries; for countries with favorable or with unfavorable agriculture; for countries regardless of colonial origin; and for countries with below or above median slave exports per capita during the African slave trade. Hence, the substantial decline in poverty is not driven by any particular country or set of countries." However, Fosu (2009) highlights the considerable heterogeneity across country experiences. For example, although high economic growth in Botswana has been transformed to only a minimal decline in poverty, Ghana has succeeded in translating its relatively modest growth to considerable poverty reduction. Fosu (2009) attributes this contrast to the difference in the levels of income inequality between the two countries.

Despite the encouraging signs of progress in the fight against poverty in sub-Saharan Africa, Chen and Ravallion (2012) alert that the lags in survey data availability and problems of comparability and coverage raise concerns about how robust this positive trend will prove to be.

9.6.5 Poverty Convergence

Given the heterogeneity among economies in terms of social improvement, a natural question is whether countries starting out with a high incidence of material deprivation tend to be the ones with higher rates of poverty reduction; i.e., whether there is *poverty convergence* (Ravallion, 2012).[119] Figure 9.23 suggests some signs of poverty convergence in absolute terms but not in proportionate terms.[120] The 1981 poverty level (\$2 line) is negatively correlated with the annualized change over the period 1981–2010, but not with the proportionate change (annualized log difference). In the first panel the regression line has a slope of −0.009 with a *t*-ratio of −4.51, based on a robust (White) standard

[119] The use of the term *poverty convergence* in this context is not entirely transparent. Another (more trivial) alternative would be assessing whether poverty measures converge toward zero, simply checking that poverty changes are negative.

[120] The analysis is restricted to countries with initial poverty above 5%.

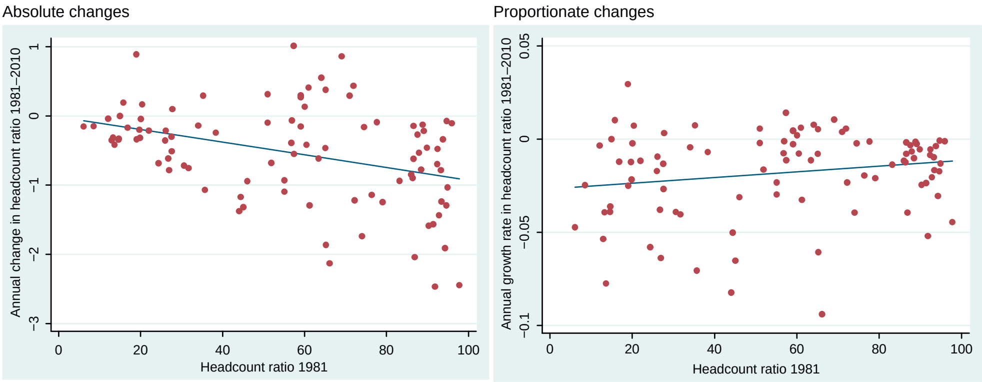

Figure 9.23 Poverty convergence among developing countries 1981–2010. *Note: Poverty computed over the distribution of consumption/income per capita with the PPP-adjusted $2-a-day per person line. Source: Own calculations based on PovcalNet (2013).*

error. This result means that on average the absolute fall in poverty has been larger in countries with higher poverty incidence, but because the difference across countries is small, there is absence of poverty convergence in proportionate terms.

The results for other poverty indices, lines, and time periods are similar (Table 9.19). The coefficients for the absolute change in poverty are negative but small, whereas the coefficients for the proportionate change are in general positive, although in most cases non-significant.[121]

Ravallion (2012) argues that the lack of poverty convergence (in proportionate terms), despite evidence for mean convergence and for the poverty-reduction impact of growth, suggests that the dynamic processes for growth and poverty reduction depend directly on the initial level of poverty. He shows evidence on two adverse effects of being a country with high poverty levels: first, these countries tend to grow at a slower pace, controlling for the initial mean, and second, a high poverty rate implies lower "productivity" of economic growth in terms of poverty reduction (lower poverty-growth elasticity).

9.6.6 Poverty and Growth

The dynamics of poverty are closely related to income growth. The economic literature has gathered abundant evidence supporting the fact that absolute poverty tends to fall

[121] The first panel in Figure 9.23 suggests an increase in the dispersion of absolute changes at higher values of the initial poverty level. A quantile regression analysis confirms that the slope of the regression line is negative and significant for the lower quantiles (the high-performers in terms of poverty reduction), and statistically non-significant for the higher quantiles. The systematic difference in the slopes across quantiles suggests that poverty convergence depends on factors beyond the initial poverty level.

Table 9.19 Poverty convergence among developing countries

with economic growth.[122] Moreover, the longer the growth spells under consideration, the larger the share of the variance in poverty that is accounted for by the growth component (Ferreira, 2010). Figure 9.24 illustrates this relationship by showing poverty along with two alternatives measures of mean income: per capita gross national income (GNI) constructed from National Accounts, and per capita consumption obtained from household surveys. The figure shows the unweighted mean of these variables among developing countries in the period 1981–2010. On average, the economic performance of the developing countries was weak in the 1980s and early 1990s, hindering the perspectives of poverty reduction. Since the mid-1990s economic growth resumed in most countries in the developing world, a process that accelerated in the 2000s, leading to a sustained decrease in all measures of income poverty. At the end of the decade that pattern was slowed down, but not halted, by the poor economic performance of several developing countries associated to the international crisis.

[122] See Chen and Ravallion (1997), World Bank (2000), Ravallion (2001, 2007, 2012), Dollar and Kraay (2002), Fields (2002), Bourguignon (2003), Besley and Burgess (2003), Kraay (2006), and Fosu (2011) as examples of a large literature.

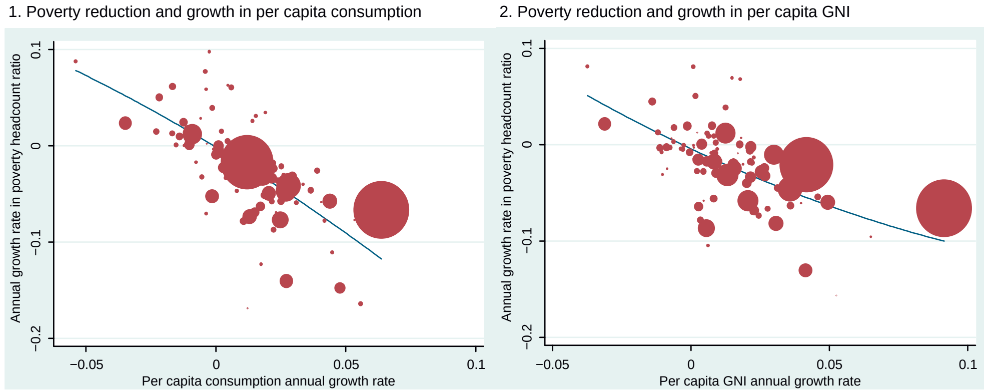

Figure 9.25 Growth and poverty reduction in the developing countries, 1981–2010. *Note: The horizontal axis shows the annual growth rate between 1981 and 2010 in per capita consumption from household surveys in constant 2005 dollars (panel 1) and in per capita gross national income in constant 2005 PPP dollars (panel 2); the vertical axis shows the annual growth change in the poverty headcount ratio ($1.25 line) in the same period. The size of each circle is proportional to the country population in 2010. Source: Own calculations based on PovcalNet (2013).*

Figure 9.25 is another illustration of the relationship between poverty reduction and economic growth. The figure shows that the change in poverty is closely negatively related to economic growth, either in per capita consumption expenditures drawn from household surveys or in GNI from NAS. Notice that in both panels the fitted line approximately crosses the (0,0) point.

Because the positive correlation between poverty reduction and growth is a well-established result, research in this area is mainly focused on estimating the magnitude of the corresponding elasticity, an issue that may have relevant policy implications. "If (the elasticity) is reasonably high, then poverty reduction strategies almost exclusively relying on economic growth are probably justified. If it is low, however, ambitious poverty reduction strategies might have to combine both economic growth and some redistribution" (Bourguignon, 2003). The growth elasticity of poverty reduction is typically estimated by regressing the annualized proportional change in a poverty indicator against the annualized growth rate of mean income (per capita income or consumption from surveys, or per capita GDP, GNI, or aggregate private consumption from NAS) in a sample of growth spells. In a regression without controls the resulting coefficient is the total elasticity, as opposed to a partial elasticity that can be obtained by holding inequality and other factors constant.

Based on a data set for 67 countries over the period from 1981 to 1994, and using the $1 line, Ravallion and Chen (1997) find a central estimate for the poverty-growth elasticity of −3.1. Values estimated by other authors are somewhat lower (in absolute terms): around −2 in World Bank (2000), −1.6 in Bourguignon (2003), −2.6 in Adams (2004), and −1.8

in Ferreira and Ravallion (2009). More recently, Ravallion (2012) reports an elasticity of −1.4 for the \$1.25 line. The elasticity is lower when using the growth rate of consumption per capita from NAS (−0.8), and also lower when using a higher poverty line. The confidence intervals around the regression coefficient are typically wide. Ravallion (2007) reports that the 95% confidence interval implies that for a poverty level of 40%, an annual growth rate of 2% is consistent with poverty reductions ranging from 1% to 7%.

Estimates of the total growth elasticity of poverty reduction over the period 1981–2010 obtained with the latest version of PovcalNet data are shown in Table 9.20.[123] All the elasticities are negative and significant at 1%. The growth elasticity of poverty reduction, as measured by the proportion of individuals below \$1.25 a day, is around −1.5. The results in Table 9.20 confirm that elasticities are lower in absolute value when considering a higher poverty line. The result of lower elasticities using GNI from National Accounts holds but only until the 2000s, suggesting a change in the relative trends between consumption reported in household surveys and output estimated in NAS. In general, the absolute value of the elasticities estimated with both sources have increased in the 2000s compared to previous decades, suggesting that growth was better translated to the poor in that period of falling inequality. For instance, although the elasticity using the \$1.25 line and consumption per capita was −1.53 for the period 1981–2010, it amounted to −1.83 when restricting the analysis to the 2000s.

So far, we have reported *total* elasticities, which can be seen as summary measures of the comovements of poverty and growth. The literature has tried to improve this characterization by adding other variables into the analysis, typically measures of inequality and development. The empirical evidence supports the intuition that higher inequality tends to reduce the absolute value of the elasticity, by shifting the gains from growth away from the poor (Kraay, 2006; Ravallion, 1997, 2001).[124] For example, based on a sample of 65 countries during 1981–2005, and using the \$1 poverty line, World Bank (2005) reported that the poverty-growth elasticity is highest among low-inequality countries (with a value of approximately −4.0 for countries with Ginis in the mid-20s) and lowest among high-inequality countries (close to −1.0 for countries with a Gini coefficient around 60). The change in inequality is also found as a significant direct determinant of the elasticity. For instance, Ravallion (2001) finds that the median rate of reduction in the poverty headcount ratio (\$1 line) among growing economies was 10% per year among countries with falling inequality, and 1% per year for those countries with rising inequality.

[123] The sample includes 725 spells in 76 countries for which consistent information for the whole period is available. Results do not significantly vary when we restrict the analysis to more recent periods, which allows a larger sample of countries.

[124] Although the intuition is compelling, the result is theoretically ambiguous. See Ravallion (2007) for a proof, and Bourguignon (2003) for a case in which assuming log-normality yields an unambiguous result.

Table 9.20 Total poverty−growth elasticities
Developing countries

Index	Poverty line	Consumption per capita			GNI per capita

Source: Own calculations based on PovcalNet (2013).

Using a sample of 114 growth spells from the mid-1980s to the mid-1990s in 26 developing countries Bourguignon (2003) finds an elasticity of −1.6 in the model without controls and −2 when controlling for the change in the Gini. The latter specification increases the R^2 from 0.266 to 0.419, suggesting that the heterogeneity in distributive changes is as much responsible for the variation in poverty changes across growth spells as the heterogeneity in the speed of growth. Bourguignon (2003) also finds positive and significant coefficients for the interaction terms between the growth rate and both (i) the initial level of inequality, and (ii) the level of development (proxied by the poverty line over mean income). He also reported negative coefficients for the interaction terms between the change in the Gini and those two variables. The first four columns in Table 9.21 in general confirm the results in Bourguignon (2003), using a larger data set spanning three decades.[125]

The results suggest the possibility of a double dividend from reducing inequality: first, given a growth rate, lower inequality is associated directly with less poverty, and second, less inequality means more poverty reaction to a given growth rate, that is an acceleration of poverty reduction for a given rate of economic growth. Ravallion (2007) illustrated the relevance of lower inequality for the perspectives of poverty reduction assuming a country with a poverty incidence rate of 40% and a growth rate of 2% per year: with an initial Gini coefficient of 30 it would take 11 years to reduce poverty by half, whereas with a Gini of 60 it would take 35 years.

A more recent study Ravallion (2012) finds that the (absolute) growth elasticity of poverty reduction tends to be lower in countries with a higher initial poverty rate (see also the two last columns in Table 9.21). Ravallion (2012) finds a large attenuating effect of a higher initial poverty rate on the elasticity: at an initial poverty rate of 10% the elasticity is −2.2, while it falls to −0.5 at a poverty rate of 80%. The results are robust to the inclusion of additional interaction effects with the initial Gini coefficient, the partial elasticity of poverty reduction holding the Lorenz curve constant, the primary school enrollment rate, life expectancy, the price of investment goods, and regional dummies.

Unfortunately, although the characterization of the growth elasticity of poverty reduction discussed in this section is useful, the literature is still far from being able to clearly identify the structural factors that are behind the differences in the elasticities, and therefore it is relatively silent about the specific policies that could foster a larger impact of economic growth on poverty.

[125] Instead, unlike Bourguignon (2003) we fail to find a coefficient close to −1 for the interaction between the growth rate and the theoretical value of the poverty-growth elasticity under the lognormal assumption.

9.6.7 Relative Poverty

So far we have presented evidence on *absolute* poverty, an option that requires keeping the real value of the poverty line fixed over time. The alternative is *relative* poverty, where the line is adjusted to reflect changes in a general measure of economic well-being. Although the measurement of relative poverty has not been common in the developing world, sustained economic growth has triggered the update of absolute poverty lines in some countries (e.g., China and India) and foster discussions on relative poverty. The measurement of relative, instead of absolute, poverty can be justified on two grounds (Chen and Ravallion, 2008; Sen, 1983). First, the very concept of poverty may depend on social norms that are likely different across countries and over the development process. Second, even for a fixed norm, an absolute line in the space of welfare may require a relative line in the space of consumption if individual welfare also depends on relative consumption with respect to the rest of the society where the person lives.

The typical relative poverty line is set as a constant proportion of the mean of the distribution, implying that poverty does not fall when all incomes grow at the same rate. This result is considered problematic by many authors who prefer weak versions in which the cost of inclusion is not a constant proportion of mean income. For instance, following Atkinson and Bourguignon (2001), Ravallion and Chen (2011) propose a poverty line that is fixed up to a critical value of the mean, where it rises with elasticity less than one. In particular, Ravallion and Chen (2011) set the line for country i at time t as $z_{it} = \max[\$1.25, (\$1.25 + M_{it})/2]$, where M_{it} is the country and date specific mean. Figure 9.26 reveals an overall trend decline in the incidence of weakly relative poverty in the developing world. The fall has been relatively meager, so that the number of poor by this

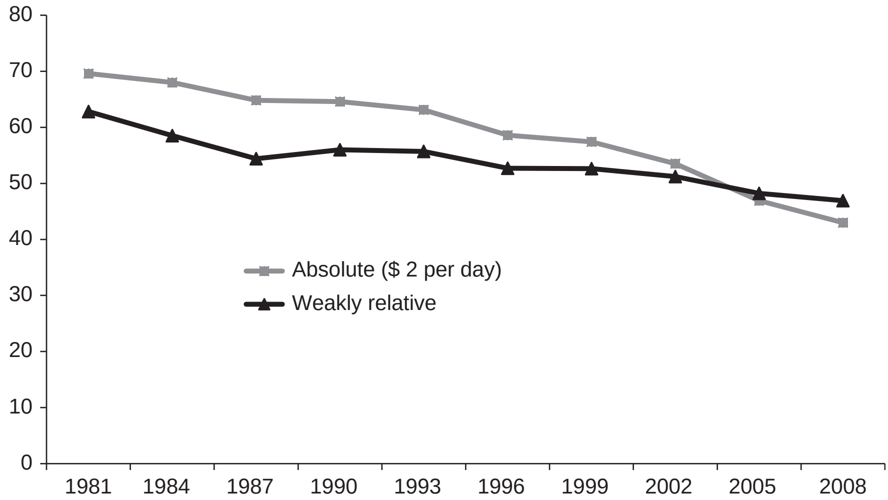

Figure 9.26 Poverty headcount ratio with absolute and weakly relative poverty lines. Developing countries, 1981–2008. *Source: Ravallion and Chen (2011).*

Table 9.22 Absolute and relative poverty
Developing countries, 1990–2010

	Unweighted				Weighted			
	absolute ($2)	weakly relative (RC)	strongly relative	anchored	absolute ($2)	weakly relative (RC)	strongly relative	anchored
1990	40.6	46.5	28.0	28.0	64.7	54.1	19.7	19.7
1993	39.8	47.9	29.0	32.9	62.7	53.7	21.1	19.1
1996	38.6	47.4	29.1	32.1	58.0	51.4	22.0	17.1
1999	38.3	47.5	30.1	31.9	56.7	50.2	22.9	16.9
2002	36.7	46.9	30.1	29.6	52.5	49.5	23.7	15.2
2005	32.3	45.0	29.5	24.8	45.6	46.5	23.7	12.3
2008	28.7	43.2	29.0	19.9	42.1	46.1	24.9	9.9
2010	27.7	42.4	28.6	18.9	39.4	45.6	26.6	9.5

Note: Weakly relative poverty computed according to Ravallion and Chen (2011). Strongly relative lines set at 50% of mean income. Anchored poverty computed by "anchoring" the relative lines (50% of mean income) to the values in 1990 and updating them only by domestic price changes.
Source: Own calculations based on data from PovcalNet (sample of 76 countries).

measure actually increased from 2.3 billion in 1981 to 2.7 billion in 2008. Although the coefficient in an OLS regression between the proportionate rate of poverty reduction (annualized differences in the logs) and the rate of growth in the mean is −1.89 (standard error = 0.23) for the absolute measure of poverty, it becomes −0.38 (standard error = 0.08) for the relative measure. Only East Asia has experienced a marked reduction in the incidence of relative poverty: from 81% in 1981 to 42% in 2008. In fact it is the only region in which the poverty count was reduced according to this measure. Weakly relative poverty measures rose or stayed unchanged in most regions in the 1990s and slowly went down in the 2000s.

In Table 9.22 we extend the estimates of Ravallion and Chen (2011) to 2010 and add estimates of strongly relative poverty (50% of mean income) and anchored poverty, computed by "anchoring" the relative lines (50% of mean income) to the values in 1990, updating them only by domestic price changes (see Chapter 8 in this volume). Our view of poverty trends widely varies across methodologies: Although the unweighted anchored poverty rate fell 32% between 1990 and 2010, the strongly relative poverty rate went up 2%. The differences are even larger when considering the population-weighted statistics.

9.7. CONCLUDING REMARKS

There has been a remarkable improvement in the availability of information for distributive analysis in the last decades due to increasing efforts by researchers, national governments, and international organizations. To be sure, the picture of inequality and poverty in the developing world is substantially sharper now than in the late 1990s, when the first volume of this Handbook was written. There remain, however, enormous data limitations that make that picture only a very rough approximation of reality. Household surveys are lacking in some countries and are carried out very occasionally in others. Changes in methodology over time are frequent, a fact that generally implies improvement in the data collection, but that at the same time introduces comparability issues with previous surveys that are difficult to deal with. Household surveys have endemic problems in capturing some income and consumption items and in dealing with selective compliance and underreporting issues. The gaps with National Accounts aggregates, usually variable over time, are a disturbing sign of measurement errors. Comparability across countries is another big problematic issue; there are few efforts among national agencies to standardize surveys or at least some criteria to gather and process information. Another issue of concern is the difficulty in obtaining statistical confidence intervals for the distributive statistics, either because agencies do not report them, or do not provide information on sampling issues, or do not release the microdata.[126] In sum, to be able to

[126] The methodology to compute statistical confidence intervals is easily implementable; see Chapter 6 of this Handbook.

characterize and track distributive changes with more accuracy, we need more efforts to extend the coverage and frequency of household surveys and improve their reliability and comparability across countries. There is still a long way to go to get an accurate assessment of poverty and inequality in the developing world.

From the data available, some general facts emerge. High poverty and inequality are pervasive characteristics of the developing world, but are not immutable features of these economies. The evidence suggests a robust decline in the levels of absolute income poverty in the developing world, driven mainly by East Asia in the 1980s and 1990s and generalized to the rest of the developing countries in the 2000s. Income poverty has been reduced in most countries and in the world as whole, making the achievement of the first MDG possible. Despite these positive results, there are reasons for concern. The task of fighting poverty continues to be very challenging: Around 1.2 billion people survive with less than \$1.25 a day, an extremely low standard. Also, most of the people who succeeded in jumping the \$1.25 line in the last decades are still poor by the standards of middle-income developing countries and remain highly vulnerable if economic conditions worsen. Moreover, due to economic growth, concerns about relative poverty may be increasingly important, and the evidence in that sense is less optimistic.

The evidence on relative income inequality suggests that on average the developing countries are somewhat more unequal than three decades ago. The patterns have been different by period and region. Inequality rose in the late 1980s and in the 1990s; the changes were larger in Eastern Europe and Central Asia, probably as a result of the transition from a central-planned to a more market-oriented economy; in East Asia, likely as a consequence of the economic takeoff; and in Latin America probably as the result of recurrent macroeconomic crises and some structural transformations. Distributive changes became more equalizing in the 2000s, but the changes were rather moderate and with considerable heterogeneity across countries. In fact, in this decade of widespread social improvement around a third of the countries did not experience falling inequality levels. Reducing inequality certainly remains a top concern in the developing world.

ACKNOWLEDGMENT

F. A. is with Nuffield College and INET-Oxford, Paris School of Economics and CONICET; L. G. is with Centro de Estudios Distributivos, Laborales y Sociales (CEDLAS), Facultad de Ciencias Económicas, Universidad Nacional de La Plata, and CONICET. This chapter was completed while L. G. was visiting professor at the University of British Columbia. We are grateful to participants to the conference "Recent Advances in the Economics of Income Distribution" (Paris), the AAEP Meetings (Rosario), Thomas Piketty, and especially Anthony Atkinson and Francois Bourguignon, for valuable comments and suggestions. We are also grateful to David Jaume, Darío Tortarolo, Carolina López, Julian Amendolaggine, Santiago Garganta, Florencia Pinto, Pablo Gluzmann, Leopoldo Tornarolli, Javier Alejo, Juan Zoloa, and Carolina García Domench (all at CEDLAS) for outstanding research assistance. We alone are responsible for any errors. Financial support from the ESRC-DFID joint fund and INET is gratefully acknowledged.

Table A.1 List of developing countries by region and population, 2010—cont'd

Countries	Pop.	Data
Eritrea	4.948	
Ethiopia	79.446	X
Gabon	1.450	X
Gambia	1.636	X
Ghana	23.264	X
Guinea	9.559	X
Guinea-Bissau	1.454	X
Kenya	38.455	X
Lesotho	2.127	X
Liberia	3.658	X
Madagascar	19.546	X
Malawi	14.005	X
Mali	14.460	X
Mauritania	3.295	X
Mauritius	1.269	
Mozambique	22.333	X
Namibia	2.200	X
Niger	14.450	X
Nigeria	150.666	X
Rwanda	10.004	X
São Tomé & P.	0.160	X
Senegal	11.787	X
Seychelles	0.087	X
Sierra Leone	5.612	X
Somalia	8.922	
South Africa	48.793	X
South Sudan	8.977	
Sudan	32.438	X
Swaziland	1.032	X
Tanzania	42.268	X
Togo	5.777	X
Uganda	31.339	X
Zambia	12.380	X
Zimbabwe	12.452	

Note: An "X" in the Data column marks that the country has distributive information in PovcalNet.
Source: Population (in millions) is taken from the United Nations Demographic Yearbook.

Abstract

We survey the literature on income mobility, aiming to provide an integrated discussion of mobility within and between generations. We review mobility concepts, descriptive devices, measurement methods, data sources, and recent empirical evidence.

Keywords

Intragenerational mobility, Intergenerational mobility, Income mobility, Earnings mobility

Handbook of Income Distribution, Volume 2A

10.1. INTRODUCTION

Most of the information that we have about income distribution is cross-sectional in nature; there are statistics about, for example, income levels, poverty rates, and the extent of inequality for a given year or for a series of years. The data sources used to provide estimates for the different years refer to different samples of individuals. In this chapter, we discuss a different but complementary perspective on income distribution to the cross-sectional one. We take an explicitly longitudinal perspective, one that is based on tracking over time the fortunes of the same set of individuals. We are interested, broadly speaking, in how individuals' incomes change over time in a society. "Income mobility" is a shorthand label for this topic. In this chapter, we address questions such as: what exactly do we mean by mobility, and why should we be interested in it? How should mobility be measured? What is the evidence about income mobility for rich industrialized nations?

The period of time over which income mobility is assessed is a fundamental issue, and different choices have led to two relatively distinct literatures. On the one hand, there is the subject of how an individual's income changes between one year and another during their lifetime; on the other hand, there is the subject of income change between generations of parents and children. We use this distinction between intragenerational and intergenerational income mobility as an organizational device in this chapter, reflecting the division in existing literature, but we shall also attempt to draw out the features of the measurement of income mobility that are common to both topics while also highlighting dimensions of them for which different approaches to analysis are appropriate.

Conceptual issues are addressed first because clarification of them is an essential preliminary to any discussion of measurement principles, data sources, and assessment of empirical evidence. In Section 10.2, we review the reasons why and how income mobility is said to be of interest. There are several distinct reasons, and this is because, as we also discuss, there are multiple concepts of mobility, each of which arguably has normative validity. This situation contrasts with assessments of an income distributions at a point in time, in which case there is greater consensus about what is meant by income inequality and how it might be accounted for in social welfare evaluations.

We review the measurement of income mobility in Section 10.3, focusing on the generic case in which there are data on income at two points in time, whether this be two years (as in the intragenerational mobility literature) or two generations (as in the intergenerational mobility literature). This is the most commonly examined situation. Thus we are interested in not only summarizing a single bivariate joint distribution of income but also comparing such distributions across time or countries to say whether mobility is greater or smaller. We explain various descriptive methods for situations in which income data are either continuous or grouped into categories. First we discuss graphical devices and methods that may be used to undertake mobility comparisons without resort to choice of a particular mobility index (so-called dominance checks). Second, we consider scalar indices of mobility ranging from regression coefficients and correlations through to other more specialized developments.

By considering measurement from a generic point of view, we aim to show how there might be greater cross-fertilization between the intra- and intergenerational mobility literatures in approaches to measurement. At the same time, we highlight how the different measurement approaches relate to different concepts of mobility identified in Section 10.2.

Evidence about income mobility is the subject of the next two sections: Section 10.4 considers intragenerational mobility; Section 10.5 considers intergenerational mobility. In each case, our strategy is to build a bridge linking concepts and measurement principles to empirical evidence by first discussing data sources, as well as issues of empirical implementation including data comparability and quality more generally.

The final section, 10.6, provides brief concluding remarks and makes some proposals concerning where the returns to future research efforts are the greatest.

Earlier research on income mobility has typically focused on either within- or between-generation topics. For surveys of intragenerational measurement issues, we build on Jenkins (2011a) who, in turn, draws heavily on other surveys such as by, e.g., Atkinson et al. (1992), Burkhauser and Couch (2009), Fields and Ok (1999a), Jenkins and van Kerm (2009), and Maasoumi (1998). For intergenerational mobility, important earlier reviews are provided by Solon (1999), Björklund and Jäntti (2009), Black and Devereux (2011), and Piketty (2000). Many of the reviews just cited appear in volumes with "Handbook" in their title. Indeed extensive surveys of cross-sectional approaches to income distribution were provided throughout the *Handbook of Income Distribution, Volume 1* (Atkinson and Bourguignon, 2000). It is timely and appropriate to give income mobility similar attention.

Although the chapter draws heavily on the work of others, it also has some distinctive features besides simply being more up-to-date. One aspect is our goal to try to integrate the discussion of intra- and intergenerational mobility insofar as this is possible, while also highlighting what aspects of each topic are intrinsically different and deserving of separate attention. Other aspects include our coverage from conceptual issues through to data, issues of empirical implementation, and evidence.

The emphasis of this chapter is on the *measurement* of income mobility, broadly defined. Of course, it is also of interest to not only describe how individuals' incomes change from one time period to another but also to explain the patterns observed. We have deliberately chosen not to systematically review *models* of mobility to make our task manageable.

There is some discussion of intragenerational models of earnings dynamics, nonetheless, in Section 10.3 because estimates from "variance components" models have been used to derive measures of mobility in the form of income risk. Other types of modeling approaches are reviewed by Jenkins (2000), who also discusses more general issues concerning the modeling of intragenerational income dynamics. These are further elaborated by Jenkins (2011a, chapter 12).

One important distinction is between reduced-form and structural empirical models, each of which has different strengths and weaknesses. The former are empirically grounded rather than derived from a well-developed theoretical model that implies specifications, the parameters of which are estimated from the data. The advantage of a structural approach is that there is a close relationship between parameter estimates and behavioral model parameters, and so interpretation is improved and one may be able to say more about underlying causes. The problem with a structural approach is that clear-cut implications for model specification and proofs of relationships can often only be derived by massive simplification—simplification that compromises claims that the model describes empirical reality. The tension between reduced form and structural approaches has existed for a long time and is likely to remain. The reason for the tension is obvious—approaches combining structure, practicality, and feasibility are very difficult to develop. The problem is that a model is needed not only for the dynamics of labor earnings for an individual but also the earnings and possibly other income sources of other individuals in a multiperson household, and the dynamics of household structure itself also needs to be modeled (Jenkins, 2011a, pp. 368–369).

Exactly the same tension has arisen in empirical modeling of intergenerational income dynamics, where there is also a need to consider not only multiple income sources but also demographic factors. The structural ("optimizing") approach is epitomized by Becker and Tomes (1986) and the reduced-form ("mechanical") approach by a series of papers by Conlisk (1974, 1977, 1984).[1] The relative merits of the two approaches are lucidly discussed by Goldberger (1989), with a "reply to a skeptic" provided by Becker (1989).

10.2. MOBILITY CONCEPTS

Writers on income mobility have long emphasized that mobility has multiple dimensions. For example, a leading survey from a decade ago commented that:

> *the mobility literature does not provide a unified discourse of analysis. This might be because the very notion of income mobility is not well-defined; different studies concentrate on different aspects of this multi-faceted concept. At any rate, it seems safe to say that a considerable degree of confusion confronts a newcomer to the field.*
>
> ***Fields and Ok (1999a, p. 557)***

[1] See also Solon (2004) for a simple model highlighting the key ingredients of an optimizing model and Mulligan (1997) for a monograph-length treatment of the theoretical literature.

The systematic reviews by Fields and Ok and others have done much to reduce the potential confusion. But they cannot banish mobility's multiple facets, and so newcomers continue to require guided tours of the concepts and literature. This section explains what the multiple dimensions of mobility are. We address the question of whether more mobility is socially desirable in each case, arguing that the answer depends on which mobility concept is the focus. A review of the implications of mobility's various facets for social welfare is used to illustrate trade-offs between different types of mobility. We also point out how different concepts have received different emphasis in studies of mobility within or between generations.

10.2.1 Mobility's Multiple Dimensions

Consider first the case in which there are observations on income for N individuals for two periods. In the first period, the income distribution is x, in the second period, the distribution is y; there is a bivariate joint density $f(x, y)$. Overall mobility for the population can be thought of as the transformation linking marginal distribution x with marginal distribution y.

In this section, we distinguish four concepts (Jenkins, 2011a): positional change (which comes in two flavors), individual income growth, reduction of longer-term inequality, and income risk.[2] The different concepts "standardize" the marginal distributions x and y in different ways to focus attention on the nature of the link $x \rightarrow y$.

Positional change refers to mobility that arises separately from any changes in the shapes of the marginal distributions in each period, for example, a rise in average income or in income inequality or, more generally, a change in the concentration of individuals at different points along the income range in y compared to in x. Standardization for such changes is most easily accomplished by summarizing each person's position not in terms of their income per se but in terms of their rank in the population normalized by the population size. (The marginal distribution of these "fractional" (or "normalized") ranks is a standard uniform distribution for both x and y.) Thus positional change mobility refers to the pattern of exchange of individuals between positions, while abstracting from any change in the concentration of people in a particular slot in each year. The latter change is "structural mobility," whereas the former is "exchange mobility": see, for example, Markandya (1984). Changes in income affect positional mobility only insofar as these changes alter each person's position relative to the position of others. Equiproportionate income growth or equal absolute additions to income for everyone raise incomes, but there is immobility in the positional sense.

There are some distinctive characteristics of the concept of mobility as positional change. Mobility for any specific individual necessarily depends on other people's

[2] This classification is similar to that employed by Fields and Ok (1999a) and Fields (2006). See also Van de gaer et al. (2001).

positions as well, which is not true for every mobility concept, as we shall see. The definition of each person's origin and destination position depends on the positions of everyone else in the society: It is these taken altogether that define a hierarchy of positions. Second, and related, if one person changes position, then so too must at least one other person. It is not possible for everyone to be upwardly mobile or, indeed, downwardly mobile. Third, the situation corresponding to "no mobility" is straightforwardly defined: Maximum immobility occurs when every person has the same position in x and in y. If income mobility is summarized using a transition matrix (see Section 10.3) in which cell entries a_{jk} show the probability that an individual in income class j in period 1 is found in income class k in period 2, then maximum immobility is the case in which $a_{jk}=1$ for all income classes (all individuals are on the leading diagonal). However, fourth, there are two different ways of thinking about what reference points to use when there is mobility, one focusing on lack of dependence and the second focusing on movement.

One situation is when one's destination is completely unrelated to one's income origin ("origin independence"). For example, the chances of being found in the richest 10th in period 2 are exactly the same for people who were in the poorest 10th in period 1 as for the people who were in the richest 10th in period 1. In transition matrix terms, this is the case in which $a_{jk}=a_{mk}$ for all origin classes j or m (each row of the transition matrix has identical entries). Another view is that the reference case when there is mobility is if destination positions are a complete reversal of origin positions ("rank reversal"), emphasizing positional movement per se. For example, the poorest person in period 1 is the richest person in period 2, and the richest person in period 1 is the poorest person in period 2, and so on. All entries in the transition matrix lie on the diagonal going from bottom left (richest origin class and poorest destination class) to top right (poorest origin class and richest destination class).[3]

Mobility as *individual income growth* refers to an aggregate measure of the changes in income experienced by each individual within the society between two points in time, where the individual-level changes might be gains or losses. Income growth is defined for each individual separately, and income mobility for society overall is derived by aggregating the mobility experienced by each and every individual.[4] This mobility concept contrasts sharply with the positional change one in several ways. No distinction is made between structural and exchange mobility; it is gross (total) mobility that is described. It is possible for everyone to be upwardly mobile or, indeed, to be downwardly mobile. Positive income growth for everyone may count as mobility even if relative positions

[3] The two reference points are sometimes referred to as cases of "perfect" or "maximum" mobility, but we resist these. The language in the former case makes potentially unwarranted assumptions about the optimality of particular mobility configurations (to be discussed below), and it is difficult to argue that origin independence represents "maximum" mobility in the literal sense.

[4] This is an assumption, albeit commonly made. It is what Fields and Ok (1996) call the "individualistic contribution" axiom.

are preserved. Thus, standardization of the marginal distributions is not an essential feature of the concept.

In the individual economic growth case, it is natural to define mobility for each individual in terms of "distance" between origin and destination income and to think of the maximum immobility case for the population as being when the measure of distance equals zero for every individual ($x_i = y_i$ for all i). Mobility is greater if the distance between origin and destination is greater for any individual, other things being equal. This is similar to the idea of greater movement, meaning more mobility according to the "reversals" version of positional mobility. Again, there is no natural maximum mobility reference point as distance has no obvious upper bound.[5] Defining the metric for "distance" in terms of the income change for each individual is, of course, vitally important for the concept, and the main distinctions have been measures of "directional" and "nondirectional" growth. In the first case, income increases over time are treated differently from income decreases; in the second, an income increase and an income decrease of equal magnitude are attributed the same distance and the measure summarizes income "flux" (more on this shortly). For more precise definitions, see Fields and Ok (1999a).

The third mobility concept defines income mobility with reference to its *impact on inequality in longer-term incomes*. The longer-term income for each individual is defined as the longitudinal average of incomes in each period (variations on this are considered later). In the two-period case, longer-term income equals $^1/_2(x_i + y_i)$ for each i. Averaging across time smooths the longitudinal variability in each person's income, and in addition, the inequality across individuals in these longitudinally averaged incomes will be less than the dispersion across individuals in their incomes for any single period. Mobility can therefore be characterized in terms of the extent to which inequality in longer-term income is less than the inequality in marginal distributions of period-specific income. See Shorrocks (1978a) and later discussion for further details. The zero mobility reference point is when the income of each person in every period is equal to their longer-term income; there is complete rigidity. At the other extreme, maximum mobility occurs when there is inequality in per-period incomes but no inequality at all in longer-term incomes. The issue of whether everyone can be upwardly (or downwardly) mobile does not arise with this mobility concept because it defines mobility using inequality comparisons, and inequality is measured at the aggregate (population) level. There are similarities between this concept of mobility and the rank reversal flavor of the positional change concept because both are concerned with movement, but they use different reference points to assess this (longer-term incomes versus base-period positions, respectively). We return to this issue later.

[5] Individual income growth cannot be represented using a transition matrix because the mobility concept in this case is intrinsically individual rather than group based. However, income growth can be represented using a mobility matrix in which category boundaries are defined in real income terms.

The fourth concept of mobility, as *income risk*, is related to the third. The previous paragraph expressed each person's period-specific income as the sum of a "permanent" component (the longer-term average) and a "transitory" component (the period-specific deviations from the average). Suppose now that the longer-term average is given a behavioral interpretation: It is the expected future income per period given information in the first period about future incomes. From this ex ante perspective, the transitory components represent unexpected idiosyncratic shocks to income, and the greater their dispersion across individuals each period, the greater is income risk for this population. The measure of mobility cited in the previous paragraph (i.e., the inequality reduction associated with longitudinal averaging of incomes) is now reinterpreted as a measure of income risk and has different normative implications (see below). Income movement over time represents unpredictability. This is essentially what Fields and Ok (1999a) refer to as income "flux" (nondirectional income movement). Despite their apparent similarities in construction, the concepts of mobility as inequality-reduction and as income risk diverge in practice when the process describing income generation is not a simple sum of a fixed individual-level permanent component and an idiosyncratic transitory component. Econometric models have been developed with more complicated descriptions of how the permanent and transitory components evolve over time and these imply, in turn, different calculations of expected income and transitory deviations from it. However, the distinction between predictable relatively fixed elements and unpredictable transitory elements of income is maintained and hence so too is a link between mobility as transitory variation and income risk.

10.2.2 Is Income Mobility Socially Desirable?

In what ways are these various mobility concepts of public interest over and above providing useful descriptive content? Does having more mobility represent a social improvement, or is it undesirable? The answers depend on the mobility concept employed, and the support for the different concepts has depended on whether one is assessing within- or between-generation mobility.

Greater mobility in the sense of less association between origins and destinations has long been linked with having a more open society; if where you end up does not depend on where you started from, there is greater equality of opportunity. For example, a classic statement by R. H. Tawney, originally from 1931, is that equality of opportunity

> *obtains in so far as, and only in so far as, each member of a community, whatever his birth, or occupation, or social position, possesses in fact, and not merely in form, equal chances of using to the full his natural endowments of physique, of character, and of intelligence.*
>
> **Tawney (1964, pp. 103–105)**

More recently, a UK government advisor's report on Social Mobility stated that "Social mobility matters because . . . equality of opportunity is an aspiration across the political spectrum. Lack of social mobility implies inequality of opportunity" (Aldridge, 2001, p. 1). For more about equality of opportunity, see Chapter 5.

From this perspective, greater mobility is socially desirable because equality of opportunity is a principle that is widely supported, regardless of attitudes to inequality of outcomes. This is relevant because independence of origins and destinations is consistent with inequality of outcomes being relatively equal or unequal. The argument just rehearsed is, however, typically made in the context of intergenerational mobility rather than intragenerational mobility, and origins refer to parental circumstances, such as "birth, or occupation, or social position" referred to by Tawney. The appeal to fairness in this context is based on the meritocratic idea that someone's life chances should depend on their own abilities and efforts rather than on who their parents were. At the same time, it is important to appreciate that the degree of intergenerational association is an imperfect indicator of the degree of inequality of opportunity.

The degree of origin independence is a direct measure of inequality of opportunity only if two rather special conditions apply (Roemer, 2004). First, the advantages associated with parental background (over which it is assumed that an individual had no choice) are entirely summarized by parental income. Second, the concept of equality of opportunity that is employed views as unacceptable any income differences in the children's generation that are attributable to differences in innate talents (which might be partly genetically inherited). This is what Swift (2006) described as a "radical" interpretation of the equality of opportunity principle and likely to command much less widespread assent than what he refers to as the "minimal" and "conventional" definitions (respectively, access and recruitment processes to life chances are free of prejudice and discrimination; and outcomes achieved depend on "ability" and "effort" but not on family background).

The social desirability of mobility as independence of origins has less force in the intragenerational context. The reason is that incomes are measured at a point within the life course. By that stage, period-1 incomes are likely to reflect differences in peoples' abilities and efforts (in addition to family background and other factors), and period-2 incomes to reflect the persisting effects of these factors. To the extent that abilities and efforts do play this role (or are seen to) and also viewed as fair on the grounds of merit or desert, the reduction of dependence between origins and destination has less appeal as a principle of social justice.

More common in the within-generation context are statements that income mobility is desirable because it is a force for reduction in the inequality of longer-term incomes. The most famous statement in this connection was by Milton Friedman six decades ago in his *Capitalism and Freedom* (though observe that he also refers to equality of opportunity in this context):

> *A major problem in interpreting evidence on the distribution of income is the need to distinguish two basically different kinds of inequality; temporary, short-run differences in income, and*

> *differences in long-run income status. Consider two societies that have the same annual distribution of income. In one there is great mobility and change so that the position of particular families in the income hierarchy varies widely from year to year. In the other there is great rigidity so that each family stays in the same position year after year. The one kind of inequality is a sign of dynamic change, social mobility, equality of opportunity; the other, of a status society.*
>
> **Friedman (1962, p. 171)**

Similar views are apparent across the political spectrum in the United States. The chairman of President Obama's Council of Economic Advisors recently stated,

> *Higher income inequality would be less of a concern if low-income earners became high-income earners at some point in their career, or if children of low-income parents had a good chance of climbing up the income scales when they grow up. In other words, if we had a high degree of income mobility we would be less concerned about the degree of inequality in any given year.*
>
> **Krueger (2012, p. 3)**

Although both authors are referring to the distributions of incomes within generations, one could extend the same inequality-reduction idea to the intergenerational context, by summarizing mobility in terms of the extent to which dynastic inequality (referring to incomes averaged over generations of the same family) is less than the inequality in any given generation. But this is rarely done, perhaps because the normative appeal of the dynastic average income is much less than that of a multiperiod average within generations, and data for more than two generations are rarely available.

According to the arguments about longer-term inequality reduction, income mobility is socially desirable for instrumental reasons rather than for its own sake. That is, society is assumed to care about income inequality (less is better, other things being equal), but inequality is assessed using longer-term incomes, and year-to-year mobility means that the inequality of this distribution is less than the inequality of incomes in any particular year. The normative content of the mobility principle therefore hinges on views concerning the nature and validity of the benchmark that is provided by the distribution of longer-term incomes. As Shorrocks points out,[6] there is

> *the presumption that individuals are indifferent between two income streams offering the same real present value. This might be true if capital markets were perfect (or if there was perfect substitutability of income between periods), but it seems likely that individuals are concerned with both the average rate of income receipts and the pattern of receipts over time. We may go further and suggest that individuals tend to prefer a constant income stream, or one which is growing steadily, to one which continually fluctuates.*
>
> **Shorrocks (1978a, p. 392)**

[6] Shorrocks also draws attention to the assumption that the same measure is used to summarize both the dispersion of longer-period incomes and the dispersion of per-period incomes.

Thus, the argument is not only about the feasibility of smoothing incomes to achieve the longer-term average, but also the undesirability of the uncertainty associated with a fluctuating income stream.

This brings us to the fourth concept of income mobility, as income risk. To illustrate this, Shorrocks defines for each individual a "constant income flow rate generating receipts which gives the same level of welfare as the income stream he currently faces" (Shorrocks, 1978a, p. 392), and he argues that

> *[r]eplacing actual recorded incomes with this alternative income concept in the computation of inequality values introduces a new dimension into the discussion of mobility. No longer is mobility necessarily desirable. Changes in relative incomes still tend over time to equalise the distribution of total income receipts, and to this extent welfare is improved. But greater variability of incomes about the same average level is disliked by individuals who prefer a stable flow. So to the extent that mobility leads to more pronounced fluctuations and more uncertainty, it is not regarded as socially desirable. A more detailed examination of these two facets of mobility will provide a better understanding of the impact of income variability and the implications for social welfare.*
>
> **Shorrocks (1978a, pp. 392–393)**

Thus, even though income mobility has an inequality-reducing impact, mobility is not necessarily socially desirable if mobility represents transitory shocks. In this case, mobility is a synonym for not only income fluctuation but also unpredictability and economic insecurity. Fluctuating incomes are undesirable because most people prefer greater stability in income flows to less, other things being equal, if only because it facilitates easier and better planning for the future. But, more than this, by definition, transitory income variation is an idiosyncratic shock that cannot be predicted at the individual level; greater transitory variation corresponds to greater income risk, and greater risk is undesirable for risk-averse individuals. The definition of the "alternative income concept" from which transitory shocks deviate is, of course, crucial, and we return to this.

What about the social desirability of individual income growth (the second mobility concept)? The answer is not clear cut because it depends on the nature of the income growth and who receives it. An increase in income for any given individual is a social improvement, and an income fall is socially undesirable. The main issue, then, is how to aggregate gains and losses in the social calculus. Evaluation of the impact of individual income growth on the welfare of society as a whole requires a weighing up of the gains and losses for different people, and opinions are likely to differ about how to do this. An egalitarian may weight income gains for the initially poor greater than income gains for the initially rich because this will contribute to reducing income differences between them over time. (On the progressivity of income growth, see, e.g., Benabou and Ok, 2000 and Jenkins and van Kerm, 2006.)

Arguments to the contrary appealing to principles of desert or incentives might also be made. It might be argued, for instance, that differential income growth rates are of less concern if income gains among the rich reflect appropriate returns to entrepreneurial activity or to widely acclaimed talents. The rise in bankers' bonuses in the manner observed in many Anglophone countries in recent years may not count as an example of the former. But as an example of the latter, we note the views of the UK's former Prime Minister Tony Blair expressed in an interview asking him whether it was acceptable for the gap between rich and poor to get bigger. His response referred instead to individual income growth:

> *[T]he justice for me is concentrated on lifting incomes of those that don't have a decent income. It's not a burning ambition for me to make sure that David Beckham earns less money, . . . [T]he issue isn't in fact whether the very richest person ends up becoming richer . . . the most important thing is to level up, not level down.*
>
> ***Interview on BBC Newsnight (5 June 2001)***[7]

Another concept of desert may also be relevant when assessing mobility. This is the argument concerning "distressed gentlefolk"—people who were previously well-off, but experience a significant fall in resources through no fault of their own. Thus income gains and income losses for an individual may not be assessed symmetrically but, again, relate to why income changed (see also the discussion of "loss aversion" below).

We end this section with two observations. First, our discussion of the social desirability or otherwise of income mobility has referred to income movement from throughout the range of base-period income origins to all potential final-period income destinations. There has been no particular focus on persistence at the bottom or at the top. In part, this is because such a focus arguably does not raise additional conceptual issues, except where to draw the cutoffs demarcating the poor and nonpoor, or rich and nonrich. Indeed if the bivariate joint distribution is summarized using a transition matrix, then suitable definition of the income groups reveals the movement at the top and the bottom. However, we do discuss selected aspects of the measurement of high- and low-income persistence in the next two sections.

Second, our discussion of the social desirability of mobility has focused on its normative aspects. We ignore the positive political economy arguments about public support for mobility. On this, see, e.g., the analysis by Benabou and Ok (2001) of the "prospect of upward mobility" (POUM) hypothesis, which is that individuals who currently have low income may not support high levels of redistribution because of their aspiration that they or their children will become rich in the future.

10.2.3 Income Mobility and Social Welfare

The discussion so far demonstrates that the impact on social welfare of greater income mobility is not clear cut and depends on the mobility concept that is emphasized. A natural question for an economist to ask is whether there are explicit welfare

[7] Transcript at http://news.bbc.co.uk/1/hi/events/newsnight/1372220.stm.

foundations for the various mobility concepts that have been discussed so far. For inequality measurement, the use of an explicit model of social welfare is known to yield dividends; see, notably, Atkinson's (1970) demonstration of how the "cost" of income inequality can be summarized in social welfare terms and how inequality comparisons based on Lorenz curves are intimately linked to orderings by social welfare functions (SWFs) that are additive, increasing, and concave functions of individuals' incomes. The corresponding literature on the social welfare foundations of mobility measurement is small, with contributions including Atkinson (1981a), reprinted as Atkinson (1983), Atkinson and Bourguignon (1982), Markandya (1984), and Gottschalk and Spolaore (2002). In this section, we focus on the nature of the SWFs employed in the mobility context; how these functions relate to mobility dominance results is discussed later.

The SWF used in the multiperiod context is a straightforward generalization of the one-period case discussed by Atkinson (1970). Overall social welfare, W, is the expected value (average) of the utility-of-income functions of individuals. In the two-period case, the utility-of-income function is $U(x,y)$ and weighted by the joint probability density $f(x,y)$. That is,

$$W = \int_0^{a_y}\int_0^{a_x} U(x, y) f(x, y)\mathrm{d}x\mathrm{d}y, \tag{10.1}$$

where $U(x,y)$ is differentiable and a_x and a_y are the maximum incomes in periods 1 and 2. It is assumed that increases in income in either period are desirable, other things being equal (so positive income growth raises utility): $U_1 \geq 0$ and $U_2 \geq 0$.

Research in this tradition concentrates on the case in which the marginal distributions x and y are identical. In other words, the economic context is the same as the one used earlier to characterize positional mobility. All relevant mobility is encapsulated by the changes in individuals' ranks or by the transition matrix when individual incomes are classified into discrete classes. Atkinson and Bourguignon (1982) show that if the SWF is additively separable across time periods (so that $U_{12} = 0$, then income mobility is irrelevant for social welfare; only the marginal distributions matter.[8] If, instead, $U(x,y)$ is a concave transformation of the sum of the per-period utilities, then $U_{12} < 0$.

How does one interpret this sign? Atkinson and Bourguignon (1982) discussed the class of least concave functions associated with a particular preference ordering and the special case in which preferences are homothetic. In this situation, the utility function $U(.)$ is neatly characterized by two parameters: $\varepsilon > 0$ summarizing *aversion to inequality of multiperiod utility*, and $\rho > 0$ summarizing the inverse of the elasticity of substitution between income in each period (i.e., the degree of *aversion to intertemporal fluctuations in income*; Gottschalk and Spolaore, 2002, p. 195). The case $U_{12} < 0$ corresponds to

[8] See also Markandya (1984) and Kanbur and Stiglitz (1986).

the situation in which $\varepsilon > \rho$, i.e., in the social welfare assessment, multiperiod inequality aversion offsets aversion to intertemporal fluctuations (which are of course reducing multiperiod inequality). When $\rho = 0$, an increase in income mobility must increase social welfare. With perfect substitution of income between periods, one is only interested in the reduction of multiperiod inequality.

Gottschalk and Spolaore (2002) pointed out that origin dependence has no role in the Atkinson–Bourguignon model.[9] In transition matrix terms, if there is any preference at all for income reversals ($\varepsilon > \rho$), not only does an increase in mobility represent a social welfare gain, but also the complete reversal scenario is preferred to the origin independence one. This feature has relevance to the application of the social welfare framework to mobility measurement using stochastic dominance checks (discussed in the next section). The irrelevance of origin dependence suggests that the approach is less applicable to intergenerational mobility comparisons because origin independence is the principle most commonly espoused in that context (see earlier discussion).

However, an important contribution of Gottschalk and Spolaore (2002) was to show that greater origin independence can be social welfare improving if the SWF is generalized to take account of aversion to future income risk. In the two-period context, they drop Atkinson and Bourguignon's assumption that period-2 income is known with certainty in period 1. Individuals take conditional expectations of period-2 incomes based on observed period-1 incomes and the joint density of outcomes. With homothetic preferences, the utility function is now characterized by a third parameter, γ, summarizing the degree of aversion to second-period risk. As Gottschalk and Spolaore demonstrated,

> *Origin independence reduces both multi-period inequality and intertemporal fluctuations, but increases future risk. Individuals will positively value origin independence as long as aversion to multi-period inequality and aversion to fluctuations dominate aversion to future risk (ε and ρ are not smaller than γ, and at least one of them is larger).*
>
> ***Gottschalk and Spolaore (2002, p. 204)***

In summary, evaluation of income mobility in terms of social welfare has payoffs. There is a single unifying framework. Within this, whether an increase in income mobility is social welfare improving depends on the priority given to different mobility concepts. For instance, reversals are less likely to be valued the greater the aversion to intertemporal fluctuations and to future income risk, but more likely to be valued the greater the aversion to multiperiod inequality. Nonetheless one limitation of the SWF framework discussed so far is that it does not incorporate evaluations of mobility in the form of individual income growth—apart from aspects of this that overlap with the other concepts. One leading exception is the research by Bourguignon (2011), who shows that the Atkinson and Bourguignon results can be applied to comparisons of alternative "growth

[9] See also similar remarks by Fields and Ok (1999a, pp. 578–579).

processes" in the case in which the pair of marginal distributions relating to the first period are identical. However, this is a severe constraint on the applicability of the results.

An alternative strategy is to define SWFs explicitly in terms of income mobility—income changes rather than income levels. For example, one may assume that individual-level mobilities are represented by some measure of "distance" between first- and second-period incomes for each individual i, $d(x_i,y_i)$, where the distance function is common to all individuals, and a social weight. Overall social welfare is the weighted sum over individuals of the d_i. King (1983) and Chakravarty (1984) assume that d_i is a function of period-1 and period-2 income ranks (the positional mobility case), and that reranking is desirable ($\partial W/\partial d_i > 0$) and the social weight is increasing in period-2 income. By contrast, for Van Kerm (2006, 2009) and Jenkins and van Kerm (2011), d_i is a directional measure of individual income growth, and the social weight depends on base-year income ranks. For a more general discussion, see Bourguignon (2011), who discussed how the Atkinson–Bourguignon utility-of-income function, $U(x,y)$, can be rewritten as $V(x,y-x)$ with the same properties on the differentials of the second (income change) argument. This framework would lead one to question, for example, the approach of Fields et al. (2002), whose SWF is the simple average of the d_i (equality of social weights), and so $\partial V/\partial x = 0$: mobility evaluations do not depend on initial income at all.

The main advantage of defining SWFs in terms of mobility directly is that there is great flexibility in the specification of the distance function d_i. The disadvantage of the approach is that it runs the risk of being ad hoc rather than a general unifying framework like the Atkinson and Bourguignon (1982) one. In particular, how should the social weights be specified? Unfortunately, the Bourguignon (2011) framework provides no simple answers.

The social welfare approaches described so far assume that W is a form of expected utility evaluation, though modified to context: Atkinson and Bourguignon (1982) incorporated preferences that were not time-additive, and in addition, Gottschalk and Spolaore (2002) abandoned complete predictability of income. A different approach altogether is to suppose that evaluations are based not on expected utility but prospect theory. Jäntti et al. (2014) explored this idea, utilizing a utility function that incorporates reference-income dependence and loss aversion. The latter feature means that, over and above any preference for smooth rather than fluctuating incomes over time, fluctuations lower individuals' welfare directly because losses outweigh gains of equal size. There is therefore an asymmetric treatment of income decreases and decreases, as for the "distressed gentlefolk" argument cited earlier but rather differently motivated. This approach is a promising area of research and chimes with more popular expressions of the problem of growing income risk. Hacker and Jacobs (2008), for instance, specifically cited loss aversion as one of the factors related to the growth of income risk in the United States.

10.3. MOBILITY MEASUREMENT

This section is about measuring mobility. First we discuss descriptive devices, by which we mean graphical and tabular methods for summarizing patterns of mobility. We consider them in more detail than other surveys because we think it is important to "let the data speak" (though there are limits to which this is possible, as we show). Second, we describe how descriptive devices also have normative implications, being linked to dominance checks for mobility comparisons. Third, we consider scalar indices of mobility. Throughout the section we relate the descriptive devices and measures to the different concepts of mobility identified earlier. Most of the examples that we use are drawn from the intragenerational literature, reflecting their greater use in that context. But one of the lessons to be drawn is that the same methods could also be applied to the intergenerational context.

10.3.1 Describing Mobility

In the two-period case, the bivariate joint distribution of income contains all the information there is about mobility, so a natural way to begin is by summarizing the joint distribution in tabular or graphical form.[10] How one proceeds depends on the nature of the data to hand and the mobility concept of interest. We have been assuming that income distributions are continuous but in practice it is often convenient to represent the data in grouped form, or the data may be intrinsically discrete as in the case of "social classes." In addition the information content of the descriptive device is related to the way (if any) in which the analyst standardizes the marginal distributions of any one bivariate distribution and, when making comparisons of bivariate distributions, makes further adjustments (e.g., to control for differences in average income between the bivariate distributions for two countries). If one is solely interested in pure exchange mobility (changes in relative position), then both issues are dealt with by working with the fractional rank implied by an individual's income rather than the income itself. In this case, all the marginal distributions are standard uniform variates and the same across time periods and countries.[11] But if the focus is on other mobility concepts, other standardizations may be used.

A mobility matrix, M, is constructed by first dividing the income range of each marginal distribution into a number of categories (which need not be the same in each period, but typically is) and cross-tabulating the relative frequencies of observations with each

[10] We consider a summary device for mobility as equalization of longer-term income in the case when there are more two periods in the next subsection.

[11] Fractional (or "normalized") ranks range between zero and one, with a mean of 0.5. Particular care needs to taken in their estimation when there are tied income values to ensure that these conditions are met. See, for example, Lerman and Yitzhaki (1989).

matrix cell: typical element $m_{i\,j}$ is the relative frequency of observations with period 1 income in range (group) i and period-2 income in range j. The graphical representation of the discrete joint probability density function is the bivariate histogram. Alternatively, the mobility process may be represented by the transition matrix and the marginal distributions. Borrowing notation from Atkinson (1981a), suppose that there are n income ranges, with the relative number of observations in group k in period-1 is m_1^k for $k=1, \ldots, n$, and correspondingly in period 2. The marginal (discrete) distribution in period-1 is summarized by the vector $m_1=(m_1^1, m_1^2, \ldots, m_1^n)$ and correspondingly for period-2. Hence,

$$m_1^k = m_2^k A. \tag{10.2}$$

When the focus is on pure exchange mobility, the ranges typically refer to quantile groups. For example, in the case of decile groups, each group contains one-tenth of the population. The transition matrix is then bistochastic. Mobility is entirely characterized by the transition matrix A.

An illustrative example is shown in Table 10.1. Mobility refers to changes in the relative positions in the United States between 1979 and 1988, and 1989 and 1998, with each individual's income defined as the equivalized real annual family disposable income of the family to which the individual belongs. The United States in the 1980s and the 1990s is a long way from the total immobility scenario (in which every cell percentage would equal to zero, except those on the leading diagonal, which would equal 100%). Clearly, there is also neither origin independence (every cell entry equal to 10%) nor total reversal of positions. The general pattern is one of much short-distance mobility with long-distance mobility being rare. For example, of those individuals in the poorest 10th in 1989, around 42% are also in the poorest 10th in 1998 with fewer than 1% making it to the richest 10th. Of the richest 10th in 1989, around 46% stay in that group, and less than 2% are in the poorest 10th in 1998. More generally, the largest transition proportions are on or close to the matrix diagonal (Hungerford (2011) reported that 73% of individuals remained in the same 10th or moved at most two deciles), and upward and downward mobility appears to be broadly symmetric. Because the U.S. situation described in Table 10.1 is not particularly close to the standard mobility reference points, it is not straightforward to say whether there is a large or small amount of mobility. It is also of interest to assess whether mobility increased between the 1980s and 1990s. Methods for mobility comparisons are discussed in the measurement section that follows. Further empirical evidence about within-generation mobility is presented in Section 10.4.

If the interest is in mobility other than of the positional kind, changes in the marginal distributions are also of interest. A particular example might be when the income class boundaries are defined as fractions of median income, or as fractions of the poverty line and there is interest in poverty rate trends as well as movements into and out of low

Table 10.1 Decile transition matrices: United States, (a) 1979–1988 and (b) 1989–1998 (percentages)

Origin group	Destination group 1	2	3	4	5	6	7	8	9	10
1979					**1988**

income.[12] More generally, defining income group boundaries that are fixed in real income terms over time provides indications about individual income growth for individuals of different origins; if each period's incomes are standardized by period-average income, the information refers to income growth relative to the average.[13] (We say "indications" regarding this mobility concept because its essence refers to income changes at the individual rather than group level.) Similarly, the dispersion across origin groups of individuals from a common income origin may be indicative of income risk, but the connection is not altogether obvious. Neither mobility matrices of this kind nor

[12] For examples, see, e.g., Hungerford (1993, 2011) for the United States and Jarvis and Jenkins (1998) for the UK.
[13] For examples, see Hungerford (1993), Hungerford (2011), and Jarvis and Jenkins (1998).

conventional transition matrices are directly informative about mobility as longer-term inequality reduction.

Graphical summaries can complement and sometimes be more effective than tabular presentations; visual impact matters. Even transition matrices and comparisons of them can be visualised. We refer, for instance, to the use of transition probability color plots introduced by Van Kerm (2011). Suppose individuals are classified into vingtile groups in each of period 1 and period 2. For the visualization, individuals are classified according to their income group in period 2, and lined up in rows with the poorest twentieth in one row at the top, the next twentieth in the row beneath, and so on down to the final row containing the richest twentieth. Each person is also tagged with their period-1 group membership using a color coding system. Suppose the poorest twentieth in period 1 is represented by blue and the richest twentieth by red, and the intermediate groups are represented by the colors of the rainbow in between. If there were no changes in relative position over time, every one would remain in their period-1 income group; there would be a one-to-one correspondence between rows and colors. (Rows would consist of full blocks of the same color.) If there were no association between income origin and income destination, every color would form an equal-sized block in each and every row. If there were complete rank reversal, the original color scheme would be reversed, with the richest period-1 group (red) in the top row and the poorest period-1 group (blue) in the bottom row.

Examples of such representations, due to Van Kerm (2011), are shown in Figure 10.1 for individuals' household income mobility between 1987 and 1995 in Western Germany (left) and the United States (right). It is immediately apparent that, over this 12-year period, there is substantial income mobility in both countries and throughout the income distribution, including a small fraction of the richest twentieth falling to

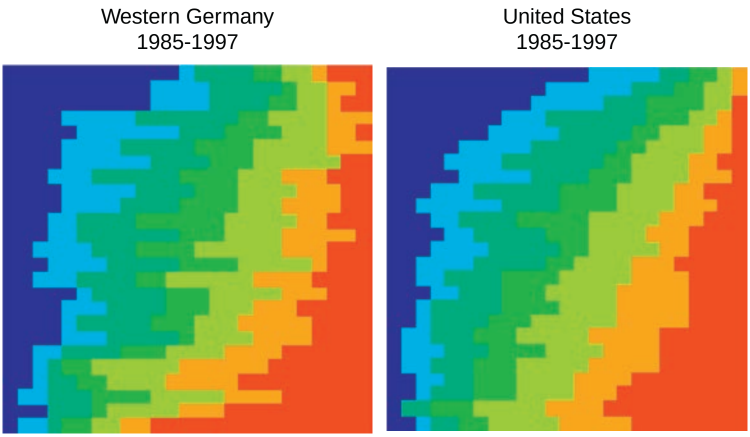

Figure 10.1 Transition color plot examples. *Source: Van Kerm (2011)*. (For color version of this figure, the reader is referred to the online version of this book).

the poorest twentieth, and vice versa. But there is clearly no origin independence in either country, let alone complete rank reversal. Interestingly, however, it is also clear that the main differences in patterns of mobility are at the bottom of the income distribution (more changes in relative position in Western Germany than in the United States). We return to this finding in the next section. The particular advantage of the transition color plots is their visual immediacy. However, color is not always available. The color transition plots summarizing income mobility in the book by Jenkins (2011a, Figure 5.1) were reproduced in black and white, and this reduced their effectiveness.

What about alternative devices? Perhaps the most straightforward way to summarize a bivariate joint distribution is using a scatter plot of period-2 incomes against period-1 incomes. Figure 10.2 provides a within-generation example using British income data for 1991 and 1992.

The advantages of the scatter plot are that it is very easy to produce and provides an immediate impression about the degree of immobility of incomes (the clustering around the 45° line), as well as the nature of the marginal distributions. For a focus on changes in relative position alone, the corresponding scatter plot would be of individuals'

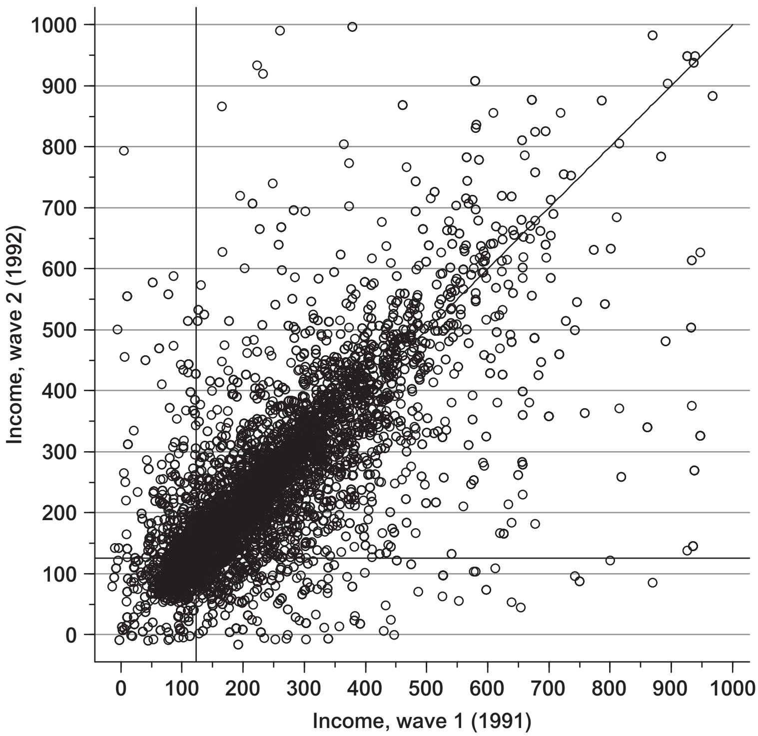

Figure 10.2 Scatter plot example. *Source: Jenkins (2011a, Figure 1.2).*

normalized ranks in each of the two periods. The main disadvantage is that potentially important detail is lost because the bivariate density is not estimated; there is no difference to the eye between 10 observations with a particular combination of period-1 and period-2 incomes and 100 observations with the same pair of incomes.

One way to proceed is derive and plot the joint density. The simplest estimates to produce are those of the bivariate discrete density (essentially plotting the bivariate histogram—see above). However, there are well-known disadvantages of such discretization: As in the univariate distribution case, the estimates are sensitive to choice of income class boundaries, and of course, information within the ranges is lost with the grouping. Kernel density estimation methods avoid the problem because of the way in which they smooth data within a moving window rather than within fixed categories. Figure 10.3 shows a "typical" joint bivariate density for West German family incomes for 2 consecutive years over the period 1983–1989.[14] Incomes in each year are normalized by the contemporaneous median, but otherwise, the marginal distributions are not constrained to be the same (so this is a representation of exchange mobility alone). Compared to the scatter plot, the concentration of individuals on and around the 45° representing perfect immobility is readily apparent. However, the fine detail remains difficult to

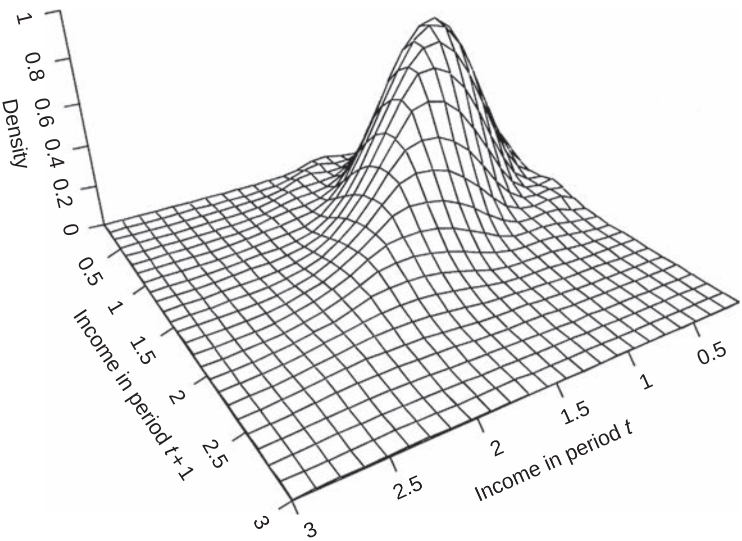

Figure 10.3 Bivariate density plot example. *Note: The charts shows a "typical" kernel density estimate for incomes in two consecutive periods. Source: Schluter (1998, Figure 1).*

[14] The source does not state which specific pair of years over the period 1983–1989 was used for the calculations.

ascertain, partly because the three-dimensional representation has to use a specific projection. What a reader perceives may change if the estimates are viewed from a different angle. Related, differences in marginal distributions are difficult to examine; so too is individual income growth. A further issue, shared with the scatter plot and bivariate histogram, is that it is difficult to compare a pair of bivariate distributions (e.g., for two different countries), even if the plots to be compared are placed adjacent to other. Overlaying one plot on another is far too messy, but without some form of overlay, detailed comparisons are constrained.

Both issues are resolved to some extent by summarizing the density estimates using contour plots in which contour lines connect income pairs with the same density. An example is provided using U.S. and West German income data for 1984 and 1993 in Figure 10.4. Income refers to the log of equivalized family income expressed as a deviation from the national contemporaneous mean. Contour lines are drawn at values that separate the quintile groups for each country (the 20th, 40th, 60th, and 80th percentiles). The solid lines are for the United States, the dotted lines are for West Germany (WG).

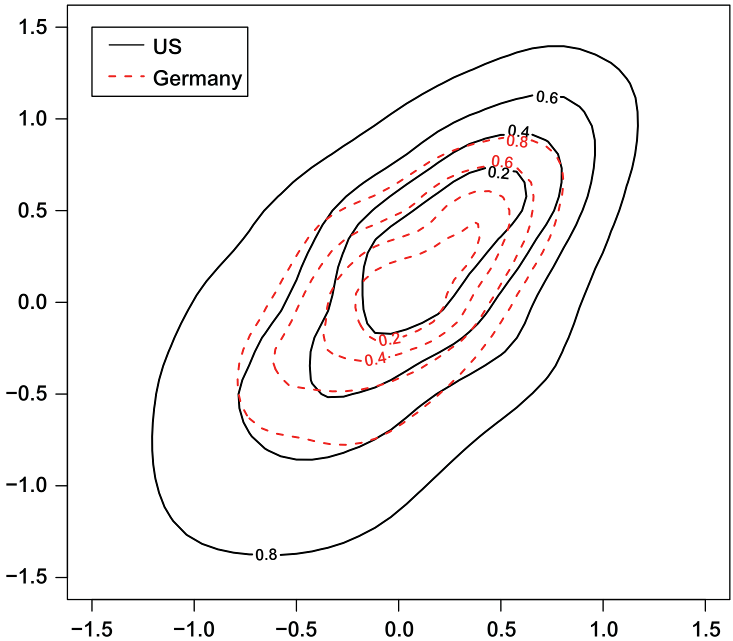

Figure 10.4 Contour plot example. *Note: The chart shows the kernel-smoothed joint density of income in 1984 and 1993 for the United States and West Germany, where income is posttax posttransfer family income equivalized by the PSID equivalence scale, and income for each year is expressed as a deviation from the year-specific mean. Source: Gottschalk and Spolaore (2002, Figure 1), redrawn by the authors.*

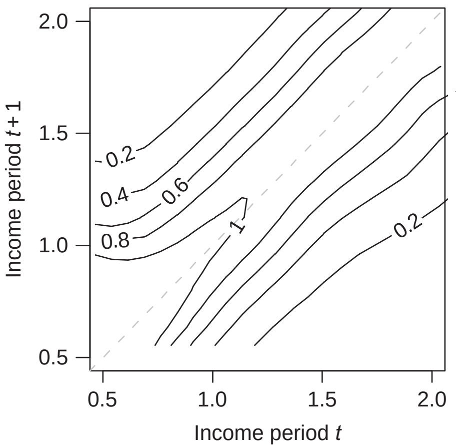
As Gottschalk and Spolaore (2002) commented, the plot reveals multiple features of the joint distribution. Each contour line for Germany lies inside its U.S. counterpart, indicating greater cross-sectional inequality in the United States. Clustering around the 45° immobility line is apparent for both countries but is greater for the United States. Also, the contour lines are generally flatter for Germany, meaning that expected period-2 income (conditional on period-1 income) varies less with period 1 in WG than it does in the United States. Gottschalk and Spolaore (2002) commented that this suggests a lower cross-period correlation in the United States, and they also pointed to a greater variation around the conditional means in the United States. Contour plots are also used in the U.S.–West German comparisons by Schluter and Van de gaer (2011, Figure 2).

Just as contour plots for continuous income distributions correspond to mobility matrices, there are also devices for continuous incomes corresponding to the transition matrix. One requires estimates of the conditional density $f(y|x)$, which is straightforwardly estimated in principle using the fact that $f(y|x) = f(y,x)/f(x)$. Estimates of the numerator and denominator are derived across a grid of values of x and y using kernel density estimation. See Quah (1996), who refers to this concept as a "stochastic kernel" and applications to income mobility include Schluter and Van de gaer (2011). Compared to unconditional joint density plots, the conditional density plots allow a more direct comparison of expected income growth across the base year income range. Examples are provided in Figure 10.5 based on data for the United States (top chart) and Western Germany (bottom chart) for 1987 and 1988. Income is equivalized net household income expressed relative to the 1987 median. Schluter and Van de gaer (2011, p. 11) pointed to not only the greater spread of contours in the United States indicating differences in marginal distributions, but also that the "particular … feature of the conditional densities is the greater upward mobility of low-income Germans" compared to low-income Americans. Note the more distinct upturn of the contours in the top left of the Western German chart compared to the shape of the corresponding U.S. contours.

Conditional densities are not the same as conditional probabilities, which is what constitute the transition matrix. Estimation of the conditional (cumulative) probability density $F(y|x)$ requires integration over the marginal distribution of y. As Trede (1998) explained, estimates of $F(y|x)$ can be inverted to give the probabilities for second-period income conditional on particular values of first-period income ("p-quantiles"). Trede's device for "making mobility visible" is a plot of these p-quantiles against first-period income values. Figure 10.6 shows one of these nonparametric transition probability plots using data for West German equivalized family incomes in 1984 and 1985. Incomes are normalized by the 1984 median, so "growth mobility is not excluded from the analysis" (Trede, 1998, p. 80). In the extreme case of origin independence, each transition probability contour would be horizontal. If, instead, there were complete immobility so that second period incomes were completely determined by first period incomes, the contours would lie on top of each other. (In particular, if there were no change in median income,



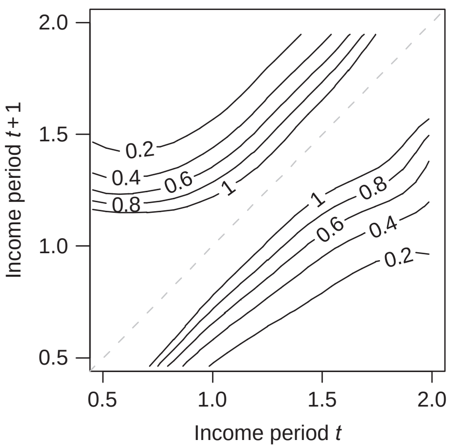


Figure 10.5 Conditional density plot example. *Note: Year t refers to 1987; year t+1 refers to 1988. The top chart refers to the United States; the bottom chart to Western Germany. Source: Schluter and Van de gaer (2011, Figure 2).*

the contours would lie on the 45° line.) The greater the gaps between the contour lines, the greater is inequality in the second period. The slope of the contours is generally less than 45°, indicating some regression to the median. Figure 10.6 shows that, among individuals with median income in 1984, around 10% have an income less than 0.7, and about 10% have an income of at least 1.7 of the 1984 median in 1985. Methods closely related to Trede's are used by Buchinsky and Hunt (1999) to derive nonparametric estimates of transition probability estimates, which the authors reported in tabular rather than chart form.

Patterns of mobility in the form of individual income growth are not shown directly in the devices discussed so far. The simplest way to focus on this aspect is to define income

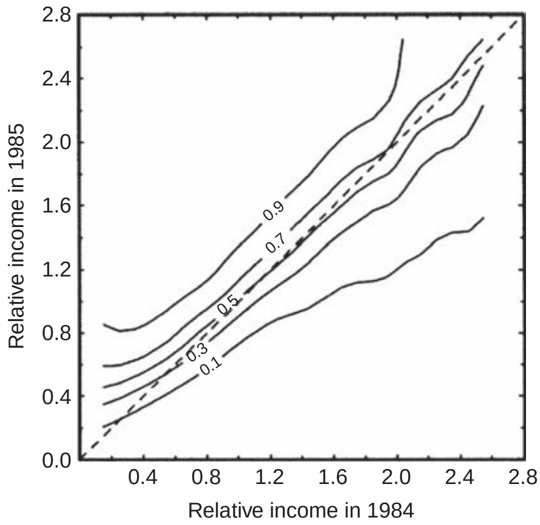

Figure 10.6 Nonparametric transition probability plot example. *Note: Relative income in each year equal to income divided by the 1984 median income. Source: Trede (1998, Figure 1).*

growth at the individual level between the two periods using some measure of directional income growth (Fields and Ok, 1999b), thereby converting the bivariate joint distribution to a univariate distribution of income changes. Then all the devices commonly used for summarizing univariate income distributions are available with one important proviso. Income changes may be negative or zero and not restricted to positive values (and the mean change may also be zero or negative). However, the ratio of second-period income to first-period income is positive (assuming incomes are positive), and it is often convenient to use this metric. Schluter and Van de gaer (2011, Figure 2) present kernel density estimates of the distribution of income ratios. Comparisons based on plots of cumulative distribution functions (CDFs) of income change distributions are also presented by Chen (2009, Figure 4) and Demuynck and Van de gaer (2012, Figure 1).

A CDF plot of this type is based on an ordering of individuals' income *changes* from smallest (most negative) to the largest. One is often interested in the extent to which individual income growth is "pro-poor," that is, whether income growth is greater for those at the bottom of the first-period income distribution relative to those at the top. In particular, pro-poor growth between two periods is a factor reducing the the inequality of second period incomes relative to first period incomes.[15] See also the discussion of SWFs in Section 10.2. Fields et al. (2003) plotted the average change in log

[15] But pro-poor growth does not guarantee inequality reduction. It also leads to reranking, which may have an offsetting effect. See Jenkins and Van Kerm (2006) for a fuller explanation and empirical examples.

per capita income between two time points against income in the base year, for four countries. Comparisons across countries are constrained by the fact that the income range on the horizontal axis (base-year income) varies tremendously. Comparability is enhanced if, instead, one plots individuals' average income change against their normalized (fractional) rank in the base-year distribution (with individuals ordered from poorest to richest). The horizontal axes in this case are bounded by 0 and 1. Such plots were developed by Van Kerm (2006, 2009) and independently by Grimm (2007). Extensive empirical examples are provided by Jenkins and van Kerm (2011) for four 5-year periods in Britain during the 1990s and 2000s, from which Figure 10.7 is taken. (Individual income growth refers to the change in the log of individuals' household income between 2 years.) It is clear that income growth is distinctly pro-poor in each of the subperiods, especially 1998–2002.[16]

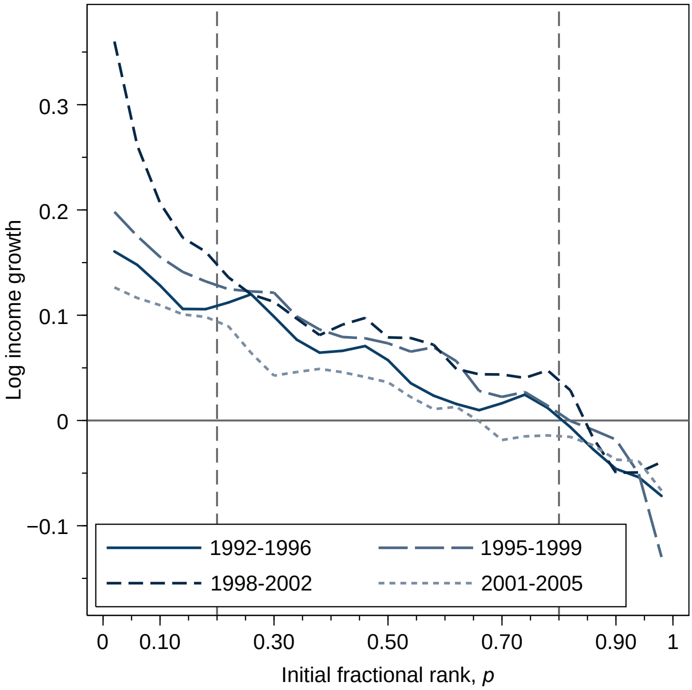

Figure 10.7 Individual income growth and mobility profiles. *Source: Jenkins and Van Kerm (2011).*

[16] As the authors explain, the negative slope to each curve is driven by "regression to the mean," and so the substantive interest is mostly in the changes in slopes of the curves rather than the slopes themselves (as well as their heights).

In sum, we have reviewed a portfolio of tabular and graphical devices for summarizing income mobility between two periods. By standardizing marginal distributions in different ways, different aspects of the mobility process can be focused on, and for individual income growth, there are separate devices.

Within-generation income mobility analysis has tended to use graphical summaries and comparisons rather more than between-generation mobility analysis, which has mainly relied on transition matrix tabulations for detailed summaries of the mobility process. In part, this emphasis is because the mobility concept most associated with intergenerational mobility is pure positional change totally separate from any changes in the marginal distributions. Nonetheless, there do appear to be opportunities forgone to use other methods to describe the distribution.

Our final observation here is that there appear to be no straightforward descriptive summaries that directly highlight the concepts of mobility as longer-term inequality reduction or as income risk. We consider the former case later. In the latter case, one wants something analogous to the mobility profile but, instead, of summarizing expected (average) income growth conditional on base-year income or income position, one would summarize conditional income dispersion.

10.3.2 Mobility Dominance

Dominance checks are a widely used part of the analyst's toolbox for comparing univariate distributions of income. To what extent can and should this be the case for mobility comparisons? We identify three main approaches.

The most well-known dominance results are those of Atkinson and Bourguignon (1982). The results are derived with reference to the social welfare framework discussed earlier. Social welfare is the expected value of individuals' utility-of-income functions defined over period-1 and period-2 income, where individual utility is a concave transformation of the per-period utilities of income and also increasing in each income.

Welfare comparisons of differences in mobility for bivariate distributions f and f^* are based the difference

$$\Delta W = \int_0^{a_y} \int_0^{a_x} U(x, y) \Delta f(x, y) \mathrm{d}x \mathrm{d}y, \tag{10.3}$$

where $\Delta f(x, y) = f - f^*$ is the difference in bivariate densities and the same $U(.)$ is used for the social evaluation of each distribution (cf. Equation 10.3).

Analysis has focused on the case in which the marginal distributions x and y are identical, and SWFs satisfy the conditions $U_1 \geq 0$, $U_2 \geq 0$, and $U_{12} < 0$ (guaranteed if $U(x,y)$ is a concave transformation of the sum of the per-period utilities). Atkinson and Bourguignon (1982) showed that a necessary and sufficient condition for a welfare improvement $\Delta W \geq 0$ is that $\Delta F(x,y) \leq 0$ for all x and y. That is, differences in the cumulative bivariate distribution are lower at each point (a first-order stochastic dominance condition).

What sorts of differences between joint distributions are associated with such conditions being satisfied? Atkinson and Bourguignon (1982) discussed the case of a "correlation-reducing transformation," which leaves the marginal distributions unchanged but reduces the correlation between x and y:

$$\left\{\begin{array}{ccc} & x & x+h \\ y & \text{density reduced by } \eta & \text{density increased by } \eta \\ y+k & \text{density increased by } \eta & \text{density reduced by } \eta \end{array}\right\}, \quad \text{where } \eta, h, k > 0.$$

When the bivariate distribution is represented using a transition matrix, this transformation is equivalent to shifting probability mass away from the matrix diagonal.[17] The cumulative density can be straightforwardly derived by cumulation across cells of the transition matrix starting from the lowest origin and destination group. For comparisons of two transition matrices, first-order welfare dominance exists when the difference in cumulative densities in corresponding cells is everywhere of the same sign. Atkinson (1981a,b) demonstrates the approach in action using intergenerational income data for Britain. Further examples are provided later in this chapter.

The dominance result is a notable addition to the toolbox for comparisons of bivariate distributions but, perhaps surprisingly, has not been widely used. There are several reasons for this. The first is that, although relevant to evaluations of pure positional change mobility, the Atkinson–Bourguignon SWF is primarily sensitive to mobility as reversals rather than mobility as origin dependence (see the earlier discussion).[18]

Second, the first-order dominance checks have not provided clear cut rankings in practice (cf. Atkinson, 1981a,b). A natural reaction in this case is to seek unanimous mobility rankings according to more restricted classes of SWFs using second- and higher-order dominance checks. Atkinson and Bourguignon (1982) provide the theoretical results. The problem, however, is that the additional restrictions on the SWF are hard to interpret. They involve the signs of third- and fourth-order partial derivatives of $U(x,y)$. Although Atkinson and Bourguignon pointed out that in the case of homothetic preferences, "the signs of higher derivatives depend on the relation between the degree of "inequality aversion" … and the degree of substitution" between periods (Atkinson and Bourguignon, 1982, p. 18), i.e., the relation between parameters ε and ρ discussed earlier, they do not elaborate. It is difficult to understand what the sign conditions mean in everyday language.

Third, analysts may be interested in alternative concepts of mobility besides positional change. Individual income growth is the most prominent example of this situation. As

[17] But see also Jenkins (1994) and Fields and Ok (1999a). Both articles question the intuitive attraction of linking correlation-reducing transformations with more mobility if the transformations are made off the diagonal.

[18] Gottschalk and Spolaore (2002) modified the social welfare function but did not derive dominance results.

discussed earlier, researchers have used social evaluation functions that are increasing functions of a measure of "distance" between first and second period incomes for each individual i, $d(x_i,y_i)$ and defined social welfare as the socially weighted sum over individuals of the d_i. For instance, Fields et al. (2002) undertook checks based on comparisons of pairs of CDFs of d_i, where d_i is defined in six different ways in their empirical application. However, as remarked earlier, their SWF has unappealing properties. The challenges involved in the derivation of stochastic dominance results for Fields and Ok (1999b) type measures of nondirectional income movement are discussed by Mitra and Ok (1998). Van Kerm (2006, 2009) explicitly derived dominance results for two classes of SWF defined over the d_i. The first is when the social weights are simply assumed to be positive. Van Kerm showed that unanimous rankings by this evaluation function are equivalent to nonintersections of mobility profiles (the graphical device discussed earlier), a first-order dominance result. If one also assumes that the social weights are nonincreasing functions of base-year income ranks (poorer individuals receive higher weights), unanimous social welfare rankings are equivalent to nonintersections of cumulative mobility profiles. Bourguignon (2011) showed that dominance conditions can be derived for SWFs more closely related to Atkinson and Bourguignon (1982) ones, but the conditions are difficult to interpret intuitively and, in any case, are restricted to the case in which marginal distributions in the initial year are identical.

Dardanoni (1993) derived stochastic dominance results for rankings of mobility processes that are summarized by transition matrices, focusing on pairs of monotone matrices with the same steady-state income distribution.[19] The SWF is defined on a vector containing each individual's lifetime expected utility (the discounted sum of per-period utility values, where each income class has a common utility value associated with it; there is no within-class inequality in utility). Overall social welfare is not the average of the individual lifetime expected utilities because linearity combined with anonymity would imply that mobility is irrelevant for social welfare assessments (as discussed earlier). Instead, Dardanoni's SWF is "a weighted sum of the expected welfares of the individuals, with greater weights to the individuals who start with a lower position in the society" (Dardanoni, 1993, p. 371). Thus there is a direct parallel with the social weight system employed in the welfare function used by Van Kerm (2006, 2009).

Dardanoni shows that unanimous social welfare rankings by this evaluation function can be checked by comparisons of the cumulative sums of the "lifetime exchange" matrices corresponding to the two transition matrices. (A lifetime exchange matrix summarizes

[19] Monotone transition matrices are those in which each row stochastically dominates the row above it. Essentially, being in a higher income class in the initial period means improved prospects in the second period. Most empirically observed transition matrices are monotone or approximately so (Dardanoni, 1993). If a regular transition matrix characterizes a first-order Markov chain, there is a constant long-run steady-state marginal distribution corresponding to that matrix.

the joint probability that an individual starting in some income class i is in lifetime income class j.) These matrices depend on the discount factor underlying them: Although in general mobility processes that improve the position of initially poorer individuals are more highly valued, the timing of utility receipt also matters. Dardanoni (1993) provided additional results for checking the robustness of dominance results to the choice of discount factor. The fact that actual societies may not be in steady state and transition matrices may imply different steady-state distributions limits the applicability of the dominance results. Dardanoni (1993) acknowledged this, but also pointed out that this could be remedied by focusing on bistochastic quantile transition matrices (as Atkinson, 1981a,b) did, in which case attention is restricted to changes in relative position). The orderings derived differ from those of Atkinson (1981a,b), however, because the SWF is different. For instance, Dardanoni (1993) pointed out that maximal mobility according to his ordering corresponds to the situation of origin independence, not rank reversal. Finally, we observe that Dardanoni's dominance results appear to have been rarely used. As with the results of Atkinson and Bourguignon (1982), we suspect that is because applied researchers have found them relatively complicated to interpret and implement.

In sum, we have shown that there are dominance results for mobility comparisons, but the "toolbox" is much less settled than it is for comparisons of univariate income distributions. In part, the reason comes back (again) to the fact that there is a multiplicity of mobility concepts and (related) a lack of consensus about how to specify the SWF function in the bivariate case.

10.3.3 Mobility Indices

In this section, we review indices that might be used to summarize intra- and intergenerational income mobility. After a brief discussion of generic properties of indices, we discuss some commonly used measures of bivariate association—what Atkinson et al. (1992) refer to as "intuitive" measures—and then move on to more specialist indices (i.e., ones more directly corresponding to the various mobility concepts identified earlier). Whether an index focuses on positional change, individual income growth, longer-term inequality reduction, or income risk accounts for many of its properties. There are general features on which we contrast indices.[20]

First, there are different normalizations. Although all indices equal zero in the case in which there is complete immobility, there is no shared maximum mobility value and, indeed, some measures have no maximum value imposed (principally the indices of income growth and income risk). Second, there is a distinction between "pure" measures of positional change and other indices. The former indices, of exchange mobility, are sensitive only to the (re)ordering of individuals and hence with values unaffected by any monotonic transformation of each income between time periods (or, equivalently,

[20] This discussion draws on Jenkins and van Kerm (2009).

also unaffected by changes in the marginal distributions of income). By contrast, structural measures register mobility even if ranks are constant but the income values associated with those positions change over time.

Third, and related, indices differ in how they reflect income changes that are common to all persons, whether by the same proportion or by the same absolute amount. Measures are "strongly relative" ("intertemporally scale invariant") if equiproportionate income growth does not affect the mobility assessment. Measures are "weakly relative" (or "scale invariant") if the units in which income are measured are irrelevant but, by contrast with strongly relative measures, equiproportionate income growth may count as mobility.[21] There are also translation invariance counterparts of these properties. Again, the principal distinction is between measures of pure positional change (exchange mobility)—which satisfy both intertemporal translation and scale invariance—and the other indices. For example, most indices of longer-term inequality reduction are scale invariant but not intertemporal scale invariant. Most indices of individual income growth are neither intertemporal scale nor translation invariant.

Fourth, there is the issue of directionality, which refers to the roles played by the base year and current year in mobility assessments. An index is directional if it matters whether a particular income change refers to a change from a base year to a current year or vice versa. This is relevant if one wishes to take the temporal ordering of changes into account, and this is particularly important for measures of individual income growth, as one would want to treat differently an income change from 100 to 150 and an income change from 150 to 100. One would want the former to represent an improvement in circumstances, and the latter a deterioration.

Fifth, indices may satisfy various decomposability properties. Mobility indices may be (additively) decomposable by population subgroup, as inequality indices are, according to which total mobility can be written as the weighted sum of mobility within subgroups defined by an exhaustive nonoverlapping partition of the population in question according to some characteristic (e.g., sex, age, or education) plus (possibly) a term representing between-group mobility. Most indices of longer-term inequality reduction can be decomposed, thus and so too can individuals of income growth, though there is typically no between-group mobility term in that case.[22] Measures based on changes in ranks are not decomposable because in general there is no one-to-one correspondence between an individual's rank in his/her subgroup and in the population as a whole.

A second type of decomposability is into structural and exchange components. Unlike decompositions by population subgroup, these decompositions are not additive

[21] For more on this distinction, see Fields and Ok (1999a).

[22] Such decompositions have mostly been used to provide anatomies of mobility during a single time period, rather than for accounting for the correlates of changes in mobility between two time periods in terms of the relative importance of changes in subgroup sizes and mobilities and between-group mobility changes.

and rely for their derivation on the use of counterfactual income distributions representing the situations when there is an absence of exchange mobility or of structural mobility. On this, see, e.g., Markandya (1984), Ruiz-Castillo (2004), and especially Van Kerm (2004).

A third decomposition idea, most commonly exploited in measures of individual income growth or income flux refers to intertemporal consistency—whether mobility calculated for income changes between times t and $t+s$ is the sum of the mobility between times t and $t+r$ and between $t+r$ and $t+s$ (with $r<s$) or, alternatively, the product. This is the concept of additive (alternatively, multiplicative) path separability or path independence. A fourth mobility-related decomposition relates changes between two years in *inequality* measured by the change in a generalized Gini coefficient to the sum of two mobility indices—one of progressive income individual income growth and the other of reranking. See Jenkins and Van Kerm (2006) for details.

We refer to these features at several points in what follows. We now turn to consider the most commonly used "statistical" or "intuitive" measures of (im)mobility, which are the Pearson (product moment) correlation, r, between the log of incomes at two time points or its close sibling Beta (β), the slope coefficient from a least-squares linear regression of log(period-2 income) on log(period-1 income):

$$r=\beta\frac{\sigma_1}{\sigma_2}, \tag{10.4}$$

where σ_1 and σ_2 are the standard deviations of log incomes in periods 1 and 2. Put differently, r is β scaled by the changes in inequality in the marginal distributions as assessed by the variance-of-logs inequality index, and it measures the degree of regression to the (geometric) mean in income between periods 1 and 2. $H=1-r$ is the Hart (1976) index of mobility, the properties of which are discussed in detail by Shorrocks (1993) and often used in the intergenerational mobility context. H ranges between -1 and 1, and $H=0$ in the case of complete immobility.

Beta, as we shall discuss later, has been used in almost every empirical study of intergenerational income mobility ($1-\beta$ is an index of mobility). This is perhaps surprising because it is the positional mobility concept that has been of the greatest interest in this context, and yet Beta and r (or H) reflect structural as well exchange mobility. A perfect linear relationship between period-2 and period-1 incomes ($r=1$, $H=0$) is consistent with unchanged ranks but also income growth. It is sometimes argued (see Section 10.5) that r is more suitable than Beta as a measure of income (im)mobility when undertaking cross-national comparisons on the grounds that r controls for differences in marginal distributions. But such controlling is only done to a rather limited extent, because changes in inequality are only one distributional feature (and uses one particular inequality measure to do so). Differences in marginal distributions would be fully controlled, however, were analysts to employ the Spearman rank correlation rather than r (because both marginal distributions would be standard uniform distributions), and this would also have the advantage in the intergenerational context of focusing on positional change. Note also D'Agostino and Dardanoni (2009a) who provided an axiomatic characterization of the Spearman rank correlation as an measure of exchange mobility, thereby taking it beyond being a mere "statistical" index.

A second question regarding Beta and r is why they should be calculated using log incomes rather than incomes. To be sure, Beta is a unit-free measure (an elasticity), but this begs the question of whether we are interested in immobility as the lack of a linear or log-linear relationship.[23]

All in all, there are probably two reasons for the continuing widespread use of Beta and r in the intergenerational mobility literature. The first, as we discuss in Section 10.5, is that various methods to assess the impact of measurement error, and discussions of the relationship between Beta, r, and sibling correlations, rely on properties of regression and moments. The second reason is simply inertia: researchers continue to use Beta because they want to compare their estimates with those of others before them. The main problem with Beta as a measure that intergenerational mobility researchers have noted is its scalar nature rather than more fundamental concerns about the mobility concepts that are reflected in it. Their developments of "vector" measures take us some back toward the more detailed graphical summaries of bivariate distributions discussed earlier.

For example, instead of fitting a single log-log regression, researchers have estimated quantile regressions of period-2 incomes on period-1 incomes (see, e.g., Eide and Showalter, 1999). (The periods refer to offspring and parental generations, rather than years within a generation.) However, it is not immediately clear what the estimates tell us about (im)mobility. At a technical level, the answer is clear. A quantile regression of, say, the 10th percentile of son's income on father's income allows the researcher to express the 10th percentile of son's income as a function of father's income. The quantile regression coefficient on father's log income then measures the elasticity of the particular quantile of son's income with respect to father's income. Differences in estimates across the quantiles tell us how sensitive different parts of the son's distribution conditional on father's income are to small changes in father's income. However, why these marginal changes, measured by slopes of the conditional quantiles, are of interest is not obvious.

One way to interpret the information provided by the vector of quantile regression coefficients is in terms of the full conditional distribution of son's income. A picture that is familiar to most students of regression analysis is the fitted regression line from a regression with one explanatory variable, with the distribution of the error term around that line drawn in a few different levels of the explanatory variable. In the classical case, all those distributions are the same, or at least have the same variance (i.e., the error term

[23] It might also be that log(income) is viewed as a measure of the utility of income, but we have not seen that argument stated explicitly in the income mobility literature.

is homoscedastic). If the distribution of y_2 (for sons), conditional on y_1 (for fathers), is homoscedastic, all estimated quantiles would have the same slope coefficient (save for random error). If the regression slopes are greater for higher percentiles of the son's distribution, it suggests that the conditional variance of son's income may be increasing with father's income.

Comparisons of the quantile regression estimates with the Beta from the loglinear regression can also reveal some further aspects of the distribution of period-2 incomes conditional on period-1 incomes. The log-linear regression line gives the conditional expectation, and the regression slope for the 50th percentile gives the expected median. If we find that for most of the range of father's incomes that the conditional mean for sons is lower than that of the relevant father's income, this suggests that, conditional on father's income, son's income is skewed to the left, rather than skewed to the right (as is usually true for income distributions). One can also use the predicted percentiles for different values of father's income to generate summary distributional statistics for the conditional distribution. For instance, one can derive the (discrete) CDFs for period-2 (son's) income, conditional on a set of period-1 (father's) income percentiles. One could then check, e.g., whether the distributions first-order stochastically dominate each other. (This relates to Monotonicity assumption of Benabou and Ok, 2000.) Any conditional summary statistics can be generated this way, including inequality statistics such as percentile ratios. Individual income growth summaries such as in Figure 10.7 refer to conditional expectations (means) of distributions like these (except that they are typically drawn at different base-year ranks rather than different base-year income levels). In sum, there are close connections between some of the "vector" measures of mobility and the graphical devices discussed earlier. In what follows, we return to focusing on scalar measures.

The second most common type of intuitive measure is an "immobility ratio" (IR). IRs summarize how much clustering there is on (or, sometimes, also around) the leading diagonal of a transition matrix—and hence summarize positional change. For example, for a decile transition matrix, an IR might be defined as the percentage of all persons who remain in the same decile group between the two periods. (A variant would be to calculate the percentage remaining in the same decile group or on either side of it.) Clearly, the IR equals 100% in the complete immobility scenario. If, instead, there is complete independence of origin, the IR for a decile transition matrix is 20% (52% in the variant). An index of mobility can easily be calculated as $1 - \text{IR}$.

Shorrocks (1978b) proposed a mobility index closely related to the IR, a Normalized Trace measure, equal to $[n - \text{trace}(A)]/(n-1)$, where A is the transition matrix with n income classes and trace(A) is the sum of the transition proportions on the leading diagonal of A. This provides a neatly normalized index: with complete immobility, $\text{trace}(A) = n$ and the normalized trace equals 0; with complete origin independence $\text{trace}(A) = 1$, and so the normalized trace equals 1.

By construction, an IR and the Normalized Trace are insensitive to any differences between transition matrices aside from those in the respective diagonals. Bartholomew's (1973) Average Jump index is a positional mobility measure that addresses this aspect. It is equal to the number of income class boundaries crossed by an individual (whether upward or downward), averaged over all individuals (and equal to 0 in the complete immobility case). One feature of the Average Jump index is that it generalizes to the situation when the researcher has individual-level data on incomes rather than simply grouped data (a transition matrix). The index is then the population average of the absolute changes in fractional ranks (i.e., the ranks normalized to range from 0 to 1 rather than from 0 to the population size).

The transition matrix also offers, as a by-product, measures of low and high income persistence defined in terms of rank-order immobility. Mobility matrices, in which class boundaries are defined in real income terms, also do so. For example, if the lowest class boundary in each period is the poverty line, then the mobility matrix shows the proportion of individuals who are poor in a base period who are still poor in some later period (or who escape poverty). And with repeated longitudinal data for multiple periods, it is straightforward to define "survival probabilities"—the chances that a person remaining poor for τ years, where $\tau = 1, 2, \ldots$. One can also define measures of high income persistence analogously (and we report some estimates in the next section).

This way of thinking about low-income persistence provides a link with the more well-known literature on poverty persistence, especially the approach pioneered by Bane and Ellwood (1986) in which consecutive periods spent poor are aggregated into spells (summarizing the total time spent poor). Rather than looking at spells of poverty (or affluence), one may simply count the number of times each person is poor (or rich) over some fixed time horizon and summarize that distribution. Low-income persistence statistics of this nature are published by, e.g., the UK Department for Work and Pensions (Department for Work and Pensions, 2009) and the Statistical Office of the European Communities (Eurostat).

There is also a nascent literature developing indices of poverty persistence that focuses attention on the way in which people's experience of poverty over time is aggregated, and hence how to compare, say, a history of 3 consecutive years in poverty followed by 3 years of nonpoverty, with a history in which the person was poor every second year in the six-year period. Research in this topic can be found in Foster (2009), Gradín et al. (2012), Mendola et al. (2011), Mendola and Busetta (2012), and Porter and Quinn (2012). This literature works with a time horizon of fixed length and summarizes individuals' experiences within that window, ignoring whether poverty spells were already in progress at the beginning of the window or remained in progress at the end of the window. If one wants to derive the shape of the poverty spell distribution in the population (rather than simply the sample), these issues of left- and right-censoring of poverty spell data (which are ubiquitous) need to be accounted for. They are given great attention in the spell-based literature on poverty persistence following Bane and Ellwood (1986), which, on the other hand, ignores longitudinal aggregation issues.

We now turn to a selection of more specialized indices of positional change that have been less commonly used than the ones mentioned so far. The first is the Gini Mobility index of Yitzhaki and Wodon (2005). It is based on the idea of mobility as (lack of) correlation but, instead of using the Pearson or Spearman correlations, it uses the Gini correlation, which, like other Gini-based measures, focuses on ranks rather than income levels per se. The Gini correlation between the income distributions in periods 1 and 2 is

$$\Gamma_{12} = \frac{\mathrm{cov}(y_1/\mu_1, F_2)}{\mathrm{cov}(y_1/\mu_1, F_1)}, \tag{10.5}$$

where y_1/μ_1 is period-1 relative income (i.e., income divided by the period-specific mean income), F_1 and F_2 are the fractional ranks in the two periods, and cov(.) means covariance. Because $1 - \Gamma_{12}$ is a directional measure of mobility ($\Gamma_{12} \neq \Gamma_{21}$ in general), the overall Gini mobility index is defined as a weighted average of the two possible directional measures, where the weights depend on the inequalities in each marginal distribution, measured using the Gini coefficient (G). That is,

$$\text{Gini mobility index} = \frac{G_1(1-\Gamma_{12}) + G_2(1-\Gamma_{21})}{G_1 + G_2}. \tag{10.6}$$

Yitzhaki and Wodon (2005) showed that if there is no positional change, the Gini mobility index equals 0, it equals 1 if there is complete origin independence, and it equals 2 if there is complete rank reversal.[24]

The Gini mobility index uses a particular weighting function when aggregating changes in individuals' ranks but one that is not immediately clear. By contrast, the King (1983) index takes an explicit welfarist approach in which differences in social weights across ranks are defined and tuned parametrically. The basic building block is the "scaled order statistic" for each individual i, s_i, equal to the absolute magnitude of the difference between i's period-2 income and the period-2 income that i would have had, were she/he to have maintained the same rank in period 1, all expressed relative to mean period-2 income. There is complete immobility if $s_i = 0$ for all individuals. Using an approach analogous to that of Atkinson (1970), King defines his mobility index as the proportion of total period-2 income that society would be prepared to forego to have the mobility observed rather than complete immobility (positional change is socially valued). Assuming a homothetic form for the SWF leads to a mobility index depending on two parameters—the degree of aversion to period-2 income inequality and the degree of aversion to income immobility (larger values of which give greater social weight to

[24] The index of reranking used in Jenkins and van Kerm's (2006) decomposition of inequality change into reranking and income growth components is a directional Gini correlation.

mobility, other things being equal). For generalizations of and commentary on King's approach, see Chakravarty (1984) and Jenkins (1994).

On the one hand, the systematic welfarist approach used by the King index (and others like it) has much to recommend it. On the other hand, it relies on a rather special characterization of what counts as mobility at the individual level (the scaled order statistic), in which the implications for social welfare of changes in ranks are summarized by income values and a particular no-mobility thought experiment. Also the SWF does not depend directly on incomes in period 1, except insofar as they characterize s_i. Compare this with the Atkinson and Bourguignon (1982) SWF defined over incomes in periods 1 and 2 that was discussed earlier. Gottschalk and Spolaore (2002) embraced (and extended) the latter in the first part of their article, but when they later defined specific mobility indices, they use an approach that is similar to King's (1983) in that the social gains from mobility are all expressed relative to a complete immobility reference point, and this is defined in the same way as in the King index. To develop their indices, Gottschalk and Spolaore (2002) also assumed homotheticity in their SWF, and the resulting class has three parameters, representing aversion to multiperiod inequality, rank reversal, and origin dependence. Although each parameter has a clear interpretation when taken individually, thinking about the implications of different combinations of values is more complicated. We are aware of no use of the Gottschalk and Spolaore (2002) indices other than by the authors themselves.

We move now to consider measures of individual income growth. As mentioned in the Introduction, these incorporate two basic ideas: (i) income increases for an individual count positively in the social calculus and income decreases count negatively, and (ii) total income growth is a function of income growth values for each individual (and the measure of each person's income growth depends only on their incomes in the two periods, and not the incomes of other people). The first idea refers to the directionality of the income growth measure. The second is a form of decomposability property across individuals, and also leads to aggregate measures that are decomposable by population subgroups. Although the empirical applications of these measures have all been to intragenerational income mobility, the indices could also be applied to intergenerational income mobility when there is interest in structural mobility over and above exchange mobility.

Fields and Ok (1999b) provided the most well-known aggregate measure of directional income growth in this tradition.[25] They show that directional measures of individual income growth that satisfy the properties of scale invariance, subgroup decomposability, and multiplicative path separability must take the form

[25] We review their nondirectional indices of income "flux" later.

$$D1 = c\left[\frac{1}{N}\sum_{i=1}^{N}\left(\log(y_i) - \log(x_i)\right)\right], \tag{10.7}$$

where c is a normalizing constant, which may be set equal to one, and N is the population size. That is, overall income growth is the average of individuals' proportional income growth. This is the case in which (directional) distance between incomes, $d(x_i,y_i) = \log(y_i) - \log(x_i)$. Observe that the social weighting scheme treats all individuals the same, regardless of their base-year income and regardless of how much income growth each experiences. Both these aspects, and some other generalizations, have been incorporated in later work.

Demuynck and Van de gaer (2012) used axioms similar to Fields and Ok (1999b), but explored the implications of assuming additive as well as multiplicative path separability, and also of imposing an axiom of "priority for lower growth" that builds in aversion toward inequality in the individual growth rates. The axiom states that "aggregate growth increases more when additional income growth is allocated to individuals with lower income growth than when it is allocated to individuals with higher income growth" (Demuynck and Van de gaer, 2012, p. 750). The authors prove that the measure satisfying their axioms is of the form:

$$S = \frac{1}{N^{\delta}}\sum_{i=1}^{N}\left(i^{\delta} - (i-1)^{\delta}\right)\widetilde{d}_i, \quad \text{with } \delta \geq 1. \tag{10.8}$$

Given a measure of individual-level income growth for each person, d_i, $\widetilde{\mathbf{d}}$ is the vector of such income "distances" ordered from largest to smallest. If multiplicative path separability is among the axioms, then $d_i = (y_i/x_i)^{\pi}$ or if, instead, additive path separability is assumed, then $d_i = \pi(\log(y_i) - \log(x_i))$, with $\pi > 0$ in both cases.

When $\delta = 1$, the general indices reduce, in the first case, to the directional measure of Schluter and Van de gaer (2011) and, in the second case, to the Fields and Ok (1999b) measure described earlier (with $\pi = c$, and also normalized to 1). In Schluter and Van de gaer's (2011) index, π is a sensitivity parameter, with higher values increasing the "distance" measured between incomes in period-1 and period-2 but keeping ranks the same. Demuynck and Van de gaer (2012, p. 754) remarked that when $\delta = 1$, correlation-reducing transformations to incomes in either period of the kind discussed earlier increase mobility according to S but $D1$ is insensitive to such changes. In the more general case, with $\delta > 1$, more weight is given to individuals with smaller values of d_i. When $\delta = 2$, the weights are like the weights used to characterize the Gini coefficient of inequality and when $\delta \to \infty$, only the smallest d_i counts. In these more general cases, S is no longer additively decomposable by population subgroup, and it is possible for correlation-decreasing transformations to reduce mobility. The larger question, however, concerns the social desirability of "priority for lower growth": why should we be concerned about the inequality of individual growth rates (the d_i) independently of incomes in the initial or final period? Because of this issue, and (related) the greater complexities involved with using a two-parameter index, we conjecture that empirical researchers will be more likely to use S with $\delta=1$ than the more general case.

The directional measures of income growth of Jenkins and van Kerm (2011) are built using a different approach and relate to a SWF defined as the weighted average of the d_i (see Section 10.2), in which the social weights are a decreasing function of period-1 income ranks, defined using a single-parameter generalized Gini scheme.[26] Put differently, Jenkins and van Kerm (2011) build in a social preference for pro-poor income growth, and the choice of different parameter values provides indices ranging from limiting cases in which aggregate growth is the simple average of the d_i values (as with $D1$) or in which only the growth rate for the poorest period in the initial year counts.[27] Palmisano and Van de gaer (2013) provide an axiomatic characterization of the Jenkins and van Kerm (2011) class of measures. The usefulness of these indices rests largely on the extent to which the concept of pro-poor income is viewed as a desirable normative principle: see the discussion in Section 10.2 about the link between progressive income growth and inequality reduction.

The pioneering paper on mobility as reduction in the inequality of longer-term income is by Shorrocks (1978a). The essential insight is that, were one to longitudinally average each person's income over a number of years (T, say), the inequality in these averaged incomes would be less than average annual inequality because each individual's income fluctuations would be smoothed out and no longer contribute to aggregate cross-sectional dispersion in incomes for the T-year accounting period. Shorrocks (1978a) defined a measure of income rigidity, $R(T)$, equal to the ratio of inequality among T-averaged incomes ("longer-term" inequality) to the weighted average of single-year inequality values:

$$R(T)=\frac{I[Y(T)]}{\sum_{k=1}^{k=T} w_k I[Y^k]}. \tag{10.9}$$

$I[Y(T)]$ is the inequality in T-averaged incomes, and $I[Y^k]$ is inequality in period-k incomes calculated using the same inequality index (e.g., $I[Y^1]$ is inequality in period-1 incomes). The weights w_k are the proportion of aggregate T-averaged income received in period k (i.e., $w_k=\mu_k/\mu$), and the weights sum to unity. Shorrocks shows that if one restricts attention to conventional relative inequality indices, then R is bounded

[26] This scheme is like Demuynck and Van de gaer's (2012), except that the weights are applied to period-1 ranks, and not to d_i values.

[27] Jenkins and Van Kerm's (2011) classes of measures focus on the cases in which income growth rates are defined in proportional or absolute terms (i.e., $d_i = \log(y_i) - \log(x_i)$ or $d_i = y_i - x_i$).

above by 1. When there is complete rigidity in relative incomes, inequality in each period corresponds to inequality for the longer accounting period.[28] The more frequent or larger that income changes are, the less rigid the income system, and thus one may define a measure of mobility: $M(T) = 1 - R(T)$.

As Shorrocks (1978a, p. 178) puts it, "mobility is regarded as the degree to which equalization occurs as the observation period is extended." In terms of the properties discussed earlier, $M(T)$ is a nondirectional index and scale invariant (because it is defined in terms of relative incomes), but not intertemporal scale invariant (given the way in which the per-period weights are defined). Although R and M are usually used to describe within-generation mobility, in principle they could also be used to describe mobility between generations. R and M are distinctive in that they are well defined when there are data for many periods, but they can also be calculated if there are only two (the typical situation with intergenerational data).

A nice feature of the Shorrocks approach is that it can be used in two ways. The first is to calculate a single index value conditional on a particular value of T (and inequality index). This fixed-window calculation can be employed, e.g., to examine trends in income mobility over time in a country using moving fixed-width windows. Second, one can examine how $R(T)$ changes as T is increased from its minimum value of 1 to some larger maximum (i.e., there is one window, the width of which is varied). The resulting rigidity and mobility profiles provide a straightforward graphical device for comparisons of the extent of mobility within a country, and also comparisons across population subgroups and countries. Rigidity profiles for the United States and Western Germany from a pioneering cross-national study of income mobility discussed further in the next section are shown in Figure 10.8. The profile for Western Germany lies everywhere below that for the United States: Whatever the accounting period used, mobility is greater in Western Germany than in the United States.

Clearly, the values derived for the Shorrocks indices are conditional on the inequality index employed for the calculations. It is also well known that inequality indices differ in the sensitivity to income differences in different parts of the income distribution (Atkinson, 1970). So, it is important to know how estimates of rigidity and mobility relate to choice of inequality index, and how differences in inequality index sensitivity translate into mobility index sensitivity. It has been found as an empirical regularity, from Shorrocks (1981) onward, that using different indices can make a big difference to the estimates of R derived and also that the Gini coefficient tends to show greater R values

[28] By conventional relative inequality indices we mean all those that are convex functions of relative incomes (incomes expressed relative to the mean income), that is, all those that satisfy the Principle of Transfers. This excludes indices such as the variance of log incomes. R is bounded below by zero, assuming all incomes are positive.

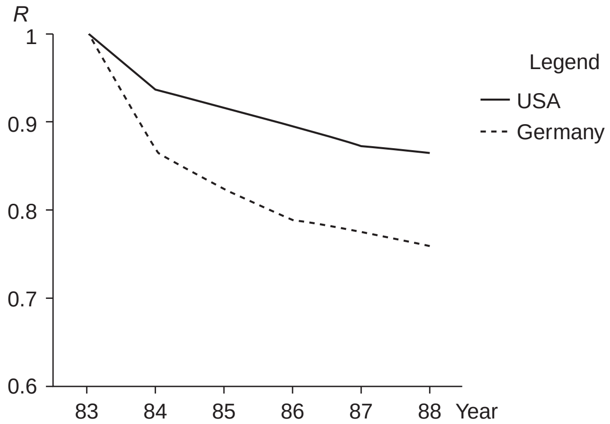

Figure 10.8 Income rigidity (longer-term inequality expressed as a fraction of total inequality) falls as the time period is lengthened. *Note: Income is posttax posttransfer income. The Shorrocks rigidity index R is computed using the Theil index of inequality. "Germany" refers to the federal states of Western Germany. Source: Burkhauser and Poupore (1997, Figure 2).*

than other inequality indices. The explanation is that "[since] the main effect of cumulating income is to average out incomes that are temporarily high or low, the strongest egalitarian trend will be found in the tails. The distribution of relative incomes in the middle range is not substantially affected by cumulating incomes over time" (Shorrocks, 1981, p. 182). Combine this information with the fact that the Gini coefficient is relatively insensitive to income transfers in the tails of the income distribution, and we have the result.

The sensitivity of *R* to the choice of inequality index is examined more systematically by Schluter and Trede (2003). For the two-period case, they show that the global rigidity measure, *R*, can be expressed, to a good approximation, as the weighted average of "local" rigidity comparisons at each point along the income range of a value for the longer-term averaged income, and the average of the per-period distributions. Differences in global measures arise, therefore, from a combination of differences in the way the different inequality indices summarize local comparisons at each point along the income range, and the different weighting systems that they incorporate. Schluter and Trede (2003) show that the sensitivity of mobility measure to choice of inequality index is partly dependent on data, but they also show some clear empirical regularities. For example, the weighting functions for commonly used generalized entropy indices and the Gini coefficient are broadly similar around the middle of the distribution (relative income = 1) and tend to place greater weight on mobility at the tails of the distribution. In addition, the overall U-shape for the weighting function is distinctly shallower for the Gini than for the other indices (as Shorrocks argued). Given the ready availability of longitudinal data on incomes nowadays (see the next two sections), it is straightforward for researchers to examine sensitivity empirically.

Refinements to the Shorrocks approach have gone in two main directions. The first addresses the assumption that individuals are able to smooth incomes across time: see the discussion in Section 10.2. This aspect is relaxed by Maasoumi and Zandvakili (1990) and Zandvakili (1992), building on Maasoumi and Zandvakili (1986). See also the survey by Maasoumi (1998). The basic idea is to allow for different degrees of substitutability between incomes in different periods. Thus, rather than defining longer-term income for each individual as the simple arithmetic average, it is defined as a generalized mean for which the choice of a parameter tunes the degree of substitutability. A common parameter is used for each individual, and yet one would expect the ability to smooth income over time to vary with, e.g., income level. Incorporating such heterogeneity into an index would be a rather complicated exercise and has not been done, as far as we are aware. As it is, researchers wishing to implement the Maasooumi–Zandavakili variant on R need to choose a substitutability parameter as well as inequality index. Of course, estimates can easily be derived for a number of combinations but the volume of results produced is probably one reason the approach is not commonly used. Also, the empirical illustrations provided by Maasoumi and Zandvakili (1990) and Zandvakili (1992) tend to suggest that the more general index tended to provided qualitatively similar results to that of the Shorrocks approach.[29]

The second refinement to the Shorrocks approach is to reconsider the reference point against which longer-term inequality values are compared. The main argument of Fields (2010, p. 410) is that "[w]hat we as empirical researchers would want to know in a given context is the extent is the extent to which the mobility that takes place works to *equalize* longer-term incomes relative to base, *disequalizes* longer-term incomes relative to base, or has no effect" (emphasis in original). This leads to Fields' proposal that the denominator in the expression for R be changed from the weighted average of the per-period inequalities to the inequality in first-period income. Chakravarty et al. (1985) emphasized rather different aspects in the derivation of their mobility index: they were concerned with "ethical" indices of relative income mobility, which are derived from SWFs and measure changes in welfare. Mobility is the percentage change in social welfare (measured by the equally distributed equivalent income, defined in the Atkinson (1970) sense) of the actual distribution of longitudinally averaged incomes compared to what social welfare would have been in the completely immobile benchmark distribution—taken to be the observed period-1 distribution.

[29] Maasoumi and Zandvakili (1990) and Zandvakili (1992) were also the first to provide decompositions of total mobility calculated using Shorrocks-Maasoumi-Zandvakili indices into components representing within-group mobility and between-group mobility. They did not provide formulas for the decomposition, however. For these, see Buchinsky and Hunt (1999, p. 354).

If the same welfare function is used to evaluate both distributions, and that SWF is homothetic, then the mobility measure "has a natural interpretation; it is the percentage change in equality of the aggregate distribution compared with the first-period benchmark" (Chakravarty et al., 1985, p. 6). Although the authors go on to state that it appears there is no convincing ethical argument for applying the same welfare function to both distributions, all empirical applications that we are aware of have applied the same welfare function. The class of mobility indices for the two-period case is then defined as (Chakravarty et al., 1985, p. 8):

$$C = \frac{1 - I[Y(T)]}{1 - I[Y^1]} - 1, \tag{10.10}$$

where I is a relative inequality index equal to one minus an index of relative equality (as is the case with the Atkinson (1970) class of inequality indices). It turns out that the Fields (2010) mobility index, $1-[I[Y(T)=I[Y^1]$, equals κC where $\kappa=(1-I[Y(T)])=I[Y^1]$, and so the measures are closely related (assuming the same inequality index is applied in each case). But it is possible for them to differ about whether mobility has increased or not: the value of κ matters. In short, ethical index C always evaluates mobility as welfare-increasing (but of different degrees), whereas the more descriptive Fields (2010) index allows mobility to be positive or negative. A more fundamental issue, common to both indices, is whether one agrees with the proposal to accord special normative status to period-1 incomes relative to incomes in other periods—which is an issue that has arisen with other mobility measures as well.

The concept of comparing short- and longer-term incomes has been used to examine poverty persistence in particular as well as income mobility in general. The basic building block is again "longer-term income," a measure of longitudinally averaged income for each individual, and people are defined as "chronically" poor if their longer-term income is less than the poverty line. Chronic poverty in aggregate is the poverty in the population calculated using a poverty index that is additively decomposable over people and time (e.g., a member of the Foster et al., 1984 class). Transitory poverty is Total Poverty (poverty calculated over individuals and separate time periods) minus Chronic Poverty. The main papers to date in this tradition are Rodgers and Rodgers (1993, 2009), Chadhuri and Ravallion (1994), and Jalan and Ravallion (1998). See also the development by Duclos et al. (2010), which takes a more explicitly welfarist approach. As with the Shorrocks mobility measures, there is an important issue concerning how longer-term incomes are calculated and (related) the assumptions made about abilities to income smooth. See, e.g., the discussion by Rodgers and Rodgers (1993, pp. 34–35).

The final group of more specialist mobility indices we discuss are those that summarize notions of income risk. These can be classified in two main ways. On the one hand, there are measures of the transitory variance of (log) income, calculated using either model-based or nonparametric approaches and generally requiring income data for multiple periods. On the other hand, there are measures of income flux, income movement, and volatility, generally defined over incomes in two periods only. We consider the approaches in turn and discuss the relationships between them and the measures of longer-term inequality reduction.

To fix ideas,[30] suppose that the dynamics of income for each individual can be described using the canonical random effects model

$$\log y_{it} = u_i + v_{it}, \tag{10.11}$$

where y_{it} now refers to the income for person i in year t. It consists of a fixed "permanent" random individual-specific component, u_i, with mean zero and constant variance σ_u^2 (common to all individuals), and a year-specific idiosyncratic random component with mean zero and variance σ_v^2 (common to all individuals) that is uncorrelated with u_i. Thus total inequality as measured by variance of log incomes is equal to the sum of the variance of "permanent" individual differences plus the variance of "transitory" shocks:

$$\sigma_t^2 = \sigma_u^2 + \sigma_v^2. \tag{10.12}$$

Assuming that permanent differences are relatively fixed over time, changes over time in income inequality (σ_t^2) arise mostly through changes in the variance of the transitory component. The interpretation of this latter component as idiosyncratic unpredictable income change leads to the association of changes in its variance with changes in income risk.

This canonical model is patently unrealistic in several respects, and three types of extension have been incorporated.[31] The first additional factor allows the relative importance for overall inequality of the permanent and transitory components to change with calendar time. For example, if there is an increase in the demand for skilled labor, and permanent component of income represents relatively fixed personal characteristics related to skills (for example human capitals of various kinds), then greater inequality resulting from widening differences over time in returns to skilled versus unskilled labor can be represented as the growing importance of the permanent component. In contrast, a secular trend toward greater labor market flexibility can be represented as a growth in the importance of transitory variations. The second additional feature is persistence in

[30] The exposition in the next few paragraphs draws heavily on Jenkins (2011a, chapter 6).

[31] For surveys of model specification and estimation methods, see inter alia, Baker and Solon (2003), Guvenen (2009), Meghir and Pistaferri (2011), Haider (2001), Shin and Solon (2011), Moffitt and Gottschalk (2012), and the references cited in these sources and in Section 10.4. Note that these variance components models have usually been applied to data on men's earnings and only rarely to household income. See Jenkins (2011a, chapter 6) for further discussion.

transitory shocks. The factors leading to a temporary fall (or rise) in income in one year are likely to have effects that last longer than a year: a transitory shock persists but with diminishing impact and eventually dies out. An example might be an accidental injury leading to a reduction in work hours that diminishes over time. This is usually characterized using an autoregressive moving average process for v_{it}.

The third modification to the canonical model is to allow the fixed individual component to change over time. Two main approaches have been followed, originally distinct but now commonly combined. One is to allow u_i to vary over time via a "random walk": this year's value is equal to last year's value plus or minus a random element. The second approach allows for individual-specific rates of growth in income (the "random growth" model). The expression for the permanent component is modified so that it also varies linearly with time but with heterogeneity in this slope. Both a random walk and random growth lead to a fanning out of the income distribution over time, other things being equal. Rankings are preserved; those at the bottom stay at the bottom but fall further behind those at the top, who stay at the top. It is increases in the transitory variance that increase mobility in the sense of reranking.

The estimation of transitory variances (mobility) and permanent variances using these models is common, but has also been criticized on the grounds that estimates are sensitive to the particular model specification employed, and there are potential identification issues with the relatively short household panels used to estimate the models (see, e.g., Doris et al., 2013; Guvenen, 2009; Shin and Solon, 2011). This has led to simpler nonparametric methods also being regularly used.

The most common nonparametric method for deriving estimates of variance components is the window-averaging method first employed by Gottschalk and Moffitt (1994), also known as their BPEA method (the acronym refers to the journal in which their work was published). The BPEA method works by first calculating the longitudinal average of each person's log income over a time window of fixed width, say T years. This provides an estimate of the person's "permanent" income for that period and is directly analogous to the longer-term income concept used to derive R except that it refers to averaging of log incomes. (If Equation 10.11 describes the income-generation process, the longitudinal average is an estimate of u_i.) The transitory incomes for each individual within the window are derived as a difference between this permanent income and observed log income, from which can be calculated the individual-specific transitory variance. The overall sample transitory variance is the average of these variances. The sample permanent variance for each window is calculated from the differences between each person's permanent income and the sample grand mean of these, with an adjustment to account for the fact that the mean contains a proportion of the transitory component that has not been fully averaged to zero over the T-year window. See Gottschalk and Moffitt (2009, p. 7) for full details of the formula, and Kopczuk et al. (2010, p. 98) for a small variation on the same theme. The BPEA method is known to provide biased estimates of the transitory variance and its trend if the permanent component's contribution changes over time (see, e.g., Shin and Solon, 2011). Using shorter-width windows for the calculations (smaller T) reduces the potential impact of this problem, but at the cost of reducing the statistical reliability of the estimate of each person's permanent income.

It is inevitable that measures derived using methods like the BPEA one will reflect the variability from permanent shocks and not only from transitory shocks. Shin and Solon (2011, p. 977) argued that this is a virtue of such measures: "The recent interest in volatility trends stems in large part from a concern about whether earnings risk has increased. Because permanent shocks, such as those experienced by many displaced workers, are even more consequential than transitory ones, it makes good sense to include them in the measurement of earnings volatility." Their own calculations use instead a measure of volatility that will be discussed shortly.

Both of the two main methods for estimating transitory variances have potential weaknesses, and there are virtues in using both as well as other measures (such as of volatility) as a sensitivity check. (This is increasingly done, as the next section shows.) Regardless of estimation method, there is a distinction between measures of mobility that are based on the transitory variance itself and measures that are based on the transitory (or permanent) variance expressed as a proportion of the total variance. Most discussion uses the former as the definition of mobility in the form of income risk.

Some authors also present estimates of the permanent variance expressed as a proportion of the permanent variance, and note that, if estimated using the BPEA method, there is a close relationship with the estimates of the Shorrocks measure of income rigidity R. See, e.g., Burkhauser and Couch (2009) and also Chen and Couch (2013, p. 202), who state that they prove that "under one testable condition a measure of economic mobility formed by the ratio of permanent to total variance employing the methods of Gottschalk and Moffitt (1994) is equivalent to the Shorrocks R constructed with a Theil General[ized] Entropy Index." It is clear that there must be some relationship, but we believe that it is not as close as stated by these authors, for the simple reason that the BPEA method calculation uses log incomes, and calculations of R invariably use incomes expressed in levels rather than logs. Evidence showing that a BPEA-estimated ratio of permanent to total variance and Theil-based estimate of R can move in opposite directions appears in Bayaz-Ozturk et al. (2014, Figure 2). For a related discussion, see also Shorrocks (1981, Section 6), who considers the shape of the profile for $M(T)$ in the case in which incomes—not log incomes—follow the basic canonical random effects model (cf. Equation 10.11) and inequality is calculated using half the squared coefficient of variation. He shows that were the model to hold, $M(T)$, would converge to its limiting value fairly rapidly. Slow convergence is evidence that the canonical model is inappropriate.

Income volatility in a given year t, V_t, is commonly measured by the standard deviation (SD) of the distribution of individual changes in log income between 1 year and an earlier year:[32]

$$V_t = \mathrm{SD}[\log(y_{it+\tau}) - \log(y_{it})]. \tag{10.13}$$

Changes are typically measured over a one- or two-year horizon: $\tau = 1$ or 2. The Fields and Ok (1999b) index of individual income growth ($D1$ discussed earlier) is the mean of the distribution of log-income changes. Volatility is therefore a measure of dispersion of the same distribution using one specific index of inequality. There are further connections: If the Gottschalk–Moffitt BPEA method is used to calculate the transitory variance in the two-period case, the resulting estimate is equal to one-quarter of the variance of the change in earnings (i.e., V_T^2 with $T = 2$). See Moffitt and Gottschalk (2012, p. 218), who also point out that the relationship no longer holds if the data window is longer than two periods.

This brings us to the measures of income flux, most commonly associated with the names of Fields and Ok (1996, 1999b), who proposed a number of measures of nondirectional income movement for the two-period case. Although such indices are rarely related to the measure of income risk discussed so far, their inventors had this application in mind: "A measure of income movement ... identifies how unstable the incomes of individuals have been throughout the time period. Since income instability may cause economic insecurity, ... measure of income movement are useful complements to the traditional measures of relative income mobility" (Fields and Ok, 1999b, p. 455). In their 1996 paper, Fields and Ok consider what they label absolute measures of income movement. First, they propose a number of axioms to describe measures for a fixed population of N individuals: linear homogeneity (equi-proportionate increases in all incomes, in base and final year, lead to the same proportionate increase in the measure); translation invariance; a normalization axiom; decomposability (total mobility for the N individuals is a symmetric function of the income changes for each individual); growth sensitivity (if two bivariate distributions are identical except that in one distribution an individual experiences more income movement than in the other distribution, total mobility differs in the two distributions); and, finally, the axiom of individualistic contribution (the contribution of each individual's mobility to total mobility does not depend on how other people's incomes change).

Fields and Ok (1996) prove that the measure satisfying these seven axioms is the sum over the N individuals of the absolute differences between period-1 and period-2 incomes (i.e., $|y_i - x_i|$, for each individual $i = 1, \ldots, N$). The final step is to consider

[32] See, e.g., Shin and Solon (2011). Other variants use a different definition of proportional income change, most often the arc percentage change See, e.g., Dynan et al. (2012). This has the advantage of allowing for zero income values in the estimation of volatility.

versions of these measures that would enable comparisons across populations of different sizes. Specifically, their per capita measure of absolute measure of absolute income movement is

$$D2 = \frac{1}{N}\sum_{i=1}^{N} |y_i - x_i|. \tag{10.14}$$

Their "percentage" measure is the same as $D2$ except that the denominator is total income in period 1 rather than population size and has been less commonly used perhaps because it is unclear that the base year should be used as the reference point (see our earlier discussion).

In their 1999 article, Fields and Ok took a similar similar set of axioms but also considered scale-invariant measures of movement as well as translation-invariant ones. This leads to the per-capita relative movement index, given by

$$D3 = \frac{1}{N}\sum_{i=1}^{N} |\log(y_i) - \log(x_i)|. \tag{10.15}$$

Both $D2$ and $D3$ are additively decomposable by population subgroup: total income movement can be expressed as the weighted sum of the movement within each subgroup, where the weights are the subgroup population shares. Fields and Ok (1996, 1999b) show that $D2$ and $D3$ also satisfy a different sort of decomposition: in each case, aggregate income movement can be expressed as the sum of a component representing income "growth" for individuals and a residual component that can be interpreted as income "transfers" between individuals. (Slightly different versions of the decomposition apply depending on whether the average of the first component is positive or negative.) It turns out in the case of $D3$ that the growth component of this decomposition is the directional measure of proportionate income growth ($D1$) discussed earlier.

To return to the remarks earlier about the links between measures of income flux and other measures of income risk, observe that the variance of log-income changes between two periods can be written as $E(d_i)^2 - E^2(d_i)$, where E is the expectation operator, and $d_i = \log(y_{it+\tau}) - \log(y_{it})$. That is, volatility-squared is equal to the average of the squared log-income changes, minus the square of the average log-income change. The first term is a measure of income flux in which the distance concept used to record income changes is Euclidean distance. Thus, there is a close relationship between orderings by this measure and a volatility measure when average log-income changes are "small." This Euclidean distance measure is characterized axiomatically by D'Agostino and Dardanoni (2009b), who also compare their approach with that of Fields and Ok (1996, 1999b). A measure incorporating the Euclidean distance concept is also characterized axiomatically by another pioneering paper on the measurement of income movement, by Cowell (1985) (see also Cowell and Flachaire, 2011) The axiom set is rather different in Cowell's

(1985) paper, however, and also leads to parametric classes of subgroup decomposable measures of "distributional change." These indices have rarely been used in empirical applications, however, perhaps because their properties (in particular the implications of choosing different parameters) are rather opaque in comparison with the overt transparency of measures like $D2$ and $D3$.

This completes our review of the many measures of income risk. A question that could be asked about all of them is whether they actually measure income "risk" in a more fundamental sense, namely the ex ante uncertainty aspect drawn attention to by, e.g., Gottschalk and Spolaore (2002). As Creedy et al. (2013, p. 236) remind us, this requires a model of expectations formation based on observed income dynamics. There are also additional complications for welfare evaluations such as the extent to which observed income changes reflect voluntary decisions of individual and families and the extent to which these are insurable (and how these aspects differ across people). These complicated underpinnings are absent from the measures we have discussed. At the other extreme are more structural models such as proposed by Blundell et al. (2008) and Cunha et al. (2005). Our overall assessment is that the measures we have discussed are useful descriptive measures despite these flaws. Their relative simplicity facilitates transparency and interpretation as well as empirical implementation. But they should be interpreted cautiously.

Our final remarks concern the applicability of the mobility measures to intragenerational and intergenerational data. As we have noted, different mobility concepts may be more relevant in one context than another. For example, positional mobility concerns appear of particular relevance to discussions of intergenerational mobility and income growth of particular relevance to discussions of intragenerational mobility. But structural intergenerational mobility is also of interest, and so too is the identification of intragenerational reranking along with income growth. By providing a unified treatment of mobility measures, we hope that some cross-context fertilization may be facilitated. In principle (and data permitting), all the measures we have discussed could be used in either context. In the two sections that follow, reviewing empirical evidence about intra- and intergenerational mobility, we reveal which measures have been used to date.

10.4. INTRAGENERATIONAL MOBILITY: EVIDENCE

This section assesses evidence about within-generational income mobility. It first considers definitional issues, the nature of the longitudinal data available, and issues of empirical implementation, and then it turns to the evidence itself. Our review of the topics is selective. We draw on and refer readers to Jenkins (2011a, chapters 2 and 3) for a much more extensive discussion of data sources for within-generation mobility and related empirical issues, as well as extensive references to other literature. Our survey of evidence concentrates on findings emerging over the last two decades, and gives greatest attention to the United States, with examination of trends over time and cross-national comparisons between the United States and (Western) Germany, but studies for other countries are also considered. Our focus reflects the emphasis in research to date, and this, in turn, is related to the availability of suitable data (as we explain). Also, to make the review manageable, the focus is on mobility of household income rather than of individual labor earnings (though selected earnings studies are referred to). We show how conclusions about trends over time and cross-national differences vary with the mobility concept chosen.

Issues of statistical inference are ignored here. On these, see, e.g., Biewen (2002) and Chapter 7.

10.4.1 Data and Issues of Empirical Implementation

Any study of income mobility faces three "W" issues: mobility of What, among Whom, and When? Studies of trends over time or across countries add another issue, that of comparability. The choices that researchers can make under these headings are much constrained by the sources of longitudinal data that are available. But the data situation has improved substantially over the last two decades. (Contrast the situation described later with the discussion by Atkinson et al., 1992, chapter 3, which focuses on earnings.) Although many of the "W" issues arise in any study of income distribution, looking at mobility adds some extras twists to those arising in cross-sectional analysis.

Mobility of "What" refers to which income sources are included in the definition of "income." Definitions typically range from measures with only a single source (typically earnings from employment) to a broader measure such as household income, which includes multiple sources. Many variations are possible (e.g., labor earnings may refer to employment earnings only, or earnings from all jobs that an individual has, and may also include self-employment earnings, thought often not). There are multiple definitions of income as well. The most common distinction in empirical work is between measures of pretax pretransfer income, pretax posttransfer income, and posttax posttransfer (also often labeled original or market or pregovernment income; gross income; and net, disposable, or postgovernment income, respectively). Pregovernment income typically includes labor earnings, income from savings and investments, and transfers received from nongovernment sources. Taxes usually refer to taxes on income (typically at national level, sometimes also including local taxes) and contributions levied for public pensions. "Transfers" usually refer to cash benefits received from the state.[33]

Mobility among "Whom" refers to the definition of the income-receiving unit. Clearly this is closely related to the issue of What. For example, it is individuals that receive labor earnings. Benefits are assessed and income taxes levied on families and

[33] For a comprehensive discussion of the various definitions and recommendations for measurement, see Expert Group on Household Income Statistics (The Canberra Group, 2001).

households. Individuals not in paid work such as stay-at-home mothers or children, often do not receive income in their own right, but benefit from income sharing with families and households. Putting things another way, note that analysis of earnings mobility is typically restricted to workers with earnings, excluding those without earnings, many of whom are women, children, or of retirement age. In contrast, it is typically assumed that each individual receives the (equivalized) total income of family (or household) to which he or she belongs. Because total household income is rarely zero, all individuals, regardless of age or labor market attachment, can in principle be included an analysis of income mobility. There is no universally correct definition of the income unit, and which should be used depends on the goals of the mobility analyst. For example, in a study of labor market flexibility, a focus on individual earnings is appropriate (though there remain questions about whether women can and should be included in such analysis—much empirical analysis is of men only). On the other hand, if the interest in mobility is stimulated by a desire to describe and summarize important features of society as a whole, then there is a strong case for using more inclusive samples. As we show later, some empirical studies focus on individuals of working age (variously defined), others on all individuals, and this can complicate cross-study comparisons.

"When" mobility issues refer to two aspects related to time. The first is the length of the period to which income refers to. For instance, is it the hour, week, month, or year? Economists often argue in favor of longer reference periods (e.g., a year) on the assumption that temporary variations and measurement error are smoothed out, thereby providing a more *accurate* measure of living standards. There is relatively little empirical evidence available about the veracity of this hypothesis because analysts rarely have income data for the same people over both shorter and longer periods. Böheim and Jenkins (2006) surveyed the literature and, from their analysis, argued that income mobility calculated using current (monthly) and annual income definitions are similar, and they provide a number of data-related reasons. Cantó et al.'s (2006) analysis is more comprehensive; based on comparisons from quarterly and annual income data for Spain, they show that use of the longer assessment period leads to higher estimates of poverty prevalence, lower inequality, and less mobility.

A second "When" issue relates specifically to mobility analysis in particular rather than income distribution analysis in general. For much mobility analysis, the data refer to a bivariate income distribution in which the marginal distributions refer to 2 years, t and $t+\tau$, and empirical analysis of longer-term inequality reduction requires a definition of how many years constitutes the longer term. In both cases, how far apart the base and final years are will affect the conclusions because the longer the interval, the greater the possibilities of mobility (as we illustrate later).[34] Choices about what interval to use have implications for the analysis that one can undertake too because data sets cover a time

[34] This issue is, of course, closely related to the issue of income reference period discussed earlier.

period of particular length (rarely more than 20 or 30 years), so researchers can only look at mobility trends if they use relatively short time windows for their measures. The constraint becomes acute with longitudinal data sets like EU-SILC (discussed later) in which the maximum time period is 4 years.

How researchers can address the three "W" issues is much constrained by the data that they have available to them, and this raises issues of comparability over time and country. Longitudinal data sources suitable for within-generation income mobility analysis are of two main types.

First, there are household panel surveys in which nationally representative samples of the private household population are interviewed about their incomes and many other domains of their lives in an initial year and then reinterviewed thereafter at regular intervals (usually a year). Second, there are administrative registers (e.g., tax files) in which income records for individuals are linked longitudinally. Household panel surveys typically utilize income definitions (i.e., resolve the "What" and to "Whom" issues) that are consistent with definitions accepted as being of good quality in large cross-sectional surveys. By contrast, administrative record data are typically designed for administration of the tax and benefit system, and the definitions used of income and the income-receiving unit, and the population that is represented, are determined by the needs of administration rather than by research. But register data also have advantages relative to surveys: Their samples are very much larger, issues of respondent dropout or measurement error do not arise in the same way (see the discussion later), and coverage of the very richest income groups is much better (they are typically not reached by surveys).

The clinching argument for empirical researchers in favor of household panel surveys over administrative registers is that the former became widely available for many countries, especially from the mid-1980s onward, with cross-nationally harmonized versions of the data following a few years later. Administrative registers with longitudinal income data have remained rare until recently in most countries, with the exception of Scandinavian countries, which have a rather longer history of use.

The longest-running household panel is the U.S. Panel Study of Income Dynamics (PSID), which began in 1968 and still continues, though it changed from annual interviewing to biennial interviewing after 1997. Panels started in the early 1980s in the Netherlands and Sweden, but the most well-known European panel is the German Socio-Economic Panel (SOEP), which started in the 1984 and is still running. Other country panels include the British Household Panel Survey (BHPS), which started in 1991 and finished in 2008. (The BHPS was recently replaced, after a break, by a new and very much larger panel (Understanding Society), which incorporates most of the original BHPS sample.) The Household, Income and Labour Dynamics in Australia (HILDA) survey began in 2001 and is ongoing. There is also Survey of Labour and Income Dynamics (SLID) for Canada, which is a rotating panel operational between 1998 and 2011.

As shall be seen later, it is the household panels cited in the last paragraph that have provided most of the empirical evidence about income mobility over the last two to three decades, both in their native format (often to examine trends over time within a country) or in a harmonized form (to undertake cross-national comparisons). The production of cross-nationally comparable household panel data with harmonized labor earnings and household income variables has been one of the major successes in social research infrastructure creation over the last few decades.

The Cross-National Equivalent File (CNEF) began in 1991 with harmonization of data from the U.S. PSID and German SOEP and incorporated the BHPS and SLID in 1999 and HILDA in 2007. (Data for more countries have been added subsequently.) It should be stressed that the project does more than simply harmonize variables; it adds value. One important example of this is the derivation of comparable posttax posttransfer household income variables. The original PSID family income variable refers only to pretax posttransfer income, and the government transfers do not include income derived from nonrefundable tax credits (the EITC) or near-cash benefit income in the form of Food Stamps (now called SNAP). The CNEF uses the NBER TAXSIM model to simulate taxes. Similarly, involvement in the CNEF project was a stimulus for the SOEP to develop and maintain a similar model in-house. (Other CNEF members also use such models.) For a more detailed discussion of the CNEF, see Frick et al. (2007).[35]

Another important initiative providing cross-nationally comparable panel data on incomes was the former European Community Household Panel (ECHP), though this has been used less often for mobility analysis than the CNEF and its constituent panels. The ECHP relied on "input" harmonization by contrast to the CNEF's "output" harmonization. That is, household panel surveys with the same design and questionnaires including the same variables were fielded in a number of countries, so that harmonization was built in from the start. Data from a maximum of eight annual interview rounds are available, covering the period 1994–2001. Twelve EU member states participated in the ECHP initially, with two more joining shortly thereafter. The ECHP never realized its full potential because, for many years, researcher access to the data was constrained and financially costly. This is in contrast with the CNEF, which from the start has had a much more open data access policy and has been more research(er) driven.[36]

The ECHP was replaced—after a gap—by the European Statistics on Income and Living Conditions (EU-SILC) from 2005. EU-SILC is explicitly designed to deliver data on a set of social indicators that include income distribution statistics. This is output

[35] For documentation and user access information, see http://cnef.ehe.osu.edu/ or http://www.human.cornell.edu/pam/research/centers-programs/german-panel/cnef.cfm.

[36] The Survey of Health, Ageing, and Retirement in Europe (SHARE) is another multicountry longitudinal study proving input-harmonized income data, and also research driven. Its focus, however, is on older individuals, and so it cannot be used to study income mobility in the wider population.

harmonization again, though the target variables are predefined by the needs of EU policy making rather than by researchers. Some member states use administrative registers to produce the data; others use panel surveys, an aspect that has led to questions about data comparability (see later). The longitudinal data in the publicly released EU-SILC data sets track individuals for a maximum of 4 years (by design), and so the scope for longer-run mobility analysis is ruled out. The great advantage of the EU-SILC longitudinal data is that, when mature, they will cover all EU member states. Understandably the EU-SILC has not been much used for income mobility to date, and this is reflected in our review of evidence that follows.

This review of data sources suggests that there has been a substantial increase over the last three decades in the volume of high-quality longitudinal data available to researchers. But there remain a number of important issues of empirical implementation that need to be kept in mind when assessing the value of a particular mobility study. So, before turning to discuss empirical evidence, we briefly review these issues.

There are generic issues associated with longitudinal surveys, notably the potential problem of survey attrition. Over time, some respondents to a panel survey drop out from the data, either no longer wishing to participate or unable to be tracked down for interviews. Attrition has two potentially adverse effects. The first is reduction of sample size, with consequences for the precision of estimates. The second potential effect, more commonly discussed, is on the representativeness of the sample. Particular groups such as young people tend to be more likely to drop out, in which case estimates may be biased.[37] Differential attrition may be related to both observed and unobserved characteristics of individuals and families. For the former case, data producers routinely produce and release sets of weights that can be used to maintain the representativeness of estimates, and virtually all the studies cited in our evidence review use these weights. By definition, it is harder to assess the effects on estimates of differential dropout related to unobserved characteristics; it requires modeling of the attrition process. For an extensive discussion of attrition in U.S. household panel surveys, see Fitzgerald et al. (1998) and other papers in the Summer 1998 issue of the *Journal of Human Resources*.

The likely impact of attrition is associated with the type of mobility analysis undertaken. Attrition between successive waves of a household panel is typically relatively low (around 5%) with the exception that dropout rates are noticeably greater between the initial and second waves. Estimates of mobility over short periods (1 or 2 years, say) are likely to be less affected by attrition than estimates based on long runs of data.

[37] Representativeness typically refers to the ability of the sample to represent the private household population in the first wave of the panel. If a country experiences significant migration or immigration, a panel inevitably becomes unrepresentative of the population in later years. Sample refreshment has been employed to counter this problem, but if mobility estimates are required for time points spanning the old and new population structures, refreshment cannot improve representativeness.

Respondents may remain in a longitudinal survey, but not provide complete responses to particular questions, either because they do not understand the question, do not know, or do not wish to provide the answer. This is the issue of "item" nonresponse leading to missing data for some respondents and, as with attrition, may be associated with both observed and unobserved respondent characteristics. Item nonresponse is particularly prevalent for questions about income sources by comparison with items such as, e.g., a respondent's age. In the public-use panel data sets used by mobility researchers, missing income values are typically replaced by an imputed value (together with a flag that enables identification of such observations) generated using procedures allocating similar values to respondents with similar sets of (observed) characteristics. Imputation is very useful for analysts but can potentially have effects on analysis because, by comparison with nonimputed data, extra "noise" is added by the inevitable imperfection of the process.[38] These can have particular effects on mobility analysis because some of the changes in a person's income over time may simply reflect the imputation process in the different years. But if one simply drops the imputed observations, there may be a critical loss of sample size and use of a potentially nonrepresentative subsample. In most of the income mobility studies discussed later, analysts have routinely used imputed data on household income. By contrast, in studies of earnings volatility, it is a more common practice to drop imputed observations. Researchers tend to find that this reduces observed volatility, but the effects are relatively small. Again, the likely effects will depend on whether the particular mobility measure employed requires, say, two years relatively close together, or many years over a longer interval.

The problems raised by imputation are closely related to the more general issue of measurement error in earnings and income data. Even if survey participants respond to a question, their answer may be incorrect either because the respondent does not want to give the true answer or simply does not know what it is. Key issues are whether observed responses are systematically under- or overreports of the (unobserved) true value or simply random, and how errors are correlated across successive years of data for the same respondent. Clearly, the answers to these questions may differ by income source. The largest body of research on measurement error has been about labor earnings and used validation studies in which linked administrative record data are used to provide a picture of each worker's "true" earnings (see, e.g., the survey by Bound et al., 2001). Few studies have looked at the effects of measurement error on measures of earnings mobility.

The perhaps surprising finding of Gottschalk and Huynh (2010) is that estimates of men's earnings mobility, defined in terms of the Pearson correlation between log earnings in 1 year and the next, are much the same in the survey data and their administrative data

[38] The imputation of households' tax payments when deriving measures of posttax posttransfer income is another important example of useful imputation that may also add noise.

set. The result arises not because measurement errors are not important; rather, it is because they are "nonclassical" in nature (i.e., mean-reverting and correlated across years), and these various features happen to offset each other. See also Fields et al. (2003), who use a nonclassical measurement error model similar to that of Gottschalk and Huynh (2010) to put bounds on estimates of income change. For the case considered, they argued that the effects of measurement error are "relatively minor" (Fields et al., 2003). Dragoset and Fields (2006) calculated a large portfolio of mobility measures from both survey and linked administrative record data on U.S. men's earnings. They concluded that most of their qualitative results are the same in both data sources, and that the estimates from the administrative source were neither systematically above nor below the corresponding survey estimates. Overall, this small body of research might be taken to imply that measurement error has relatively unimportant effects on measures of mobility in practice. We would caution against this interpretation, convenient as it is for empirical researchers; the situation is more that we know rather little at present. All the studies cited refer to earnings for U.S. men, and results may differ for household income and in other countries. (The only similar study for household income that we are aware of is by Rendtel et al, 2004, who also reported finding mean reversion and serial correlation.) There is also a more fundamental question of whether administrative record data can be assumed to provide error-free representations of the truth (Abowd and Stinson, 2013).[39]

A rather different sort of measurement error arises in the case of outlier observations, for example, very high or very low observations. These may be genuine but may also represent errors of, e.g., transcription leading to additional zeros being added. The problem is that even if the number of observations with this kind of data is very small, they may have a big influence on the estimates that are derived. This lack of robustness is undesirable. See Cowell and Schluter (1999) for a discussion of this problem in the context of income mobility analysis. Empirical analysts' response to this issue is usually to simply drop a fraction (e.g., 1%) of the very richest and of the very poorest income values in each year. This procedure, known as "trimming," or similar algorithms directed at removing potential outliers, has been applied in virtually every study cited in our discussion of empirical evidence.

A final empirical issue is whether income changes over time represent genuine mobility or, instead, systematic changes associated with life cycle patterns of such earnings following an inverse-U shape with age. Many income mobility studies do not adjust for this

[39] Aside from analysis based on validation studies, there have been a small number of model-based assessments of the impact of measurement error on estimates of poverty transition rates: see, e.g., Breen and Moisio (2004) and references therein. Longitudinal data on observed transitions are combined with an assumption that the "true" transition probabilities are stable over time, so that difference between them is attributed to measurement error. In technical terms, the statistical approach involves fitting latent class models with a Markov structure. For further discussion, see Jenkins (2011a, pp. 53–55).

factor; they look at observed incomes. Some other studies, mostly of earnings mobility, have regressed observed earnings against variables such as age, and then the mobility analysis is of the earnings residuals: see later discussion.

10.4.2 Intragenerational Income Mobility in the United States: Levels and Trends

We take as our initial reference point the estimates of income mobility for the United States provided by Hungerford (2011), as he uses good-quality comparable data from PSID (as released via the CNEF) and provides a range of mobility summaries. (Transition matrices from the study were presented in Table 10.1 earlier.) Hungerford compared mobility over two 10-year intervals, 1979–1988 ("1980s") and 1989–1998 ("1990s"). The measure of income is annual disposable (posttax posttransfer) family income adjusted for differences across families in household size and composition using the equivalence scale proposed by Citro and Michael (1995). His samples include all individuals within households. In the 1980s sample, about half the SEO sample was dropped in 1997. All estimates are derived using the PSID's weights. We noted earlier that, in both periods, there appeared to be substantial short-distance mobility over a 10-year period, but long-distance moves were relatively rare. Moreover, the chances of upward mobility from the bottom and downward mobility from the top appeared symmetric. We now compare mobility in the two decades in greater detail, in particular considering whether mobility increased or decreased according to various mobility concepts and measures.

To assess changes in positional mobility, a natural first approach is to apply the dominance check of Atkinson and Bourguignon (1982) based on the differences in the discrete cumulative densities implied by the decile transition matrices in Table 10.1. See Table 10.2 for the estimated differences. First-order dominance does not hold; there is a mixture of positive and negative differences.[40] There is an interesting pattern, however. Most of the positive differences (greater cumulative density in the 1980s) are found in cells corresponding to movements out of or into the poorest fifth of the distribution. Put another way, there is greater movement in the 1980s than the 1990s into and out of the richest 80%, broadly speaking.

Saying conclusively that mobility increased or decreased in the United States between the 1980s and 1990s, and by how much, requires additional assumptions about the weighting of mobility in different parts of the distribution. Also, the answers depend on the mobility concept. These points are illustrated by the mobility index estimates reported by Hungerford (2011) and summarized in Table 10.3. The first three rows

[40] The density estimates and conclusions drawn from them need to be interpreted cautiously, not the least because they are susceptible to measurement error and sampling variability. If the estimates in Table 10.2 are rounded to 2 d.p. to reflect this (rather than 3 d.p. as reported), then many matrix entries become zero, and there is now dominance; positional mobility is greater in the 1980s than the 1990s.

Table 10.2 Differences in cumulative density: United States, 1979–1988 versus 1989–1998

Origin group	Destination group 1	2	3	4	5	6	7	8	9	10
1	0.2	−0.1	−0.2	0.0	0.3	0.2	0.1	0.1	−0.1	0.0
2	0.0	0.0	0.4	0.6	0.5	0.2	0.2	0.1	0.0	0.0
3	−0.2	−0.5	−0.2	0.0	0.0	−0.5	−0.1	−0.1	0.0	0.0
4	−0.2	−0.7	−0.6	−0.6	−0.7	−0.7	−0.2	−0.3	0.1	0.0
5	0.0	−0.3	−0.3	−0.5	−0.7	−0.5	0.0	−0.1	0.4	0.0
6	0.1	−0.1	−0.1	−0.4	−1.1	−1.3	−0.9	−0.5	0.4	0.0
7	0.1	0.2	0.0	−0.3	−0.8	−0.9	−0.8	−0.3	0.3	0.0
8	0.1	0.2	−0.2	−0.2	−0.3	−0.7	−1.1	−0.7	−0.3	0.0
9	0.0	−0.1	−0.3	−0.2	−0.4	−0.4	−0.7	−0.6	−0.6	0.0
10	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0

Note: The estimates are in percent, rounded to one decimal place, and show in each cell the cumulative discrete density for the 1980s minus the corresponding cumulative discrete density for the 1990s.
Source: Authors' calculations from Hungerford (2011, Tables 2 and 3), based on PSID data.

Table 10.3 Selected mobility indices (%): United States, 1979–1988 versus 1989–1998

Index	1979–1988	1989–1998
Decile mobility	79.1	77.0
Normalized trace	87.9	85.6
Gini mobility	36.2	34.4
Equalization (Shorrocks, Gini-based)	10.9	11.1
Equalization (Fields, Gini-based)	2.1	8.2
Average of absolute income changes (*D*l)	11,368	13,878
Average of absolute income share changes	0.421	0.459

Note: The estimates are in percent, rounded to one decimal place, apart from those in the last two rows (in constant-price dollars). Decile mobility is the proportion of persons changing at least one decile group. The normalized trace is the Shorrocks (1978b) index calculated from the decile transition matrix. The Gini mobility index is the index of Yitzhaki and Wodon (2005). The Equalization indices are those of Shorrocks (1978a) and Fields (2010). On the average of absolute income and income share changes, see Fields and Ok (1996) and Fields (2010). See text for more details.
Source: Authors' calculations from Hungerford (2011, Tables 4 and 8, and p. 97), based on PSID data.

of the table provide estimates of positional mobility (reranking), and all the indices show a small decline between the 1980s and 1990s. In contrast, the Shorrocks and Fields equalization indices record an increase, and so too do the two measures of income flux shown in the bottom two rows. For the last four indices, the estimated increase is small, with the exception of the Fields equalization measure, for which the large change reflects the increase in (cross-sectional) income inequality over the period. The general lesson is that conclusions about whether mobility increased or decreased between the 1980s and 1990s depend on the mobility index employed.

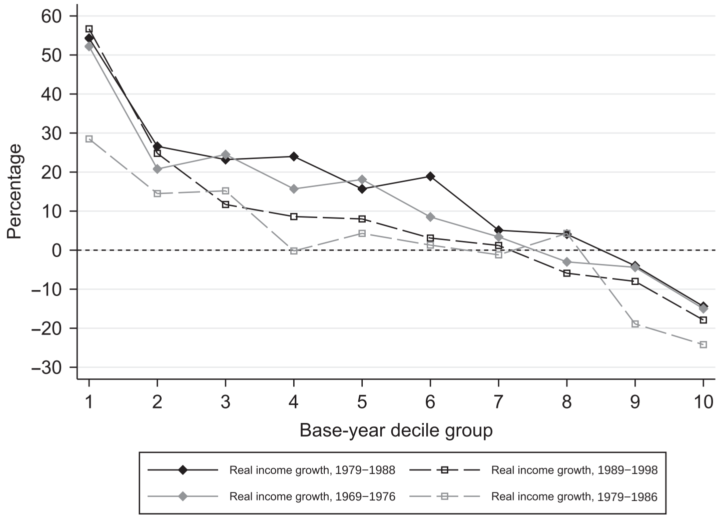

Figure 10.9 Median real income growth, by base-year decile group: United States, by period. *Note: The estimates show median income growth for each base-year decile group over the relevant period. Source: Hungerford (1993, Table 9) and Hungerford (2011, Tables 5 and 6).*

Mobility as individual income growth is also summarized by Figure 10.9, which shows the median real income growth for each base-year decile group, by period. (This is a grouped data version of Figure 10.7 discussed in the previous section.) Clearly income growth is pro-poor in the United States (consistent with regression to the mean), but the patterns differ between the 1980s and 1990s. Income growth was greater in the 1990s than the 1980s for the richest eight base-year decile groups, but no different for the two poorest base-year decile groups.

The extent to which U.S. mobility comparisons can be extended to periods before the 1980s and after the 1990s is restricted by data availability (e.g., the PSID only started in 1968) because different studies use different income variables and estimation samples and often do not report the same mobility statistics.

For example, Hungerford (1993) provides much information about U.S. income mobility in the 1970s and 1980s, but the estimates are not fully comparable with those in Hungerford (2011) because the earlier study uses a different income definition (pretax posttransfer income rather than equivalized posttax posttransfer income), and the interval between base- and final-years differs (8 years rather than 10; e.g., 1979–1986 rather than 1979–1988). The relevance of definitional differences is illustrated by the estimates for the "1980s" from the two studies of the proportions of individuals remaining in the poorest 10th and remaining in the richest 10th: 44.3% and 40.0% according to Hungerford (2011), but 49.0% and 42.1% according to Hungerford (1993, Tables 1 and 2). Look also at the different estimates of real income growth rates for the 1980s for the two periods in

Figure 10.9. Using the Hungerford (1993) definitions, the overall growth rate for the 1980s is smaller (which is unsurprising because aggregate income growth was positive throughout the mid-1980s; Hungerford, 2011, Table 1), but observe that the estimates of pro-poorness in income growth also differ (the income growth curves from the two studies do not have the same slope).

One can compare mobility in the 1970s and the 1980s, however. If we examine differences in cumulative densities using Hungerford's (1993) estimates, again there is no clear-cut mobility ordering (authors' calculations), and there is a broadly similar pattern of differences to that described earlier. Hungerford (1993) does not report summary indices to compare with those in Table 3, but two statistics based on the transition matrices (Cramér's V) and the contingency coefficient "are the same . . . suggesting that the degree of association between a person's decile rank in one year and another was the same in the 1970s and 1980s" (Hungerford, 1993, p. 407). Fields and Ok (1999a) used exactly the same data as Hungerford (1993) and reported that their measure of income flux, the average of the absolute changes in log income, increased from 0.498 in the 1970s to 0.528 in the 1980s.[41] So, again, changing the mobility concept leads to a different conclusion about trends.

Hungerford's (1993) study is also useful because it analyzes whether the estimated mobility patterns are robust to adjustment for transitory income variation. Specifically, Hungerford calculated each individual's 5-year longitudinally averaged income (centered on the year in question) and used these "permanent" incomes instead of the single-year incomes to define base-year and final-year income positions. Interestingly, the patterns of mobility revealed are remarkably similar, though with perhaps less movement at the top and bottom of the distribution.[42] For example, according the annual income calculations for 1979–1986, 12.9% of the poorest fifth remain in that group and 11.0% of the richest fifth remain in that group. According to the permanent income calculations, the corresponding estimates are 11.5% and 9.6% (authors' calculations from Hungerford, 1993, Tables 2 and 4).

To examine trends in U.S. income mobility further, we turn to Bradbury (2011). She provides estimates using consistent definitions for the period 1969–2006 and for a large portfolio of mobility indices. Her estimates are not fully comparable with Hungerford's, however. Although she and Hungerford (2011) both use posttax posttransfer real family income measures from the CNEF version of the PSID, they use different samples. Bradbury focuses on adults who are a family head or spouse rather than all individuals

[41] Fields and Ok's (1999a) decompositions reveal that the increase in income movement is entirely accounted for by persons with education to high school level or above and by young adults rather than prime-age adults.

[42] One potential noncomparability is that the estimation samples differ slightly; the permanent income estimates are based on balanced samples with valid data for all 5 years within the relevant period.

within families, both head and spouse (if present) are required to be of working age (16–62 years), and the time interval spans 11 years rather than 10. She used the square-root-of-household-size equivalence scale rather than the Citro and Michael (1995) one.

Trends in three general indices of positional mobility are displayed in Figure 10.10: the fraction of individuals changing decile group ("decile mobility"), one minus Spearman's rank correlation, and Yitzhaki and Wodon's (2005) Gini mobility index. All three indices are broadly constant over the 1970s and decline over the 1980s (11-year intervals starting at the end of the 1970s), with the rate of decline perhaps slowing from the late 1980s onward. The fall in mobility over the 1980s is consistent with Hungerford's estimates of trends based on only two intervals during this period, but is rather larger in magnitude. The Gini mobility index fell by about a sixth between the intervals starting in 1979 and 1989 (but only about 5% according to Hungerford, 2011). One minus the rank correlation fell by about one-fifth over the same period, and so the decline in positional mobility is relatively large. It is unclear what lies behind the secular decline in mobility, but we note that it was at the end of the 1970s that U.S. family income inequality also began to increase (Burkhauser et al., 2011), suggesting that inequality and positional mobility share some common drivers. There is no very obvious association between series' turning points and the business cycle (there were recessions at the beginning of the 1970s and 1980s).

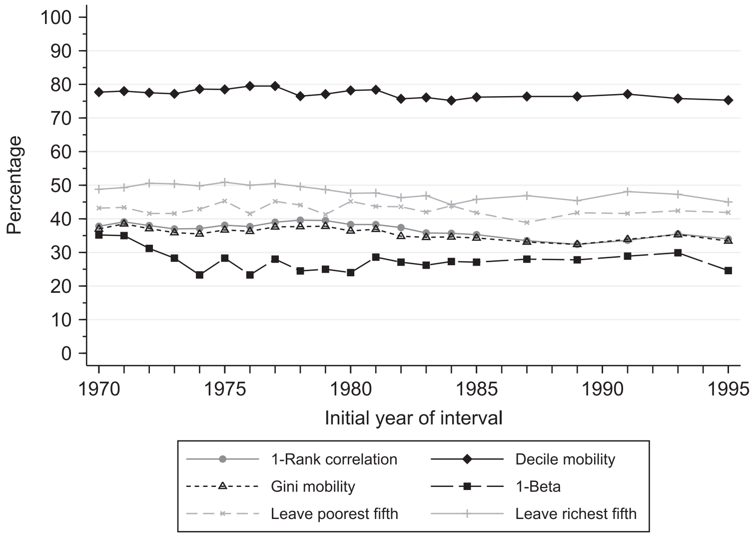

Figure 10.10 Indices of positional income mobility: United States, 1970–1995. *Note: The estimates refer to 11-year intervals, with incomes in base- and final-year averaged over 2 years. For example, the estimates labeled as 1970 refer to incomes longitudinally averaged over 1969 and 1970 (base year) and 1979 and 1980 (final year). See text for index definitions. Source: Bradbury (2011, Tables 2 and 3).*

The conclusions about trends cited so far refer to income changes over an interval of 10 or 11 years, and it is of interest to know how results change if rather different interval lengths are used. The research of Gittleman and Joyce (1999) suggests some sensitivity. Using PSID data for 1967–1991 and, like Bradbury (2011), focusing on working-age adults and employing a broadly similar income definition,[43] they calculated IRs, defined as the percentage of individuals remaining in the same fifth, for intervals of 1, 5, and 10 years. Gittleman and Joyce (1999, Table 1, Figure 2) show that the level of positional mobility increases (the IR falls) as the interval width is widened. But conclusions about mobility trends are also affected. For the 10-year interval case, there is a small downward trend during the 1980s consistent with Bradbury's (2011) estimates. However, 5-year IRs exhibit no similar trend, and 1-year IRs generally decline from the end of the 1960s until the end of the 1970s and increase in the following decade (though the changes are not large in absolute magnitude).

To provide a comparison with another commonly used mobility index, we also show trends in one minus Beta. It follows a different trend, which is perhaps unsurprising given that it is not a purely positional measure (see Section 10.3). Compared to the trends shown by the three positional indices, the decline during the 1970s is earlier and sharper, and there is no decline during the 1980s.

The final two measures shown in Figure 10.10 are two "corner probabilities" from a quintile transition matrix (cf. Section 10.3), specifically the proportion of individuals in the poorest fifth in the base-year who are in a different fifth in the final year and, analogously, the proportion leaving the richest fifth over the relevant interval. These statistics pick up on particular aspects of positional mobility. Interestingly, it appears that the trend in the percentage leaving the richest fifth tracks the trend in overall positional mobility better than does the trend in the proportion leaving the poorest fifth. The estimates also bear on our earlier comments that the U.S. decile transition matrices for the 1980s and 1990s suggest that there is a broad symmetry to upward and downward mobility. We now see that asymmetry is more apparent if mobility is summarized using quintile rather than decile groups. In particular, it appears from Bradbury's (2011) estimates that the chances of downward movement from the top (richest fifth) are typically several percentage points greater than the chances of upward mobility from the bottom.

This asymmetry finding also may be contingent on the particular samples and other definitions used. For example, Bradbury and Katz (2002, Annex A) report quintile transition matrices for 1969–1979, 1979–1989, and 1988–1998 using similar PSID samples to Bradbury (2011), except that "working age" now refers to a wider age range (head and spouse [if present] less than 66 years), and family income is pretax postgovernment family income, equivalized using the PSID scale. The two probabilities are approximately equal

[43] But see later for more about differences.

in each matrix (50% in the first two periods, 47% in the last one). In contrast, Gittleman and Joyce (1999, Table 5) report quintile transition matrices for 1967–1979 and 1979–1991 using a similar income definition (but equivalized using the U.S. poverty line), and "working age" refers to head and spouse between 25 and 65 years. According to this study, the chances of leaving the poorest fifth are distinctly smaller than the chances of leaving the richest fifth (around 50% compared to around 60%).

Trends in mobility defined as equalization of longer-term incomes are summarized by Figure 10.11 using Shorrocks's (1978b) measure $M = 1 - R$. The long series (shown in black) are derived from Bradbury (2011); we discuss the series in gray shortly. Although mobility levels differ substantially depending on which inequality index is used—there is much greater mobility according to the Theil index compared to the Gini—the patterns of change over time are the same according to the two series. There was a decline in mobility between the early 1970s and the mid-1980s, followed by a rise over the following decade, with leveling off around the mid-1990s. Although the changes are small in absolute terms, they are relatively large in proportionate terms. For example, between the mid-1980s and mid-1990s, the Theil-based measure increased by some 15% and the

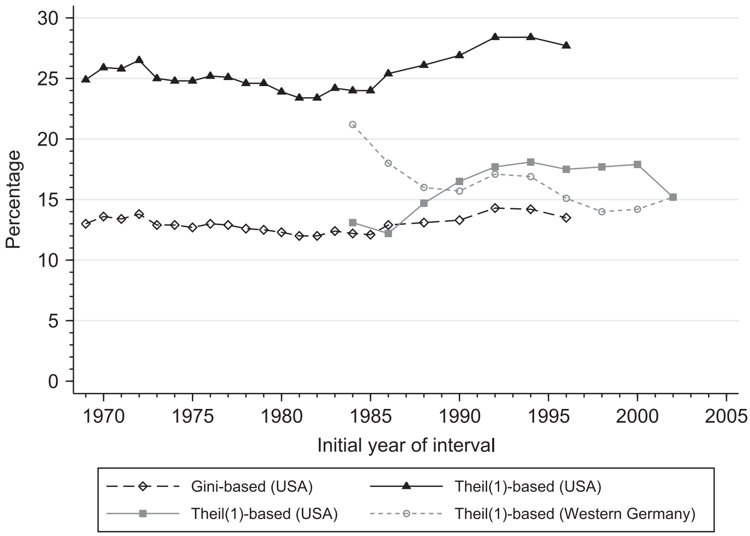

Figure 10.11 Mobility as longer-term income inequality reduction: United States, 1970–1995. *Note: The estimates refer to the Shorrocks equalization measure, $M = 1 - R$, calculated using the Gini and Theil inequality indices. The Bradbury (2011) calculations are based on 11-year intervals with longer-term average incomes calculated using every second year's income to handle the PSID's change to alternate-year interviewing in the late-1990s. The Bayaz-Ozturk et al. (2014) calculations use 5-year intervals, with interval base-years 2 years apart. Sources: Bradbury (2011, Table 4) for the series shown in black and Bayaz-Ozturk et al. (2014, Table A1) for the series shown in gray. Both use PSID (CNEF) data.*

Gini-based measure by almost 13%. The results are consistent with Hungerford's (2011) finding of only a small increase in a Gini-based measure between the 1980s and 1990s, but Figure 10.11 shows that this is partly a consequence of the timing of measurement; Hungerford's two intervals lie on either side of the bottom of a U-shaped series. Also, the turning points in the these two series differ from those for the positional measures shown in Figure 10.10, suggesting that the different aspects of mobility have different underlying causes. In addition, mobility according to the Shorrocks measure is much the same (Gini-based index) or greater (Theil-based index) in the mid-1990s than in the early 1970s, whereas mobility is lower according to the positional mobility indices shown in Figure 10.10.

The research of Bayaz-Ozturk et al. (2014) allows to consider what happened to mobility as equalization after the mid-1990s. Although they also use a Theil-based measure, similar income measures, and the same data source, their series are not directly comparable with all individuals in families in their analysis samples (not only working-age adults) and they use a 5-year rather than 11-year interval. As a consequence, mobility levels are estimated to be substantially lower in all years (compare the gray line for the United States with the black one). Reassuringly, however, the series show broadly similar trends (and turning points) over the period for which they overlap. Bayaz-Ozturk et al.'s (2014) estimates indicate that mobility changed little in the second half of the 1990s, with a suggestion that it fell again in the 2002–2006 period.

All estimates of trends in household income mobility presented so far in this section are based on PSID data, and it is of interest to know whether the evidence from other data sources tells a similar story. The main reference point on this issue is Auten and Gee's (2009) work based on income data from tax administration records covering the two decades between 1987 and 2005. The data and definitions used are not fully comparable with those in the PSID studies, but there are advantages from having much larger sample sizes and much better coverage of top incomes. The analysis focuses on tax filers and their spouses (if present), excluding taxpayers aged under 25 years. An individual's income is the income of the his/her tax filing unit, divided by the square root of household size. Income is a measure of pretax income and includes all taxable income sources reported on tax returns supplemented with data about Social Security benefit income provided to the Internal Revenue Service.

The first part of Auten and Gee's (2009) article describes mobility between 1996 and 2005 in terms of positional mobility (transition proportions) and income growth (by base-year income group). The results are broadly consistent with the studies cited earlier in terms of pointing to substantial movement between quintile groups but with short-distance moves the most prevalent, and real income growth is greater the poorer the base-year income group. The distinctive feature of the study is the information about mobility at the very top of the distribution with mobility statistics also provided for the very top income groups. The authors report that there is a large amount of turnover at the top and that "the incomes of many taxpayers at the highest levels are very volatile" (Auten and Gee, 2009, p. 311). For example, among the richest 0.01% in 1996, only 23% remained in the group in 2005. Although over 80% were still in the top 1%, 6% dropped out of the richest fifth (Auten and Gee, 2009, p. 311).

The second part of Auten and Gee's (2009) article assesses changes in mobility between 1987 and 1996 and 1996 and 2005 using the same measures, and the authors state with regard to positional mobility that "the basic finding . . . is that [it] is approximately the same in the last 10 years as it was in the previous decade" (Auten and Gee, 2009, p. 311). Also, although overall real income growth was around 23% in the first decade compared to 8% in the second, its pro-poor pattern was similar across most of the distribution. (Median real income increased by about 15% points for the top four quintile groups and by about 10% points for the poorest base-year fifth). Things were different at the very top, however. Real income growth was −32% for the top 1% in 1987, and −31% for top the 1% in 1987 (Auten and Gee, 2009, Table 10.7).

Further information about persistence in the top 1% is provided by Auten et al. (2013) for tax filers aged 25–60. Their Table 10.3 shows survival rates in the top 1% (i.e., taking taxpayers in this group in some base year t, what proportion of them were in the top 1% in each and every subsequent year $t+\tau$, where $\tau=1, 2, 3, 4, 5$). Base years run from 1991 to 2009. The 5-year survival rates range between 21% and 36% and the 1-year survival rates between 52% and 70%. The authors pointed out that lower persistence rates tend to occur in recessionary periods (1991, 1999 through 2001, and 2007), and they suggest that income sources of particular relevance for the richest groups such as capital gains and net business income are relatively sensitive to the business cycle.

The body of evidence on trends in measures of mobility as family income risk is much smaller than for the other concepts and also is difficult to synthesize because a wide range of descriptive and model-based measures has been used. One set of PSID-based estimates derived by Gottschalk and Moffitt (2009) is shown in Figure 10.12. The estimates refer to all individuals in families, and income is the PSID pretax posttransfer measure equivalized using the U.S. poverty line for the family type in question. The chart shows that the transitory variance of log annual family income increased substantially, by around 70%, between the mid-1970s and 2000, though this included a period during the 1980s when there was little change. Other PSID-based studies report a similar rise taking the period as a whole (and concur on the increase during the 1990s), though they use different measures, time periods, and analysis samples. See inter alia Hacker and Jacobs (2008) and especially Dynan et al. (2012), who also include a useful review of earlier studies for the United States.

There is ongoing debate about the robustness of the PSID-based estimates, notably for the 1990s onward. This is illustrated by the findings of Dahl et al. (2011). They assess household income volatility using data in which responses to the Survey of Program Participation are linked to earnings data from Social Security Administration records

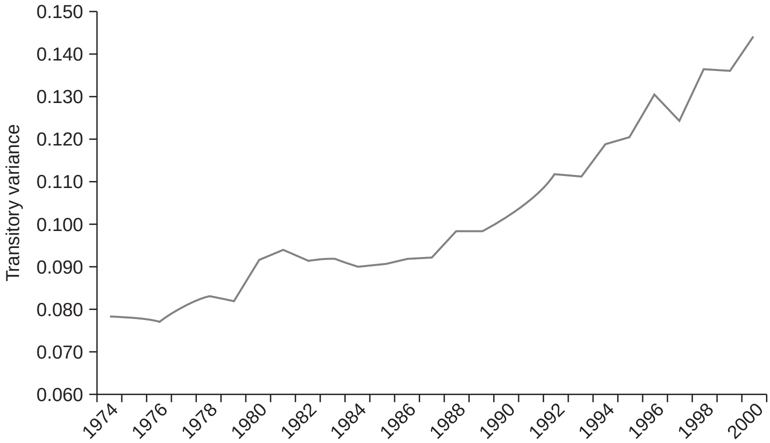

Figure 10.12 Transitory variance of log annual family income: United States, 1974–2000. *Note: Transitory variances computed using the Gottschalk and Moffitt (1994) window-averaging method, with rolling 9-year windows. Source: Gottschalk and Moffitt (2009, Figure 5), based on PSID data.*

("SIPP-SSA" data).[44] Household income is calculated as the sum across household members of earnings from the SSA records plus the survey reports of nonlabor income (but income is apparently not equivalized), and the analysis samples refer to individuals in households with heads aged 25–55 years. Using multiple SIPP panels, the authors derived 1-year volatility estimates at eight time points between 1985 and 2005. The headline finding is that there is no upward trend in volatility, and in particular there is little change over the 1990s. Dahl et al. (2011, p. 769) conclude that they cannot reconcile their results with the divergent set of results from the PSID and other survey data sources, but draw attention to the potential roles of differences in the data per se (rather than the summary measures applied to them). Reconciliation of results is an important task for future research.

The recent study of DeBacker et al. (2013) is a helpful contribution in this respect. It is based on a 1/5000 sample of the U.S. taxpayer population with panel data covering 1987–2009, analyzing individuals aged 25–60 years. There are no potential issues arising from matching or imputation for missing values as in the SIPP-SSA data. The definition of household income is similar to the Auten and Gee (2009) one (see earlier). The authors calculate 1- and 2-year volatility measures and the transitory variances using descriptive and model-based estimates. According to all three measures, there was a small rise throughout the period considered (Figures VI, VII, A.1(e)). DeBacker et al. (2013)

[44] Between 10% and 20% of respondents were not matched with SSA records and up to 40% in the 2001 SIPP panel (Dahl et al., 2011, p. 755). This is a potential source of bias and one that the authors were unable to address.

attributed the rise in the transitory variance primarily to changes in spousal labor earnings and investment income.[45]

We finish this discussion of U.S. mobility trends with reference to evidence about the mobility of individual labor earnings. The recent literature on trends is dominated by analysis of what we have described as measures of income "risk," as summarized by the transitory variance and volatility of earnings, and is almost entirely about men's earnings. (The estimates for household income risk cited earlier are usually by-products of this analysis.) Most analysis is of earnings residuals rather than raw earnings. That is, researchers first run regressions to control for differences in education, age, and work experience and work with the residuals from the fitted models.

Most studies show that men's earnings instability increased during the 1970s, but then leveled off somewhat through to the early- to mid-1980s or fell slightly. Findings about what happened in the 1990s and 2000s depend on the data set and measure used. This is particularly so when measures of volatility are used. Estimates derived from the PSID suggest a rise in volatility (Celik et al. (2012), Shin and Solon (2011), Moffitt and Gottschalk (2012)), whereas those derived using linked-CPS data, administrative record data, or survey data linked to administrative record data, suggest that volatility either remained flat (Celik et al., 2012; Dahl et al., 2011; DeBacker et al., 2013; Ziliak et al., 2011) or at least appear not to have risen (Juhn and McCue, 2010). There appears to be more agreement across studies and data sets about what happened in the 1990s and afterward if the focus is on the transitory variance of men's earnings rather than volatility, namely that the earlier rise leveled off in the 1990s and thereafter: see, e.g., Gottschalk and Moffitt (2009), Moffitt and Gottschalk (2012), and DeBacker et al. (2013). This is consistent with a finding that it is the variance of the permanent component of men's earnings that has grown most over this period, and note that measures of short-term volatility reflect permanent as well as transitory shocks. For further discussion of the different findings across measures and data sets, see Moffitt and Gottschalk (2012, Section V).

For analysis of trends in earnings mobility using other measures, we refer to Buchinsky and Hunt (1999) and Kopczuk et al. (2010). (There are few other relatively recent studies.) Buchinsky and Hunt (1999) is a detailed study of mobility of in wages and annual labor earnings over the period 1981–1991 using the cohort of young people in the National Longitudinal Study of Youth (aged 14–24 in 1979), excluding military personnel and individuals who are self-employed or in education. Mobility is summarized using the Shorrocks equalization measure (M, using multiple inequality indices) and transition probabilities estimated using the nonparametric density method cited in Section 10.3. The main result about trends is that mobility declined between 1981 and 1991, regardless of which inequality index M is calculated with and using window lengths of 1, 4, or 6

[45] Although the transitory variance increased, DeBacker et al. (2013) emphasized that it was the increase in the permanent variance that contributed most to the increase in inequality over the period.

years (Buchinsky and Hunt, 1999, Table 2). Positional mobility also declined; the chances of remaining in the same quintile group, and the average jump and normalized trace indices also fell. The decline in mobility as equalization is the opposite trend from what we discussed earlier for household income. One potential reason relates to the fact that this is a youth cohort, and Buchinsky and Hunt (1999) discussed the difficulties of separately identifying time and age effects.

Kopczuk et al. (2010) is a landmark study of earnings mobility because of its rich data. They used longitudinal Social Security Administration data on earnings stretching from 2004 right back to 1937. The focus is on men and women aged 25–60 years with annual earnings from employment in the commerce and industry sectors greater than a minimum threshold (one-fourth of the full-time full-year minimum wage in 2004 indexed forward and back).[46] Kopczuk et al. (2010) exploited their long series to examine trends in mobility with multiple short- and long-term measures. They variously used longitudinally averaged earnings over 5- and 11-year windows and looked at measures defined for intervals of various length between base and final year. With their large samples and coverage of the tax data, they could also analyze mobility at the top of the earnings distribution.

Short-term mobility is summarized using three measures, the rank correlation for earnings 1 year apart, and a Gini-based Shorrocks rigidity measure ($R = 1 - M$) and transitory variance of log earnings (calculated using a method similar to the BPEA one), each derived using income averaging over moving 5-year windows. According to the first two measures (Kopczuk et al., 2010, Figures IV, V), earnings mobility for all workers increased sharply over the years of World War II and then fell, reaching prewar levels by around 1960. Thereafter, there was remarkably little change. The transitory variance for log earnings was also roughly constant from around 1960 until the mid-2000s. This result is at odds with the PSID estimates for 1970s discussed earlier (see, e.g., the increase shown by Gottschalk and Moffitt, 2009, Figure 1), but consistent with the IRS-data based study from 1987 onward by DeBacker et al. (2013) (which also, like Kopczuk et al.'s 2010 study, emphasizes the increase in the permanent rather than transitory variance).

From 1978 onward when earnings data were no longer top-coded, Kopczuk et al. (2010, Figure 6) examined the probabilities of remaining in the top 1% over one-, three-, and 5-year intervals. There is remarkable stability in these series (e.g., the 1-year probability ranges between 72% and 79%, and the 5-year probabilities between 60% and 65%). These staying probabilities are greater than those shown by Auten et al. (2013, Table 3) for pretax income (for 1991–2009). It is the pretax income components other than labor

[46] The authors undertake extensive checks of the sensitivity of their findings to different assumptions about sample selection, top-coding, coverage of the various administrative sources, and so on and report that their conclusions are robust.

income that are apparently sensitive to the business cycle (and note also that Kopczuk et al.'s (2010) series predate the onset of the Great Recession in 2007/2008).[47]

To summarize long-term (im)mobility, Kopczuk et al. (2010) used the rank correlation between long-term earnings in years t and $t+\tau$, where $\tau=10$, 15, 20. For each year, earnings positions are measured by the 11-year average earnings centered around the year in question. The results suggest, first, that mobility is greater the larger that T is, which is unsurprising, and yet even after 20 years, the correlation is relatively large (around 0.5 for all workers). Second, for all workers, the rank correlation decreased (mobility increased) between the early 1950s and the early 1970s and was then broadly constant. The trends differ for men from those for all workers: The mobility increase is much less pronounced and appears to rise again slightly from the early 1970s (Kopczuk et al., 2010, Figure VIII).

10.4.3 Is There More Income Mobility in the United States than in (Western) Germany?

Perhaps the most well-known "stylized fact" about income mobility is that mobility is greater in Germany than in the United States. One of the reasons for it being well known is that it is surprising: many people expect more mobility in the United States because, compared to Germany, the United States has the more flexible labor market and less comprehensive social safety net to cushion income shocks. What is often forgotten is that the original finding refers to one particular mobility concept (equalization of longer-term incomes) and to one particular time period (the 1980s, prior to German reunification in 1990).

In this section, we review the evidence about income mobility in United States compared to Western Germany. Unless stated otherwise, the data source for the United States is the PSID. We use the term "WG" to refer to the states included in the Federal Republic of Germany before reunification. The German data source, the SOEP, surveyed the former Eastern German states as well from 1990 onward, but few mobility studies to date have included these data (see later discussion). We focus on studies that examine household income mobility (which, as it happens, form the vast majority of US–WG comparative analyses). In Table 10.4, we refer to 11 studies, and summarize them in terms of the time period covered, the mobility measure(s) employed, and the main findings relevant to our question.

The pioneering study by Burkhauser and Poupore (1997) is the source of the stylized fact that we referred to earlier. It was the first major cross-comparative study of household income mobility using the new generation of comparable household panel survey data

[47] Auten et al.'s (2013) staying probabilities for years t to $t+\tau$, $\tau>1$, are also greater than the corresponding Kopczuk et al. (2010) ones because the latter's refer to presence in the top 1% in each year rather than simply in the base year and final year. For a brief discussion of persistence in the top 1% of the Canadian earnings distribution, see Saez and Veall (2005).

Table 10.4 Studies comparing household income mobility in the United States and Western Germany (WG)

Study	Time period covered	(Im)mobility measure(s)	Remarks
Burkhauser and Poupore (1997)	1983–1988	Shorrocks *R*	First finding that mobility greater in WG than in the USA
Burkhauser et al. (1998)	Year pairs t, $t+\tau$, $\tau=1, \ldots, 5$, 1983–1988	Quintile transition matrices	Slightly more income mobility in WG
Maasoumi and Trede (2001)	1984–1989	Maasoumi–Shorrocks *R*	Greater mobility in WG; statistically significant
Gottschalk and Spolaore (2002)	1983, 1993	SWF-based indices	WG–USA difference depends on index parameters
Schluter and Trede (2003)	Year pairs t, $t+1$ between 1984 and 1992	Shorrocks *R*	WG's greater mobility arises from greater mobility in low-income ranges
Van Kerm (2004)	1985, 1997	Portfolio of indices	More income movement in the USA; otherwise varies by index
Jenkins and Van Kerm (2006)	Year pairs t, $t+5$: U.S. 1981–1993, WG 1985–1999	Indices of reranking, progressivity	Reranking and pro-poorness of income growth greater in WG
Schluter and Van de gaer (2011)	Year pairs t, $t+1$ between 1984 and 1992	Index sensitive to upward structural mobility	U.S. "typically" has more mobility
Allanson (2012)	Year pairs t, $t+5$: U.S. 1981–1996, WG 1985–2004	Indices of reranking and structural mobility	Reranking and pro-poorness of income growth greater in WG
Demuynck and Van de gaer (2012)	1984–1985, 1996–1997	Indices of "inequality-adjusted" income growth	USA–WG ranking depends on weight given low-income-growth individuals
Bayaz-Ozturk et al. (2014)	5-year windows, alternating years, 1984–2006	Shorrocks *R*, ratio of permanent to total variance, log incomes	More mobility in the USA from around 1990 onward

Note: Studies are listed in order of publication year. Each study measures income as equivalized posttax posttransfer household income (using various equivalence scales), analysis samples are all individuals in households (except Burkhauser et al., 1998, all individuals aged 25–55). Western Germany: The states included in the Federal Republic of Germany before reunification.
Data sources: PSID (USA) and SOEP (WG).

becoming available in the 1990s.[48] The period covered is 1983–1988, a time of upswing in the economic cycle in both countries. Income immobility was summarized in terms of equalization of longer-term incomes using the Shorrocks R measure computed with three inequality indices (the Gini coefficient and the two Theil indices). The base year is 1983 and R is calculated as the time period is lengthened from one to a maximum of 5 years (corresponding to 1988). The headline results were summarized earlier in Figure 10.8 and refer to estimates based on the Theil index. (The other two indices yield similar profiles and orderings: see Burkhauser and Poupore, 1997, Figure 3.)

There is greater longer-term income equalization (less rigidity, lower R) in WG than in the United States in each year: the curve for the United States lies everywhere above that for WG. In numerical terms, inequality of 6-year-averaged income is 86% of average annual inequality in the United States, compared to 76% in WG (i.e., some 13% larger). The authors show that this mobility ordering is preserved if one uses different income concepts and analysis samples, including labor earnings (for all workers, workers aged 25–50, and the subsets of full-time workers in each case), and equivalized pretax pretransfer ("pregovernment") household income.[49] For example, among full-time workers aged 25–50, the 6-year R for annual labor earnings is 88% for the United States and 79% for WG. For the subset of men, the corresponding estimates are 86% and 78%; for women, 87% and 66% (Burkhauser and Poupore, 1997, Table 4).

The mobility of labor earnings over the same period is analyzed in greater detail by Burkhauser et al. (1997) using different summary methods: statistics based on quintile transition matrices, the rank correlation, and regression-based variance components modeling. Interestingly, given the subsequent focus by researchers on the US–WG differences in household income mobility, Burkhauser et al. (1997) emphasized the similarities in earnings mobility:

> *While we have found evidence of differences in the dynamic earnings movements of workers in the United States and Germany, it is perhaps the similarities of the "end results" of the two labor markets, despite substantial differences in their institutions, that highlight our multiperiod look at these two industrial giants.*
>
> ***Burkhauser et al. (1997, p. 793)***

Burkhauser et al. (1998) supplemented the two earlier studies from the Burkhauser team. As in the first study they used multiple measures of income (and associated samples), but analyzed individuals aged 25–55 years; like the second study, (im)mobility is summarized in positional terms using quintile transition matrices, not R. Again, the conclusions point

[48] Duncan et al. (1993) and Fritzell (1990) are examples of earlier cross-national studies of poverty dynamics and income income mobility using data that were not as comparable. For an earlier cross-national study of earnings mobility across 8 countries, see OECD (1996).

[49] The equivalence scale for all measures of household income in this study is derived from those in the U.S. official poverty line thresholds.

more to cross-national similarities rather than differences: "[i]ndividual mobility patterns in the two countries are remarkably similar" (Burkhauser et al., 1998, pp. 143–144). For example, the proportion of individuals in the same quintile group of posttax posttransfer household income in 1983 and 1988 is 44.7% in the United States compared to 41.4% in WG; for labor earnings mobility, the corresponding proportions are 52.6% and 53.8% (Burkhauser et al., 1998, Tables 6.2, 6.5).

It is the cross-national difference in R that received the most attention in the later studies, with most authors concerned with the robustness of the conclusion to use of different mobility indices. And all the subsequent studies that we are aware of have focused on household income, not labor earnings. Schluter and Trede's (2003) article is rather different in that they aimed to examine the Burkhauser–Poupore result in greater detail. As discussed earlier, their methodological contribution was to explain how R reflected the aggregation of distributional changes, differently weighted, at each point along the income range from poorest to richest, and to explore how the aggregation function differed by inequality index. Using a moving 2-year window over the period 1984–1992 for the calculation of R, Schluter and Trede (2003) confirmed that mobility is greater in WG than the United States. But their main substantive contribution was the finding that this difference in aggregate reflected a combination of greater mobility in low-income ranges combined with greater local weight given to these changes by the mobility index. The cross-national differences in mobility at the bottom are reminiscent of those revealed in Section 10.3 by graphical devices such the transition color plot (Figure 10.1) albeit for a different period (1985 compared with 1997).

Maasoumi and Trede's (2001) article built on earlier work by Maasoumi and Zandvakili (1986), which modified the Shorrocks R measure to use different measures of longer-term income (essentially a generalized mean rather than a simple arithmetic average). Maasoumi and Trede (2001) examined US–WG mobility differences using these Maasoumi–Zandvakili–Shorrocks indices and essentially the same household income data as Burkhauser and Poupore (1997), and also derived the sampling distribution of the indices, thereby allowing consideration of whether mobility differences were statistically significant. The substantive findings are threefold: mobility is greater for WG than the United States regardless of the indices (i.e., regardless of the measure of longer-term income, or the inequality index); that cross-national differences were statistically significant; and mobility is greatest among 16- to 25-year-olds but for all six age groups considered, mobility is statistically significantly greater in WG than the United States.

Gottschalk and Spolaore (2002) is the first (and only) paper that we are aware of that undertakes US–WG comparisons using an explicit SWF-based approach (the application considers mobility between 1984 and 1993). As indicated in Section 10.2, their approach allows for different weights to be placed on mobility as reversal and as time independence (as well as incorporating intertemporal inequality aversion of varying degrees). If the reversals and time independence aspects are ignored, so that the SWF reflects inequality-aversion considerations only, Gottschalk and Spolaore (2002) reported that the United States "gains more" from mobility than does WG. But "this reflects similar gains from reversal in the two countries but greater gains in the United States from origin independence. The introduction of aversion to intertemporal fluctuations and aversion to future risk makes the impact of mobility in the two countries more similar" (Gottschalk and Spolaore, 2002, p. 191). Put simply, conclusions about mobility differences depend on the mobility concept(s) taken and how they are weighted.[50]

Van Kerm (2004) was the first to use Fields and Ok (1999b) indices of income movement to compare the United States and WG among a portfolio of measures of household income mobility. (He also studied Belgium.) Changing the mobility concept leads to a reversal in the country ranking: the average absolute change in log incomes between 1985 and 1997 is 0.523 in the United States but only 0.392 in WG (and 0.335 in Belgium). Van Kerm remarked that "[d]ifferent concepts of mobility may indeed lead to completely different rankings of economies . . .. In all cases, mobility is higher in Western Germany than in Belgium, but the United States can stand at any of three positions depending on the index considered" (Van Kerm, 2004, p. 233). Van Kerm's decompositions highlight that the importance of distinguishing between mobility measures sensitive to positional change and those also reflecting individual income growth and changes in the marginal distributions. The "exchange" factor of distributional change is greater for WG than the United States, whereas the "growth" and "dispersion" factors are greater for the United States (Van Kerm, 2004, Table 4).

Parallel research by Formby et al. (2004) comparing mobility in individual annual labor earnings in WG and the United States between 1985 and 1990 underlines the relevance of the mobility and income concepts chosen. Using measures based on quintile transition matrices, the authors showed that there is more positional mobility in the United States than WG according to four out of five indices, and there is no dominance in the Atkinson and Bourguignon (1982) sense. However, when origin and destination earnings groups are defined as fractions of mean or median earnings (so the mobility matrices reflect real income growth as well), all five summary indices show greater mobility in the United States. The fact that US–WG positional mobility differences are less pronounced (or reversed) for individual earnings compared to household income underlines the conclusions of Burkhauser et al. (1997) cited earlier.[51]

A range of different mobility indices and time periods is used in the remainder of the studies cited in Table 10.4. Jenkins and van Kerm (2006) showed that indices of both

[50] Gottschalk and Spolaore (2002, Table A.4) provide quintile transition matrices "for comparison to other studies." Unfortunately, the scope for doing, for example, dominance checks is limited by the fact that the matrices are not bistochastic. The column sums differ greatly from 100% in several cases.

[51] The main focus of Formby et al.'s (2004) article is methodological—to derive statistical inference procedures for transition matrices and summary mobility indices based on them.

reranking and of progressive individual income growth are greater in WG than in the United States. Using related methods and data, Allanson (2012) confirmed the greater reranking in WG but also highlighted other dimensions of mobility differences. Schluter and Van de gaer (2011) and Demuynck and Van de gaer (2012) proposed classes of mobility indices that are sensitive to individual income growth, with different indices reflecting differences in the weights given to income changes of different sizes. Unsurprisingly (in the light of our earlier discussion), both papers report that mobility from this perspective is generally greater in the United States than WG but, also, the ranking can be reversed for some weighting functions.

The final article cited in Table 10.4 brings us full circle because Bayaz-Ozturk et al.'s (2014) research is in effect a reanalysis of the original Burkhauser and Poupore (1997) study, but using more up-to-date data (1984–2006).[52] The main mobility index is the Shorrocks R calculated using the Theil inequality index, but now also supplemented with estimates of the transitory variance of log income expressed as a proportion of the total variance (calculated using the Gottschalk and Moffitt [1994] "BPEA" method). If the two indices are calculated taking 1984 as the base year and extending the period over which longer-term incomes are calculated to the full 23 years (i.e., also restricting analysis to a sample with fixed structure), income mobility is greater in WG than the United States in each year. The profile of R (and for the other measure) for the United States lies above that for WG thoughout, though the gap between them gets smaller over time (Bayaz-Ozturk et al., 2014, Figure 10.1). In this sense, the results are consistent with the Burkhauser and Poupore (1997) finding (see also Figure 10.8). However, when the indices are calculated using a moving 5-year window (and hence also different samples) to examine mobility trends, an interesting result emerges, which is illustrated in Figure 10.11. We remarked earlier in an apparent increase in mobility in the United States in the late-1980s (though Bayaz-Ozturk et al., 2014 reported that the changes in their estimates are not statistically significant). Figure 10.11 shows that mobility in WG fell between the late 1980s and 1990s (the changes are statistically significant). The result is that, compared to the late 1980s when the WG–US mobility differences were statistically significant, they were no longer so in the period thereafter.

An interesting substantive question is why WG mobility fell, and to what extent it reflects changes in the (West) German labor market and economy associated with reunification or with other structural factors (observe that the downward trend apparently started before 1990). Bayaz-Ozturk et al. (2014) reported that when they applied their methods and samples to examine the mobility of labor earnings for men aged 25–59, they found similar patterns of change over time and cited Aretz (2013) as also finding a

[52] Alternating years are used to account for the change to biannual interviewing in the PSID. The authors reported that using contiguous years over the periods where it was feasible leads to similar results.

downward trend in earnings mobility when using administrative record data covering 1975–2008. Interestingly, Aretz's (2013) work shows that the downward trend in WG was broadly U-shaped between the mid-1970s and late-1980s, but did decline again sharply from around 1990. The decline in mobility the former Eastern Germany (measured only after 1990) fell even more rapidly, down to around WG levels by the mid-2000s.[53] See also Riphahn and Schnitzlein (2011), who pointed to the role of increasing job stability in Eastern Germany.

In sum, although income mobility in the United States and Germany has received much attention, there remains plenty to learn. The sensitivity of conclusions about cross-national differences suggests the need for a more comprehensive analysis using a portfolio of measures within the same study and using up-to-date data. The income concept also matters; researchers have highlighted WG–US differences in household income mobility, and the similarities in earnings mobility have received less attention. Looking at earnings mobility is also informative for tracing the sources of changes in household income mobility.

10.4.4 Intragenerational Income Mobility: Selected Other Evidence

The remainder of our discussion of evidence about intragenerational income mobility reviews cross-national comparative studies for a wider set of countries and selected country studies analyzing trends over time. The focus remains on household income mobility. We consider work done in the last two decades rather than earlier studies.

A natural place to begin is with the analysis of Aaberge et al. (2002) and Chen (2009) because both include mobility comparisons between the United States and with other countries. In the former case, the comparisons are with three Scandinavian countries (Denmark, Norway, and Sweden) in the 1980s. In the latter case, they include Canada, Germany, and GB over the 1990s. Chen (2009) also provides some information about mobility trends.

Aaberge et al.'s (2002) research is based on diverse sources of longitudinal data. For Denmark and Norway, the income data and samples come directly from registers; for Sweden, incomes refer to register data linked to respondents to the Level of Living Survey (the analysis sample is survey rather than register based), and for the United States, the source is the PSID (sample and income data come from a survey). This diversity leads to some compromises in the search for comparability. For instance, the posttax posttransfer income concept in the main analysis refers not to a household total but an aggregate across two adults (in the case of a legally married couple) or one adult (all other cases), and equivalized by the number of adults (two or one, respectively). The constraint is what

[53] This is found for both men and women and using the average jump index of positional mobility as well as the Shorrocks R.

is possible with the Swedish data: no account can be taken of cohabitation, and the number of children is unknown. As it happens, when the authors reran their analysis using more conventional definitions (but excluding Sweden), mobility levels changed for all countries, but "the mobility ordering of countries is unaffected by this sensitivity check" (Aaberge et al., 2002, p. 457).

The Aaberge et al. (2002) study provides analysis for 1986–1991 and 1990–1991, with the end chosen because a major Swedish tax reform in 1991 made later income data noncomparable (the registers covered a different combination of income sources). Mobility is measured using a Gini-based Shorrocks M index and summaries of the directional income movement in the Fields and Ok (1999b) sense. The perhaps surprising finding is that, across the four countries, and despite the substantially greater cross-sectional income inequality in the United States than the three Scandinavian countries, "the pattern of mobility turns out to be remarkably similar in the sense that the proportionate reduction in inequality from extending the accounting period for income is much the same" (Aaberge et al., 2002, p. 443). This finding arises whether the analysis is of individual labor earnings or disposable income. The "remarkable similarity" is also reported by Fritzell (1990) in an earlier study of income mobility in Sweden and the United States. Clearer cross-national differences are apparent, however, when Aaberge et al. (2002) looked at the distribution of changes in relative incomes changes between 1 year and the next over their sample period (relative income is the ratio of income to the year-specific mean; relative income change is a directional summary of individual income movement). As it happens, the distribution of relative income changes is more dispersed in the United States than in the Scandinavian countries for both individual earnings and disposable income. Once again, the conclusions about mobility that are drawn depend on the measure employed.

Chen's (2009) article is based on data from the CNEF, covering from the early 1990s to around 10 years later. Income refers to posttax posttransfer household income, equivalized using the square root scale; the analysis is of all individuals in households with positive incomes. Germany refers to the unified country here, not WG as earlier. Comparisons with the United States in the late 1990s are complicated by the move to alternate-year interviewing by the PSID.

Chen (2009) summarized short-term positional mobility in terms of 2- and 5-year IRs for decline transition matrices, calculated over moving time windows. Choice of measure matters. For example, over the 1990s, around 40% of British individuals remained in the same 10th between one year and the next, compared to nearer 50% in Canada, with Germany's rate in between. With a 5-year interval, the cross-national differences become much smaller, with the proportion remaining in the same decile group falling to between 25% and 30% for all the countries. Chen's summary refers to "a high degree of similarity in relative income mobility across nations" (Chen, 2009, p. 81), rather than to differences.

Chen (2009, Table 1) presents estimates of the Fields and Ok (1999b) index of income flux, the average absolute log-income change calculated over 5-year intervals using between 1991 and 2002. The United States and GB have broadly similar income flux over the period, Germany's is the lowest, and Canada's is in between. Only for the United States is a trend over time apparent (slightly upward). Assessment of these patterns is complicated because the estimates reflect a combination of differences in overall national income growth rates and changes in how pro-poor the income growth is. Chen (2009, Table 1) shows that economic growth accounts for an increasing share of total income flux in each country (all four countries were in an economic upswing over the period) but does not discuss pro-poorness.

Chen's final set of estimates refers to mobility as equalization of longer-term incomes, summarized using the Shorrocks measure $M = 1 - R$, with 1993 taken as the base year and time periods of up to 6 years (Canada), 10 years (GB and Germany), and 8 years for the United States (1995 and 1997 are excluded). The finding is that mobility is greatest in GB and least in Canada for all time periods, with the profiles for Germany and the United States in between and very similar to each other. Chen (2009, Figure 5) shows this for the case in which M is calculated using the mean logarithmic deviation index, but his Table A2 shows that the result is the same if calculations are done instead with the Theil or Gini index. (If half coefficient of variation squared is used, the U.S. profile is closer to Britain's.) These results echo Bayaz-Ozturk et al.'s (2014) finding of similar longer-term income equalization in the United States and WG after 1990 (see earlier). In his discussion of Burkhauser and Poupore's (1997) results, Chen commented that his results suggest that "income mobility has increased considerably in the United States between the 1980s and 1990s, while it has declined in Germany" (Chen, 2009, p. 88).

Leigh (2009) extended comparisons to include Australia, using estimates of R for periods of 2 and 3 years and using CNEF data for Britain, Germany, and the United States, plus data from the Australian household panel HILDA (HILDA data were not included in the CNEF at the time). He found that "[a]round 1990, the U.S. was more immobile than either Britain or Germany. . . . During the 1990s, Germany became somewhat less mobile, and the U.S. somewhat more mobile" Leigh (2009, p. 16) and that Australia was more mobile than all three other countries in the early 2000s.

A different set of countries is included in the cross-national analysis of Ayala and Sastre (2008), based on ECHP data covering 1993–1997: Great Britain, France, Germany, Italy, and Spain. Income is posttax posttransfer household income equivalized by the modified-OECD scale, and mobility is examined for all individuals using a balanced five-wave panel for each country. According to the Fields and Ok (1999b) index of income flux (Ayala and Sastre, 2008, Table 2), the average absolute log-income change, and looking at income changes between 1993 and 1997, Spain, Great Britain, and Italy had relatively high income flux (index values of 0.390, 0.373, and 0.360, respectively), whereas Germany and especially France were low-income-flux countries (0.309 and 0.250). Income flux is shown to be greater among individuals in single-parent households, and relatively stable among older persons (as might be expected). A second set of estimates relates to mobility as equalization of longer-term incomes assessed using the ethical indices proposed by Chakravarty et al. (1985) and calculated using multiple inequality indices and for an interval of 2 years only (individuals' base-year income is the average of their 1993 and 1994 incomes; their final year income is the average of their 1995 and 1996 incomes). Regardless of the inequality index used, Italy had the greatest mobility, but Spain slipped down the ranking and Germany rose up to second place. As the authors commented, the "results show that cross-country comparisons of income mobility can be dependent on the approach used" (Ayala and Sastre, 2008, p. 470). They also referred to potential issues related to differences in national samples (including, e.g., a relatively high attrition rate in the Spanish data), and the particular time period covered.

Gangl (2005) was more ambitious in that his mobility comparisons involved eleven EU countries (data from the ECHP) and the United States (PSID). The periods covered are 1994–1999 (ECHP) and 1992–1997 (PSID). Income is equivalized posttax posttransfer household income samples restricted to individuals aged 25–54 years. Gangl calculated two principal measures, namely, Shorrocks *R* for a 6-year period and the transitory variance of log income expressed as a proportion of total inequality (derived using a regression decomposition). Discussing *R*, Gangl emphasized similarities across countries rather than differences: For example, using a Theil-based index, "about 75–80% of observed income inequality has been permanent over the 6-year observation period in most countries" (Gangl, 2005, pp. 149–151). Nonetheless, Germany, Ireland, and the United States are relatively immobile countries and the Netherlands and Denmark the most mobile ones. Interestingly, "low-inequality countries . . . also tend to be the countries exhibiting the lowest degree of persistence in income inequality over time" (Gangl, 2005, p. 151). Germany is an exception to this description: It is a relatively low inequality country but also with relatively high immobility. This description of Germany also fits with the findings of Aaberge et al. (2002) discussed earlier (for an earlier period). In sum, and on balance, it is unclear whether there is a positive relationship between cross-sectional inequality levels and rigidity of longer-term incomes.

Gangl's (2005) results for household income are consistent with those of Gregg and Vittori (2009), who examined the mobility in labor earnings of individuals aged 20–64 in Denmark, GB, Germany, Italy, and Spain, also using ECHP data. Using *R* calculated for different inequality indices, they found that longer-term earnings inequality reduction is greatest in Denmark followed by Italy, and Germany is the least mobile, with GB and Spain in between. Applying the methods of Schluter and Trede (2003), Gregg and Vittori (2009) also found that most of the cross-national mobility differences are accounted for by differences in mobility patterns in the lowest earnings ranges.

With his variance components measure, Gangl (2005) found that

> *most (i.e., 65%–70%) of the observed total income inequality for any single country is permanent income inequality with countries like Denmark, the Netherlands, Spain, or Italy at the low end and Ireland, Portugal, the United States, and Germany at the upper end of the scale. Still, cross-national variations in relative income persistence are small, and the country ranking in terms of permanent income inequality in consequence almost exactly mirrors the country ranking for total income inequality*
>
> **Gangl (2005, p. 152)**

However, if one focuses on the variance components in absolute levels rather than as expressed as a share of the total variance, the picture changes somewhat. For example, the countries with the lowest transitory variances are Denmark, Germany, and Ireland, and the largest are for Italy, the United States, and Spain.[54]

The most comprehensive analysis of income mobility to date using the new EU-SILC longitudinal data is by Van Kerm and Pi Alperin (2013), who also pointed to a number of important issues concerning the cross-national comparability of the constituent data sources and the short period covering by the data. On these issues, see also Jenkins and Van Kerm (2014).

We now turn to country studies of income mobility with a focus on trends, of which there are few. Jenkins's (2011a) book contains a comprehensive study for GB, using BHPS data covering from 1991 through to 2006 and examining trends in various concepts of mobility.[55] The headline finding is that, for all but one concept of mobility, there is virtually unchanged mobility throughout the period. This is found for a portfolio of measures, including 1-year positional mobility, Shorrocks R measures calculated over moving 6-year windows, and the transitory variance of log household income (Gottschalk and Moffitt, 1994, "BPEA" method, using moving 7-year windows).[56]

Jenkins (2011a) reported the same lack of trend if one looks at the earnings of prime-age men and women: see also Jenkins (2011b) and Cappellari and Jenkins (2014). (These studies also cautiously suggest that transitory variances of household income and men's earnings in Britain are larger than their counterparts for the United States.) The lack of

[54] The estimates are not directly comparable with those reported for the United States earlier because Gangl's (2005) decomposition uses a model specification that is nonstandard. For example, he did not allow for persistence over time in transitory shocks. Also, Gangl included the variance of heterogeneous income trends in the transitory component rather than permanent component.

[55] The book also reviews earlier British studies of income mobility, most of which are by Jenkins and collaborators and based on shorter spans of BHPS data. For example, Jarvis and Jenkins (1998) used four waves; Jenkins (2000) used six waves.

[56] Using Jenkins's (2011a) data, we have compared the decile transition matrices for 1991–1998 and 1999–2006 and found that there is no stochastic dominance. Nor is there if we compare the British matrix for 1991–1998 with the decile transition matrix for the United States for 1989–1998 shown in Table 10.1.

change in earnings mobility during the 1990s found in BHPS data was also found by Dickens and McKnight (2008) using administrative record data on earnings covering the period between financial years 1978/1979 and 2005/2006.[57] They summarized mobility using the Shorrocks equalization measure $M=1-R$, calculated using multiple inequality indices, and over moving windows of 2, 4, 6, 8, and 10 years, and each series tells the same story. Interestingly, Dickens and McKnight's (2008) research also found that mobility was on a downward trend between 1978/1979 and the beginning of the 1990s (though this trend is less pronounced for women than for men).

Jenkins (2011a) observed that the lack of change in British income mobility between the early-1990s and mid-2000s is surprising given significant changes over the period considered in tax–benefit policies and the upswing in the macro-economy from trough to peak. Jenkins (2011a, chapter 6) adduced some evidence to suggest that the lack of trend in aggregate may reflect a balance between changes in mobility associated with different income sources comprising total household income, but he conceded the exploratory nature of the analysis.

The exceptional measure for which some (relatively small) changes are observed is in the pattern of individual growth. Jenkins and van Kerm (2011) showed that income growth between 1998 and 2002 was more pro-poor than in earlier periods (1992–1996 and 1995–1999), but not so compared with 2001–2005. (An extract from their results was shown earlier in Figure 10.7.) The authors suggested that the pro-poor nature of individual income growth in the 1998–2002 period arose because the economy was buoyant, with unemployment rates continuing to fall relatively rapidly from their early-1990s peak, and the incoming Labour government had an explicit antipoverty agenda, unlike the preceding Conservative governments. It is speculated that the subsequent fall in the progressivity of income growth had to do with the slowdown in the economy from around 2000.

Trends in transitory (and permanent) earnings variances of earnings in Western Germany were studied by Bartels and Bönke (2013). Bartels and Bönke worked with samples of man aged 20–59 years over the period 1984–2009, calculating variance components using the Gottschalk and Moffitt (1994) "BPEA" method (using moving 5-year windows). The striking finding (2013, Figure 2) is that, although the transitory variance of log earnings rose over the period as a whole, the transitory variance for equivalized posttax posttransfer household income (for the same sample) does not change at all over the period, pointing to important roles played by the German welfare state and by families in offsetting shocks to men's earnings. When the same methods were applied to Britain (BHPS data for 1991–2006), Bartels and Bönke (2013) found, like Jenkins (2011a), that

[57] They make pioneering research use of the Lifetime Labour Market Database (LLMDB), a 1% sample of individuals identified by National Insurance numbers and originally designed to estimate workers' National Insurance contributions and State retirement pension entitlements.

the transitory variance for equivalized posttax posttransfer household income did not change over time; unlike him, they also reported (2013, Figure 6) a rise in the transitory difference of men's earnings (and higher levels). These differences are traced to differences in samples: Jenkins (2011a) considered men aged 25–59 (as in most similar U.S. studies), whereas they argued that transitory earnings shocks are more important for this group. Overall, the authors concluded from their analysis that "redistribution and risk insurance provided by the welfare state is more pronounced in Germany than in the United Kingdom" (Bartels and Bönke, 2013, p. 250). Whether this also applies to other groups beyond prime-aged men requires examination.

Mobility in top incomes in Germany over the period 2001–2006 was studied by Jenderny (2013) using tax administrative data, a 5% balanced sample of all tax filers in those years. Income is the tax unit's gross pretax income (i.e., including tax-exempted income, but not realized capital gains). One-year probabilities of remaining in the top 1% are about 78% and thus larger than the estimates of around 70% reported by Auten et al. (2013) for nonrecessionary periods in the United States (see earlier discussion). Five-year survival rates are also larger in Germany than in the United States.[58] Jenderny (2013, 32) concluded that the increase in top income concentration in Germany since the 1990s described by Bach et al. (2009) is unlikely to be offset by high or rising top income mobility.

10.4.5 Summary and Conclusions

Empirical studies of income mobility show that, in all countries, there is a substantial degree of longitudinal flux in incomes, whether looking at incomes 1 year apart, or 5 or 10 years apart, resulting in changes in relative position and a reduction in the inequality of longer-term incomes. It is also clear, however, that most income changes are relatively small so that, even after many years, relative positions are quite highly correlated and substantial inequalities in longer-term incomes remain.

To the big questions of whether income mobility in country A has increased or decreased over time, or is greater or less than in country B (or C or D or . . .), we have found few clear-cut conclusions—apart from a general finding that the answers to the questions depend on the mobility concept that is used, and other issues such as the time period considered and the measure of income are relevant.

This is illustrated by the comparisons of the United States with WG. Early research suggested that income mobility in the 1980s was (surprisingly) greater in WG than in the United States (Burkhauser and Poupore, 1997) when mobility is measured in terms of equalization of longer-term income. But more recent research (Bayaz-Ozturk et al.,

[58] The stayer rates for the top 0.1% are also slightly higher than the Canadian estimates reported by Saez and Veall (2005, Figure 2).

2014) for the 1990s using the same measure suggests that mobility in the two countries is now similar. And it is often forgotten that the Burkhauser team had long argued that earnings mobility in WG and United States was remarkably similar. Moreover, when one switches the mobility concept to one of income movement (or individual income growth), mobility in the United States shows up as greater than in most other countries—the ranking consistent with many people's expectations given the nature of the U.S. economy, labor market, and welfare state.

It remains an open question, as well, whether there is a systematic cross-national relationship between levels of income mobility and cross-sectional income inequality. The evidence is mixed, and the issue deserves to be revisited. (Note the widespread interest too in whether there is a corresponding relationship for intergenerational income mobility—see the discussion of the "Great Gatsby" curve in Section 10.5). Because the evidence we have reviewed suggests similarities across countries in the extent of mobility (positional and longer-term income equalization) rather than marked differences, we are inclined to conclude that there is no obvious relationship between mobility and inequality because cross-national differences in inequality are pronounced.

Looking at trends over time in income mobility within countries, the picture is one of diversity and depends on the mobility concept and the length of time period over which trends are assessed. Mobility changes are observed in the United States over the 30 years since the early 1970s and in Germany between the late 1980s and the 1990s, though whether these count as large or small changes partly depends on the eye of the beholder. For Britain, there is a clearer case that income mobility in Britain changed hardly at all in the 1990s and 2000s (again with the exception of mobility as individual income growth). Relatively large changes in mobility are more apparent to most eyes once trends are assessed over a relatively long period. The U.S. study of earnings mobility by Kopczuk et al. (2010), with data going back to 1937, is the best example we have of this.

In sum, our review of evidence about income mobility suggests that there is much to learn. The advent of cross-nationally comparative household panel surveys over the last three decades facilitated a relative boom in intragenerational mobility analysis. There are signs that the next generation of studies will make greater use of administrative register data or surveys linked to administrative data, at least for analysis of trends over time. As we have discussed, data from sources such as tax administrative records provide the advantages of huge samples with good coverage of top incomes and can provide long historical series as well. On the other hand, these benefits come at the potential costs of having income definitions that are not as useful for mobility analysis as those now in comparative survey collections such as the CNEF (and may change over time as tax laws change), and data access and undertaking the analysis are also nontrivial issues. For cross-national comparisons, administrative record data also have potential, but the problems of comparability are an order of magnitude greater, and data may simply be unavailable for countries of key interest.

10.5. INTERGENERATIONAL MOBILITY: EVIDENCE

Section 10.3 presented a set of measures by means of which we can describe not only intra- but also intergenerational associations in a society. This section reviews evidence on such associations.

There are several earlier reviews of intergenerational income mobility. Solon (1999) reviewed intergenerational labor market with a focus on long-run earnings, whereas Solon (2002) focused on a subset of that literature, namely cross-national differences in mobility. Björklund and Jäntti (2009) built on and extended the empirical evidence assembled by Solon (1999). Black and Devereux (2011), who examined intergenerational links in income and education, emphasized evidence on causal links in intergenerational mobility. Blanden (2013) contrasted the crossnational evidence on intergenerational income, earnings, and education mobility with mobility in social class. Corak (2006, 2013a), in turn, emphasized policy implications. Corak (2013a) also drew on recent research about both socioeconomic gradients in child development and the emergence of economic persistence in labor markets.

Several recent reviews present international evidence on intergenerational income persistence in a scatter plot, plotting the estimated persistence in different countries on the vertical axis and estimated income inequality, often in the parental generation, on the horizontal, adding a linear bivariate regression line (Björklund and Jäntti, 2009; Blanden, 2013; Corak, 2013a). Labeled the "Great Gatsby" curve by the then-chairman of the U.S. Council of Economic Advisors (Krueger, 2012), such plots are interpreted to suggest countries with higher persistence are also countries with greater inequality. Figure 10.13 reproduces the most recent such graph, from Corak (2013a, Figure 1). Although the precise estimates used by different authors vary, the results are broadly similar. The Nordic countries have low persistence and low inequality; the United States, the UK along with France and Italy, have high persistence and reasonably high inequality.

There are theoretical models that can account for the positive association between inequality and persistence. For instance, in Solon's (2004) version of the Becker and Tomes (1979, 1986) model, the factors that drive intergenerational persistence, such as the heritability of human capital endowments, the returns to education, and the progressivity of public education expenditure, affect cross-sectional inequality with the same signs. In Hassler et al.'s (2007) model, which examines links between inequality and mobility under different kinds of labor market institutions, some institutional arrangements have mobility and inequality being inversely related (and hence persistence and inequality positively correlated). Checchi et al.'s (1999) model of beliefs about own ability, educational choice and mobility can also generate positive as well as negative associations between inequality and mobility depending on the model parameters. As we shall see, however, it is far from clear that intergenerational persistence and inequality are, in fact, as clearly positively correlated as Figure 10.13 suggests.

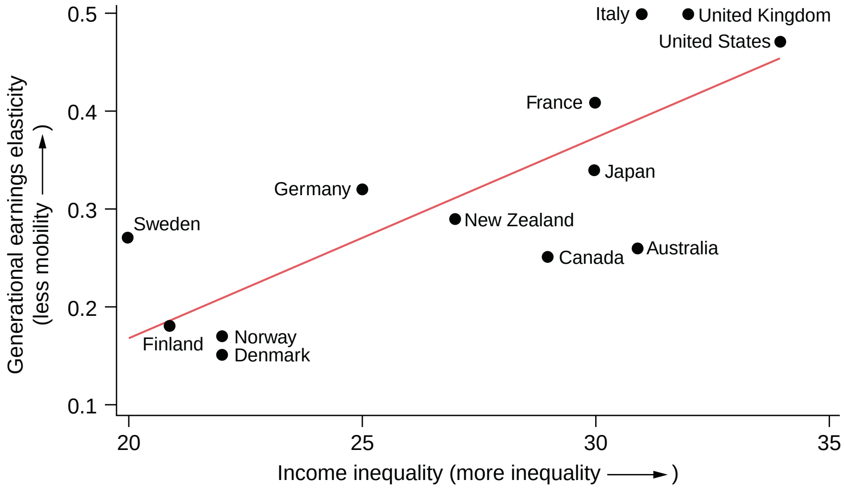

Figure 10.13 The Great Gatsby curve: the relationship between intergenerational earnings persistence and cross-sectional income inequality. *Note: Income inequality is measured by the Gini coefficient of disposable household income in 1985 taken from the OECD. Persistence is measured as the Beta of parental and son earnings. Sons are born in early 1960s, and outcomes for them are measured in late 1990s. See Corak (2013a,b) for further detail. Source: Corak (2013a, Figure 1).*

This part of the chapter proceeds as follows. In Section 10.5.1, we discuss data requirements and special problems that come up in estimating intergenerational and family associations. In Section 10.5.2, we review studies of intergenerational persistence and mobility in the United States. The focus on this country is motivated, as in the intragenerational mobility case, by the sheer amount of evidence about mobility in the United States relative to that in other countries. First, we examine evidence on the level of the intergenerational elasticity (IGE) of earnings or income—first for father–son pairs, and then widen the scope to look at broader pairings of parents and offspring—and then examine evidence about trends in the IGE over time. (The IGE is the Beta measure discussed in Section 10.3; we use both terms interchangeably in this section.) We then examine evidence that is based on measures that go beyond the simple log-linear Galtonian regression Beta (IGE), product–moment correlation coefficient *r*: for example, quantile regressions, transition matrices, nonparametric conditional mean functions. In Section 10.5.3, we examine evidence on intergenerational mobility from other countries, following the same structure as for the United States. In Section 10.5.4, we examine evidence on another way to measure the importance of family background, the sibling correlation; and in Section 10.5.5, we discuss other approaches to intergenerational mobility, old and new. Section 10.5.6 concludes.

10.5.1 Data and Issues of Empirical Implementation

As discussed in Section 10.4.1, any study of income mobility faces three "W" issues: mobility of What, among Whom, and When? For intergenerational mobility, each question must be answered twice, once in each of the parental and offspring generations. As with intragenerational mobility, researchers' choices are constrained with the available data.

At one level, just as with intragenerational income mobility, mobility of "What" refers to the income concept that is used. The overwhelming majority of studies we review use the labor market earnings of the parent and the offspring with several variations, discussed in Section 10.4.1. Other choices might add nonlabor income sources from the market such as capital income to measure factor or market income. If the goal is to examine the intergenerational association of living standards, it would make sense to study disposable income (i.e., to add public transfers and deduct income taxes paid). It would seem reasonable to have identical answers to the "What" question in both generations. It is frequently the case that available data do not support such a choice; it is not unusual for "income" to be family income in the parental generation and to be earnings in the offspring generation.[59]

The aim of early research on this topic was to measure the intergenerational association of "permanent" income, which was believed to be captured quite well by labor market earnings. It has long been recognized (see Atkinson, 1981b) that short-run income measures are different from longer-run measures because of transitory fluctuations, and that the associations sought were those of the more stable or permanent measures of living standards.

As with intragenerational mobility, "Whom" refers to the definition of the income-receiving unit in both the parent and child generation. Most studies that are modeled on Solon (1992) examine mobility of father–son pairs, ignoring the incomes of other household members. Many departures from this are due to data-related reasons. For instance, studies such as that of Zimmerman (1992), which relies on data from the U.S. National Longitudinal Survey of Youth (NLSY), uses family income in the parental generation, as that is the only income concept available in that data source.[60]

The Whom question becomes more complex when the intergenerational associations of women's incomes are studied and compared with those of men. Over the last four to five decades, women's labor market attachment has increased substantially in most developed nations, with female labor force participation rates increasingly resembling those of men. However, around the age commonly believed to be appropriate for measuring men's long-run income (around age 40), women often have breaks from employment

[59] This is the case in U.S. studies that rely on the NLSY and UK studies that rely on the BCS and NCDS. Note that the Galtonian regression of child height on parent height also used midparent height on the right-hand side; see Galton (1886) and Goldberger (1989).

[60] The Galtonian regression Beta that is the most often used measure of (im)mobility originally related offspring height to "midparent" height. See Goldberger (1989) and Galton (1886).

due to childbirth and child care. Studies that examine women's intergenerational mobility are more likely to examine family or household income as a better gauge of their living standard than individual incomes. Comparing mobility across men and women would then naturally also need to examine family or household income for men (Chadwick and Solon, 2002; Raaum et al., 2007).

There is an added dimension to the Whom question, namely the nature of the parent–offspring relationship. In the early intergenerational studies of Atkinson (1981b), Solon (1992), and Zimmerman (1992), the parent–child association was more or less driven by the survey design—"children" were the children of the sample parents who were followed up in adulthood. However, children can have multiple parents—stepparents, adoptive and foster parents in addition to birth parents. Common choices are to restrict the population to those parent–offspring pairs where the offspring was observed as living with the parent at some age, say 10 or 16, or to birth parents. One aspect of this Whom dimension is the role of separated families. Should one focus on associations of offspring income with the head in lone-parent families or on father–child associations? Some studies, especially based on register data, have examined the sensitivity of the population of parent–child relationships and found differences across definitions and family types to be relatively small.[61]

As with the two other "W" questions, the When question for intergenerational mobility analysis is mostly a superset of that for intragenerational mobility. Most of the same questions addressed in Section 10.4.1 need to be resolved for both the parent and offspring generations. The underlying data record income for a specific period: often annual income data but in some cases "current" income data are available. But, in contrast to the case of intragenerational mobility, shorter-run fluctuations are noise that make more difficult the uncovering of the more interesting underlying longer-run incomes. This leads directly to the issue of over what periods, and over what ages, incomes should be studied (and aggregated) to give reasonable measurements of longer-run economic status. And if, due to data limitations, ideal measurements cannot be made, how are mobility measurements affected? The two main issues that have been addressed are transitory variation in observed income measures, and "life cycle" bias (Jenkins, 1987; Grawe, 2006). We discuss these in turn.

Since at least Atkinson (1981b), it has been recognized that transitory errors in parental income lead to an errors-in-variables (downward) inconsistency in the estimated intergenerational elasticity. Since the seminal paper to empirically address this issue (Solon, 1992), many studies have exploited this finding.[62] Solon's estimate of intergenerational persistence for the United States, based on averages across 5 years of parental

[61] See Björklund and Chadwick (2003), and, using mobility in education, Holmlund et al. (2011) and Björklund et al. (2007b).

[62] It is much less common to correct for measurement error in other ways to asses mobility, such as transition matrices. For the econometrics involved and evidence based on simulations, see O'Neill et al. (2007).

income, resulted in point estimates of Beta that are between 10% and 70% larger than the estimates derived using a single year of parental income.

Recent work on so-called generalized-errors-in-variables (GEIV) model calls into question the assumption that transitory income variations have the same properties as classical measurement errors (Böhlmark and Lindquist, 2006; Haider and Solon, 2006). The GEIV model for the annual income process of an individual in family i in generation j (=Offspring, Parent) at age t relates permanent income y and transitory errors v to annual or current income by (Haider and Solon, 2006)

$$y_{ijt} = \lambda_{jt} y_{ij} + v_{ijt}, \quad j = O, P. \tag{10.16}$$

The key advance here is the introduction of the age-dependent parameter λ, which "loads" underlying permanent income onto annual income and is hypothesized to be lower than one early in the life cycle, equal to one at some point, and higher than one thereafter. Note that we allow for the λ parameters to differ across generations.[63]

The measurement error model in Equation (10.16) is the same as the classical measurement error model if (i) $\lambda_{jt} \equiv 1$, and (ii) the random fluctuations v are orthogonal to true long-run income ($y \perp v$), and the vs are identically and independently distributed within a generation. An estimate of the IGE β using annual incomes for both parents and children has the probability limit

$$\begin{aligned} \text{plim}\hat{\beta} &= \frac{\text{Cov}[y_{iOt}, y_{iPt}]}{\text{Var}[y_{iPt}]} \\ &= \frac{\text{Cov}[y_{iO}, y_{iP}] + \text{Cov}[v_{iOt}, y_{iP}] + \text{Cov}[y_{iO}, v_{iPt}] + \text{Cov}[v_{iOt}, v_{iPt}]}{\text{Var}[y_{iP}] + \text{Var}[v_{iPt}] + 2\text{Cov}[y_{iP}, v_{iPt}]}. \end{aligned} \tag{10.17}$$

For the classical measurement error model (and assuming, in addition, that the random fluctuations v are uncorrelated across generations), the last three terms in the numerator in Equation (10.17) are all zero. In that case, also the third term in the denominator is zero, and only the presence of the random fluctuation in parental income in the denominator leads to downward inconsistency, a point made in this context first by Atkinson (1981b). Denote the variance of permanent earnings in generation $j = 0, P$ by $\text{Var}[y_{ji}] = \sigma^2_{y_j}$ and similarly the variance of transitory earnings by $\text{Var}[v_{jit}] = \sigma^2_{v_j}$. The most common empirical solution to deal with the inconsistency is to diminish it by taking multiyear averages of parental income, in which case the measurement error variance in the denominator is $\sigma^2_{y_P}/T < \sigma^2_{v_P}$, an approach first used by Solon (1989, 1992) and Zimmerman (1992) and now standard in the literature.[64]

[63] The current exposition treats the transitory errors as being white noise. In case they are autocorrelated, the attenuation factor involves also the parameters of that process. If v follows an AR(1) process, such autocorrelation worsens the errors-in-variables inconsistency. See, for example, Mazumder (2005b, Table 1).

[64] A consistent estimator can also be constructed if there is a valid instrument for permanent income, an approach that has also been used (see, e.g., Dearden et al., 1997).

However, the age- or time-dependent factor loading λ_{jt} leads to two additional sources of bias in the IGE, namely the age/time point at which child incomes is measured—leading to a biased estimate of Cov[y_{iO},y_{iP}]—and when parental income is measured—leading to biased estimates of both Cov[y_{iO},y_{iP}] and Var[y_{iP}].

If only parental income is measured with error, we would have

$$\text{plim}\hat{\beta} = \frac{\text{Cov}\left[y_{Oit}, y_{Pi}\right]}{\sigma^2_{y_P}} = \theta_{Ps}\beta, \tag{10.18}$$

where s is the age at which parental income is measured, and

$$\theta_{Ps} = \frac{\text{Cov}\left[y_{Pis}, y_{Pi}\right]}{\text{Var}\left[y_{Pis}\right]} = \frac{\lambda_{Ps}\sigma^2_{y_P}}{\lambda^2_{Ps}\sigma^2_{y_P} + \sigma^2_{v_P}} \tag{10.19}$$

is the linear projection coefficient of y_{Pi} on y_{Pis} (Haider and Solon, 2006). If parental income is measured at an age at which $\lambda_{Ps} \approx 1$, θ is the standard errors-in-variables attenuation factor. If only *offspring* income were characterized by the GEIV process, the probability limit of the IGE estimated using annual income would be

$$\text{plim}\hat{\beta} = \frac{\text{Cov}\left[y_{Oit}, y_{Pi}\right]}{\sigma^2_{y_P}} = \lambda_{Ot}\beta. \tag{10.20}$$

Whenever $\lambda_{Ot} \neq 1$, the IGE is inconsistently estimated (Haider and Solon, 2006). Thus, when in the life cycle offspring incomes are measured matters for estimates of intergenerational persistence. This is the issue of "life cycle bias."

If both offspring and parental incomes are characterized by the GEIV model, which is plausible, the estimated IGE is (Gouskova et al., 2010; Haider and Solon, 2003)

$$\text{plim}\hat{\beta} = \lambda_{Ot}\theta_{Ps}\beta. \tag{10.21}$$

Note that λ can be either below or above unity, and θ is constrained to lie in the unit interval, so β can be underestimated (when $\lambda < 1$), be correctly estimated (when $\lambda_{Ot}\theta_{Ps} \approx 1$), and be overestimated (when $\lambda_{Ot}\theta_{Ps} > 1$). Finally, the Pearson correlation coefficient r has in this case the probability limit

$$\text{plim}\hat{r} = \theta_{Ot}\frac{\sqrt{\lambda^2_{Ot}\sigma^2_{y_O} + \sigma^2_{v_O}}}{\sigma_{y_O}}\theta_{Ps}\frac{\sqrt{\lambda^2_{Ps}\sigma^2_{y_P} + \sigma^2_{v_P}}}{\sigma_{y_P}}r. \tag{10.22}$$

The probability limit of the correlation coefficient depends on the θ in both generations, on the ratio of the observed standard deviation to that of long-run income in both generations, as well, of course, on the true r.

Empirical evidence from both the United States and Sweden on the age profile of λ_t based on the GEIV model, suggests that earnings early in life (even abstracting from a population age-earnings profile) are a downward-inconsistent measure of lifetime earnings and later in life an upward-inconsistent measure (Böhlmark and Lindquist, 2006; Haider and Solon, 2006). Around age 40, at least for men in both the United States and Sweden, $\lambda_t \approx 1$ in which case deviations from a multiyear average are approximately classical, thus lending themselves to the analysis of intergenerational association of long-run income under the assumption that the λs in both generations are approximately equal, i.e., $\lambda_{Pt} \approx \lambda_{Ot}$ (or at least that they were equal at about the same age).

Grawe (2006), building on insights in Jenkins (1987), examined the extent of both attenuation and life cycle bias in Betas estimated in several different countries and data sets. He found, using data for Canada, Germany, and the United States, that life cycle biases in fathers' age are an important source of bias and proposed several rules of thumb to diminish it: either to use points in time at which measurement errors are roughly classical, as suggested earlier, or at least to use observations on income for parents and children at similar points in their life cycle.

There are several caveats, however. First, as implied earlier, the λs may well change from one generation to the next. Second, the λs that apply to, say, earnings, may differ from those that apply to, say, disposable household income. Third, the λs that apply to men may be quite different than those that apply to women depending, for instance, on patterns of labor force withdrawal and reentry due to child bearing. Finally, the λs can be quite different in different countries. Without access to estimates of these, cross-country differences in the IGEs can be driven not by differences in the underlying βs but by different values of λ_{Ot} and θ_{Ps}, even if the ages at which incomes are measured are kept constant.[65]

It may be interesting to know how large the bias in Beta or r is in a given population. However, we are often interested in comparing these parameters in two different populations, for example, across time in a country, or between two countries. Denoting the two populations by A and B and focusing on Beta, and assuming for simplicity we are measuring both parents and offspring at the same ages, we have

$$\hat{\beta}^A - \hat{\beta}^B \simeq \lambda_{Ot}^A \theta_{Ps}^A \beta^A - \lambda_{Ot}^B \theta_{Ps}^B \beta^B. \tag{10.23}$$

Unless we have estimates of λ and θ in both countries, we must assume that $\lambda_{Ot}^A \theta_{Ps}^A \approx \lambda_{Ot}^B \theta_{Ps}^B$ is able to deduce from the estimated difference that the underlying βs are different, also. A similar argument applies, of course, to r. We can in that case infer

[65] Moreover, Nybom and Stuhler (2011) used nearly complete actual lifetime incomes for both fathers and sons. By comparing regression coefficients based on multiyear averages of sons' income with that based on their full lifetime incomes, they found that the biases in the intergenerational elasticity estimates are still quite considerable. This may mean that more complex models that link short-run to "permanent" income need to be explored.

the sign of their difference without bias (but cannot know its size unless we know λ and θ), or we can estimate their ratio.

The almost exclusive focus on permanent income (which, in some sense, involves both the What and When questions) can be questioned in light of the more complicated measurement models that link short-run to long-run income. The focus on permanent income is based on the notion that differences between short- and long-run income are transitory and largely classical, i.e., positive and negative shocks are roughly as likely (low or not autocorrelation), and the magnitude of the shocks does not vary by either permanent income or other characteristics (shocks are homoscedastic and orthogonal to permanent income). If capital markets are well functioning and individuals have a fair idea of what their permanent income is (so they know if they have been hit by a negative or positive shock), they smooth their consumption by relying on saving and borrowing. These demanding conditions would justify the focus on permanent income (see the discussion in Section 10.2). In this view, it is permanent income, not short-run fluctuations, that best captures the distribution of well-being.

It follows that, if the assumptions are violated, even short-run fluctuations are interesting from a well-being perspective. Jäntti and Lindahl (2012) demonstrated that income volatility in Sweden is strongly but nonmonotonically associated with the level of long-run income. Moreover, analysis of intergenerational associations in income suggests that not only long-run incomes but also income volatility is associated across generations (Jäntti and Lindahl, 2012; Shore, 2011). Thus, a focus on long-run incomes alone probably understates the extent to which economic well-being is associated across generations.

Before we discuss commonly used data sources for intergenerational analysis, we point to an additional complication in interpreting the evidence. The most commonly used measure of intergenerational mobility is the persistence as measured by Beta (the IGE). Arguably, we would like to abstract from the marginal distribution of offspring and use the correlation, r, related to Beta by the ratio of parental to offspring standard deviation (see Equation 10.4). In steady state, the two are equal but, when inequality increases (decreases) across generations, r is lower (higher) than Beta. Extra care should then be taken in comparing Betas across countries, as different Betas may be consistent with the same, or at least more similar r, depending on how marginal distributions have changed across generations in the two countries. Björklund and Jäntti (2009) cited evidence that suggests the ratio σ_P/σ_O in the United States is less than one—inequality increased—and in Sweden greater than one—inequality decreased—suggesting the difference in r is likely to be less than that in the Betas. (Note, however, that it is only changes in inequality in the marginal distributions that are controlled for, and in a particular way.)

Suitable data for intergenerational analysis need to meet two basic criteria. The data need to be able to identify and link parent–child pairs.[66] They need to include measurements of the incomes in both generations at comparable points in the life cycle and preferably multiple such measurements to allow for the effect of measurement errors.

Three main types of data are used. Many studies rely on longitudinal household surveys that have been running long enough to allow for the offspring to be observed living with their parent(s) as a child or youth and then followed up as adults, having often formed households of their own. These data sources, discussed in greater detail in Section 10.4.1, include the U.S. PSID and the German SOEP. The UK BHPS has only recently been used for intergenerational analysis. Cohort studies are another type of data that are commonly used for intergenerational analysis. Such data sets, including the U.S. National Longitudinal Study of Youth (NLSY) and the UK National Child Development Study (NCDS; cohort of 1958) and British Cohort Study (BCS, cohort of 1970), have been specifically designed to collect data on children and follow them across time as they grow older. The income and other information used are mostly gathered through interviews with the parents and children in such studies, and the parent–child link is ascertained from both information about both birth and living arrangements.

A variation of the survey-based approach was taken in the UK, where Atkinson (1981b, 1983), using data originally collected by Rowntree and Lavers (1951) for the study of cross-sectional poverty in York, built an intergenerational data set by interviewing the adult children of the original survey households, creating a longitudinal data set from what was originally a cross-sectional data set.

Register-based data sets are another important source of data. Such data, which underlie intergenerational mobility estimates in Canada and the Nordic countries, and increasingly also in the United States, rely on administrative records, often drawn from data originally collected for purposes of taxation or Social Security, to measure income, and identify parent–child links based either on administrative records that link parents to children or on census data.[67] The key to the use of such data is the use of personal identifiers and the presence of a reliable parent–child link.

A third approach to data is to use synthetic parent–child links. One way to do this is to use two-sample methods (i.e., to estimate Beta using empirical moments based on different data sets). This requires a sample of "parents" to provide information on the

[66] Intergenerational persistence can be estimated using two-sample methods (Björklund and Jäntti, 1997), which we discuss later.

[67] For instance, Canadian father–son pairs in studies such as Corak and Heisz (1999) rely on tax records for not only the earnings information, but also the father–son link. In the Nordic countries, parent–child links are from either Census data or from birth records (Bratsberg et al., 2007).

unconditional distribution of income in the parental generation and of the distribution conditional on a few key predictors of income, as well as a sample of "offspring" to provide information on both their income distribution and on the predictors for their parents. Two-sample methods, first used in the intergenerational context by Björklund and Jäntti (1997) for a comparison of the United States and Sweden, have later been used in several countries, including Britain, Italy, France, Brazil, and Australia.[68]

Each of these three types of data is subject to measurement challenges (see Section 10.4). Measurement errors in income and other data used in the analysis are an issue, and not only in survey- but also in register-based sources, although the nature of the errors are likely different (e.g., recall error in survey data and underreporting due to tax evasion in register data).[69] Attrition, especially selective attrition, is a concern in longitudinal surveys, a problem that may be compounded in intergenerational follow-up. The reliability of the identification and linking of parents and children is a concern when that is done using administrative data.

Before we delve into the evidence, we should note that the overwhelming majority of studies, in the United States as well as in other countries estimate elasticities (i.e., estimates of the Beta measure discussed in Section 10.3). When correlations are available (either directly, reported by the authors, or derived using Equation 10.4 based on Betas and the standard deviations), they are product–moment (Pearson) rather than rank (Spearman) correlations. Fully controlling for the marginal distributions would require the latter. Moreover, we are unaware of any study that explicitly recognizes the implications of the GEIV model for estimated elasticities that attempts to control for those effects.

One reason most analysts may estimate Betas rather than Pearson or Spearman correlation coefficients, or transition matrices, is convenience: controlling for systematic life cycle effects in both generations is simple in a multiple regression framework. Moreover, the impact of transitory errors, when classical, is well understood and simple to mitigate. Estimation of the Pearson correlation is subject to the same errors-in-variables inconsistency as the Beta, but transitory errors in both offspring and parent income cause r to be underestimated, so reducing the inconsistency requires time-averaging income in both generations. Transitory errors lead to inconsistent estimates of rank correlations also. O'Neill et al. (2007), who presented simulation evidence based on bivariate normal distributed parent–offspring income that are subject to a range of different kinds of measurement error, suggest robustly that intergenerational persistence is underestimated and mobility overestimated in the presence of measurement error. Finally, in many cases,

[68] Two-sample methods were independently developed by Angrist and Krueger (1992) and Arellano and Meghir (1992). Methods to estimate the variance of such estimators were derived by Inoue and Solon (2011).

[69] For a discussion, see, for example, Ehling and Rendtel (2004).

Beta and *r* are estimated using instrumental variables, often using sample moments from different samples. These techniques are well understood in moment-based estimation, but less so for rank correlations and nonparametric techniques.

10.5.2 Intergenerational Persistence in the United States

Although there are many studies of intergenerational mobility in the United States as well as in other countries, the literature is characterized by a surprising number of omissions. For instance, we have been unable to locate transition matrices for different cohorts of parent–child pairs, so we are unable to examine the change across time in mobility using the dominance approach.[70] Most U.S. researchers report only Betas, not *r* or rank correlations, so standardization for changes in the marginal distribution of earnings or income is incomplete at best. And yet this is a period in which there have been pronounced increases in inequality in the United States (and many other countries).

By the late 1980s, two longitudinal data sets in the United States, the Panel Study of Income Dynamics (PSID) and the National Longitudinal Study of Youth (NLSY) had been running for sufficiently long to allow the study of the incomes of parents and children at economically active ages. Around that time, three papers were published in reasonably close succession that made use of these data, by Solon (1992), Zimmerman (1992), and Altonji and Dunn (1991). The papers by Solon (1992) and Zimmerman (1992), which appeared prominently in the same issue of the *American Economic Review*, made two major contributions.[71] First, they pointed out some of the statistical problems involved in estimating the relationship between "long-run" incomes of members of the same family. Most earlier studies used single-year measures of permanent earnings and were based on nonrepresentative, homogeneous samples. Their analyses suggested that the estimates of intergenerational correlations in previous studies most likely were considerably downward biased. By using multiple years of fathers' earnings, this downward bias could be reduced. Solon also presented an estimator that most likely overestimates the correlation and thus produced a range within which the true correlation must lie. Second, their results suggested Betas between fathers' and sons' long-run incomes as high as 0.4 or 0.5, numbers that are much larger than those in the previous studies surveyed by Becker and Tomes (1986). Solon and Zimmerman obtained similar results using two different data sets, which lends additional credibility to their findings.

Solon (1992) also estimated the correlation by use of an instrumental variables (IV) method, arguing that this produces an *upward* inconsistent estimate of Beta. The argument, in brief, is to treat parental education as an omitted variable, but also to use parental

[70] Fertig (2003) shows evidence based on transition matrices for multiple cohorts of offspring but does not report the full transition matrices.

[71] Altonji and Dunn (1991) received far less attention, in part because it was published in a less well-known journal.

education as an instrument, so it is an invalid instrument. If the true direct effect of parental education is positive and it is positively correlated with parental income, such an IV estimate produces an overestimate of the intergenerational income elasticity. Thus, the OLS estimator using time-averaged parental income underestimates and the IV estimator overestimates the elasticity, bounding the parameter from below and above. Moreover, in pointing to the possibility of using an IV estimator, Solon (1992) also opened the door to estimating elasticities, reliably as it turned out, in cases where actual father–son pairs are unavailable.[72]

Mazumder (2005b), using earnings information from the U.S. Social Security Administration (SSA), examined intergenerational earnings Betas for U.S. sons and daughters with respect to fathers' earnings. His focus is on variations in the number of years across which fathers' earnings are averaged, along with several other measurement issues such as whether or not to require fathers to have positive earnings in all years, if zero earnings due to noncoverage of Social Security by registers are imputed or not, as well as whether or not zero earning offspring are included in the analysis. The results demonstrate, among other things, that attenuation from transitory variation in earnings remains substantial even after averaging fathers' earnings over up to 16 years, especially if transitory errors are characterized by autocorrelated errors. In a striking demonstration of the the impact of averaging across multiple years of parental income, Mazumder (2005b, Table 4) reported an elasticity of 0.253 (se 0.043) when only 2 years (1984–1985) of fathers' incomes are used, increasing to 0.553 (se 0.099) and 0.613 (se 0.096) when averages across 1976–1985 and 1970–1985 are used, instead. The U.S. estimates he reported thus encompass the majority of the estimates reported in Figure 10.13, excluding only Peru at the top end and Canada, Finland, Norway, and Denmark at the low end. Note, however, that in extending the number of periods over which fathers' income is averaged conflates two types of effects, namely transitory errors (whose variance is reduced) and life cycle effects (which become averaged). In the absence of estimates of λ_{Ps} and θ_{Ps}, it is hard to tell which of these is empirically responsible for the change in the elasticity.

Dahl and DeLeire (2008), also using data from the SSA but with data on noncovered years as well and using even longer time spans for fathers' earnings than Mazumder (2005b), estimated Betas for father–son and father–daughters pairs. The father–son estimates vary between 0.259 and 0.632, spanning, again, much of the observed range in the cross-country evidence on display in Figure 10.13. The father–daughter Betas range from −0.041 (which is not significantly different from zero) to 0.269. Naga (2002) used

[72] The first example of such work is that by Björklund and Jäntti (1997), which used an IV estimator based on two independent samples to estimate the intergenerational elasticity in Sweden and constructed a similar estimate for the United States. Betas estimated using actual Swedish father–son pairs are almost exactly the same as the two-sample IV estimate. There have been a large number of studies subsequently that use two-sample IV estimators including for Italy (Checchi et al., 1999), Brazil (Dunn, 2007), Australia (Leigh, 2007), and France (Lefranc et al., 2009).

father–son pairs observed at the same point in the life cycle and estimated elasticities using three methods—OLS on time-averaged data, IV, and a MIMIC latent variable estimator—and found elasticities that range from 0.297 to 0.7.

Chadwick and Solon (2002), Minicozzi (2002), and Fertig (2003) also examined Betas for women. Chadwick and Solon (2002) highlighted the importance of using family income when comparing Betas for men and women (in which case they are quite similar; when using individual earnings, Betas for women tend to be much lower). The sensitivity of Betas to sample selection rules was examined by Couch and Lillard (1998) and Minicozzi (2003). In both of those papers, sample selection issues were found to be very important for the Betas. Hertz (2005) examined racial differences in the elasticity. Estimates of Beta for the United States can also often be found in research that is either comparative or primarily about other mobility in other countries, Examples include the studies of Germany by Couch and Dunn (1997), Australia by Leigh (2007), Sweden by Björklund and Jäntti (1997), and Singapore by Ng et al. (2009).

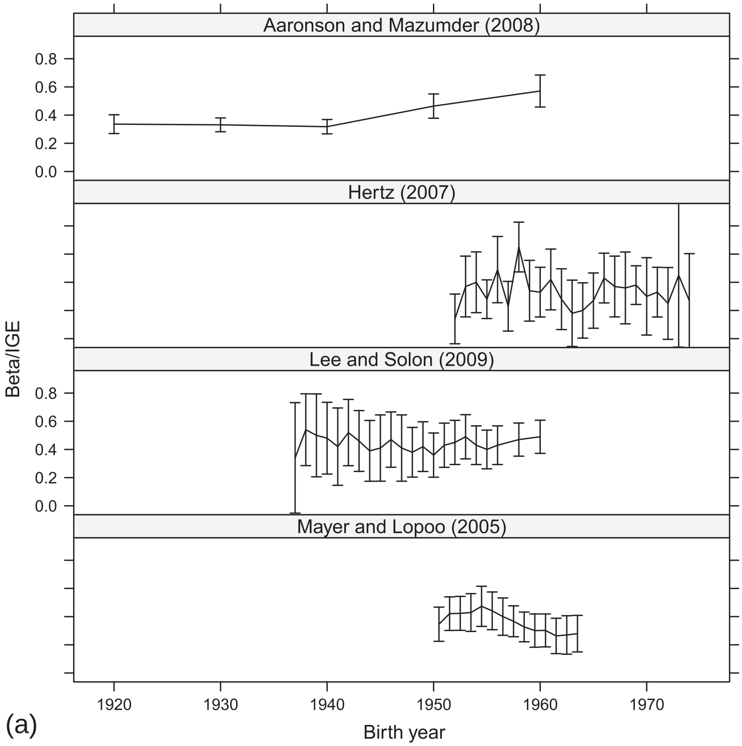
Two U.S. papers that drew attention early on to the possibility that estimates of intergenerational persistence may be subject to not only attenuation inconsistency from transitory errors in fathers' earnings or income, but also to life cycle effects in the offspring generation, were Buron (1994) and Reville (1995). Instead of adjusting for the average life cycle effects, Buron (1994) allowed earnings profiles to vary across demographic groups, which leads to a higher estimated persistence than when using the same adjustment. Reville (1995) in turn investigated how varying the age and outcome year of sons changes the estimated persistence. For instance, by following the same cohort of offspring as they age from 26–30 to 34–38 and using a 4-year average of their earnings (keeping father's earnings constant), the Pearson correlation r increases from 0.296 to 0.423 (Reville, 1995, Table 5). Hertz (2007), Lee and Solon (2009), Gouskova et al. (2010), and Chau (2012) all try to take into account biases from both transitory errors and life cycle effects.

Gouskova et al. (2010), applying the insights of both Haider and Solon (2006) and Grawe (2006), estimated earnings elasticities for father–son pairs using data from the PSID, where the fathers and sons are of the same age. Using age ranges 25–34, 35–44, and 45–54, regressing a 3-year average of sons' earnings on a 5-year average of fathers' earnings, they found elasticities of 0.29, 0.41, and 0.42, respectively. These estimates, especially the low value for the 25–34 age range, are consistent with the patterns for λ in Haider and Solon (2006). Another recent study considering the implications of the results in Haider and Solon (2006) and Chau (2012) models the income processes of both fathers and sons using heterogeneous growth profiles and autocorrelated errors. Intergenerational elasticities are then estimated based on data simulated using the parameter estimates. The U.S. estimates, based on PSID data, show an estimate of Beta of 0.392, but elasticities are as high as 0.662 when the earnings processes of sons and fathers are allowed to be different.

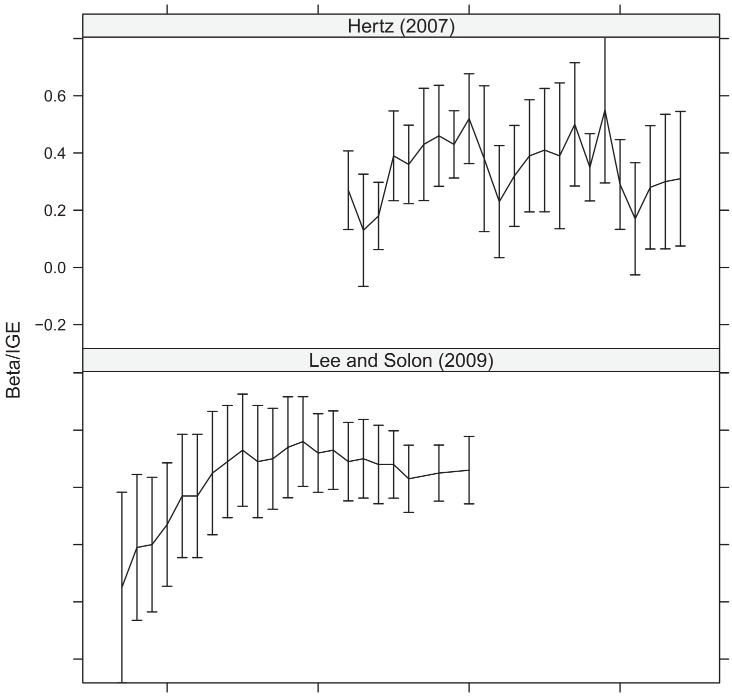
Muller (2010) tackled another complication with estimating the measurement of permanent income, namely if the elasticity varies because of shocks to parental income that take place when the offspring was living in the parental home. Parental income earned in childhood years is associated with much higher elasticities than either before the child was born or after he had left home, a result that is broadly robust with respect to standardizing the stage of the life cycle at which incomes are measured in the two generations. The results are consistent with the view that transitory shocks in childhood do affect offspring income. Although the purpose of the literature on intergenerational mobility reviewed here is not to uncover causal effects of income, this finding lends weight to the view, discussed in Section 10.5.1, that income risk may also be intergenerationally correlated.

Trends over time in intergenerational mobility in the United States, as measured by changes in Beta, have been estimated by Hertz (2007), Mayer and Lopoo (2005), Lee and Solon (2009), and, using two-sample methods, by Aaronson and Mazumder (2008). We show a selection of estimates in Figure 10.14, indexed by the birth year of the offspring, ranging from men born in the 1920s to men and women born in the early 1970s. The elasticities are evaluated at somewhat different ages, but the picture that emerges is one that suggests little systematic trend among men, with the possible exception that persistence may have increased among men from the 1940s to 1960s, mainly on display in the Aaronson and Mazumder (2008) estimates and weakly supported by both Hertz (2007) and Lee and Solon (2009). The estimates for women in Hertz (2007) and Lee and Solon (2009) suggest increasing persistence for the early cohorts but little change from around 1960 onward. The differences across studies suggest care must be taken in interpreting trends based on but a few data points and sets of definitions. The large confidence intervals around each point estimate also highlight the importance of statistical inference. Indeed, all the confidence intervals in the series from Hertz (2007), Lee and Solon (2009), and Mayer and Lopoo (2005) overlap. Although this does not mean there cannot be significant differences between point estimates, it does warrant some caution.

The IGE (Beta) is related to a "global" log-linear regression, forcing the slope of the conditional expectation of offspring log income to be a linear function of parent log income. There are many ways to relax the assumption that the slope is the same everywhere. Differences in the slope at different levels of parental income can be motivated by theoretical concerns. A commonly cited concern is the potential presence of borrowing constraints with respect to parental investments in child human capital (Becker and Tomes, 1986; Bratsberg et al., 2007; Grawe, 2004b). Bratsberg et al. (2007) fit a polynomial in parental income to the data for the United States drawn from the NLSY to allow for a flexible shape between offspring and parental income. They found that a second-order polynomial in parental income provides a reasonable fit for U.S. data. The IGE based on a log-log regression is 0.542, whereas those based on the polynomial imply elasticities of 0.489, 0.575, and 0.646 at the 10th, 50th, and 90th percentiles of parental income, respectively. Couch and Lillard (2004) demonstrated that these results are highly sensitive to the procedure applied. Using both second- and third-order



(a)



(b)

Figure 10.14 (See legend on next page) polynomials in both the log and the level of parental income, they estimated elasticities in the first, third, and fifth quintile groups of fathers' income to be 0.124, 0.234, and 0.292 using a quadratic, and 0.219, 0.230, and 0.171 for the cubic polynomial, compared to 0.158 in the log-log. Thus, using the second-order polynomial, elasticities increase monotonically across fathers' income but, using the third-order polynomial, they increase to decline at higher levels. Another option is to estimate the conditional mean (and, by implication, its slope) nonparametrically, for instance using kernel regression.

The elasticity is a measure of average *persistence* of income rather than of *mobility*. In other words, the regression coefficient on father's log (permanent) earnings tells us how closely related, on average, an offspring's economic status is to that of his or her parent. It is quite possible for two distributions to have highly similar average persistence, but for one to have substantially more mobility around that average persistence. The elasticity can thus be the same, but arguably the distribution with a greater residual variation—variability around the average persistence—is the one with greater mobility (see the discussion of the Gottschalk and Moffitt "BPEA" measure in Section 10.3). Moreover, two distributions with the same regression slope may have quite different, and varying, conditional variances around that slope. For instance, a distribution with a "bulge" in the variance at low levels of fathers' earnings, that is, a pear-shaped bivariate distribution, will exhibit relatively more mobility at the low end of the distribution than will a distribution with a constant conditional variance.

One approach is to examine both the regression coefficients and residual variances. Other approaches, such as nonparametric bivariate density estimates, similar to Figure 10.4 in the intragenerational case in Section 10.3, would in principle be available (see, e.g., Bowles and Gintis, 2002). Very few studies take that route, however. Quantile regression (Koenker, 2005) can also be used to examine the conditional distribution of offspring income, conditioned on parental income. Although the slopes of the conditional quantiles of offspring income can be of interest in and of themselves, we tend to find what they say about the full conditional distribution of greater interest than the slopes of individual quantiles (cf. the discussion of this in Section 10.3.3). In the prototypical homoscedastic regression, where the variance (or indeed, any higher moments) of the

Figure 10.14 Trends in U.S. intergenerational income persistence. *Note: The estimates in Lee and Solon (2009) are the elasticities for different outcome years at age 40, presented here by subtracting 40 from the outcome year and are derived using a 3-year average of parental income. Mayer and Lopoo (2005) estimate elasticities for 4-year birth cohorts, which are centered here, observe offspring at age 30, and use a 7-year average of parental income (at ages 19–25). Hertz (2007) presents elasticities at age 25 and uses a 3-year average of income. His estimates further control for panel attrition. Aaronson and Mazumder (2008) uses two-sample methods applied to (IPUMS) census data, with elasticities applying to 35- to 44-year-olds, here centered at age 40. Source: Aaronson and Mazumder (2008, Table 1, column 6), Hertz (2007, Table 4), Mayer and Lopoo (2005, Table A1), and Lee and Solon (2009, Table 1).*

residual does not depend on the explanatory variable, the quantile regression slopes should all be straight lines with slopes equal to the conditional mean and median. Deviations from these patterns are informative of variations in the shape of the conditional distribution.

Eide and Showalter (1999) estimated quantile regressions for several percentiles using PSID data on father–son pairs where the sons are 25–34 years old, using a 3-year average of parental income and 7-year average of sons' earnings. They found a Beta of 0.34 and slopes of the conditional quantiles with respect to parental income of 0.77 at the 5th percentile, 0.47 at the 10th percentile, 0.37 at the 50th percentile (median), 0.17 at the 90th percentile, and 0.19 at the 95th percentile. That is, they (mostly) find the slope to be decreasing in the percentile but also that the Beta is lower than the slopes of the quantiles up to the 75th percentile.[73]

Conditional quantiles can be combined with nonparametric techniques to allow for the slope to change flexibly. We illustrate this in Figure 10.15 from Lee et al. (2009), who used PSID data for U.S. sons and fathers to nonparametrically estimate the conditional quantiles of sons' income conditioned on fathers. We can see that the slopes of lower quantiles tend to be steeper at low parental income than for the higher quantiles and that the slopes tend to level of as parental income increases.

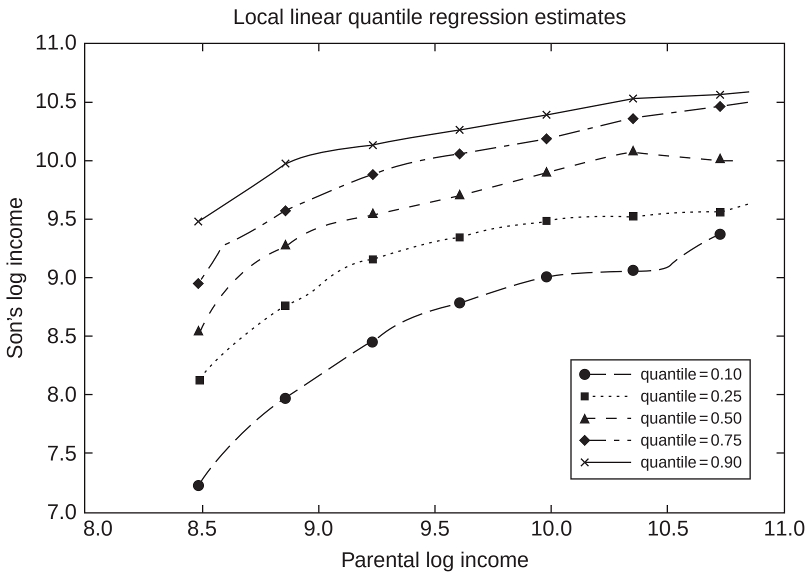


Figure 10.15 Intergenerational income persistence: nonparametric quantile regression for U.S. father–son pairs. *Note: Estimates based on PSID father–son pairs as prepared by Minicozzi (2003). Sons' income is the average of labor income at ages 28 and 29, and parental income is predicted parental income as defined by Minicozzi (2003). Source: Lee et al. (2009, Figure 1).*

[73] See also Grawe (2004a) for additional U.S. estimates.

Asymmetries in intergenerational mobility can be straightforwardly described using transition matrices, a simple but underused device for illustrating intergenerational mobility. In allowing for fairly general patterns of mobility, mobility or transition matrices offer the additional advantage of allowing for asymmetric patterns, for example more mobility at the top than at the bottom. To illustrate, we show in panel A of Table 10.5, a decile transition matrix for U.S. fathers and sons.

The cell entries show, for each decile group of origin (i.e., fathers' decile group), the percentage of sons in each destination decile group. Specific aspects of the transition matrix tend to be highlighted. For instance, the main diagonal shows the percentage of sons who remain in their father's decile group. One descriptive statistic is the sum of the main diagonal probabilities (the matrix trace), in this case 165. With ten income classes, there is origin independence if each entry in the table is 10%, which implies an average "excess" immobility relative to origin independence of 6.5% points. Conversely, 83.5% of U.S. sons are in a different decile group than their fathers. The Normalized Trace index (Shorrocks, 1978b) for this matrix is $(10-165/100)/(10-1)=0.93$.

The corner probabilities are often of special interest also. In this case, 22% of the sons of the poorest 10th of fathers are in the poorest 10th themselves, whereas 26% of the sons of the richest 10th of fathers are in the richest 10th. Conversely, upward mobility from the lowest 10th is $100-22=78\%$, and downward mobility from the highest 10th is $100-26=74\%$. By contrast, 7% of sons of poorest fathers and 3% of the richest end up in the top and bottom decile groups, respectively. Somewhat to our surprise, we are unable to illustrate an application of dominance analysis to examine the change across cohorts in U.S. intergenerational mobility. We are unaware of a comparable transition matrix for a later or earlier cohort.

A final observation can be made regarding the "shape" of the transition matrix. Transition matrices for bivariate normal data, such as the simulated data in O'Neill et al. (2007) or the illustrations of the consequences of different r in Björklund and Jäntti (1997), are symmetric. For instance, the two corners on the main diagonal are equal as are the corners on the antidiagonal, and the upper triangle is the mirror of the lower triangle. The U.S. father–son transition matrix clearly exhibits very little symmetry of this sort. The lack of symmetry implies that both mobility and persistence may be different across the distribution, and of course that the data are unlikely to be well described by a bivariate log normal distribution.

Recently, Bhattacharya and Mazumder (2011) proposed a set of measures based on the bivariate percentile distribution, focusing specifically on upward and downward mobility relative to a parameter τ that specifies the number of percentiles one needs to move up to be considered upward mobile, illustrating their approach by comparing mobility differences between racial groups in the United States using data on men from the NLSY. Whites are found to be distinctly more likely to move upward than blacks.

Table 10.5 Intergenerational decile transition matrices for earnings, father–son pairs, Canada and the United States

A. United States

10.5.3 Cross-National Comparative Evidence on Intergenerational Associations

We now turn to examining evidence on intergenerational income mobility in other (mostly rich) countries. To illustrate the importance of how mobility is measured for cross-country rankings, we start this subsection by reporting results from two recent papers, each of which compares three countries. Corak et al. (2013) compared earnings mobility between fathers and sons in Canada, Sweden, and the United States. Their focus is on comparing upward and downward mobility, but we rely here on their three estimates of persistence: Beta (IGE), the Pearson correlation *r*, and the Spearman rank correlation are reported in Table 10.6 along with the ranking of the three countries in each case. The estimated Betas are in line with those found in previous research and show intergenerational income persistence to be the greatest in the United States, followed by Canada and Sweden. The ranking by the product–moment correlation *r* is the same, but now the U.S. point estimate is much closer to those of Canada and Sweden. By contrast, according to the rank correlations, Canada has the lowest persistence, and Sweden and the United States are tied. This, arguably the preferred scalar index of persistence (as it most clearly abstracts from differences in marginal distributions), suggests a very different ordering of countries with respect to intergenerational mobility than that on display in the "Great Gatsby" curve of Figure 10.13.

Eberharter (2013) estimated persistence in terms of Betas for disposable income among men and women in Germany, the UK, and the United States, using data from the U.S. PSID, the German SOEP, and the UK BHPS. The elasticity estimates are reported in the left panel of Figure 10.16 together with the 95% confidence intervals. This is a rare study because it presents estimates for several countries using measures of disposable income. It is also unusual to pool sons and daughters, although that choice is arguably well motivated when the purpose is to examine the persistence in living standards.

Table 10.6 Intergenerational earnings mobility in Canada, Sweden and the United States: Beta, *r*, and the rank correlation

	Beta		r		Rank correlation	
Country	**Estimate**	**Rank**	**Estimate**	**Rank**	**Estimate**	**Rank**
Canada	0.26	(2)	0.23	(2)	0.24	(1)
Sweden	0.25	(1)	0.21	(1)	0.30	(2)
United States	0.40	(3)	0.26	(3)	0.30	(2)

Note: Canadian estimates rely on tax records. Father's earnings are a 5-year average and son's a 3-year average 1997–1999 when they were 31–36 years old. Swedish estimates, also based on tax records for earnings, rely for fathers on 20 years of earnings data measured at ages 30–60 and for sons on an 11-year average across ages 30–40. The U.S. estimates stem from the Survey of Income and Program Participation panels using earnings from Social Security records. Fathers' earnings are a 9-year average between 1979 and 1986 when they were 30–60 years old. Sons' earnings are a 5-year average between 2003 and 2007 in years they were at least 28 years old.
Source: Corak et al. (2013, pp. 10–11).

Although Eberharter (2013) did not report rank correlations, these results bring out quite forcefully the importance of being wary of changes in marginal distributions across the cohorts, especially when comparing estimates from different countries.[74] As can be seen by comparing the left panel of Figure 10.16, which plots the elasticities, with the right panel, which reports the implied (Pearson) correlations r, the results are dramatically different in the two cases. The United States has a substantially higher elasticity than either Germany or the UK (0.68 as opposed to 0.48 and 0.50), but when we derive

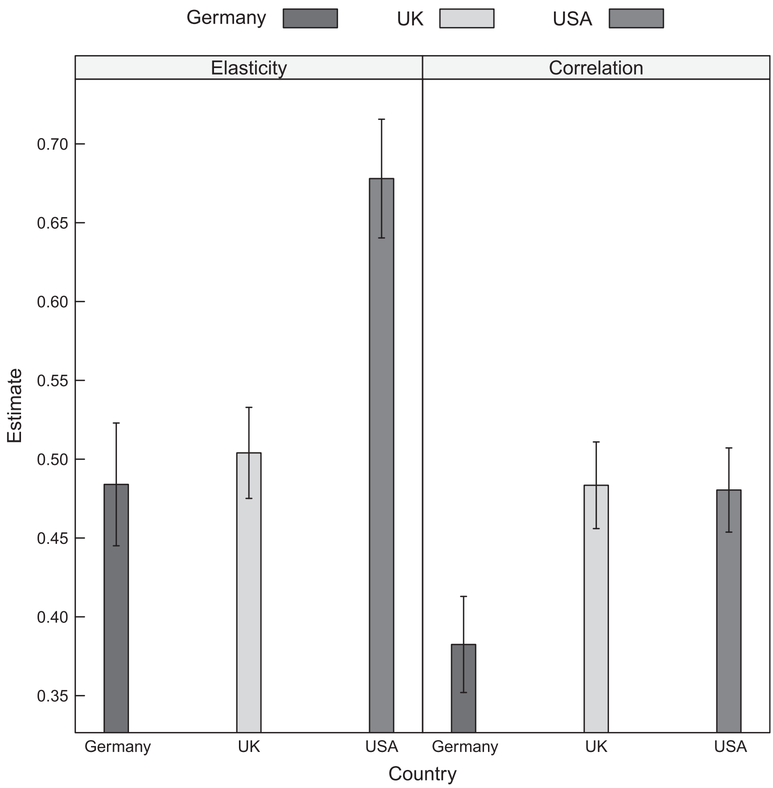

Figure 10.16 Intergenerational persistence of disposable income: elasticities versus correlations. *Note: Error bars show 95% confidence intervals. Estimates are for posttax, posttransfer income for all individuals (for sons and daughters combined). Offspring incomes are observed for those older than 24 who are out of full-time education and are averaged across 2005–2009 (Germany), 2003–2007 (USA), and 2004–2008 (UK). Parental income are observed as offspring were 14–20 years old and are averaged across 1988–1992 (Germany), 1987–1991 (USA), and 1991–1995 (UK). Eberharter (2013) reports standard deviations in parental and offspring generations for full samples rather than the estimation samples, so the estimated implied correlations, obtained using* $\rho = \sigma_P/\sigma_O\beta$ *are approximate only. Source: Authors' elaborations based on Eberharter (2013, Tables 1 and 2).*

[74] See, for example, Björklund and Jäntti (2009).

the correlations, the UK has a correlation that is higher than that in the United States, and Germany's is substantially lower than either of those.[75] It is not possible, of course, to infer what the rank correlations are from the Betas and *r*.

Thus, even confining ourselves to scalar measures of mobility, switching between Beta and the two correlations leads to rank reversals. The fact that Sweden and the United States, two countries that inhabit very different regions in the "Great Gatsby" curve diagram, have equal mobility as measured by the rank correlation, is particularly notable.

Most studies of intergenerational income persistence and mobility were inspired by the U.S. studies of Solon (1992), Zimmerman (1992), and Altonji and Dunn (1991). An exception is the study of intergenerational mobility in the UK (Atkinson, 1981b; Atkinson et al., 1983; cited several times by Solon, 1989, 1992, possibly serving as inspiration for the U.S. studies). Intergenerational income persistence in the UK, especially the question of whether it has changed, has been subject to substantial controversy recently. We therefore start our discussion of single-country studies with UK evidence.

The early estimates of father–son Betas in Atkinson (1981b) and Atkinson et al. (1983) using a geographically limited and truncated sample were around 0.44. Atkinson et al. (1983, p. 111) discussed the impact of measurement error in parental income, finding that for plausible value of the signal-to-noise ratio, the true Beta might well be at least 0.5. Dearden et al. (1997), using data from the cohort study of 1958-born children (the NCDS), estimated Beta to be around between 0.29 (OLS) and 0.58 (2SLS). Later studies by Blanden and Machin (2008), Blanden et al. (2010), and Blanden et al. (2013) have generated a reasonably wide range of UK estimates.

One particularly contested UK finding is that mobility has decreased, based on the finding that the IGE estimated for the cohort born in 1958 (NCDS) is greater than the IGE for the cohort born in 1970 (BCS). Depending on estimation method, the elasticity increased from 0.31 to 0.33 (OLS) or 0.33 to 0.50 (2SLS), both measured for sons at age 34 (Blanden and Machin, 2007). Most recently, using a single-year measure of parental income and no controls for parental age, Blanden et al. (2013) reported an increase in the IGE between NCDS and BCS cohorts from 0.211 to 0.278 for parent–son pairs, corresponding to a difference of 0.067 (se 0.034). These estimates have been widely referred to in UK public policy debates about social mobility, as discussed recently by Goldthorpe (2013).

The UK debate provides several lessons. First, two estimates provide little evidence about the existence of a trend. U.S. estimates for different birth cohorts vary quite substantially; see Figure 10.14, where there is no apparent trend. Moreover, different data

[75] The orderings are statistically robust: the confidence interval for the U.S. elasticity does not overlap those for Germany or the UK and, as the intervals for the correlations between Germany on the one hand and the United States and the UK do not overlap, pairwise *t*-tests reject the null that the correlations are the same.

sources and estimation methods may generate different results. For example, Nicoletti and Ermisch (2007) derived Betas for Britain using two-sample methods applied to BHPS data. They estimated relatively stable elasticities and correlations for cohorts born between 1950 and 1960. For the cohorts born between 1961 and 1972, elasticities rose somewhat over time but correlations are stable. These results are only partially consistent with the estimates derived from the BCS and NCDS cohorts. Second, data quality has serious implications for public policy. Part of the UK controversy centers around whether the two cohort studies in question, the NCDS and BCS, have sufficiently comparable data. Third, measures of intergenerational *income* mobility may change over time in a different way from measures relating to other concepts of intergenerational economic and social mobility. These differences may in turn be informative of the nature of societal change.

The possibility that intergenerational income persistence in the UK has increased, but class mobility has not, led Erikson and Goldthorpe (2010) to examine mobility in the earnings/income and class spaces. They concluded that problems with the measurement of income in the parental generation render the finding of an increase in income persistence suspect, and they emphasized the stability of social class mobility over time as indicating that there has been little change in intergenerational mobility in the UK.

More recently, Blanden et al. (2013) used an approach proposed by Björklund and Jäntti (2000) to decompose the *r* (strictly speaking, the partial correlation) into the correlation of "class-predicted" incomes, the correlation of deviations of actual from class-predicted incomes, and their cross-correlations. Their results are consistent with there being stable class mobility, as suggested by there being no contribution (but in fact, a small negative one) from the "class-predicted" income correlation to the change, whereas all three correlations involving the residuals contributed to an increased partial correlation. The results can be interpreted as saying income and class mobility decreasingly capture the same phenomena, as the relationship between income and class appears to be different in the later than in the earlier cohort. The discussion of these results by Blanden et al. (2013), Erikson and Goldthorpe (2010), and Goldthorpe (2013) provides valuable insights into the scientific and public debates about social and economic mobility.

A key conclusion that we draw about the UK debate, not least in light of the divergent U.S. estimates of both levels and trends, is that much richer data than those provided by the NCDS and BCS cohort studies are needed to draw firm conclusions about the level and trend in UK income mobility.[76] It is also possible that class and income mobility are diverging because the processes that generate transitory errors are changing in ways that

[76] We note, in passing, that the dominance analysis conducted by us of the income quintile group transition matrices reported by Blanden et al. (2010, Table 3) for the NCDS and BCS suggest that, except for the cells (5,3) and (5,4) all BCS–NCDS differences in the cumulated matrices are positive (but those entries are negative). Thus, there is no dominance between the two cohorts.

suggest intergenerational advantage is increasingly transmitted through deviations from the systematic components of income. In our view, the UK debate underlines the need for high-quality data to resolve what has turned out to be a question of great social concern.

Corak and Heisz (1999) provided Betas for both earnings and total market income for Canadian father–son pairs, using (at most) a 5-year average of parental income and a single year for sons' in 1995 at which point they are 29–32 years old. They find elasticities for earnings of 0.131 and for market income of 0.194. In addition to transition matrices, discussed later, they also estimated the conditional expectation, and its slope, of sons' earnings with respect to fathers', nonparametrically. They found that the elasticity varies substantially and quite nonmonotonically across the distribution of fathers' earnings.

Leigh (2007) estimated the intergenerational earnings elasticity for Australian men using two-sample methods. For men born in 1949–1979, he estimated an elasticity of 0.181. This compares to a U.S. elasticity for a similar cohort of sons, obtained using similar estimation methods, of 0.325. The difference is statistically insignificant, but still suggests Australian persistence is lower. His results for older cohorts vary substantially, however. For men born in 1911–1940 and 1919–1943, the point estimates are 0.26, but for men born in 1933–1962, the estimate is 0.413. Gibbons (2010) estimated intergenerational mobility for New Zealand father–son and father–daughter pairs of 0.25 and 0.17, respectively.

Lefranc (2011) used two-sample methods to estimate Betas for cohorts of men born between 1931 and 1975 in France. The estimates, which start at 0.626 for men born 1931–1935 decline to 0.441 for cohorts born 1956–1960 and increase thereafter, being 0.559 for cohorts born 1971–1975. Estimates for Spain are provided, e.g., by Cervini-Plá (2009) and for Italy by Mocetti (2007), both of which are high by international standards at about 0.4 and 0.5, respectively.

Pekkala and Lucas (2007) estimated intergenerational elasticities for Finnish cohorts born between 1930 and 1970, using census data on annual earnings for offspring and family income for parents. The intergenerational elasticities declined substantially; for sons from more than 0.30 to around 0.20, and for daughters from 0.25 to around 0.15 for cohorts born in 1930 to those born in 1950 and later. It may be of special interest to note that Pekkarinen et al. (2009) found comprehensive school reform, treated as a quasi-experiment, reduced the Finnish Beta by almost a third. The Norwegian trend studies have focused on the post-1950 cohorts. Bratberg et al. (2007) found a small decline in father–son and father–daughter elasticities from 1950 to 1965 cohorts. However, Hansen (2010) reported that this result does not hold when using the income of both parents. Instead, she found a small increase in the elasticities for the 1955–1970 cohorts. This difference suggests an increasing role for mothers, which has not been much explored in the literature. The Beta for Swedish father–son pairs is around 0.25 (see, e.g., Björklund and

Chadwick, 2003), but much higher at the top of the distribution (Björklund et al., 2012). Estimates from Denmark suggest quite low levels of persistence (e.g., Bonke et al., 2005).

Lefranc et al. (2013) estimated Betas for Japanese sons and daughters using two-step sample methods. The estimates for men are all quite close to 0.35. For daughters, estimates vary between 0.182 and 0.367. The evidence on whether or not the Betas increased for younger cohorts is mixed, at best. Ueda (2009) used instrumental-variable techniques to estimate elasticities for men and women in Japan also and found elasticities of around 0.411–0.458 for men, and 0.229–0.361 for women, depending on marital status and the use of family or individual income.

Nonlinearities in the parent–child conditional income expectation were explored in a multicountry study by Bratsberg et al. (2007), who found the data for the United States, UK, Denmark, Norway, and Finland all suggested the relationship is convex, with elasticities low at low levels of parental income, and increasing thereafter. At all quantiles of parental income, the elasticities are lower for the Nordic countries than for the UK and the United States. Interpreted in terms of borrowing constraints on investments in child human capital, the results suggest capital market imperfections may be more of an issue not at the bottom but more around the middle of the distribution of parental income.

Raaum et al. (2007) tackled another question in a multicountry study, namely how the mobility of daughters compares with that of sons across countries. Drawing on Chadwick and Solon (2002) and Björklund and Chadwick (2003), they found women's intergenerational income persistence is very similar across countries relying only on individual earnings. When family earnings are used for both men and women, the country ordering of intergenerational persistence for women looks very much like that for men. Using a framework that involves the intergenerational transmission of human capital endowments, assortative mating, and labor supply that responds to both own and spouse's wage, they inferred that female labor supply is likely more (negatively) responsive to husband's earnings in the UK and especially the United States than in the Nordic countries.

We proceed to compare transition matrices across countries. To illustrate, consider the decile group transition matrices for the United States and Canada shown in Table 10.5 and derived from Mazumder (2005a) and Corak and Heisz (1999). Using the dominance approach discussed in Section 10.3.2, we can cumulate the transition matrices and take the United States–Canada difference. This leads to the results shown in Table 10.7. The vast majority of the cell entries are positive, suggesting Canada dominates the United States. However, given the two negative entries in cells (10,1) and (10,9), this result does not hold, strictly speaking.[77]

[77] We have not forced the rows or columns of either transition matrix to sum to 1, as they should in a bistochastic matrix. The U.S. matrix in particular fails this condition (most likely due to a smaller sample size and rounding error). If we do force the rows to sum to 1, the negative entries vanish, and we have dominance.

Table 10.7 Cumulated differences in intergenerational mobility tables across earnings decile groups for father–son pairs in Canada and the United States (USA–CAN)

Source: Authors' derivations using transition matrices shown in Table 5 from Mazumder (2005a) and Corak and Heisz (1999).

Recall from Figure 10.16 that between the Betas and *r*s for disposable income, the United States and the UK were reranked, whereas Germany was least persistent in both. In Table 10.8, we illustrate again the use of the dominance approach, this time using quintile group transition matrices also from Eberharter (2013). The differences in the cumulated transition matrices suggest that Germany dominates both the UK and United States (all entries in the United States–Germany and UK–Germany matrix are positive), but that the United States and UK cannot be ordered. Note, however, that there is only one strictly positive entry in cell (3,2), indicating the United States is close to dominating the UK.

10.5.4 Evidence on Sibling Correlations

In this section, we show evidence on sibling correlations and relate them to intergenerational correlations. Why are sibling correlations of interest in the study of intergenerational income mobility? One way to motivate the interest in intergenerational mobility is to argue that it is related to equality of opportunity (see Section 10.2). A society in which a person's position is heavily dependent on the family he/she is born into is one in which there is likely to be less equality of opportunity than one in which intergenerational persistence is very low.[78] But if we would like to understand how important family background is for the distribution of economic status, a focus on parent–child association captures only one part of the association. A fuller (but still incomplete) accounting of the

[78] As we argued earlier, and to underline a point made repeatedly in the literature, the link between intergenerational mobility and equality of opportunity is far from straightforward.

importance of family background can be done by comparing the economic status of siblings. It turns out that the *sibling correlation* can be thought of as an R^2 of family background, capturing the importance of factors that siblings share in (most often) the variance of log income or earnings. Although part of what siblings share is parental income, a large part is not. That is why sibling correlations are useful in assessing the importance of family background in the distribution of economic status.

To clarify the interpretation of a sibling correlation, we follow the exposition of Solon et al. (1991). Suppose that we observe annual income, assumed to equal long-run income plus transitory errors, assumed to be classical. The natural logarithm of income in year t, y_{ijt}, for sibling j in family i, for brevity, assumed to be measured as deviations from the population average, is modeled as

$$y_{ijt} = a_i + b_{ij} + v_{ijt}, \tag{10.24}$$

where a_i is a permanent component common to all siblings in family i, and b_{ij} is a permanent component unique to individual j, which captures individual deviations from the family component. The error term v_{ijt} picks up deviations of annual income from long-run income. The family and individual components are orthogonal by construction, so the long-run income variance is the sum of the family and individual component variances, $\sigma_a^2 + \sigma_b^2$. The share of the variance of long-run income that can be attributed to family background is

$$\rho = \frac{\sigma_a^2}{\sigma_a^2 + \sigma_b^2}. \tag{10.25}$$

This share coincides with the Pearson correlation in long-run income of randomly drawn pairs of brothers, which is why ρ is called a sibling correlation. As the conceptual model underlying the sibling correlation is defined in terms of variances, it can only vary between 0 and 1 (i.e., negative correlations are ruled out).

A sibling correlation can be thought of as an omnibus measure of the importance of family and community effects. It includes anything shared by siblings—parental income and parental influences such as aspirations and cultural inheritance, as well as neighborhood influences such as from school, church, and peers. Genetic traits not shared by siblings, differential treatment of siblings, time-dependent changes in neighborhoods, and so on are captured by the individual component b_{ij}. The more important the effects that brothers share, the larger is the brother correlation.

Part of what siblings share in a is parental income. A useful analytical insight is that (assuming for ease of exposition marginal distributions are in steady state) the brother correlation in income can be thought of as the sum of the intergenerational income correlation squared and the correlation of other factors siblings share but that are orthogonal to income:

$$\rho = r^2 + \text{correlation of other shared factors}. \tag{10.26}$$

When the steady-state assumption is untrue, the first part of the sum on the right-hand side of Equation (10.26) also involves the marginal distributions of income in the two generations. This decomposition allows us to apportion the overall importance of family background, as captured by ρ, onto that part accounted for by intergenerational persistence, measured by Beta or r, and the other factors siblings share that affect income.

Evidence about sibling correlations in earnings (and income) was surveyed by Solon (1999), Björklund and Jäntti (2009), and also by Schnitzlein (2014), who provided new estimates for Denmark, Germany, and the United States. We show in Table 10.9 evidence based mostly but not only on long-run earnings for several countries. The evidence is based on three main methods for estimating the variance components that constitute the sibling correlation: (unbalanced) ANOVA, restricted maximum likelihood estimates (REML), and generalized method of moments. As Björklund et al. (2009) reported, whether or not the transitory errors are allowed to be autocorrelated has a big impact on the estimated sibling correlations. Allowing errors to be autocorrelated tends to reduce the individual variance, so increasing the estimated sibling correlation, so cross-country comparisons should be made across similarly defined models.

Although there are multiple estimates for several of the countries, we have sibling correlations in earnings or income for no more than seven countries for brothers, and six for sisters. The estimates for Nordic countries are low (and by far the lowest for Norway), highest for China, and of similar magnitude in Germany and the United States. For men, 43–49% of the variance in long-run earnings in Germany and the United States is accounted for by family background. This compares to 14% in Norway and 20–25% in the other Nordic countries. The ordering is similar, but levels for women are lower across the board. Family background accounts for 30–39% of long-run earnings in Germany and the United States and between 11% and 23% in the Nordic countries.

The sibling correlation is a ratio of the variance of the family component in income to the variance of long-run income. In the spirit of the "Great Gatsby" curve, shown in Figure 10.13, it is of interest to compare now another measure of persistence, the sibling correlation, with another measure of cross-sectional inequality, namely that of permanent earnings or income. We plot in Figure 10.17 the brother and sister correlations against the standard deviation of (the natural logarithm of) permanent earnings/income for those cases listed in Table 10.9 where we have been able to find all variance components.[79] In each panel, we have drawn the least-squares regression line.

Despite the small number of countries some insights can be gained. Among men, the estimated levels of permanent income inequality are consistent with very different degrees to which family background accounts for long-run earnings. Finland, Denmark, and Norway have a standard deviation of log permanent earnings on either side of 0.4, as

[79] Figure 10.13 has a single point for each country, whereas we have included repeated observations for a country in Figure 10.17 for some cases.

The vertical axis shows the level of the estimated sibling correlation. Also shown in each panel is the least-squares regression line. Source: See Table 10.9.*

do Germany and the United States but, in the former group of countries, brother correlations are between 0.14 and 0.25. In the latter group, they are 0.43 and as large as 0.49. The regression line for men has all negative deviations for low brother correlations and all positive ones for high correlations, suggesting the least-squares line gives a poor fit. Indeed, if we look at the two "clusters" in each panel—the Nordic countries as one and Germany and the United States as the other—one conclusion may be simply that the Nordic countries differ form the United States and Germany. Thus, although the least-squares line in both panels has a positive slope, it may be premature to talk of a "Great Gatsby" curve for sibling correlations.

There is some evidence about changes across time in brother correlations both in the United States and Sweden. Levine and Mazumder (2007) examined brother correlations in earnings, family income, and hourly wages for two sets of cohorts: those born in 1942–1952 and those born in 1957–1965. The brother correlations in earnings increased from 0.263 to 0.452, in family income from 0.207 to 0.415, and those in hourly wages from 0.277 to 0.472. In no case is the change statistically significant at the conventional 5% level but, taken together, the estimates suggest the importance of family background may have increased quite substantially. By contrast, Björklund et al. (2009) studied change in brother correlations in Sweden starting with cohorts born 1932–1938 and ending in 1962–1968 and found a decline in the importance of family background in the long-run income of men of roughly 13% points. Although the authors are unable to pinpoint the reason for the decline, it coincides with the development of various welfare-state institutions.

We close by noting that, as with intergenerational associations, research on sibling associations should in the future provide more estimates for us to be able to draw robust conclusions about the importance of family background. Apart from the obvious question of why it is that siblings are so similar (what is it that families do?), we would like to see sibling correlations estimated (using the same methods and definitions) for a much wider group of countries than those seven for which we now have information.

We would also like to see rank correlations, not only Pearson correlations, to allow for a full standardization of the marginal distribution when comparing across time, countries, as well as estimates for both women as well as men. A minor point in that regard concerns estimation. Most of the estimates of sibling correlations in Table 10.9 rely on either unbalanced ANOVA or REML to estimate the variance components. Although REML estimates could in principle be defined for data that follow an arbitrary distribution, in practice the likelihood is that of a normal distribution, as a and b are both modeled as conditionally normally distributed variables. Although this may produce reasonably accurate estimates for the log of earnings or income, it is unlikely that REML would produce good estimates if applied to ranks, which are uniformly distributed by definition. Thus, the most feasible way of estimating sibling rank correlations would be to work with pairs of siblings rather than multilevel models.[80]

10.5.5 Other Approaches to Intergenerational Mobility

In this section, we discuss three other approaches to intergenerational mobility. Two, based on occupation and on analysis of surnames, have recently been used to study very long-run trends in intergenerational mobility for which income information is not available. The third concerns an emerging literature on intergenerational links across more than two generations.

Economists have much to learn from sociologists when it comes to the study of intergenerational mobility. The study of the transmission of socioeconomic advantage from generation to generation is one of the core issues in sociology. Empirical research has taken place for almost a hundred years, and the theoretical discussion is also rich. Not

[80] Note that the GMM-based estimates for Sweden reported in Table 10.9 also rely on pairs of brothers.

surprisingly, the available data, the statistical techniques, as well as the possibility to handle large data sets with statistical techniques have improved markedly in the last couple of decades. Hence, the prospects for comparative research based on reasonably comparable data have improved. Nonetheless, comparability is a major concern in the literature that we have come across.

One can distinguish between two strands of intergenerational research in modern sociology.[81] One of them focuses on the relationship between status or prestige attainment of two generations, in general fathers and sons. Occupation is used as the basis to define status and alternative scales that attach status levels to occupations have been suggested in this literature. For example, the famous Duncan status index (Duncan, 1961) used the average education and income of each occupational category. Treiman (1977) has constructed prestige scales from survey data on the average prestige that people attach to various occupations.

The other strand of research defines socioeconomic status in terms of social class but emphasizes that social classes are intrinsically discrete and unordered. Hence, the analytical task is to measure mobility between these classes. The pros and cons of these two approaches to intergenerational mobility have been subject to a more than lively discussion within the sociological research community. Both approaches are prevalent, and each has strong support.[82] The sociological literature on social mobility is far too vast to be reviewed here. One milestone is the monumental book by Erikson and Goldthorpe (1992b), discussed, e.g., in Erikson and Goldthorpe (1992a), Hout and Hauser (1992), and Sorensen (1992). This is a highly mature field that has generated enormous insight into intergenerational mobility.

Indeed, to study long-run changes in intergenerational mobility, class mobility may be the only option. Using census data with names and occupational information, Ferrie (2005) and Long and Ferrie (2007, 2013a) identified father–son pairs by tracking the son of a given father in a later census in the United States and the UK. Ferrie (2005) studied long-run trends in occupational mobility in the United States, and Long and Ferrie (2007, 2013a) compared long-run trends in the United States and the UK. They found that the United States was more fluid in the late nineteenth century than either the UK or the United States in the third quarter of the twentieth century, a finding for which changes in agricultural occupations is central. Their paper generated two critical comments by prominent sociologists, Xie and Killewald (2013) and Hout and Guest (2013), to which they replied (Long and Ferrie, 2013b). Taken together, these papers provide a useful introduction to the use of historical census data to study intergenerational mobility across long periods of time.

[81] Ganzeboom et al. (1991) provide an informative survey of this literature.

[82] For discussions, see, e.g., Ganzeboom et al. (1992, pp. 3–7), Erikson and Goldthorpe (1992a), Hout and Hauser (1992), and Sorensen (1992).

Another emerging strand of literature relies on the fact that surnames convey information on social status. Gregory Clark and collaborators have researched social mobility using data about surnames in Sweden, the United States, England, Japan, India, and China.[83] Güell et al. (2007) and Collado et al. (2012) examined intergenerational mobility in Spain using surnames. This approach has great promise, but it would be more convincing if it could be validated using data that contain either occupation or income so mobility using names could be compared with other, more traditional methods.[84]

Finally, there are a handful of papers that examine intergenerational persistence across more than just two generations. The multigenerational view is lucidly discussed by Mare (2011). Income persistence across multiple generations are estimated at least by Marchon (2008) and Lindahl et al. (2012). In both of those papers, both the parents' and grandparents' income affects offspring income, suggesting that the simple "AR(1)" model of intergenerational transmission is incomplete. These papers provide a perspective that most often goes unremarked on in the intergenerational mobility literature, namely that it relies on a "dynastic" view of parent–child associations. Once grandparents are included in the analysis, care must be taken to distinguish between maternal and paternal grandparents.

10.5.6 Summary and Conclusions

The large literature on intergenerational income mobility that has been surveyed in this section suggests that incomes are, indeed, persistent across generations. What has been learned?

The main lesson is that differences in data (the three "W"s discussed in Section 10.5.1) may account for many of the differences in estimates. Put another way, because of the impact of the combination of life cycle effects and transitory variation in both parent and offspring generations, combined with other data issues, we know surprisingly little either about how income persistence varies across countries, or how it changes within countries over time. We also know very little about exchange mobility (fully standardizing for differences in marginal distributions).

Thus, despite the public prominence of the "Great Gatsby" curve, very little is known about how intergenerational income persistence and mobility vary across countries and how this relates to cross-sectional inequality. More research, using comparable data for multiple countries across multiple cohorts of parents and offspring, is required. With a set of stylized facts about mobility differences and trends, we can then set out to try to explain them.

[83] See, e.g., Clark (2012), Clark (2010), Clark and Cummins (2012), Clark and Ishii (2012), Clark and Landes (2012), Clark et al. (2012), and Hao and Clark (2012).

[84] The UK and U.S. data used by Long and Ferrie (2013a) would be ideal for validating the use of names because the father–son link was initially established using names.

10.6. CONCLUSIONS

This chapter shows that substantial progress has been made in the analysis of income mobility over the last few decades, much of which has been stimulated by the increasing availability of suitable longitudinal data. For within-generation analysis, new household panel and administrative record data abound by comparison with the situation described by Atkinson et al. (1992). For between-generation analysis, the number of suitable data sets has also increased substantially, though not to the same extent (for obvious reasons), and issues of data quality remain relatively more important. Put another way, there has been a more general increase in the availability of good-quality intragenerational income data sets across a relatively large number of rich countries. Good-quality data for analysis of intergenerational income mobility are concentrated among a smaller number of countries. Most longitudinal data (in either context) refers to rich industrialized nations, and it would be interesting to examine the extent to which the patterns found also extend to middle- and low-income countries.

Although the availability of good data has increased substantially, many substantive issues of interest are not yet resolved. Our discussion of within-generation mobility revealed few clear-cut conclusions about whether mobility has been increasing over time or decreasing in particular and whether mobility is greater in one country rather than another. The same can be said in regard to the evidence about income mobility between generations. In short, there remains much scope for systematic empirical analysis.

We have also shown that there has been a substantial increase in the number of mobility measures per se, but the literature has not yet matured in the same way as the measurement of (cross-sectional) income inequality has. Relatively underdeveloped are measures of individual income growth and, especially, of income risk. We would like to see empirical researchers making greater use of the descriptive methods that we have outlined—in order to show the data "as they are" as far as possible—while also carefully selecting summary measures that reflect the mobility concept that is of particular interest. In the intergenerational mobility context, for instance, we have recommended greater use of measures of positional change and less reliance on Beta. More generally, transition matrices are underused.

Our discussion of income mobility has focused on mobility between two time points (with the exception of the discussion of mobility as longer-term inequality reduction). This simplifies the measurement task substantially, but does not remove the need for development of methods for describing individual income *trajectories* over multiple periods. In the intergenerational context, the interest is in not simply the similarities or differences between parents' and children's income, but also the prevalence of "rags to riches and back in three generations" trajectories (for example) relative to other patterns. In the intragenerational context, we are interested not simply in each person's total lifetime income, but also in the patterns of variation over calendar time and age, and how these patterns differ across individuals.

With multidimensional (multiperiod) data, the natural reaction of most analysts is to fit models, with a small number of parameters summarizing the key differences between trajectory patterns. In the Introduction, we briefly cited literatures about the modeling of incomes within or between generations. One of the greatest challenges facing income mobility researchers is to develop tractable models of household income dynamics (not simply earnings dynamics for individuals) both within and between generations. Compared to the field of mobility measurement that we have reviewed in this chapter, mobility modeling is underdeveloped and deserves greater attention in the future.

ACKNOWLEDGMENTS

We wish to thank Daniele Checchi, Philippe Van Kerm, and especially Tony Atkinson and François Bourguignon, for their comments and suggestions on early drafts of this chapter. S. P. Jenkins acknowledges partial financial support for his research from the core funding of the Research Centre on Micro-Social Change by the UK Economic and Social Research Council Core (Grant RES-518-28-001) and the University of Essex.

Abstract

This chapter investigates recent advances in our understanding of the global distribution of income, and produces the first estimates of global inequality that take into account data on the incomes of the top one percent within countries. We discuss conceptual and methodological issues – including alternative definitions of the global distribution, the use of household surveys and national accounts data, the use of purchasing power parity exchange rates, and the incorporation of recently available data on top incomes from income tax records. We also review recent attempts to estimate the global distribution of income. Our own estimates combine household survey data with top income data, and we analyze various aspects of this distribution, including its within- and between-country components, and changes in relative versus absolute global inequality. Finally, we examine global poverty, which is identified through the lower end of the global distribution.

11.1. INTRODUCTION

As the world has become increasingly interconnected through trade, investment, migration and communication, people's interest in and knowledge of international comparisons of living standards has grown. Correspondingly, the global distribution of income has become the subject of numerous research papers and articles, and commentaries in the media. In the popular imagination it seems self-evident to be of interest that great wealth and great poverty coexist in the world. In this chapter we examine the concept of global inequality, the normative motivations for studying it, and the available evidence on the global distribution of income. Widely varying estimates of global income inequality have been published, using a variety of data and methodologies. We critically discuss the different approaches and assumptions behind them, with a view to determining what we believe to be best practice. We also construct a global distribution using both household surveys and top income shares from tax data.

Inequality is a broad concept, and the global distribution of income allows various interpretations. For this reason we start by clarifying different conceptions of the global distribution of income. The distribution of primary interest for us, and the subject of most of this chapter, is that among individuals in the world, each assigned his or her per capita household income. This is what we will refer to as the global distribution of income. But other distributions of global income are also of interest for certain questions. Studies of economic growth and convergence, for instance, are based on changes in the distribution among countries of per capita national income, which is a type of global income distribution that is only indirectly related to the global distribution of income among individuals.

Because individuals around the world are naturally partitioned by country of residence, we examine the between-country and within-country components of global inequality, which can have different definitions depending on the inequality measure used. Although we do not discuss the causes of changes in global income inequality, this decomposition provides a breakdown of those changes, allowing us to isolate the contributions of differential growth in per capita income across countries, and of changes in inequality within countries. This decomposition is a necessary precursor to any causal explanation because one would expect different mechanisms to explain the two components.

Studying the global distribution of income raises difficult empirical and measurement issues. To compare real incomes across countries one needs to convert them using purchasing power parity (PPP) exchange rates, rather than market exchange rates, to take account of aggregate price differences between countries. There are different methods for calculating PPP exchange rates, which have their respective merits and are used by different studies. All methods depend on the price surveys conducted by the International Comparison Program (ICP). In some cases those price surveys have themselves been controversial. We do not discuss PPP exchange rates in detail (q.v. Anand and Segal, 2008), but we highlight some of the features and controversies that are most relevant for studying the global distribution of income.

Another empirical controversy concerns the measurement of mean incomes within countries. Any global distribution of income must rely on national household surveys to estimate inequality within countries. But some studies, instead of using the mean incomes recorded by those surveys, have taken the relative distributions implied by them and "scaled" them to national accounts estimates of per capita GDP or household consumption expenditure. We argue that there is no good reason to scale to GDP, but that the use of household final consumption expenditure (HFCE) from the national accounts, which is available for most countries, may provide a useful robustness check. Using HFCE rather than the mean incomes from household surveys changes both the level and trend of estimated global inequality.

Beyond reviewing the conceptual and measurement issues underlying the study of the global distribution of income, the empirical aim of this chapter is to use the best available data to construct global distributions of income based on alternative plausible assumptions. The main innovation is to supplement data from household surveys with newly available estimates of top income shares derived from tax data in a range of countries. These data constitute a significant advance in our understanding of the distribution of income both within countries and globally because individuals at the top of the income distribution are either not represented or are underrepresented in household surveys. Unsurprisingly, their inclusion leads to substantially higher estimates of global inequality.

The chapter continues as follows. Section 11.2 discusses the motivation for the study of global income inequality. Section 11.3 analyzes the different concepts of the global distribution of income. Section 11.4 discusses methodological issues and describes the available data, including the top income share data. Section 11.5 presents our constructed global distributions of income and the corresponding estimates of global inequality. Section 11.6 decomposes global income inequality into between-country and within-country inequality and discusses their significance and evolution. Section 11.7 examines the distinction between relative and absolute inequality and presents some preliminary estimates of absolute global inequality. Section 11.8 turns to the estimation of global poverty and considers its level, trends, and regional concentration. Section 11.9 concludes the chapter.

11.2. WHY STUDY THE GLOBAL DISTRIBUTION OF INCOME?

Interest in global inequality reaches far beyond academia and has increased dramatically in recent years—among activists and NGOs, the news media, and national and international institutions and policymakers. This is in part due to the perception that the benefits of rapid economic growth in recent decades, which has coincided with a period of rapid globalization, have been distributed highly unequally. Thus, the worldwide "Occupy" movement launched in 2011, with its slogan "We are the 99%," has focused on the sharply increasing concentration of income and wealth among the top 1% of income recipients compared to the other 99%. In the news media, *The Economist* has described growing inequality as "one of the biggest social, economic and political challenges of our time" (Beddoes, 2012). At the 2012 World Economic Forum meeting at Davos, "severe income disparity" was featured as the single most likely global risk, and with one of the highest potential impacts.[1] Again at Davos in 2013, Christine Lagarde, managing director of the International Monetary Fund, stated that "[e]xcessive inequality is corrosive to growth; it is corrosive to society. I believe that the economics profession and the policy community have downplayed inequality for too long" (Lagarde, 2013).

There is indeed a positive case for being concerned about the consequences of inequality for economic growth and social cohesion; crime rates and population health, for instance, have been linked to income inequality within countries.[2] To the extent that such (within-) country inequality contributes to global inequality, there will be a corresponding concern about the latter. One might equally be concerned about the "corrosive" effects of global inequality itself. Davos, where Lagarde made her comments, is a meeting place of the global élite (i.e., those at the top of the global income distribution, and not just their respective national distributions).

The normative case for studying global inequality seems obvious to some, but it is contested by philosophers who believe that the distribution of income among individuals can be a matter of justice only if they share a government. Nevertheless, even these philosophers typically agree that "there is some minimal concern we owe to fellow human beings threatened with starvation or severe malnutrition and early death from easily preventable disease," and that therefore "the urgent current issue is what can be done in the world economy to reduce extreme global poverty" (Nagel, 2005, p. 118). In itself this warrants study of at least the lower end of the global distribution of income.

An alternative understanding of justice may lead to a normative concern about global inequality. Some cosmopolitan political theorists argue that egalitarian principles apply equally at the global as at the national level simply because all human beings are entitled to equal respect and concern.[3] On this view, national borders are not relevant to an ethical concern with inequality.

It can also be argued that the institutional arrangements that exist in the global economy—the international rules and organizations that govern the flows of goods,

[1] World Economic Forum (2012), reported by Tett (2012).
[2] See, for example, Pickett and Wilkinson (2010).
[3] For discussion see Sen (2000) and Bernstein (2011).

capital, and labor between countries—are sufficient to generate a normative concern for inequality among individuals in the world, even if they fall short of a global government. These international arrangements are largely determined by rich countries and tend to benefit citizens in rich countries at the expense of citizens in poor countries. Rich countries may therefore bear some responsibility for global inequality. Sen (2009, p. 409) puts the issue as follows: "The distribution of the benefits of global relations depends not only on domestic policies, but also on a variety of international social arrangements, including trade agreements, patent laws, global health initiatives, international educational provisions, facilities for technological dissemination, ecological and environmental restraint, treatment of accumulated debts (often incurred by irresponsible military rulers of the past), and the restraining of conflicts and local wars."

In studying the global distribution of income, we need to distinguish between the recognition of inequality and the obligation and capacity to reduce it. Through its domestic policies, a sovereign state can have more influence on national inequality than on global inequality. This might suggest that, from a policy viewpoint, we should assess within-country inequality differently from between-country inequality (see Section 11.6)—especially if international institutions have limited powers to address between-country inequality. In any case, as we improve our understanding of global inequality, we will be in a better position to diagnose its causes and discuss ways of mitigating it.

In this chapter we take the global distribution of income to be of intrinsic interest. We will analyze various aspects of this distribution, including its within- and between-country components, and also its lower end, which is needed to identify global poverty. Constructing the global distribution of income can be the first step in a broad exercise, which should ultimately permit us to examine many different aspects of global inequality—such as the extent to which gender, ethnicity, education and other socioeconomic variables contribute to global inequality, the characteristics of the global poor, and the composition of the global top 1%.

11.3. WHICH GLOBAL DISTRIBUTION OF INCOME?

Our starting point must be to clarify what we mean by the global distribution of income. Following Milanovic (2005) and Anand and Segal (2008), we can define four concepts of the global distribution of income and their associated levels of inequality, distinguished by the population unit and the income concept (which may be a measure of consumption expenditure) to which they refer. The four concepts of global distribution are relevant to addressing quite different questions, as we discuss in this section. We must also decide on the numéraire to make the income concept comparable across countries, and use either market exchange rates or PPP exchange rates. PPP exchange rates account for the fact that one U.S. dollar will typically buy less in the United States than one dollar's worth of, for example, Indian rupees purchased on the currency markets, will buy in India. Later we will discuss different approaches to PPP exchange rates and some of the complications that arise in estimating and using them. Which exchange rate is appropriate will depend on the question being asked.

Our first concept of the global distribution of income, denoted *concept 0*, is the distribution of global income by country. In other words, the "population unit" is the *country* and the "income concept" is the (total) *national income* of the country. Thus India and Canada, both with GDPs of US$1.8 trillion in 2012, count as equal, despite the fact that India has a population of 1237 million and Canada only 35 million. It is this concept 0 global distribution that is most relevant for questions of geopolitics and market access. In international negotiations over trade rules and macroeconomic policies it is a country's total economic size that tends to determine its bargaining power. For such questions, it is a country's weight in international markets—its command over internationally traded goods and services, or financial assets—that matters, and hence income at market exchange rates is likely to be relevant. One might refine the measure, of course, depending on the geopolitical question at hand. For example, in matters concerning global energy markets, countries with relatively small economies but large fuel exports tend to be important.

Next, the *concept 1* global distribution again takes the *country* as the population unit, but now the income concept is the *national income per capita* of the country, not its total national income.[4] This is the concept typically used in analyses of economic growth, and in particular of economic convergence, where the question is how the set of characteristics and policies associated with a given country affects its per capita income growth rate. Because it is real output that is of interest in this case, income levels will be measured at PPP exchange rates.

In the *concept 2* global distribution, the population unit is the *individual*, and the income concept is again *national (household) income per capita*. (This is equivalent to taking the country as the population unit, as in concept 1, but weighting each country by the size of its population.) It is not obvious why this concept of global inequality would be intrinsically interesting, but some older studies have analyzed its evolution over time, mainly because of the ready availability of data on national income or GDP per capita (Boltho and Toniolo, 1999; Firebaugh, 1999, 2003; Melchior et al., 2000). Concept 2 is of instrumental interest, however, through its relationship with concept 3, which is the focus of this chapter.

The *concept 3* distribution also takes the *individual* as the population unit, but the income concept is the *per capita income of the household to which the individual belongs*—under the assumption of equal sharing of household income (or consumption expenditure). It is the global analogue of the type of distribution typically used to calculate inequality within

[4] It follows that this *concept 1* distribution—unlike the concept 0 distribution—is not a "distribution of (total) global income among countries."

Table 11.1 Concepts of global income distribution and inequality

	Unit of analysis	Ranking variable	Numéraire
Concept 0	Country	National income	US$ or PPP$
Concept 1	Country	National income per capita	PPP$
Concept 2	Individual	National (household) income per capita	PPP$
Concept 3	Individual	Household income per capita of individual	PPP$

countries.[5] Henceforth we use the terms "global distribution of income" and "global inequality" without further qualification to refer to their *concept 3* counterparts. Because it is real income or consumption that we are interested in, national currencies will be compared using PPP exchange rates. Concept 3 is also the only concept that tells us something directly about global welfare.

Concept 2 global inequality can be seen as the between-country component of concept 3 global inequality. Concept 2 inequality tells us what concept 3 inequality would be if there were no inequality within countries and each person in a country received the national (household) income per capita of that country. For decomposable measures of inequality, concept 3 inequality will then be equal to concept 2 inequality plus a weighted average of inequality within countries (the within-country component of concept 3 inequality). We will discuss these distinctions further when we present our calculations later in this chapter.

Table 11.1 summarizes the four global income distributions defined in terms of unit of analysis (population unit), associated ranking variable (income concept), and numéraire. It is important to emphasize that the four different concepts of global inequality can move in different directions. It should be immediate from the decomposition just mentioned that concepts 2 and 3 can move in different directions: a modest fall in between-country (i.e., concept 2) inequality may coexist with a rise in concept 3 global inequality if within-country inequality increases sufficiently.

Moreover, the same changes in national income may have opposite effects on different concepts of inequality. For example, China is the second-largest economy in the world, both in PPP$ and in current US$, but its per capita GDP in 2012 was PPP$7960, below both the unweighted mean GDP per capita across countries of PPP$12,300 and the

[5] In country studies of income inequality, an adjustment for differential needs and economies of scale in household consumption is sometimes made by taking account of the age and sex composition of a household, in addition to its size. This is done through "equivalence scales," which allow the calculation of the number of "equivalent adults" in a household. Each individual in the household is then assigned the household's income per equivalent adult. Given the type of survey data at our disposal, it is not possible to estimate the number of equivalent adults in each household and rank individuals by their household income per equivalent adult. Hence, like other studies of interpersonal global inequality, we simply rank individuals by their household income per capita.

population-weighted mean across countries of PPP$10,260.[6] The fact that China's above-average total national income has been growing much faster than the world average therefore implies that China is a disequalizing force for concept 0 inequality. However, the fact that its below-average GDP per capita is growing faster than the world means of both unweighted and population-weighted GDP per capita is an equalizing force for concepts 1 and 2 global inequality, respectively. The latter implies that it is also an equalizing force for concept 3 global inequality.

Consider now the notion of "convergence" in the literature on economic growth, which is the closest that many economists get to thinking about global inequality. There are two commonly used definitions of "convergence," namely beta and sigma convergence. Beta convergence means that when a country's growth rate is regressed on its national income per capita, the coefficient on income is negative and significant.[7] Thus, on average, countries with higher per capita national income (where per capita GDP is the measure typically used in these studies) have lower growth rates. Sigma convergence means that the dispersion across countries of per capita national income declines over time, often measured by the standard deviation of the logarithm of per capita national income. Both therefore refer to the concept 1 global distribution with the country as the population unit and per capita national income as the income concept.

In their survey of growth econometrics, Durlauf et al. (2009, p. 1098) state that sigma convergence has "a natural connection to debates on whether inequality across countries is widening or diminishing." If "inequality across countries" refers to concept 1 inequality, then it is a tautology that sigma convergence will measure "whether inequality across countries is widening or diminishing."[8] However, sigma convergence or divergence has no necessary connection to any other concept of inequality across countries (e.g., concept 0 inequality as seen in the China example) or to global inequality across a different population unit (e.g., individuals). A rise in the dispersion across countries of per capita national income (i.e., concept 1 inequality) may be associated with a fall in concepts 2 and 3 global inequality, as the following example demonstrates.

The Philippines has a population of 97 million people, and a per capita GDP of PPP$3800. Its per capita GDP is below both the unweighted and the population-weighted world means of PPP$12,300 and PPP$10,260, respectively, noted earlier. There are 35 countries that both have populations below 5 million and also, like the Philippines, have per capita GDP below the respective unweighted and population-weighted world means. For the purposes of sigma convergence, each of these 35 small

[6] PPP$ are in 2005 prices, and data are from *World Development Indicators*, http://data.worldbank.org/data-catalog/world-development-indicators.

[7] *Conditional* beta convergence means that the coefficient on income is negative and significant when other variables are controlled for in the regression.

[8] One concern about this argument is that the standard deviation of log-income is not a good inequality measure, as it does not satisfy the principle of transfers at the top end of the income distribution (Sen, 1973).

countries has the same weight as the Philippines, yet their combined populations amount to 57 million, below that of the Philippines.[9] Now imagine that there is sigma divergence, where all other countries are growing at a common rate, but the Philippines is growing faster and the 35 small countries are growing slower than this common rate. Global inequality is increasing according to concept 1 because while one country (the Philippines) whose per capita GDP is below the unweighted world mean is converging to the world mean, 35 other countries whose per capita GDP is below the world mean are diverging from it. But global inequality may be decreasing according to concept 2 because the convergence of the Philippines' large population toward the weighted world mean outweighs the divergence of the populations of the 35 small countries away from the weighted world mean. Assuming that inequality within countries is unchanged, global inequality may therefore also be decreasing according to concept 3.

We conclude that global inequality *tout court* is an underspecified concept, and estimates of different definitions of global inequality can move in different directions—as we find in our empirical estimates in Sections 11.5 and 11.6.

11.4. DATA

11.4.1 Household Surveys and National Accounts

Household surveys are the most widely available source of data for estimating income distributions within countries, and it is the great expansion in their global coverage that has permitted estimates of global inequality. One could in principle use census data or other sources—but in practice these are available for far fewer country-years than household surveys. Survey coverage has expanded dramatically in the last 30 years; the surveys used by the World Bank to estimate global poverty in 1981 covered only 51.3% of the population of the developing world, whereas in 2005 they covered 90.6% (Chen and Ravallion, 2008).

Although there is no credible alternative to using household surveys for estimates of global inequality, they do suffer limitations. Beyond the obvious sampling and measurement errors, surveys may suffer from biases due to underreporting of incomes by the rich and undersampling of both very rich and very poor households. Most important for our purposes, differences in definitions and coverage mean that different surveys are typically not strictly comparable with one another (see Anand and Kanbur, 1993, pp. 33–36). Atkinson and Brandolini (2001) described such problems in the Deininger and Squire database, which collates estimates of inequality within countries; Anand and Segal (2008) discussed these issues in the context of measuring global inequality, observing that in some surveys incomes are gross-of-tax and in others net-of-tax; some refer to cash

[9] GDP and population data are from *World Development Indicators*, http://data.worldbank.org/data-catalog/world-development-indicators.

incomes, whereas others include certain items of income-in-kind; some impute the rental value of owner-occupied housing, whereas others do not. Moreover, all global data sets of household surveys combine surveys of income and of consumption expenditure. There is no reliable way to infer an income distribution from an expenditure distribution, or vice versa, so one simply has to live with the noncomparability. For brevity we will refer to "income or consumption expenditure distributions" as "income distributions."

The World Bank's Living Standards Measurement Surveys, initiated in 1980, have been instrumental in increasing both the quantity of survey data available and its quality. The Luxembourg Income Study (LIS) specifically attempts to harmonize survey data to ensure their comparability, and the LIS data set currently covers 47 countries. Still, non-comparability cannot be avoided in a global data set of household surveys, which cover most of the world's population.

Although all recent studies of global inequality use survey data for estimates of within-country inequality, most then "scale" the within-country distributions to national accounts estimates of mean income or consumption expenditure. For instance, Chotikapanich et al. (1997), Dowrick and Akmal (2005), Sala-i-Martín (2006), and Schultz (1998) use the Deininger and Squire (1996) inequality database for estimates of *relative* inequality within countries and peg the relative distributions around an absolute mean from the national accounts.[10] Milanovic (2002, 2005, 2012) and Lakner and Milanovic (2013) are the only studies we know of that estimate global income inequality using levels of income or expenditure directly from surveys, rather than scaling relative distributions to NA means (though Lakner and Milanovic do use NA means in imputing top incomes, as we discuss later). The World Bank also uses absolute incomes from household surveys for its estimates of global poverty (Chen and Ravallion, 2001, 2008, 2012).[11] The distinction between using survey data directly and scaling them to national accounts categories matters because both the levels and rates of change of global inequality and poverty can vary substantially (Deaton, 2005).

For studies that use household surveys only for their relative distributions and scale them to national accounts means, there are two widely available estimates of NA "mean income": per capita GDP and per capita household final consumption expenditure (HFCE). In principle, one would want to use the category of personal income, but countries do not usually report this category. Most studies of global inequality simply use per capita GDP as a proxy for individual mean (per capita household) income.[12]

[10] See Anand and Segal (2008) for detailed descriptions of their methodologies.

[11] The World Bank's own estimates are based on unit record data. These data are available to the public only in coarser, grouped form from the World Bank's Povcalnet Website: http://iresearch.worldbank.org/PovcalNet/index.htm.

[12] These studies are Bourguignon and Morrisson (2002), Bourguignon (2011), Sala-i-Martín (2006), Dowrick and Akmal (2005), Schultz (1998), Chotikapanich et al. (1997), and Korzeniewicz and Moran (1997). Dikhanov and Ward (2002) use "personal consumption expenditure," which we take to mean HFCE.

As argued in Anand and Segal (2008, pp. 66–68), if it is national household consumption expenditure that one wishes to measure, then there is no reason to use GDP when HFCE is available. Moreover, GDP is also a poor measure of *household income*: GDP includes depreciation, retained earnings of corporations, and the part of government revenue (taxes) that is not distributed back to households as cash transfers. Deaton (2005, p. 4) noted that "much of saving may not be done by households, but by corporations, government, or foreigners, so that household income may be closer to household consumption than to national income." In the case of the United States, which is one of the few countries that does report measures of aggregate household income (referred to as "personal income"), it amounts to only about 70% of GDP. Deaton estimates that, across 272 surveys of household income from around the world, survey household income amounts on average to only 57% of GDP, but equals 90% (101% population-weighted) of HFCE from National Accounts.

The question remains, however, whether one would want to use *any* National Accounts figures when mean household income (or consumption) is available in the surveys themselves, which are the source of the income (or consumption) distribution for countries. We saw earlier that surveys have their own problems. But they are at least a direct measure of the variable of interest. HFCE, on the other hand, includes the category of "non-profit institutions serving households" (e.g., religious organizations and political parties), and suffers from being calculated as a residual of aggregate consumption minus estimates of firms' consumption and government consumption. Errors in any of the latter magnitudes will translate into errors in estimates of HFCE.[13]

New evidence on national accounts data in low-income countries casts more general doubts on their reliability. Jerven (2013) noted that Ghana revised its GDP upward by 60.3% in November 2010 owing to a change in base year,[14] and argues that similarly large revisions are to be expected in other sub-Saharan African countries.[15] Young (2012) also found that national accounts provide a poor measure of growth in sub-Saharan Africa and produces independent estimates of consumption growth based on data from Demographic and Health Surveys.[16]

Most of our analysis that follows will refer to the global distribution based on mean incomes from household surveys, but we also calculate global inequality where mean per capita household income is taken to be equal to per capita HFCE as reported in the National Accounts and compare the differences in the results.

[13] See Anand and Segal (2008, p. 68) for detailed discussion.

[14] The 1993 base-year estimates excluded parts of the economy that were important in the new base year of 2006 (Jerven, 2013, p. 11).

[15] These countries are Nigeria, Uganda, Tanzania, Kenya, Malawi, and Zambia. Jerven's explanation is that many of these countries suffered drastic cuts to statistical services in the 1980s and 1990s.

[16] Note, however, that Young's method of inferring aggregate consumption from data on assets has been criticized by Harttgen et al. (2013).

11.4.2 Top Income Data

Perhaps the most important recent innovation in estimating national income inequality has been the collation of data on top income shares from income tax records. These estimates present the incomes of the top 0.1%, top 1%, and top 10% as a share of "control" income, where control income is an estimate of total personal income in the economy (not just taxable income). They are important primarily because they make a substantial difference to estimated inequality. Household surveys typically undersample (exclude) the richest individuals or underreport their incomes, or both. In the United States in 2006, for instance, tax data excluding capital gains imply a top percentile share of 18.0%, whereas survey data imply a share of 13.7%. Using data for 2006, the U.S. Gini based on household survey data (the Current Population Survey) is 0.470, whereas correcting the top percentile's income using the tax data raises it by nearly 0.05 to 0.519. Moreover, the increase in the U.S. Gini from 1976 to 2006 using survey data alone (corrected for a change in definition) was 0.053, which more than doubles to an increase of 0.108 using the top income data (including capital gains; Atkinson et al., 2011, p. 31; see Burkhauser et al., 2009 for further discussion of U.S. data).

Atkinson et al. (2011, pp. 4–5) describe the top income data in detail, and discuss their limitations. These include the fact that the income shares refer to gross income before tax; the data vary with respect to the unit of observation, some referring to individuals and others to households; in some cases they are not consistent over time, as tax regimes change; and they may be biased owing to tax avoidance and tax evasion. Although they are typically much better than surveys at capturing capital income, this varies depending on the extent to which capital income is taxed and hence reported in the tax records (Atkinson et al., 2011, p. 35). Alvaredo and Londoño Vélez's (2013) study of top incomes in Colombia notes that different definitions of the control income, of which top incomes are expressed as a share, lead to somewhat different estimates. For these reasons international comparisons of these top income shares may suffer from inconsistencies. Nonetheless, we will set aside such concerns and use these data on the presumption that excluding them would cause a large negative bias in estimates of global inequality. Clearly, however, these noncomparabilities do add uncertainty to the estimates.

11.4.3 PPP Exchange Rates

International comparisons of living standards require the use of PPP exchange rates to convert national currencies into a common numéraire.[17] Two standard sets of PPPs are publicly available: those produced by the International Comparison Program (ICP) of the World Bank (World Bank, 2008) and those produced by the Penn World Tables (PWT), which also uses the underlying price survey data collected by the 2005

[17] An early discussion of this issue may be found in Berry et al. (1983).

ICP.[18] PPPs for years before and after the "benchmark" year 2005 are derived from each country's domestic price indices.

The price surveys undertaken for the 2005 ICP were both more detailed and more representative globally than in previous rounds of the ICP. China had never taken part in an ICP before the 2005 round, and India had not taken part since 1985, but both countries were surveyed in the 2005 ICP. Previous estimates of PPPs were therefore based on imputations. Partly for this reason, the results from the 2005 ICP have in some cases led to dramatic changes in estimated GDP. Both China and India were found to have real GDPs nearly 40% lower than previous estimates[19] because prices were found to be higher than previously estimated. In the case of China, at least some of this downward revision appears to have been due to sampling problems: its price surveys took place in cities and their environs and did not cover rural areas. For this reason Chinese prices are likely to have been overestimated, and its real income underestimated. Following Chen and Ravallion (2010), and like Milanovic (2012), we make an adjustment to account for this (described later). Milanovic (2012) found that the revisions in the 2005 ICP make a substantial difference to estimated global inequality, raising the Gini by 4.4–6.1 percentage points over the period 1988–2002 and Theil T by 12.5–16.4 percentage points. Other studies that use the 2005 PPPs are Lakner and Milanovic (2013) and Bourguignon (2011), and we discuss their findings later.

Starting from the vector of prices in each country provided by the ICP, the World Bank and PWT use different methods to calculate PPPs. World Bank PPPs are based on the Elteto–Köves–Szulc (EKS) method, whereas PWT uses the Geary–Khamis (GK) method (both with a variety of adjustments made in the process of estimation).[20] EKS arose from a statistical approach to index numbers (Deaton and Heston, 2010) and is a multilateral generalization of the Fisher index for two countries (for further discussion, see Anand and Segal, 2008, p. 71). However, under certain assumptions EKS applied to incomes yields an index of real living standards, or utility, and for this reason Neary (2004) included it as an example of the "economic" approach to index numbers. Under the economic approach it is assumed that observed quantities arise from the optimizing behavior of some representative agent with a well-defined utility function. Real relative

[18] A new ICP with base year 2011 was released recently in June 2014, as this chapter was already in press.

[19] This was calculated by comparing the countries' respective incomes relative to U.S. income in 2005 at 1993 PPP$ and at 2005 PPP$.

[20] See Anand and Segal (2008) for details of these two methods, and for discussion of the "Afriat method" used by Dowrick and Akmal (2005) to measure global inequality. The World Bank's PPPs use EKS within regions of countries and then link regions using a "ring" of 18 countries with at least two in each region. See Deaton and Heston (2010) for discussion of both the World Bank and PWT PPP methods. These authors also noted that a single global EKS calculation leads to some nontrivial differences compared to the ICP PPPs, including a real GDP in China that is 6.6% higher.

incomes measured using EKS PPPs represent relative utility levels when utility is quadratic (i.e., in these circumstances it is a "true" index).

GK, on the other hand, is an example of the "test" or "axiomatic" approach. The GK index has no interpretation in terms of optimizing behavior, but its putative advantage with respect to EKS is that it passes the test, or obeys the axiom, of *matrix consistency*. That is to say, GK provides a vector of "international prices" for individual goods that enable disaggregation of the economy into subsectors whose values at those prices sum to the total value of the economy. This is not true of EKS, which computes the relative size of aggregate incomes but does not provide a set of international prices with which economies can be consistently disaggregated. If one is interested in analyzing the structure of economies, then matrix consistency would seem to be a useful property. For instance, it is hard to interpret the relative size of manufacturing in two different countries when manufacturing plus nonmanufacturing within each country does not add upto 100% of its economy.

Matrix consistency would seem less relevant, however, when our concern is international comparisons of living standards. In this case, it is the overall value of consumption, not its composition, that concerns us. More important for our purposes is the drawback of the GK method, which is that it suffers from Gershenkron (or substitution) bias. Because consumers tend to substitute away from goods that are relatively expensive and toward goods that are relatively cheap, valuing the output of both country A and country B at country B's prices will lead to an overestimation of the income of country A relative to that of country B. The relative prices arising from the standard GK method more closely resemble those in rich countries than in poor countries, leading to an overvaluation of the incomes of poor countries relative to rich countries and therefore to an underestimation of inequality between countries. Ackland et al. (2004) found that the GK method overvalues the incomes of poorer countries compared to EKS. They regress log per capita GDP from GK on log per capita GDP from EKS and find the slope to be 0.94 and to be significantly less than 1.0. Deaton and Heston (2010) found that the Gini for concept 2 (between-country) global inequality, with per capita GDP as the income concept, is slightly higher using EKS than GK, at 0.533 as opposed to 0.527.

Almås (2012) also found that PWT PPPs underestimate global inequality when accounting for both substitution bias and differences in the quality of goods across countries. However, her estimates are based on the strong assumption that "there is a stable relationship between the budget share for food and household income; i.e., there is a unique Engel relationship for food in the world" (Almås, 2012, p. 1094). Deaton and Heston (2010, p. 5) pointed out that "there are many places in the world, such as North and South India, where there are large differences in consumption patterns of food in spite of only modest differences in relative prices."

Neary (2004) presents a method that he denotes "Geary–Allen International Accounts" (GAIA) for constructing PPPs that is "economic" in the sense of being based on the assumption of optimizing behavior and therefore does not suffer from substitution bias, but that also satisfies a form of matrix consistency. However, the form of matrix consistency satisfied is not the form that GK satisfies; the sectoral quantities that sum to the value of the whole economy are not the actual observed sectoral quantities, but virtual quantities that a reference consumer, whose preferences are estimated from the data, *would* have chosen. So it is also the case in the GAIA method that observed manufacturing plus observed nonmanufacturing within an economy will not, in general, add upto 100% of the economy.

The theoretical advantage of GAIA over EKS is that it is a "true" index (i.e., produces estimates of relative real incomes that are consistent with optimizing behavior) for a wider range of utility functions. But because all such indices make the false assumption of identical tastes in all countries worldwide, this seems a rather limited benefit. EKS, on the other hand, has the advantage of being relatively transparent. Although GAIA requires the estimation of a demand system, the EKS exchange rate for a country is simply the geometric mean of that country's Fisher price indices relative to every other country and, as already mentioned, has a natural statistical interpretation that is attractive to national income accountants if not to consumer theorists (Deaton and Heston, 2010).

In our calculations that follow, we use the EKS-based World Bank consumption PPPs from the 2005 ICP. Following Chen and Ravallion (2008, 2010) we make the following adjustments. For both India and China, where the survey data are provided separately for rural and urban strata, we deflate urban incomes relative to rural incomes from price indices used for the construction of domestic urban and rural poverty lines. For India we assume that the World Bank estimated PPP is a weighted average of the urban and rural PPPs. For China we assume that the reported PPP is for urban areas and adjust rural prices downward. This is because the price surveys in China in 2005 were restricted to 11 metropolitan areas, which did not include any rural areas (Chen and Ravallion, 2010). The result is a lower overall price level for China, and thus higher average living standards, than those implied by the use of the 2005 ICP.

A limitation to all standard PPP estimates is that they assume all households within a country face the same price level for their expenditure basket. This may be problematic for at least two reasons. First, urban and rural areas typically have different price levels, and although we have taken this into account for China and India, where the urban and rural price surveys are distinct, it is not possible to do so for most countries. Second, different quantiles of a national income distribution will typically consume different baskets of goods and services,[21] and hence face different costs of living. For instance, the poor may face higher unit costs for a good because they have to buy it in smaller quantities. Moreover, they purchase goods in different proportions from the nonpoor so the prices of goods will have different expenditure weights for them. At the other end of the

[21] Deaton and Dupriez (2011) discussed this in the case of the poor and have come up with PPPs specifically for estimating global poverty.

distribution, the very rich (such as those captured by the top income data) may tend to buy more goods from outside their country of residence, to which market exchange rates would apply. But to the extent that the very rich spend their income on nontradable goods and services—for example, country estates, urban mansions, and domestic labor within their country of residence—PPPs with different expenditure weights may be more appropriate than market exchange rates.

11.4.4 Estimation Errors

The preceding discussion of the available data indicates that there are several sources of error in estimates of global inequality, including our own. These include sampling errors, which arise from the sample not being representative of the world population. Our global income distribution is constructed as the union of national income distributions, each of which is based on a national household income (or expenditure) survey with a distinct sampling frame and sampling errors (including undersampling of both the rich and the poor in a country). This global distribution is not estimated from a stratified random sample of the world population, so standard methods are not applicable to calculate sampling errors or confidence intervals for estimates of global inequality.

It is important to distinguish sampling errors from other types of estimation error, which arise from imprecise data and invalid or inaccurate assumptions and methods used to calculate global inequality. For example, there are measurement errors in the income or expenditure data in household surveys (e.g., underreporting of incomes of the rich) and in any national accounts data that may be used; there are also estimation errors in the PPP exchange rates used to construct a global income distribution from national distributions. Major revisions in the estimation of PPPs in the 2005 ICP round, discussed earlier, suggest great sensitivity to the assumptions and methods employed. Given such instability, we may expect further revisions in the next set of PPPs from the 2011 round of the ICP.[22] Moreover, as mentioned earlier, a single PPP exchange rate for a country may fail to capture differences in price levels faced by households in different quantiles of the income distribution or in different geographical locations in the country.

Bourguignon and Morrisson (2002) estimated global inequality from 1820 to 1992 through the use of inevitably limited data and manifold assumptions. Given the limitations of their data, they simulated "uncertainty" in their mean income (i.e., GDP) numbers and in their country-group distributions (11 data-points for each of 33 countries or groups of countries) and calculated standard errors for global inequality on this basis. Under their simulation assumptions, the resulting standard errors on the global Gini turn out to be small: in 1820 the standard error is 0.9 Gini points, in 1950 it is 0.2 Gini points, and in 1992 it is 0.1 Gini points (where 1 Gini point is 0.01 in the Gini scale of

[22] These PPPs were not available at the time of writing.

0.00–1.00). In our view the other sources of error discussed earlier would imply much larger confidence intervals than these standard errors suggest.

11.5. ESTIMATING THE GLOBAL DISTRIBUTION OF INCOME

In this section we present new estimates of the global distribution of income that combine household survey data with top income data. These estimates are constructed from Milanovic's (2012) global distribution data set of household surveys for five "benchmark" years in the period 1988–2005, which we have supplemented with top income estimates from income tax data. Milanovic's data are provided in quantiles, in most cases 20 income groups each comprising 5% of the population. For those countries for which Milanovic (2012, pp. 10–11) has unit record data, he compared inequality based on individual records with that based on the constructed vigintile (5%) shares and found that the underestimation of the Gini using vigintile shares varied from 0.001 to 0.006 with a mean of 0.003. We agree with Milanovic that this is small enough to be inconsequential.

The five benchmark years 1988, 1993, 1998, 2002, and 2005 each have surveys for between 103 and 124 countries and cover between 87% and 92% of the world population and between 95% and 98% of global GDP in PPP$. The Milanovic data set provides incomes in national currencies, which we convert to our numéraire of international dollars using World Bank PPPs.[23] We thus have incomes from household surveys in PPP$ for 87% of the world population in 1988, and 90–92% in the later years. There are 67 countries for which we have both survey and PPP data in *all* five benchmark years, which we refer to as the "common sample over time".

As seen in Table 11.2, we have a total of 537 country-years in our data set. Of these, 104 country-years, ranging from 18 to 23 countries in each year, also have income tax data on the share of the top percentile of the population, which we downloaded from the World Top Incomes Database.[24] These countries include the three largest developing countries—China, India, and Indonesia; one Latin American country—Argentina; one African country—South Africa; and all the G7 countries.

The rationale for using income tax data for top percentile shares is that household surveys typically fail to capture the incomes of the richest members of society. For example, Székely and Hilgert (1999) found that in most surveys in Latin America the richest

[23] For Soviet republics in 1988 we use Milanovic's calculations based on Milanovic (1998). These are not strictly comparable to World Bank PPPs because they are based on an earlier set of price surveys. For some other countries without PPP exchange rates in the World Bank's World Development Indicators online database, we derived PPPs implicitly from World Bank Povcalnet data, http://iresearch.worldbank.org/PovcalNet/index.htm2.

[24] The World Top Incomes Database, constructed by Facundo Alvaredo, Tony Atkinson, Thomas Piketty, and Emmanuel Saez. Data downloaded from http://topincomes.g-mond.parisschoolofeconomics.eu/.

Table 11.2 Coverage of countries and populations with *both* household surveys and PPP data, 1988–2005

Year	Number of countries	Population in billions (% of world population)
1988	92	4.45 (87)
1993	104	5.06 (91)
1998	109	5.32 (90)
2002	113	5.78 (92)
2005	119	5.95 (92)
Total	537	

Source: Authors' calculations.

individuals had an income no higher than what would be expected of a midlevel manager in an international firm. This suggests that very rich households are simply excluded from surveys, which is the assumption we make in incorporating top income data into our survey distributions. In other words, we assume that the survey data in the Milanovic data set represent only the bottom 99% of the population in each country. Accordingly we multiply the population in each income group in the surveys by 0.99 and append the top percentile with its income share from the tax data (assuming that its share of "control" income is equal to its share of survey income). The exclusion of the top percentile implies that mean income in the surveys is underestimated, and our procedure results in a corresponding increase in mean income for each country.

For those country-years that do not have top income data, we impute top percentile shares on the basis of regression. The income share of the top decile in Milanovic's household survey data is strongly correlated with the income share of the top percentile in the independently estimated top income data. Excluding one visible outlier in the 104 country-years with both Milanovic data and top income data,[25] the simple OLS regression coefficient of the income share of the top percentile against the income share of the top decile (on the remaining 103 datapoints) has a *t*-statistic of 7.46 and an R^2 of 0.36. We then added the original mean income from the surveys as a further regressor. Mean income is found to be highly significant with a *t*-statistic of 6.69, the top decile share becomes still more significant with a *t*-statistic of 10.33, and the regression R^2 rises to 0.55.[26] We use this latter regression to generate predicted values for the income share of the top percentile for country-years without tax data.

[25] The outlier is South Africa for 1993, for which the top decile share in Milanovic's data is exceptionally large at 46%, whereas the top percentile share from income tax data, at 10.3%, is much smaller than would be expected given this.

[26] The estimated regression equation is topone $= -6.8 + 0.51$topten $+ 0.30$meaninc where topone and topten are, respectively, the shares of the top percentile and the top decile in percentage points, and meaninc is mean survey income in PPP$ thousand. Year dummies and demographic variables were insignificant.

Lakner and Milanovic (2013) take a different approach to imputing top income shares in estimating global inequality between 1988 and 2008.[27] Following Banerjee and Piketty's (2010) finding in India that a significant part of the discrepancy between estimates of consumption expenditure in the national accounts and in household surveys can be accounted for by missing or underreported top incomes, Lakner and Milanovic attributed the difference between HFCE and survey incomes (when the former is larger than the latter) entirely to the top decile of the national distribution in each country-year, and add this residual to the income of the top decile reported in the survey. They then calculated a Pareto coefficient for each country-year distribution on the basis of the unadjusted survey income in the ninth decile and the adjusted income in the top decile (following the procedure described in Atkinson, 2007). Assuming this Pareto distribution applies *within* the top decile of each country-year distribution, they estimated income shares for the income groups P90–P95 (i.e., percentile 90 to percentile 95), P95–P99, and P99–P100, yielding 12 income groups per country-year.

An implicit assumption behind Lakner and Milanovic's procedure for imputing top incomes is that HFCE per capita is the *correct* measure of mean consumption expenditure (or income), when it is larger than the corresponding survey mean. We have argued against using national accounts means in Section 11.4 and in Anand and Segal (2008). It should also be noted that Milanovic's (2002, 2005, 2012) own previous estimates of "true" global inequality are based on his assumption that survey means are preferable to national accounts means.

11.5.1 Global Inequality Estimates With and Without Top Income Data

Our results for global inequality are presented in Table 11.3 and Figure 11.1. The first notable finding is the very high level of global inequality. Considering the global distribution with top incomes over the period 1988–2005, the Gini varies between 0.722 and 0.735, MLD (or Theil L) between 1.093 and 1.156, and Theil T between 1.114 and 1.206. The top percentile in the world has a share between 17.3% and 20.7% of global income, and the top decile between 58.5% and 62.0%. The richest percentile in the world have mean incomes almost 21 times the world mean income in 2005, or a mean per capita household income of about PPP$90,000 in 2005. The threshold for being in the top percentile in 2005 was PPP$42,000.[28]

As anticipated, the inclusion of top income data raises the estimated levels of inequality relative to those based on household surveys without top income data. The average

[27] Unfortunately, the Lakner and Milanovic data for the benchmark year 2008 were not made available to us for our own calculations of global inequality.

[28] For comparison, the threshold defining the top percentile in the United States in 2005 was a total household income of PPP$342,000, which for a four-person household implies a per capita figure of PPP$85,500, or approximately double the global threshold.

Table 11.3 Global inequality with and without top incomes, 1988–2005

Year	Income share of top percentile (%)	Income share of top decile (%)	Gini	Between-country Gini (% of global Gini)	MLD	Between-country MLD (% of total)	Within-country MLD (% of total)	Theil T	Between-country Theil T (% of total)	Within-country Theil T (% of total)
With top incomes										
1988	17.3	58.5	0.726	0.649 (89)	1.136	0.886 (78)	0.250 (22)	1.114	0.780 (70)	0.334 (30)
1993	17.6	58.5	0.727	0.636 (88)	1.142	0.836 (73)	0.306 (27)	1.115	0.753 (68)	0.362 (32)
1998	19.0	59.5	0.722	0.632 (88)	1.093	0.780 (71)	0.314 (29)	1.145	0.750 (66)	0.395 (34)
2002	20.6	62.0	0.735	0.649 (88)	1.133	0.830 (73)	0.303 (27)	1.206	0.809 (67)	0.397 (33)
2005	20.7	60.0	0.727	0.633 (87)	1.156	0.806 (70)	0.349 (30)	1.188	0.755 (64)	0.433 (36)
Without top incomes										
1988	11.2	54.8	0.705	0.642 (91)	1.063	0.861 (81)	0.202 (19)	0.967	0.764 (79)	0.202 (21)
1993	11.6	54.9	0.707	0.632 (89)	1.069	0.819 (77)	0.250 (23)	0.976	0.745 (76)	0.231 (24)
1998	13.1	56.9	0.698	0.624 (89)	1.008	0.757 (75)	0.251 (25)	0.969	0.732 (76)	0.236 (24)
2002	14.1	58.5	0.711	0.640 (90)	1.046	0.801 (77)	0.245 (23)	1.027	0.788 (77)	0.239 (23)
2005	14.9	56.5	0.701	0.622 (89)	1.060	0.775 (73)	0.285 (27)	0.977	0.725 (74)	0.252 (26)

share of the top percentile over the period 1988–2005 increases from 13.0% on the basis of the surveys alone to 19.0% when top income data are included. Correspondingly, the average top decile share over the period is 56.3% with survey data alone, and 59.7% when top income data are added. Depending on the year, the Gini increases by 3–4%, MLD (or Theil L) by a larger margin of 7–9%, and Theil T by the largest margin of 14–22%. For all measures the increase is greatest in 2005, when the inclusion of top income data raises the global Gini by 4%, MLD by 9%, and Theil T by 22%. These differences in impact reflect the different sensitivities of the measures to income changes at the top end of the distribution.

Turning to changes in inequality with top income data during 1988–2005, the income share of the top percentile rises monotonically from 17.3% to 20.7%. The share of the top decile rises from 58.5% in 1988 to 60.0% in 2005, peaking at 62% in 2002. The Gini coefficient shows very little movement in this period: the highest Gini value is 0.735 (in 2002), which is only 0.013 higher than the lowest Gini value of 0.722 (in 1998), a difference of under 2%. MLD (or Theil L) and Theil T show somewhat larger movements, with the difference between the highest and lowest years for the measures being 6% and 8%, respectively. MLD peaks in 2005 and Theil T in 2002, and for both of these measures inequality rises over the period 1988–2005—for MLD by 1.8% and for Theil T by 6.6%.

The top income data modify both the estimated level of global inequality and its rate of change over time. Although inequality rises over 1988–2005 according to MLD and Theil T with top income data included, inequality is virtually unchanged over the period according to all three measures when top income data are not included. In the latter case the Gini is 0.705 in 1988 and 0.710 in 2005, MLD is virtually unchanged at 1.06, and Theil T rises marginally from 0.967 to 0.977; however, the income share of the top percentile rises from 11.2% to 14.9%.

The changes in inequality over time are not large compared to changes witnessed in some individual countries. This is particularly so in the case of the Gini coefficient, where the peak-to-trough difference is only 1.3 Gini points with the top income data, compared to a rise, for example, of about 5 Gini points in the United States over the period 1988–2005.[29] Moreover, given the different sources of estimation error that we described in Section 11.4, the small changes we find in the global inequality indices may not be statistically significant—particularly in the cases of the Gini and MLD, which are less than 2 percentage points different in 2005 from 1998. However, the rise in the share of the global top percentile, from 17.3% to 20.7% during 1988–2005, seems less trivial; it implies that the incomes of the top percentile increased by 20% relative to mean income—though we note that this is also smaller than the rise in the share of the top percentile in the United States over the same period, from 15.5% to 21.9%.[30]

In the Appendix we provide analogous results for the "common sample over time" of 67 countries. Whereas the full sample shown earlier comprises between 87% and 92% of the world population depending on benchmark year, the common sample over time comprises between 79% and 82%. As can be seen in Appendix Table 11.A2, the global inequality estimates are very similar to those in Table 11.3 shown earlier. The Gini coefficient for the common sample is never more than 1 percentage point different from that for the full sample, whereas MLD and Theil T are never more than 3 percentage points different. Note that the common sample over time is not necessarily more representative of the global income distribution than our full sample in each benchmark year, and estimates of the level or rate of change of global inequality based on the common sample are not necessarily more accurate.

Our calculations with top income data assume that household surveys do not capture the top percentile of the national income distribution. An alternative way to include the top income data is to assume that surveys are indeed representative of all households, but that they underreport the incomes of the top percentile in the national distribution. This is the assumption made by Alvaredo and Londoño Vélez (2013) and requires a different calculation. Rather than multiply the population of each income group in the survey data by 0.99 and then append the top percentile with its income share from the tax data, on the alternative assumption one simply *replaces* the income of the top percentile in the survey data with that from the tax data. We have performed this calculation as well, and it leads

[29] See Atkinson et al. (2011, p. 33, Figure 6), series adjusted with tax data including capital gains.

[30] This refers to the share of the top percentile including capital gains, downloaded from the World Top Incomes Database, http://topincomes.g-mond.parisschoolofeconomics.eu/.

to marginally lower estimates of global inequality: in the five benchmark years the global Gini is upto 0.4% smaller, and MLD and Theil T are upto 1.2% smaller. However, for the latter two decomposable indices, the within-country component is noticeably smaller, by 3.6–5.2% for MLD and by 2.4–4.1% for Theil T—but the between-country component is about 0.5% larger for both indices.

11.5.2 Comparison of Alternative Estimates of Global Inequality

We saw earlier that only three previous studies have used 2005 PPPs to estimate global inequality: Bourguignon (2011), Milanovic (2012), and Lakner and Milanovic (2013). Milanovic's (2012) estimates of global inequality are directly comparable to our estimates without top incomes in Table 11.3, as they are based on the same survey data and methodology. The only substantial difference we know of is in the PPPs used for countries for which the World Bank does not have data (see footnote 23 for the sources that we use in these cases). Milanovic found the Gini coefficient to vary between 0.684 and 0.707 in the period 1988–2005, whereas in our estimates given earlier it varies between 0.698 and 0.711. However, whereas we find Theil T at virtually the same level in 1988 as in 2005, he found it to rise from 0.875 to 0.982 over the same period.

Lakner and Milanovic (2013), like us, estimated global inequality both with and without imputed top incomes. Their estimates without top incomes also follow the same methodology as Milanovic (2012) and are based directly on survey data. Lakner and Milanovic's estimates of the global Gini without top incomes are close to ours, varying between 0.705 and 0.722 in the period 1988–2008. Their Theil T is slightly higher than ours, varying between 1.003 and 1.049 in the period. Significantly, their MLD shows a marked decline, from 1.142 in 1988 to 1.027 in 2008.

Lakner and Milanovic—like us—found that imputing top incomes leads to higher estimates of global inequality. Their HFCE-based method of imputing top incomes, discussed earlier, raises the global Gini by 3.8–6.3 Gini points, with the difference rising over time in the period 1988–2008.[31] Nonetheless, their Gini ends the period at almost exactly the same level as it began, declining marginally from 0.763 in 1988 to 0.759 in 2008. This is a much larger effect than we find from adding top income data to the survey data. As we saw in Table 11.3, our method leads to the Gini being approximately 2 Gini points higher in each year. Lakner and Milanovic themselves pointed out that their imputation assumption is rather extreme in some cases. For example, in 2008 in India—the country that appears to have motivated their procedure—they find the survey mean to be only 53% of HFCE per capita, so they attribute the remaining 47% of total HFCE *entirely* to the top decile, adding it to the income of the top decile reported in the survey. This adjustment seems implausibly large to us. Conversely, for China in both 1988 and 2008,

[31] Lakner and Milanovic do not give estimates of other inequality measures for their distribution with imputed top incomes.

HFCE is smaller than survey income, so no adjustment is made by the authors for under-reporting or undersampling of top incomes.

The final study that uses 2005 PPPs to estimate global inequality is Bourguignon (2011), which—unlike the other studies mentioned in this section—scales within-country distributions to GDP per capita. Bourguignon found the Gini coefficient to decline from approximately 0.70 to 0.66 between 1989 and 2006 (these numbers were read off his Figure 1). This is a substantial decline compared with the findings reviewed earlier of virtually no change in the Gini without top incomes. The main difference between Bourguignon's estimates and the other estimates without top incomes discussed here is that Bourguignon scales to national accounts data. In Section 11.4 we argued that if one uses national accounts data then HFCE is preferable to GDP as an approximation to household income, so we compare estimates based on survey means with estimates based on HFCE means in the next section.

11.5.3 Global Inequality Estimates Using NA Means, Without Top Income Data

In this section we report global inequality estimated by scaling household survey incomes so that the scaled mean is equated to per capita HFCE from NA in each country (in contrast to using incomes directly from the surveys). HFCE figures in PPP$ are not available for all the country-years for which we have household survey data. In each year, we distinguish between the "full sample" defined as the set of all countries with survey data, and the "common sample" *across data sets* defined as the subset of the full sample countries that *also* have HFCE data in PPP$ (note that this is *different* from the "common sample over time," defined earlier). In 1988 the common and full samples are quite different: in that year the countries that have *both* survey data and HFCE data in PPP$ comprise only 77% of the world population, compared with 87% of the world population for countries in the full sample (see Table 11.2).[32] In the other years covered in Table 11.2, the common sample has 3–4% less of the world population than the full sample.[33]

For each of our indices, Table 11.4 presents three different global inequality estimates without top income data: first, the full sample estimates as in Table 11.3; second, estimates based on survey data restricted to the common sample; and third, the common sample estimates based on per capita HFCE (as described earlier). We will refer to the first as the

[32] For some countries where World Development Indicators (WDI) does not have HFCE data in PPP$, HFCE is nevertheless available in local currency units (LCUs). By definition, these countries do not have PPP exchange rates in WDI, but for 11 of them we have PPPs (see footnote 23), which we use with the survey data. However, in almost all cases using these PPP conversion rates gives implausible results for HFCE. For this reason we do not use these data.

[33] For the years 1993, 1998, 2002, and 2005 the common sample covers 87%, 87%, 89%, and 89%, respectively, of the world population compared to the full sample percentages in Table 11.2.

Table 11.4 Global inequality estimates using survey means and HFCE means, without top incomes, 1988–2005

	Gini			MLD			Theil T		
Year	Survey means, full sample	Survey means, common sample	HFCE means, common sample	Survey means, full sample	Survey means, common sample	HFCE means, common sample	Survey means, full sample	Survey means, common sample	HFCE means, common sample
1988	0.705	0.721	0.739	1.063	1.148	1.243	0.967	1.024	1.094
1993	0.707	0.706	0.721	1.069	1.074	1.133	0.976	0.970	1.036
1998	0.698	0.699	0.711	1.008	1.010	1.062	0.969	0.973	1.017
2002	0.711	0.710	0.706	1.046	1.039	1.032	1.027	1.022	1.016
2005	0.701	0.698	0.698	1.060	1.044	1.024	0.977	0.967	0.984

Note: Full sample consists of all countries for which household survey data are available, as in Tables 11.2 and 11.3. Common sample in a given year consists of the subset of countries with *both* survey data and HFCE data in PPP$ in that year.

full sample survey-means estimates, the second as the common sample survey-means estimates, and the third as the common sample HFCE-means estimates. This highlights the fact that in the first two, mean incomes in each country are obtained directly from the surveys, whereas in the third the mean is externally imposed from HFCE data. These estimates exclude the top income data so that we can focus on the differences in global inequality using survey and NA mean incomes. Figure 11.2 plots the Gini coefficients for the three different sets of data.

The most notable difference between the full sample survey-means estimates and the common sample HFCE-means estimates is that whereas the former appear relatively flat, the latter have a clear downward trend. The two estimates are approximately the same in 2002 and 2005, but because of their different starting points in 1988 the full sample survey-means Gini declines by only 0.004 between 1988 and 2005, from 0.705 to 0.701, whereas the common sample HFCE-means Gini declines by 0.041, from 0.739 to 0.698. However, the common sample survey-means estimates indicate that about half this difference is explained by the difference between the full and common sample: the common sample survey-means Gini declines by 0.023, from 0.721 to 0.698.

The second factor that appears to explain the difference in trend for the HFCE-means Gini and the survey-means Gini is the divergent trend for India specifically in comparing survey and HFCE means, a phenomenon that has been examined in detail by Deaton and Kozel (2005). In our data the average annual growth rate of per capita household consumption expenditure in India from 1988 to 2005 was 2.8% according to surveys, and more than twice that at 5.8% according to HFCE from the National Accounts. When we both restrict the estimates to the common sample *and* exclude India from it, the survey-means Gini declines by 0.029, whereas the HFCE-means Gini decreases by a

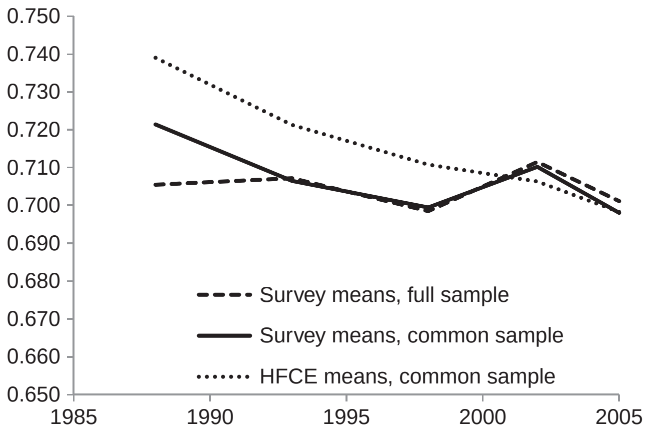

Figure 11.2 Global Gini without top incomes, using survey means and HFCE means, 1988–2005. *Note: Common sample consists of surveys restricted to country-years with HFCE data. Source: Table 11.4.*

similar magnitude of 0.034.[34] Thus ensuring a common sample and excluding India virtually eliminates the difference in trend between HFCE-means and survey-means estimates of the Gini.[35]

Thus the divergence between HFCE-means and survey-means estimates seems to be due to the loss of as much as 10% of the world population in the "common sample" that has *both* survey and HFCE data, and the divergent trends in India. Given this, in our view the decline in global inequality implied by the HFCE calculations is likely to be illusory. We have not examined estimates based on GDP means, as opposed to HFCE means, for the reasons mentioned earlier. Still, these findings do not seem to corroborate Bourguignon's (2011) result for the period 1989–2006, based on GDP data and discussed earlier, that "inequality decreases, and it decreases at a very fast pace."

11.6. BETWEEN- AND WITHIN-COUNTRY INEQUALITY

Table 11.3 also presents estimates of between-country and within-country inequality, and Figure 11.3 plots these estimates. Between-country inequality is defined as global inequality under the hypothetical assumption that every individual is assigned his or her country's mean per capita household income. It suppresses inequality within countries and measures inequality in the global distribution among world citizens where the only source of variation is mean per capita income across countries (in other words, between-country inequality is just concept 2 global inequality). Between-country inequality is well-defined for any inequality index, and we report it in Table 11.3 for the Gini, MLD (or Theil L), and Theil T measures. For the decomposable measures MLD and Theil T, the difference between overall global inequality and between-country inequality is a weighted average of inequality in each country, and is denoted as *within-country inequality*. In the case of MLD (i.e., Theil L), within-country inequality is a population-share weighted average of the MLD in each country, whereas for Theil T it is an income-share weighted average of the Theil T in each country (Anand, 1983, pp. 86–92).

In the case of MLD (Theil L) only, the within-country component has an additional interpretation: it is equal to what global inequality would be under the hypothetical assumption that mean per capita incomes are equalized between countries, while relative inequality is kept constant within each country. In this sense it is a natural complement to the definition of between-country inequality, and for this reason we consider MLD to be strictly decomposable, but Theil T to be only weakly decomposable (Anand, 1983, pp. 198–202).

[34] The levels are different, however, with the survey-means Gini declining from 0.701 to 0.671 and the HFCE-means Gini declining from 0.722 to 0.689.

[35] This procedure also substantially reduces the difference in trend for MLD and Theil T, but does not eliminate it as effectively as with the Gini.

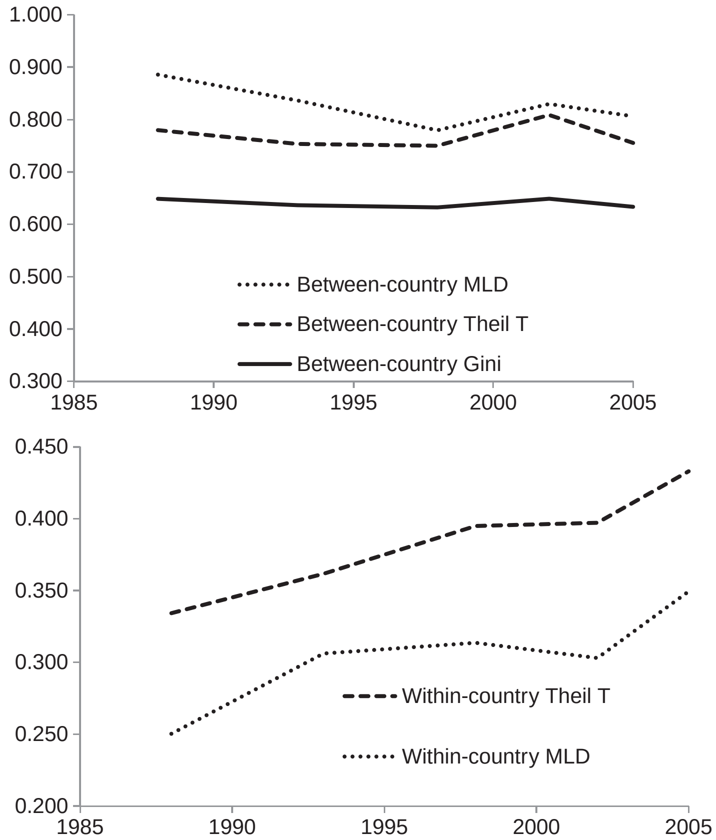

Figure 11.3 Between-country and within-country global inequality with top incomes, 1988–2005. *Source: Table 11.3.*

Considering estimates of global inequality with top incomes, we make four observations from Table 11.3 (top panel). First, between-country inequality is larger than within-country inequality for both the decomposable indices. Between-country inequality ranges between 70% and 78% of overall global inequality for MLD and between 64% and 70% for Theil T.

Second, the inclusion of top income data increases the within-country component substantially, as would be expected. For MLD the within-country component rises by between 23% and 25%, depending on the year, whereas for Theil T it rises by between 57% and 72%. The between-country component also changes because our imputation of the income share of the top percentile increases country mean incomes by different proportionate amounts.

Third, from 1988 to 2005 between-country inequality declines by all three measures, as shown in Table 11.3. For the estimates with top income data, the between-country

Gini falls by 2% from 0.649 to 0.633, the between-country MLD declines 9% from 0.886 to 0.806, whereas the between-country Theil T declines 3% from 0.780 to 0.755.

Fourth, over the period 1988–2005 within-country inequality clearly increases for both decomposable indices as seen in Figure 11.3. For estimates with top income data, the within-country MLD rises by 40% from 0.250 to 0.349, and the within-country Theil T rises by 30% from 0.334 to 0.433.[36]

The Gini coefficient is not a decomposable measure in either the weak or strong sense. Although we can define the between-country Gini straightforwardly, the residual from overall global inequality cannot be interpreted as within-country inequality (see Anand, 1983, pp. 311–326). However, as with any inequality index, we can answer the question of what happens to the global Gini and to Theil T when country mean incomes are equalized but relative inequality is kept constant within each country (Anand, 1983, p. 201). This question is relevant in assessing the following claims.

On the basis of the fact that between-country inequality is greater than within-country inequality, Sala-i-Martín (2002, p. 39) stated that "the best strategy to reduce world income inequalities is to induce aggregate economic growth in poor countries." Similarly, Rodrik (2013, p. 12) noted that "the more rapid growth of poor countries since the 1990s is the key behind the recent decline in global inequality," concluding from this that "aggregate economic growth in the poorest countries is the most powerful vehicle for reducing global inequality." For economic growth in poor countries to reduce global inequality, it would of course have to be more rapid than growth in richer countries. In this case, the greatest reduction in global inequality that could possibly be achieved without addressing within-country inequality is calculated by eliminating between-country income differences while keeping inequality within each country constant. Conducting this exercise for 2005 with top income data, the Gini would decline from 0.727 to 0.437 and Theil T from 1.188 to 0.433; in the case of the strictly decomposable MLD, the decline is from 1.156 to its within-country component of 0.349. This is a large decline, but global inequality would still remain at about the level of a high-inequality country such as China, where in 2005 we find the Gini to be 0.430, MLD to be 0.367, and Theil T to be 0.324.

In Section 11.3 we pointed out that the concept of sigma convergence in the growth literature has little relationship to any other concept of global inequality. Bourguignon et al. (2004) used GNI per capita and found that what we call concept 2 inequality fell between 1980 and 2002, while concept 1 inequality rose. Similarly, in our data, between-country inequality (i.e., concept 2 global inequality) declines by all measures during 1988–2005, whereas we find "sigma divergence" when we calculate concept 1 global

[36] It should be noted that changes over time in population shares of countries in the case of MLD, and income shares of countries in the case of Theil T, will lead to changes in "within-country inequality" even holding inequality constant *within* each country.

Table 11.5 Concept 1 inequality, calculated using per capita incomes from survey data with top incomes

Year	Gini	MLD	Theil T	Sigma (std. dev. of log-income)	World mean per capita income (PPP$)	China mean per capita income (PPP$)
1988	0.501	0.538	0.414	1.15	3424	342
1993	0.535	0.574	0.480	1.12	3683	526
1998	0.552	0.594	0.523	1.11	3923	863
2002	0.575	0.655	0.573	1.15	4148	1042
2005	0.578	0.665	0.580	1.17	4364	1916

Source: Authors' calculations.

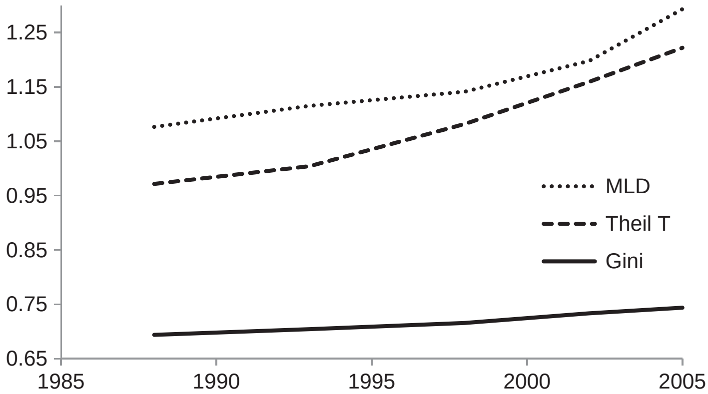

Figure 11.4 Global inequality without China, based on survey data with top incomes. *Source: Authors' calculations.*

inequality, as shown in Table 11.5. The three inequality measures increase when applied to the concept 1 distribution: the concept 1 Gini increases from 0.501 to 0.578, MLD from 0.538 to 0.665, and Theil T from 0.414 to 0.580. The standard deviation of (unweighted) log mean income also rises from 1.15 to 1.17.[37]

Table 11.5 also presents mean per capita survey incomes for the world, and for China separately. Several papers have estimated global inequality excluding China (e.g., Milanovic, 2012; Sala-i-Martín, 2006; and Schultz, 1998), and we present our estimates in Figure 11.4, which include the top income data. They indicate that global inequality without China increases by all three measures: the Gini rises by 0.050, MLD by 0.217 and Theil T by 0.250. We would note, however, that although these estimates are

[37] These figures use per capita incomes calculated from survey data with top incomes. Without the top income data, the surveys alone imply much the same trend for concept 1 inequality: the Gini rises from 0.503 to 0.576, MLD from 0.543 to 0.663, Theil T from 0.417 to 0.576, and sigma again from 1.15 to 1.17.

instructive from the point of view of accounting for global inequality and its evolution, they have no global welfare implications because they exclude approximately one-fifth of the world population.

11.7. RELATIVE AND ABSOLUTE GLOBAL INEQUALITY

In an article entitled "What Are We Trying to Measure?" the development economist Dudley Seers (1972, pp. 34–35, endnote 2) made a telling distinction between relative and absolute inequality when he wrote: "Suppose, for example, that a perspective plan specified that [the] per capita income of Brazil doubled in the next thirty years, but assumed no change in distribution or in the proportion unemployed. Then at the turn of the century, a big landowner in the Matto Grosso could run four cars, instead of two, and a peasant in the North-East could eat two kilogrammes of meat a year instead of one. His son might well be still out of work. Could we really call that 'development'?". Although relative inequalities in this example have remained unchanged, the absolute differences have grown in proportion to the expansion of the economy. In addition to considering relative global inequality, there is clearly a case for examining absolute global inequality—as noted, for example, by Ravallion (2004).

The first thorough investigation of measures of absolute global inequality is by Atkinson and Brandolini (2010). They posited a "world social welfare function," which exhibits a changing social marginal valuation of income at different points along the global income distribution (see also Anand and Sen, 2000). The absolute cost of inequality is then expressed in terms of Atkinson's (1970) concept of "equally distributed equivalent income" for this social welfare function (see also Kolm, 1969). For any income distribution, Atkinson defines the equally distributed equivalent income as that level of income per head, which, if equally distributed, would yield the same level of social welfare as the existing distribution. Then the absolute cost of inequality is the income per head that is "wasted" as a result of inequality (i.e., it is mean income minus the equally distributed equivalent income). (The relative cost of inequality is the absolute cost divided by the mean, which is the definition of Atkinson's index of relative income inequality.)

For the Gini welfare function, the absolute cost of inequality is mean income μ multiplied by the Gini coefficient G, and the relative cost is simply G (Anand, 1983; Sen, 1973). In general, mean income μ times a relative inequality measure produces the corresponding absolute inequality measure. For the relative global inequality measures G, MLD, and Theil T, we also estimate the absolute global inequality measures μG, μMLD, and μT, respectively, where μ is the world mean income. The world mean income at 2005 PPP$ is shown in Table 11.6 for the years 1988–2005.

Table 11.7 shows the evolution of absolute global inequality with top income data between 1988 and 2005 as measured by the Gini, MLD, and Theil T, expressed as a ratio of 2005 world mean income calculated from surveys with top incomes added (PPP$4364).

Table 11.6 World mean income at 2005 PPP$, alternative estimates

Year	World GNI per capita	World mean income from surveys, with top incomes	World mean income from surveys, without top incomes
1988	6433	3424	3115
1993	6524	3683	3342
1998	7262	3923	3514
2002	7934	4148	3713
2005	8772	4364	3865

Table 11.7 Absolute global inequality using survey data with top incomes added, as a *ratio* of 2005 world mean income (PPP$4364)

Year	Absolute Gini	Absolute MLD	Absolute Theil T
1988	0.569	0.891	0.874
1993	0.614	0.964	0.941
1998	0.649	0.983	1.029
2002	0.698	1.077	1.146
2005	0.727	1.156	1.188

Source: Authors' calculations.

Over the 17-year period 1988–2005, there has been an unambiguous rise in absolute global inequality according to all three measures. This is unsurprising given the rise in world mean incomes over this period. To prevent a rise in absolute inequality, relative inequality has to decrease at a faster rate than the rise in mean incomes—which seems an unlikely prospect for the global economy.

In Section 11.2 of this chapter we noted and discussed the widespread concern about global income inequality—in terms of both its level and change. Given that there appears to be little movement in relative global inequality (see Section 11.5), whereas there is a significant widening of absolute global inequality (Table 11.7), the widespread concern about inequality may be based on people making comparisons of living standards in *absolute* rather than relative terms.

11.8. GLOBAL POVERTY

11.8.1 Methodology

Like absolute global inequality, global poverty is a measure based on absolute living standards. To measure global poverty, an absolute poverty line is applied to the global distribution of income and the number of individuals below it calculated. This procedure is employed to monitor global poverty over time—including for the first Millennium Development Goal. Chapter 9 of this volume discusses poverty in developing countries and regions using different poverty lines. The most widely quoted estimates of global poverty for an absolute poverty line are those produced by Chen and Ravallion (2008, 2012) at the World Bank. The Millennium Development Goal refers to consumption poverty, but the limited availability of surveys around the world and over time necessitates that Chen and Ravallion use a mixture of (consumption) expenditure and income surveys.

Chen and Ravallion's (2008, 2012) estimates for the World Bank use the 2005 ICP PPPs, which, as discussed earlier, are preferable to PPPs based on the earlier ICP rounds. Theirs are the only estimates of global poverty based on unit record data from surveys, which are not publicly released, and which are clearly preferable to the grouped data that are available to other researchers. The World Bank's methodology has been criticized for not scaling the survey data to national accounts (NA) means.[38]

In Section 11.4 on data we discussed the question of whether to use NA means or survey means in the context of estimating global inequality. The methodology used by the World Bank to measure global poverty, like that used by us to estimate global inequality, uses survey data directly to estimate income (or consumption) levels—converted into international dollars using consumption PPPs. As in the case of global inequality, some authors have calculated global poverty by using survey data for within-country relative distributions and NA data for country mean incomes.[39] In the context of global inequality we argued that using means directly from surveys is preferable to scaling them to NA levels, and those arguments apply even more for measuring global poverty.

There is a further consideration that makes scaling to NA categories even less appropriate for estimating global poverty. We know that surveys tend to exclude very rich households and/or underreport their incomes, and for this reason they are likely to underestimate mean income or consumption. But this implies that scaling up the income (consumption) of *every* household to ensure that the survey mean is made equal to the NA mean will imply overestimating the income (consumption) of *all* but the richest households. Put another way, the "missing" income of the rich will be inappropriately divided among the entire population. Poverty will therefore be underestimated (for further discussion, see Anand et al., 2010, pp. 13–14).

Turning to the choice of poverty line, the World Bank uses what is commonly known as the "$1-a-day" line. This was originally defined in World Bank (1990) as PPP$1-per-day at 1985 PPP. This poverty line was chosen informally as being representative of the poverty lines of the poorest countries, converted into 1985 PPP$.

The difficulty arises over how to update a 1985-based PPP$ value.[40] Within a single country, one would usually update a poverty line by using a price index based on

[38] For example, see Sala-i-Martín (2006).
[39] See Sala-i-Martín (2006).
[40] This discussion draws on Anand et al. (2010).

measured inflation. Because the international PPP dollar is indexed to the US dollar in the ICP benchmark year, one might think that all we need to do is to deflate by the US inflation rate. But updating a poverty line that is denominated in PPP$ is not so simple. As discussed earlier, calculating a set of PPP exchange rates involves the prices of all countries, so that changes in a country's PPP exchange rate will depend on price changes in all countries. Bangladesh's 1985 poverty line in 1985 PPP$, adjusted for US inflation during 1985–1993, would not be expected to be equal to Bangladesh's 1993 poverty line in 1993 PPP$.[41]

The World Bank updated the 1985 global poverty line to PPP$1.08 a day at 1993 PPP and now uses PPP$1.25-a-day at 2005 PPP. This represents a lower rate of inflation than in the US, but as Chen and Ravallion (2001, p. 288) pointed out: "the fact that $1.08 in 1993 has a US purchasing power less than $1 in 1985 does not mean that the real value of the poverty line has fallen. Indeed, if we had simply adjusted the $1 per day line for inflation in the US between 1985 and 1993 we would have obtained a poverty line which is well above the median of the ten lowest poverty lines at 1993 PPP." The World Bank has chosen consistency with those domestic poverty lines as the most important criterion in setting a global poverty line. This can be justified by arguing that domestic poverty lines will have maintained their real value within their respective countries better than a PPP inflation-adjusted measure. Therefore each time they updated the poverty line, it was derived as the median of the lowest 10 poverty lines in their data set converted into PPP$ from the most recent ICP (Chen and Ravallion, 2001, 2008). Although this has an obvious logic to it, Deaton (2010) pointed out that the fact that the composition of the bottom 10 countries will change over time can lead to inconsistency: India exited the bottom 10 countries in their data set in the 2005 update owing to its relatively high growth rate, and because its poverty line was relatively low for its income level, this exit led to a rise in the poverty line relative to where it would be with India in the bottom 10 countries. This has the paradoxical implication that a rise in India's income can lead to a rise in estimated global poverty.

A more fundamental challenge to the PPP$1-a-day poverty line has been made by Reddy and Pogge (2010). They objected to the money metric approach to global poverty measurement, noting that the PPP$1-a-day poverty line does not correspond to any "achievement concept" or set of capabilities that are common across countries. That is, there is no reason to think that PPP$1-a-day in one country will enable the same set of achievements—for example, in terms of nutrition or shelter—as PPP$1-a-day in another country. Although domestic poverty lines are often set according to some achievement concept, this interpretation is lost when a global poverty line is constructed

[41] More generally, national income at PPP$ calculated in year $t+n$ is not equal to national income at PPP$ calculated in year t multiplied by intervening domestic growth and deflated by intervening U.S. inflation (see Anand et al., 2010, p. 6).

using standard PPP exchange rates. Reddy and Pogge argued that an explicit achievement-based threshold should be used to define a global poverty line. This would require costing a minimal basic set of capabilities in each country to yield a money-metric poverty line denominated in local currency. Thus the global capability-based poverty threshold would be represented in income space by the set of these national poverty lines, one for each country.[42] Although this has theoretical attractions, it has not been implemented in practice.

11.8.2 Poverty Estimates

The question of updating the global poverty line remains contentious, and the World Bank reports poverty headcounts for several different poverty lines. Its poverty measurement website Povcalnet[43] also allows the user to choose a poverty line for which it then provides estimates. The latest official publication of global poverty numbers (Chen and Ravallion, 2012) presents poverty headcounts using the following poverty lines all at 2005 PPP$: PPP$1-a-day, which they describe as "close to India's (old) national poverty line" and "an exceptionally frugal line even by the standards of the world's poorest countries" (Chen and Ravallion, 2012, p. 1); PPP$1.25-a-day, the line derived from domestic poverty lines in poor countries as described earlier; and PPP$2-a-day. We report the World Bank estimates in Tables 11.8 and 11.9.

Table 11.8 indicates that the first Millennium Development Goal, which was to halve the percentage of people living below "PPP$1-a-day" (i.e., PPP$1.25 at 2005 PPP) from its 1990 level by 2015, was almost achieved by 2008: this percentage declined from 43.1% of the developing world to 22.4%. Chen and Ravallion (2012) reported that the goal was in fact achieved in 2010, though the data for 2010 are not fully representative. If the poverty line of PPP$1-a-day at 2005 prices is used, then the goal was fully achieved in 2008, with the percentage of the poor in developing countries falling from 30.8% in 1990 to 14.0% in 2008 (Table 11.8).

It is clear from Table 11.9 that the distribution of this decline in poverty was highly uneven. The poverty rate in sub-Saharan Africa at the PPP$1.25 line was only slightly lower in 2008 than in 1981, at 47.5% rather than 51.5%. It is little comfort that the 2008 figure for this region is a larger drop from the 1993 peak of 59.4%. As is well known, a large share of the decline in global poverty is due to China, which managed to cut poverty from 84% in 1981 to 60.2% in 1990 and to 13.1% in 2008. The world excluding China

[42] One could then use the relative cost of this capability set in different countries to infer the implied "PPP" exchange rates. There is no reason to think that such exchange rates would be similar to extant PPP exchange rates.

also succeeded in reducing poverty, but at a much slower rate. Excluding China, global poverty declined by less than a third since 1990, from 37.2% to 25.2%.

One notable feature of the global distribution of poverty is that much of it is found outside the poorest countries. For instance, in 2008 India was a lower-middle-income country,[44] yet it contained approximately 380 million people below the PPP$1.25 poverty line,[45] or 30% of the global total and about the same number as in all of sub-Saharan Africa.[46] Indeed, Sumner (2012) points out that a majority of people below the World Bank poverty line live in middle-income countries.

In Section 11.6 we noted that within-country inequality has risen over the past two decades, suggesting that the decline in global poverty has been driven by aggregate growth in low- and middle-income countries. It does not follow, however, that continued aggregate growth is the only way to continue to reduce poverty. Redistribution within countries could also play a significant role in poverty reduction in poor countries, just as it does in rich countries.[47]

The average annual income of those living below the PPP$1.25-a-day poverty line was PPP$421 in 2005.[48] Using our estimated global income distribution presented earlier, the individuals in the richest percentile of the world, whose annual incomes averaged PPP$90,000, were therefore 214 times richer than individuals in the poorest 21% of the world. Put another way, the richest 1% of the world, or 65 million people, had a *total income* a little more than 10 times that of the poorest 21%, or 1390 million people.

11.9. CONCLUSION

Rising top income shares in many countries have pushed inequality up the public agenda, while globalization has given this concern a global reach: people no longer compare their lot only to those within their own country. Moreover, the global financial crisis and recession have made the interconnectedness of people's material well-being around the world all the more obvious. Hence the global distribution of income, global inequality, and global poverty are increasingly in the public view.

[44] The World Bank defines lower-middle income countries in terms of US$, not PPP$. They are defined as those countries with per capita GNI between US$1036 and US$4085 in 2012 prices, calculated using the Atlas method. India's per capita GNI in 2008 was US$1050 in current prices, or US$1120 in 2012 prices (inflating by the US CPI). In PPP$, its per capita GDP in 2008 was PPP$2900 in current prices.

[45] This is calculated by applying the poverty headcount for 2009 from Povcalnet (the closest year available) to the 2008 population (http://iresearch.worldbank.org/PovcalNet). Applying the poverty headcount reported in Table 11.9 to sub-Saharan Africa's population in 2008 implies 389 million poor in that region.

[46] For this reason Collier's (2007) book *The Bottom Billion*, which is about a set of poor countries whose populations sum to about one billion, is misleadingly titled: those one billion individuals are not the poorest billion people in the world (Segal, 2008).

[47] In the EU15 countries, for example, 16% of the population were living below their respective national poverty lines in 2003, a figure that would rise to an estimated 25% in the absence of cash benefits that comprise a total of 6.6% of GDP (Guio, 2005). Ravallion (2009) considers the capacity of targeted redistribution within developing countries to eliminate poverty, asking which countries could eliminate poverty by taxing only those with incomes above PPP$13-a-day. Segal (2011) considers the impact on poverty of a universal unconditional transfer, or "basic income," funded by a country's own natural resource rents.

[48] This was calculated from a reported poverty gap index of 7.78% in Povcalnet.

A number of studies have estimated the global distribution of income using a variety of data and methods. Recent advances in data collection have provided us with a much more detailed and accurate view of the global distribution of income than was possible even a decade ago. Household surveys now cover the vast majority of the population of the world, whereas intercountry real income comparisons have been greatly improved with the 2005 round of the ICP. This chapter has also highlighted and used the additional information provided by the growing database of top incomes from tax records. Because survey data typically underestimate or underreport the incomes of the very rich, we have estimated global inequality by appending top income data to the available survey data.

This chapter has described the conceptual foundations of the analysis of the global distribution of income, the confusions that can arise by conflating different concepts of that distribution, and the divergent inequality trends that they can display. Its main focus was the global interpersonal distribution of income, or the concept 3 global distribution. Implicitly this analysis assumes a cosmopolitan symmetric social welfare function, according to which the country or location of an individual in the world is irrelevant.

Our calculations show that when the global interpersonal distribution of income is estimated through household survey data *without* top incomes, inequality in this distribution is very high but remains virtually unchanged from 1988 to 2005. The Gini is 0.705 in 1988 and 0.701 in 2005, MLD decreases slightly from 1.063 to 1.060, and Theil T rises marginally from 0.967 to 0.977. However, the income share of the top percentile rises from 11.2% to 14.9%. The equivalent estimates by Milanovic (2012) and Lakner and Milanovic (2013) also find the Gini virtually unchanged at much the same level as us, but the former finds a rise in Theil T, whereas the latter find a fall in both MLD and Theil T.

We argued that the method used in all of these estimates, which take household incomes directly from surveys, was preferable to the method of "scaling" within-country distributions to NA means. Moreover, we argued that if one were to scale in such a way, then HFCE would be preferable to GDP. Bourguignon (2011) scaled within-country distributions to per capita GDP and found a substantial decline in the global Gini coefficient during 1989–2006, which we also find when we use HFCE. However, we find that the divergence in global inequality estimated using HFCE-means and survey-means is due to a reduced coverage of HFCE data relative to survey data in the first year, 1988, and to the sharp divergence between the survey and HFCE means in India in particular.

When we append data on top incomes to the survey distributions, including imputed incomes for countries without such data, we find that inequality is higher, and there is some indication of an increase in global inequality. In this case the Gini, which is less sensitive to inequality at the top end of the distribution, remains virtually unchanged over the period, at a higher level of 0.722 to 0.735. But MLD and Theil T increase over the period—MLD only slightly from 1.136 to 1.156, and Theil T from 1.114 to 1.188. Given the diverse sources of potential error in estimates of the global distribution of income, these changes may not be statistically significant. A larger proportional rise occurs in the income share of the top percentile—from 17.3% to 20.7%. Thus the increase in estimated global inequality over time with top income data added appears to be driven by the rising income share of the top percentile in the global distribution. We find that in 2005, individuals in the top 1% of the world had an annual average income of PPP$90,000. These individuals were on average 214 times richer than those in the poorest 21% of the world, who were living below PPP$1.25-a-day. Put differently, the richest 1% in the world, or 65 million people, had a total income equal to 10 times that of the poorest 21%, or 1.4 billion people.

Inequality in the global distribution can be decomposed into within-country and between-country components using decomposable inequality measures. We find that between-country inequality declined modestly during 1988–2005, whereas within-country inequality increased substantially. Between-country inequality is the larger component of global inequality, comprising 64–81% of overall inequality, depending on the inequality measure (MLD or Theil T) and year. Nevertheless, even if between-country inequality were eliminated, global inequality would remain at about the same level as in a high-inequality country such as China.

Although the extent to which global inequality has risen depends on the measure used, global poverty has declined substantially in recent decades. Given that inequality within countries has tended to rise, this decline has been driven by aggregate growth in low- and middle-income countries. It does not follow, however, that continued aggregate growth is the only way to continue to reduce global poverty. Redistribution of income within countries—by checking or reversing the rise in within-country inequality—could also make a significant contribution to the reduction of global poverty.

ACKNOWLEDGMENTS

We are very grateful to the editors, Tony Atkinson and François Bourguignon, for their detailed comments, and to Branko Milanovic for discussions regarding data. For helpful comments, we would also like to thank Angus Deaton and participants of the "Income Distribution Handbook Conference" at the Paris School of Economics in April 2013.

APPENDIX. ESTIMATES OF GLOBAL INEQUALITY BASED ON THE COMMON SAMPLE OVER TIME

The common sample over time for which we have both survey and PPP data in *all* five benchmark years comprises 67 countries. Table 11.A1 shows the total population of these 67 countries in each year and their share of the world population in that year.

Table 11.A1 Country and population coverage of common sample over time

Year	Number of countries	Population in billions (% of world population)
1988	67	4.16 (82)
1993	67	4.45 (80)
1998	67	4.76 (80)
2002	67	4.98 (80)
2005	67	5.13 (79)

Abstract

The chapter examines how the various dimensions of economic inequality between men and women are analyzed today. Beyond the gender wage gap—a central issue—and of course the still far from equal sharing of housework, the chapter also reviews research on gender inequality in access to self-employment, the gender gap in pensions, and the emerging topic of a gender gap in wealth, attempting to highlight the paths between the various facets of gender inequality. Throughout the review, much attention is paid to measurement issues, the scope of empirical evidence, and to limitations due either to the small number of large and comparable data sets or to conventional approaches that limit the possibilities to compare men and women.

12.1. INTRODUCTION

While it is undisputable that the economic status of men and women has greatly converged in the second half of the twentieth century, it is also well documented that it is still not equal: women receive, on average, lower employment incomes than men, they more often work part-time or not at all, and they carry out the lion's share of unpaid work in the home. But while there are so many clues suggesting that women's overall income is lower than that of men, there is no straightforward measure that would allow the size of such an overall gender gap in income or in economic well-being to be assessed. The main limitation is that, in most income data sets, only some components of income, essentially related to work, are received and available at an individual level; the others are either received by households or measured as if received at the household level. The rationale for this household-level conceptualization is that multiperson households are assumed to benefit equally from shared resources within the household. This strong assumption about the distribution of income is made in the absence of reliable indications of the actual extent of intrahousehold sharing, so indicators of gender inequality in income or living standards are limited, if not biased. Then, as long as it is not possible to measure individual income—that is, being able to distribute the household income between the household members—gender inequalities are best assessed by various outcomes such as wages, pensions, or time spent in unpaid work than on the basis of a synthetic indicator assuming that all individuals who live together necessarily achieve an equal level of economic well-being.

The household is not only a measurement issue: many men and women live together in couple households, and many decisions are made in the context of the household. Then, what happens within the household, especially regarding the allocation of time to paid and unpaid work, is central to the understanding of the gender gap in economic outcomes, particularly gender differentials in earnings, pensions, and wealth accumulation. So it is not surprising that the issues of childcare and housework are repeatedly put forward in the analysis of various facets of gender inequality. Labor market institutions, firms' management, public policies, and social norms, however, also play a major role in shaping male and female behavior, constraints, and opportunities. Conversely, labor market status, earnings, and career perspectives influence the allocation of time and relative bargaining power within the household.

In other words, studying gender inequality entails considering the interaction of several influences relating to the family as well as the public sphere, as tentatively depicted in Figure 12.1. It also brings together research questions otherwise mostly addressed in separate strands of literature.

The aim of this chapter is to provide an up-to-date review of what is known and what we do not know, at least not well, about gender economic inequalities. The review is centered on "Western"/industrialized countries. This is not because other countries would be less interesting or less prone to gender inequality—it may even take more radical forms—but because it would lead to include other (too) vast issues, especially those of economic development and economic transition.

The chapter is organized as follows: Section 12.2 provides a brief overview of the current standard approach to income and living standards in statistical information, in

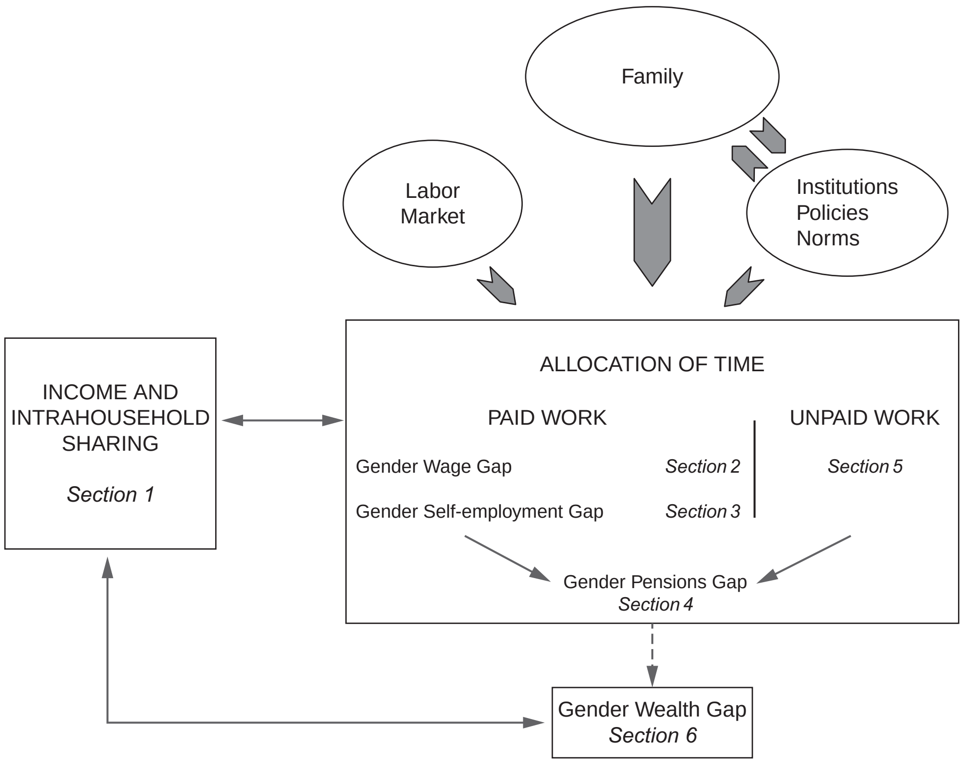

Figure 12.1 Main dimensions of gender economic inequality.

which the basic unit is the household, and its consequences for the measurement and analysis of income inequality between men and women. Sections 12.3–12.5 present an overview of the gender earnings gap. Section 12.3 is devoted to the central issue of the gender gap in wages, which has been and remains abundantly researched. Section 12.4 turns to self-employment, focusing on the question of the underrepresentation of women in this status. The gender gap in pensions, a result of past career and family trajectories, is examined in Section 12.5. Section 12.6 addresses the questions of "time and money" in the household, focusing on the unbalanced distribution of paid and unpaid work between men and women. Section 12.7 reviews the relatively small but growing literature on gender inequality in wealth.

12.2. INDIVIDUAL AND/OR HOUSEHOLD INCOME AND LIVING STANDARDS: FROM MEASUREMENT ISSUES TO CONCEPTUAL ISSUES AND BACK TO MEASUREMENT ISSUES

How to assess the extent of gender inequality in economic well-being? In rich countries, the most usual indicator of economic well-being is the living standard, a notion based on income. But in income statistics, many income components are available only for households,[1] not individuals, and living standards—that is, the household income adjusted for the household size and composition—are measured assuming that all incomes are shared within households and are assumed to be equal for all members of a given household. In other words, no inequality can be found between men and women living together in a couple-household, a very frequent situation. Assessing a gender gap in economic resources or well-being on such bases is hardly possible: If incomes are not pooled and fully shared, using household-level information may result in seriously biased estimates of income and living standard inequality. But how seriously? The problem is that not much is known about the actual distribution of income within households. This first section, then, is not so much about gender inequality in income as about the limitations to its measurement, the methodology and conceptualization behind measurement, and the implications for the analysis of gender inequality.

That income statistics do not systematically provide individual-level income components is in accordance with the current international standard, following the guidelines

[1] A household is defined as "either (a) a person living alone [. . .] or (b) a group of two or more persons who combine to occupy the whole or part of a housing unit and to provide themselves with food and possibly other essentials for living. The group may be composed of related persons only or of unrelated persons or of a combination of both. The group may also pool their income" (Canberra Group, 2011, p. 25). Note that there is not necessarily a strict correspondence between the dwelling, the household, the family, and the fiscal unit. There are also many debates on the actual extent of a "household," especially in relation to the increasing share of reconstituted or multiresidence families (e.g., children of divorced or separated parents), further complicating household income statistics.

defined by the Canberra Group[2] (2001, 2011). Acknowledging that economic well-being is more an individual than a collective notion, these guidelines nevertheless refer to the household as the best statistical unit for the production of income statistics, for pragmatic reasons: "The starting unit is the individual, but as individuals typically share income with the other persons with whom they live, most surveys collect information on the income streams of all members of a larger statistical unit, most commonly the household. [. . .] A full appraisal of income sharing within a household would require collecting data on the income transfers made within the household which would obviously be very difficult to implement. For these reasons, the choice of the household as the basic data collection unit for collecting income data remains the best compromise" (Canberra Group, 2011, pp. 24–25).

In support of pragmatism, one must recognize that it is really very difficult to "distribute" all the income components between individuals. First, some incomes are difficult to attribute precisely to one or another household member—for instance, family benefits or the income from assets owned jointly by spouses. Second, the household members may actually share all or part of their incomes and benefit together from shared assets such as housing; measuring an individual's income would require knowing the amount of income he/she receives from (or transfers toward) another individual within the household. In addition, living with others results in economies of scale (from sharing a dwelling, equipment, etc.); although this is not, strictly speaking, "income," it must also be taken into account in the comparison of living standards between individuals. So, except in the case of one-person households, measuring income or living standards at the individual level requires either restricting the notion of income to components that can be precisely attributed to one or another household member or having some knowledge of the extent of income sharing and the distribution of income within households. The same goes for wealth. But knowledge is replaced by two crucial, and distinct, assumptions: that of income pooling and that of equal living standards in the household—as if equality was an automatic consequence of income pooling, while it is an independent assumption. Lack of knowledge replaced by assumptions is the main

[2] The Canberra Group is one of the United Nations' groups of experts on statistical methodology, known as "city groups" (http://unstats.un.org/UNSD/methods/citygroup/index.htm). The Canberra Group was established at the initiative of the Australian statistical agency in 1996, bringing together representatives of about 30 national statistical agencies and international organizations such as the Organisation for Economic Co-operation and Development, the International Labour Organization, and the World Bank. Its purpose was to define a harmonized framework for income statistics, both consistent with the concepts of national accounts and allowing pertinent cross-country comparisons at a micro level. It resulted in a first edition of guidelines (Canberra Group, 2001), which have become an international reference (see also Smeeding and Weinberg, 2001). The concepts and definitions remain broadly the same in the 2011 update. "Income" is broadly understood as the amount a person/household can spend or save over a given period of time without being worse off at the end of this period than at the beginning.

obstacle to the comparison of income and living standards between individuals in general and between men and women in particular.

This section starts with a brief presentation of the components of household income, focusing on the articulation between categories of incomes and income units and of the standard approach to living standards. Then it turns to the conceptual background, presenting the unitary model of the household and its limits and an overview of other, non-unitary models and of the socioeconomic approach to the financial organization of the household from the perspective of their implications for operational statistical practice. The consequences of lacking knowledge and information at the individual level, especially the consequences for the analysis of gender inequality, are discussed, focusing on the assessment of poverty and the implications of a "unitary" perspective in policies against poverty.

12.2.1 Measuring Income: Components and Units

Household disposable income—that is, the amount a household can spend or save without drawing on its assets—is measured as the sum of all the incomes received in the household over a given period of time net of the sum of social contributions and direct taxes paid by the household and transfers to other households. Three main types of income can be received in a household: income from work/employment, income from property, and transfers, some received from other households (e.g., alimonies, child support) and most received from the state.[3] In this set of components, the primary unit of income is more or less obvious: income from work and employment, including wages, salaries, profits or losses from self-employment, some state transfers related to work (unemployment, sickness and maternity benefits, pensions), some other social benefits such as incapacity benefits or scholarships, and some transfers with other households, such as alimonies, are clearly received by individuals. As for deductions, the social contributions attached to earnings or pensions are "individual," too. But some other components can be individual or "collective": for instance, who receives the income from property depends on who the owner is. Attributing this income to one or another member of the household then requires detailed information on ownership, that is, on who holds the assets or, in the case of joint ownership, the shares held by the different owners. Yet

[3] The Canberra Group also mentions the value of goods and services produced by the household for its own consumption as well as social transfers in kind. These elements, while not monetary incomes, increase the household's actual resources. However, measuring the goods and services produced for the household's own consumption or distributing the value of state transfers in kind between households raises serious difficulties of estimation (especially a very high sensitivity to estimation assumptions), and the current definition of household disposable income does not yet include them (even though some data sets provide estimates, for example, imputed rent). This chapter will not go further into this aspect of the measurement of income, which involves long-running debates on the concept of income, recently renewed with the "Stiglitz-Sen-Fitoussi" report (Stiglitz et al., 2009).

wealth is perhaps even more conceptualized at household level than income; we return to this issue later in the chapter (Section 12.7). Taxation can be joint or separate. Some other components are more "collective," for instance, family or housing benefits. Of course, none of these doubts arise in the case of one-person households, for which the household and the individual income are the same.

Identifying the unit who receives/pays is one thing, but what counts in practice is the level at which the information is available in statistical data sets; by definition, strictly household-level data sets do not provide any information at the individual level. Individual datasets most often provide information limited to earnings (sometimes pensions and social benefits); and data sets providing both individual-level and household-level information do not always detail all the components collected at an individual level.[4] Table 12.1 displays a tentative classification of the components of household income by primary income unit and the level at which they are most often available in large-scale datasets (excluding occasional surveys). It shows clearly that, on the basis of the information available in data sets, employment-related income is the only notion of income that can be easily implemented at the individual level. In consequence, the statistical information on income currently available in most large-scale data sets does not allow one to compute a disposable income at the individual level if the individual does not live alone.

12.2.2 From the Household's Disposable Income to the Standard of Living at the Individual Level: The Statistical Approach

The statistical notion of living standard (or "equivalent income" or "income per consumption unit") is intended to make comparable the economic well-being of households of different sizes and composition. Its quality as a proxy for economic well-being is much debated (see also Decancq et al., 2014, Chapter 2, in this volume), but for the time being, it remains the most often used and the basis for the measurement of poverty thresholds (or, in the United States, poverty lines).

The standard of living is a construction based on the disposable income (or consumption) of a one-person household taken as a measure of his or her economic well-being. When the household counts more than one person, it is measured so as to take into account the fact that the needs of two (three, etc.) individuals living together are less than twice (three times, etc.) those of one person living alone because of the economies of

[4] For instance, European Union Statistics on Income and Living Conditions (EU-SILC), the European statistical source on income and living conditions, which is the basis for the computation of a system of indicators, provides information at both levels but (at the time this chapter was written) does not give the details of certain individual benefits (maternity benefits or parental leave allowance, for instance, are not detailed at the individual level and are aggregated with family benefits at the household level), nor does it provide the detailed amount of taxes when the household is not a married couple or when taxation is separate. In addition, it aggregates taxes and social contributions at the household level.

Table 12.1 Income components, income units, and availability in statistical data sets

Category	Income component	Income unit	Availability in data sets
Primary distribution	*1. Income from employment*		
Market income	a. Employee income (wages, salaries, bonuses, severance/termination pay)	Individual	Individual level Household level
	b. Income from self-employment (profit/loss from unincorporated enterprise)	Individual[a]	Individual level Household level
	2. Property income		
	c. Income from financial assets (interest, dividends)	Owner (individual or household)	Household level
	d. Income from nonfinancial assets (rent)		
	e. Royalties		
Redistribution	*3. Current transfers received*		
State transfers	f. Social security pensions/schemes	Individual	Individual level
	g. Other insurance benefits (unemployment, sickness, incapacity, etc.)	Individual	Individual level Household level
	h. Family, housing benefits	Household	Household level
	i. Other social benefits (universal or means-tested)	Individual or household	Household level
	j. Current transfers from other households (alimony, child or parental support)	Individual or household	Household level
	4. Current transfers paid		
Taxes and contributions	k. Social insurance contributions	Individual	Individual level Household level
	l. Direct taxes	Fiscal unit (individual or household)	Household level
	m. Current interhousehold transfers paid	Individual or household	Household level
	Disposable income = 1 + 2 + 3 − 4	Household	

[a]The "individual" nature of incomes from self-employment is questionable in the case of a family-owned business. There are, in general, well-known difficulties in measuring the income from self-employment (see Canberra Group, 2011, pp. 34–35). One particularity is that self-employment income includes income from both employment and capital; the income it yields is generally measured as the amount of profit over an accounting period (or losses; it can then be negative). Another particularity is that self-employment includes a specific category of employment: "family workers," who participate in the business of a family member but are not paid.

scale that result from sharing a dwelling and durable and consumption goods and the benefits of the household's production. The additional income needed to keep the household at the same level of economic well-being when additional members are included in the household is difficult to measure because individuals' consumption within households is not observed. It is most often estimated on the basis of the observed expenditure of households of different sizes and demographic composition. These estimations result in "equivalence scales," which give a weight, assumed to reflect the additional income needed relative to a one-person household, to each additional household member. Whatever the equivalence scale actually implemented, the weight of any additional member is less than 1 (because, as mentioned above, adding a second person to a one-person household does not double the needs of the household). The dominant statistical approach to the standard of living (or equivalent income) currently uses the so-called "OECD-modified" equivalence scale,[5] which gives a weight of 0.5 to an additional adult in the household and a weight of 0.3 to an additional child (a child being an individual younger than 14 years old).

While in this section we are more interested in the assumptions behind the measurement of the household's standard of living and its meaning at the individual level, it is worth briefly illustrating the difference between the household disposable income (INC), a "per head" approach (INC_{PH}), and the standard of living, or "equivalent" disposable income (INC_{EQ}). There is, of course, no difference for a one-person household: in this case $INC_{PH} = INC_{EQ} = INC/1$. If the household is composed of two adults, then $INC_{PH} = INC/2$ and $INC_{EQ} = INC/(1+0.5)$; if it is a couple with one child, $INC_{PH} = INC/3$ and $INC_{EQ} = INC/(1+0.5+0.3)$; INC_{EQ} is always greater than INC_{PH}; the difference accounts for economies of scale. Leaving aside a possible debate on the weightings, it is reasonable (and widely accepted) that INC_{EQ} is a better basis than INC or INC_{PH} for comparing the level of economic well-being between these three households. But current statistical practice goes a step further, since each individual in a given household is considered to achieve the level of economic well-being he or she would achieve if living alone with an income equal to the household's equivalent income; in other words, all the household's members have the same living standard—that of the household. As pointed out by Woolley and Marshall (1994): "The standard approach solves the problem of measuring resource distribution within households by ignoring it" (p. 429). In turn, this practice raises many questions about the actual meaning

[5] The "OECD-modified scale" has gradually replaced the "OECD-scale" or "Oxford scale" (which gave a weight of 0.7 to an additional adult and 0.5 to an additional child). Neither is unanimously validated, and there are various other possible weightings. The many debates on the estimation of equivalence scales will not be recounted here (see, e.g., Lechene, 1993; Van Praag and Warnaar, 1997; a survey in Lewbel and Pendakur, 2008; a discussion of statistical practice in OECD, 2013). Note that American statistics do not explicitly refer to an equivalence scale, but the official poverty lines (measured for households of different sizes/composition and in different locations) are implicit equivalence scales.

of indicators *at the individual level* (including indicators of poverty) based on the household's equivalent income: if one of the household members holds back some or all of his or her income from the common pool, or if the pooled income is not equally distributed among the household members (or if the equivalence scale does not allow for economies of scale to be "distributed" at individual level; see also Browning et al., 2006a), the approach is much less relevant. This highlights how essential the assumptions of income pooling *and* equal sharing within the household are both necessary conditions for using equivalence scales (Lise and Seitz, 2011) and deriving individual-level indicators from variables measured at the household level. The standard approach also results in a measure of individual well-being, which, by construction, ignores the possibility of inequality within the household and, by construction, makes intrahousehold inequality virtually impossible to assess.

12.2.3 Behind the Statistical Approach: The Household "As If" an Individual

Curiously enough, the statistical practice of attributing the same living standard to all the individuals living in a household is rooted in a conceptualization of the household "as if" it was a single individual. The household "as an individual," first developed in the framework of consumer theory, is the household of the unitary model. This model has many implications for the analysis of gender inequality (Section 12.4); the focus here is on its assumptions and limitations in relation to the practice of income measurement.

12.2.3.1 The Unitary Model of Household Behavior

The unitary model consists in a transposition of individual (consumer) behavior to the household level: according to its preferences, the household maximizes a single utility function under a single budget constraint. For a household to function "as if" an individual, two main assumptions are needed.

First, individual preferences must converge, one way or another, so that the household can be considered a single decision unit. Considering that the actual agent of the consumer theory is a household (a family), Samuelson (1956) proposed that the family acts as if it were maximizing a joint consensual welfare function, a solution that does not explain the process resulting in a consensus. Another solution to the shift from several individual preferences to a single utility function was provided by Becker (1974a, 1991), proposing that the household is ruled by a "head"—an altruistic or "benevolent" member of the household—who cares about the welfare of the other family members. This would be consistent with the view of marriage based on mutual interest (the gains it provides compared to remaining unmarried) plus love and caring—the addition of optimal associations resulting from the marriage market even making the possibility of shared preferences plausible (Becker, 1973, 1974b). In this approach, the head of household transfers resources to the other household members; the household then acts as a single unit, since the only way the household members can increase their utility is to act in a way that maximizes the utility of the head of household, who in turn will increase his transfers.[6] However, this approach has been shown to hold only under very restrictive conditions (Bergstrom, 1989); a further assumption, which is actually crucial, is also necessary: the altruistic head of household has to be able to control the distribution of resources, meaning either he is richer than the other household members (Ben-Porath, 1982) or he has more power by other means (Folbre, 1986; Pollak, 1985).

Second, the incomes of the household members have to be fully pooled—a necessary condition for there to be only one budget constraint. Income pooling means that the way the income is used (by the household) depends only on the level of the whole/pooled income (and the household's preferences) and not on the origin of the income.

In the perspective of income measurement, the unitary model then tells us that there is no need to complicate income statistics with information collected at the individual level because it is only the total income of the household, not whose income it is, that counts in the end. However, the head of household does not necessarily treat all the household members equally; then the statistical practice of imputing the same living standard to all the household members may carry the approach a step further.

12.2.3.2 Methodological and Empirical Issues

The unitary model has been challenged on both theoretical and empirical grounds since the 1980s. At the theoretical level, the approach contradicts the methodological principle of individualism at the basis of neoclassical theory (Apps and Rees, 1988; Chiappori, 1992). According to this principle, there is no such thing as "group behavior," only outcomes from individuals' decisions. Folbre (1986) also underlines the paradox of "individuals who are entirely selfish in the market (. . .) [and] entirely 'selfless' within the family" (p. 247). The unitary model, along with Becker's theories on marriage and specialization within the family, also have been much discussed by feminist economists in a general examination of its implications for the analysis of gender (in)equality.[7]

Empirical results do not provide much support. Basically, a test of the unitary model consists of verifying that a change in the distribution of nonlabor income within the household does not modify the structure of the household's consumption or labor supply behavior (since both are expected to result only from the household's preferences and the budget constraint, i.e., the pooled income and prices); in short, how the (pooled) income is used should be independent from whose income it is. On the contrary, it has been

[6] Note that the "head" is not explicitly a "he": Becker's formulation here is "gender neutral." However, it is most likely "he" in the Beckerian approach to specialization within the family (see Section 12.6.3), as well as empirically, given the likelihood of women having, on average, lower independent incomes than their male partners.

[7] Nelson (1994), Bergmann (1995), Katz (1997), and Woolley (1996). See also an in-depth review of Becker's main assumptions founding his approach to the economics of the family by Pollak (2003).

shown that changes in the personal income level of the partners influence the household's allocations (Bourguignon et al., 1993; Browning et al., 1994; Phipps and Burton, 1998; Thomas, 1990). Empirical work on developing countries also casts doubt on the validity of the unitary approach (e.g., Kanbur and Haddad, 1994) to the point that, in the mid-1990s, several economists thought that the time had come "to shift the burden of proof" onto the unitary model (Alderman et al., 1995). The early results were supported by results obtained from the analysis of the impact of exogenous changes in the household members' relative incomes, which makes it possible to avoid possible endogeneity biases (for instance, a change in relative incomes resulting from a change in the labor supply). Here, an emblematic study is that of Lundberg et al. (1997); they show that a reform in the payment of family benefits in the United Kingdom—initially paid to fathers, then after the reform to mothers—resulted in an increase in household expenditure on children's clothes, a result not consistent with the unitary model.[8] Such conditions of "natural experiments" (more precisely, changes that exogenously redistribute the incomes within households) are difficult to find, and comparable studies do not exist for rich countries.[9] However, considering the results of empirical studies over a period running from 1994 to 2008 in different contexts and for outcomes as different as, for example, labor supply, children's health, savings, demand for clothes, and demand for alcohol and tobacco, Browning et al. (2011) concluded that: "the evidence seems overwhelming: a principal implication of the unitary model is rejected on a wide set of data sets for a wide range of outcomes" (p. 225).

12.2.4 Other Representations of the Household

Several other nonunitary models of household economic behavior have developed since the early 1980s. Parallel with these developments, a strand of research in sociology and economic psychology examines the financial organization of the household. We now look at these alternative economic models[10] and socioeconomic approaches and the alternatives for statistical practice they offer.

[8] Ward-Batts (2008) obtains the same result using a different type of data.

[9] Duflo (2003), who used a reform extending the benefit of a social pension program to a formerly excluded black population in South Africa, or Attanasio and Lechene (2002), who used the Mexican welfare program Progresa, in which transfers go exclusively to women, obtain results rejecting the income pooling assumption, and both suggest a shift of power in favor of women. Comparing Progresa and Procampo, another welfare scheme targeting men (farmers), Davis et al. (2002) found that the former results in better outcomes than the latter in terms of schooling expenditures and health, but the outcome does not differ in terms of households' total expenditure and food security (see also Ruiz-Arranz et al., 2006). Analyzing the impact of a law extending alimony rights to cohabitants in Brazil, Rangel (2006) also founds a shift of power toward women in decision making on time allocation and a redistribution of resources toward schooling expenditure on first-born girls.

[10] See Browning et al. (2011) for an in-depth review of models of household behavior and recent developments, and see Donni and Chiappori (2011) for a survey.

12.2.4.1 Nonunitary Models of the Household

Contrary to the unitary model, nonunitary models explicitly consider the individuals within the household in accordance with the methodological principle of individualism, and they take into account a notion of relative power in decision making, allowing for a gendered approach to intrahousehold organization. Nonunitary models generally consider two decision makers (spouses), each with his or her own utility function,[11] allowing for externalities—that is, including the partner's preferences in their utility functions. The partners' relative power in the decision-making process is taken into account either as the utility each partner would obtain outside the marriage or in a sharing rule. Two categories of goods are considered: private goods, corresponding to goods that can be consumed only by one partner (and will be included only in one partner's utility function), and public goods that can be consumed at the same time by both partners. Children do not directly influence household decisions, but their well-being is taken into account as a public good in the parents' preferences. Incomes are not necessarily assumed to be pooled (but they can be), and the origin of income contributes to the partners' relative power, as well as various other distribution factors, that is, factors that may influence the decision process but do not change the budget constraint: typically the partners' nonlabor incomes, education levels, health status, wealth, or social capital. The distribution factors can also be external to the partners' characteristics: the state of the labor market or the marriage market may shift the power balance through the opportunities they offer outside the partnership. Folbre (1997) also refers to "gender-specific environmental parameters" such as women's rights in general, marriage and divorce laws, and property rights. Agarwal (1997) extends the understanding to the influence that this environment, including social norms, can have on the actual scope for bargaining within the household.

Beyond these broad characteristics, nonunitary models differ in the assumptions made about whether decisions result in Pareto-efficient outcomes—that is, when improving one partner's well-being is not possible without reducing the other's—and in the way they represent the process of decision. There are three main categories of nonunitary models: cooperative bargaining models (Manser and Brown, 1980; McElroy and Horney, 1981), noncooperative bargaining models (Ulph, 1988; Woolley, 1988), and collective models (Bourguignon and Chiappori, 1992; Browning et al., 1994; Chiappori, 1988). Drawing on game theory, bargaining models have in common the assumption of a certain process of decision making but not necessarily that the outcome is Pareto-efficient; on the contrary, collective models do not specify a particular decision-making process but assume Pareto-efficiency, justified by the stability of the relationship (see more detailed presentations in Chiappori and Meghir, 2014, Chapter 16; Browning

[11] Considering two decision makers with their own preferences avoids the methodological problem of the unitary model; however, some level of "collective" rationality needs be introduced for the outcome to be Pareto-efficient (see Bourguignon, 1984).

et al., 2006b; Donni and Chiappori, 2011). However, Pareto-efficiency becomes difficult to assume when the household's environment is not stable, for example, when decisions change the partners' relative bargaining power or if what seem to be optimal in a given context can lead to nonoptimal outcomes when the context is changed. The exploration of these dynamic aspects is one of the directions taken by most recent research (e.g., Basu, 2006; see also Chiappori and Meghir, 2014, Chapter 16).

Bargaining models have introduced the notion of "threat point"; the basic idea is that neither partner would agree on a decision resulting in a lower level of individual utility than that he or she could achieve if the partners did not come to an agreement. The individual level of utility (the utility at the threat point) defines a partner's bargaining power. The threat point was formulated first as a divorce threat—a rather radical argument of negotiation, as underlined by Bergstrom (1996). Another formulation is that of the model of "separate spheres" (Lundberg and Pollak, 1993); here, the threat is not defined in terms of union dissolution but as minimal cooperation, with each partner being responsible for a given sphere (defined by social gender norms) of common consumption.[12,13] The interest of the bargaining approach is to provide a framework for analyzing unequal power relations within the household and how they can be influenced by environmental factors. Folbre (1986) emphasizes the importance of this difference from the unitary model: "It is the juxtaposition of women's lack of economic power with the unequal allocation of household resources that lends the bargaining power approach much of its persuasive appeal" (p. 251). However, these models present serious difficulties of estimation, especially the need to identify a threat point, as described by Himmelweit et al. (2013).

Because they do not refer to a specific decision process, collective models do not face this particular problem. They can be seen as a general class of cooperative models and are nowadays the dominant approach to household decision making. In these models, the partners maximize a household utility function, which can be seen as a weighted average of each partner's utility function; the weighting corresponds to a sharing rule, which depends on distributional factors and reflects the partners' relative power (instead of "points" where marriage or cooperation breaks down). Empirical results regularly show that the sharing rule is influenced, as expected, by various characteristics of the household members and contextual parameters (Browning et al., 2011). Empirical applications, however, often require more assumptions because neither the outcome nor the sharing rule are observable and statistical information is most often available only at household

[12] The difference from the external threat, where the bargaining power depends on the utility the partners would get outside the partnership, is that in Lunderg and Pollak's (1993) setting it depends on the resources the partners bring to the marriage. These two views of the threat point may lead to completely opposite policy implications.

[13] Other models that are not detailed here introduce the possibility of transfers between partners (Carter and Katz, 1993; Chen and Woolley, 2001) or specify several threat points (Bergstrom, 1996).

level. In addition, while variations in the sharing rule can be estimated, it is much more complicated to obtain estimations of the sharing rule itself[14] (Himmelweit et al., 2013).

Nonunitary models provide a conceptual alternative to the unitary approach and have allowed many improvements in the analysis of the household members' behavior within the household, but, in the perspective of statistical practice, they do not provide the operational alternatives that would allow going beyond the convenient assumptions of the unitary ground, in part because their estimation requires additional assumptions that reduce their scope and in part because of the lack of large-scale individual data on income.

12.2.4.2 Intrahousehold Finances: A Socioeconomic Perspective on Income in the Household

In sociology and economic psychology, the household (actually the couple-household, as in most economic models) is analyzed as a place of bargaining between partners of unequal power and may have conflicting interests. The household's domestic organization is explained within the main framework of the theory of resource exchange, which predicts that the partner with the highest resources—income, education, status—will have more power within the household (Blood and Wolfe, 1960; Sabatelli and Shehan, 1993). The notion of resources may include opportunities outside the relationship and the costs of an exit solution—an idea interestingly close to that of economic nonunitary models.

The issue of intrahousehold distribution of income is addressed in terms of financial organization, characterized by the management of and control over money by the partners. Another notion, not present in economics, is that of different categories of money—or "monies," according to the term introduced by Zelizer (1989, 1994)—depending on whose money it is and linking it to specific uses, some of which are shaped by gender norms: as in the case of labor division, money management reveals gendered relations of power (Tichenor, 1999). "Money" is not "income," but the questions addressed about money in the household are strikingly similar to those addressed in economics about the distribution of income within the household: Does the origin of money matter? Is it possible to lack money in a rich household? Who has power over what money? Who is responsible for given expenditures? Who makes decisions about what?

A very influential classification of money management systems, intended to reflect gradations of control over money, was proposed by Pahl (1983, 1989). She defined four main systems.[15] (1) The "whole wage" system: one partner hands over all his or her wage (minus an amount of "pocket money") to the other, who is in charge of managing the household's finance; this other partner may or may not have a personal income. (2) The "housekeeping allowance" system: here, one partner hands over an amount to be used for

[14] Examples of such estimations can be found in Couprie (2007) or Kalugina et al. (2009), who use methodologies that are clearly not likely to be implemented on a systematic basis.

[15] Further refinements distinguish between men's and women's control over resources (Pahl, 1995).

housekeeping spending and manages the rest him/herself. In these first two systems, only one partner has control over the household money. (3) The "pooling" or shared system: both partners manage and use the money as they need either for common or personal expenditure. (4) The "independent management" system: each partner keeps separate control over their income; unlike the three other systems, there is no notion of household money and neither partner has access to the other's money. This classification has been central in many dedicated studies of quantitative sociology and socioeconomics over the 1990s (e.g., Burgoyne, 1990; Burgoyne and Morison, 1997; Treas, 1993; Vogler, 1998) and remains the reference in recent empirical work (see Bennett, 2013).

One of the interests of Pahl's classification is that it provides usable survey questions[16]: typically, the respondents are asked whether they pool all, some, or none of the income, and sometimes the share of their income they pay into a "common pot" or the share they spend on their own private consumption.[17] Empirical work generally finds that the pooled system is more often observed in the case of married couples (Heimdal and Houseknecht, 2003; Ludwig-Mayerhofer et al., 2006; Lyngstad et al., 2011), couples who have children (Hamplova and Le Bourdais, 2009; Kenney, 2006; Laporte and Schellenberg, 2011; Vogler et al., 2008), in one-earner families or when the income imbalance is significant (Elizabeth, 2001; Halleröd, 2005), and when money is tight. It is less frequent when the partners have higher education levels (Laporte and Schellenberg, 2011), in the case of past partnerships, or when there are financial ties with other households (Burgoyne and Morison, 1997; Heimdal and Houseknecht, 2003; Treas, 1993). In summary, bearing in mind that different methodological options[18] and data limitations sometimes make the results difficult to compare, duration, the presence of public goods (especially children), a traditional division of labor, and the need to monitor low resources seem to have a positive influence on the probability of pooling

[16] Pahl's classification was based on a very small number (from a statistical point of view) of in-depth interviews—about 120 in all.

[17] Examples of such questionnaires can be found in the EU-SILC 2010 module on "Intra-household allocation of resources" (Eurostat, 2010), in the Statistics Canada General Social Survey 2007 (see Laporte and Schellenberg, 2011), or the International Social Survey Program (waves 1994 and 2002). An earlier example can be found in work by Woolley and Marshall (1994), who use Pahl's categories to compare various measures of intrahousehold inequality. In other formulations, the respondents are asked whether they see their earnings as their own or as the family's money and whether they feel free to draw on the common pool without asking permission. Questions on the respondents' opinion about or satisfaction with the household income also have been developed; this type of information was used in the estimation of the sharing rule by Kalugina et al. (2009) and Bonke and Browning (2009). Some studies use the existence of a joint bank account rather than questions on the financial regime (Woolley, 2003), but the two approaches are not comparable, as shown by Burgoyne et al. (2007).

[18] Options include whether to aggregate Pahl's categories, especially those of partial pooling and separate money. Aggregation is often intended to contrast collective systems—allocative and pooled systems—with all the other systems that are categorized as individualized (Vogler et al., 2008).

incomes. Beyond this general pattern, comparative studies show significant cross-country variation that might relate to different institutional and cultural contexts (Hamplova and Le Bourdais, 2009; Heikel et al., 2010; Heimdal and Houseknecht, 2003; Yodanis and Lauer, 2007). As for the overall incidence of the pooled system, the main result is that significant proportions of couples declare that they keep at least some of their money separate,[19] another dent in the unitary model insofar as the concept is the same as that of income pooling in the economic literature.

From the perspective of statistics appropriate for the study of income inequality between individuals, implementing "pooling" questions on a systematic basis has some appeal. It would be an easy way to determine whether incomes are fully pooled. If so, this would justify a unitary approach; if not, some additional questions on the share of different incomes held back from the "common pot" by the household members would make it possible to estimate the amount of income actually available to, or controlled by, each member. However, several questions can be raised. One is what is actually captured by the answers to pooling questions: a perception of more or less collective money, a practice of management, or actual control over one's own or the household's money? It is also difficult to deduce whether there is equality within the household from the pooling regime. Transfers between partners can take place without income pooling, and hence no pooling does not mean no sharing; conversely, income pooling does not necessarily entail equal or fair sharing. Another issue is how the respondents understand the income/money questions: contrary to in-depth interviews, where the researcher can interact with the respondent to ensure a common understanding, survey questions may be understood differently from their intended meaning. Finally, there is the question of the identity of the respondent: is it a unique respondent, representative of the household, or both partners? Questions asked of only one partner may provide reductive information, but asking both partners may lead to dealing with conflicting answers.[20,21] Beyond "technical" questions, the pertinence of the information obtained from survey questions on the pooling regime is questioned in qualitative research. For instance, exploring the case of partial pooling and separate finances, Ashby and Burgoyne (2008) suggest that they may conceal more complex practices relating to perceived ownership and commitment in the

[19] A presentation of the main results of the EU-SILC 2010 module on "Intra-household allocation of resources" shows that, among the 27 EU member states, about 70% of the households (with at least two adults)—ranging from as low as 50% in Austria to about 85% in Malta—reported that all the incomes are treated as common (Eurostat, 2012).

[20] In an analysis of individual or household responses to questions on perceived economic well-being, Plug and Van Praag (1998) found that, when asked about the minimum income needed to maintain a family like their own, there was no difference between the partners' responses in one-earner and two-earner couples, as long as the earnings differential was not substantial.

[21] The analysis of the Eurostat module on intrahousehold sharing of resources (EU-SILC, 2010) shows that there are significant proportions of households in which the partners' responses are not coherent, as well as of "full pooling" households in which at least one partner reports that they keep some of their own income from the pool (Ponthieux, 2013).

relationship, and hence do not provide accurate insights into the partners' living standards or control over money.

Another issue is whether the pooled system actually corresponds to the income pooling assumption. The few studies that have addressed this question seem inconclusive: Bonke and Uldall-Poulsen (2007) found a high correlation between the "pooled system" and an experiment-type measure based on answers to a question asking whether the respondents would spend more or less on themselves if their own and their partner's incomes were changed in opposite directions; partners using a pooled system were more likely not to change their personal spending. This result suggests that the two approaches correspond to the same notion. But Bonke (2013), using the same data set (the Danish expenditure survey) and questions allowing the household's consumption over a large set of goods to be assigned, finds that the structure of the household's expenditure seems to be correlated with the income distribution, even in households having reported a pooled system. In that case, the pooled system would not correspond to the assumption of income pooling.

12.2.5 Back to Measurement and the Pending Question of Intrahousehold Distribution of Income: Where We Stand, the Consequences, and Gendering the Issue

Concern about the distribution of income within the household is not new; in 1952, an article on "The distribution of income within the family" (Young, 1952) started as follows: "It is painfully obvious to the student of social policy that growing knowledge about the distribution of the national income between families has not so far been matched by a growth in knowledge about the distribution of the family income between its members. In place of knowledge, the assumption has often been made, though not stated, that the family . . . can still be treated as a unit for the purposes of spending. It has been taken for granted that some members of a family cannot be rich while others are poor. . . . To replace assumption by information is no small venture" (p. 305). More than 60 years later, it is painfully obvious that statistics on income and economic well-being remain based on the unitary version of the household,[22] as if stuck in a

[22] Nonmonetary indicators of poverty are not examined in this chapter, but it is worth mentioning that the measurement of material deprivation is, except in occasional surveys, also based on information collected from only one respondent, most often about "the household" in general or (rarely) about that respondent and their partner or children. With such data, the comparison of individuals within households is, of course, not possible (see, e.g., Adelman et al., 2002, who compare men and women living in different households). Using an Irish survey from 1999 allowing for intrahousehold comparisons, Cantillon (2013) founds that women tend to be relatively more deprived than their partners, especially concerning some specific items (for instance, going without a meal), and more significantly when the usual set of items used to measure deprivation is extended to leisure activities or personal spending, especially in couples with children. The combination of relatively low proportions of couples experiencing privation and the sensitivity of the responses to the conditions of the interview (whether the other partner is present) do not allow conclusions about clear patterns to be made—a point made in a previous study by Cantillon and Nolan (1998) using an earlier survey.

conceptualization now widely considered inappropriate. The gap between research and statistical practice has simply increased over time.

Statisticians are not unaware of the problem when deriving indicators of inequality between individuals from variables at household level. Although it is acknowledged that, in principle, the unit of interest is the individual, the argument that because incomes are shared the pertinent unit of collection is the household still holds[23] (Canberra Group, 2011, p. 24) or that, in doubt, it is preferable to assume that incomes are shared rather than the contrary (Förster and Mira d'Ercole, 2009, p. 7). So, at present, how to get a better idea of inequality in living standards within households remains an open issue. Taking a step forward in the conception of income data would entail a shift from household-level data to data systematically providing individual-level information on income components received or transfers made by and to individuals. There would, of course, be a cost in terms of data collection, and this would not in itself solve the question of the actual extent of sharing within households; but being able to use information disaggregated as much as possible would give more flexibility to testing various assumptions about income pooling and sharing and would allow escape from a situation in which the measurement of individual economic well-being and the analysis of inequality between individuals is conditioned in the first place by the assumption that individuals are equal within the household in which they are observed.

12.2.5.1 "How Serious Is the Neglect of Intrahousehold Inequality?"[24]

One major difficulty in assessing the potential consequences of ignoring inequality within households is, ironically, the lack of data on individual income. It is nevertheless possible to illustrate what the standard approach ignores when attributing an equal standard of living to each member of a household. We draw here on the framework proposed by Jenkins (1991, pp. 476–477). For a couple-household, a simplified formulation of the living standard (Eq-Y), taken as the household budget constraint, defines it as the sum of each partner's earnings plus the couple's net nonlabor incomes (NL) divided by the number of equivalent adults (n_{eq}) to account for the economies of scale[25]:

[23] It is interesting to note that the issue finally raised by the Canberra Group (2001) is not that of the assumption of income pooling and equal sharing within the household, but that of defining the pertinent income unit: "Then the relevant unit is either a person or group of related persons, within a household, whose command over income is shared" (p. 38), a condition that is taken for granted rather than checked.

[24] This title is borrowed from Haddad and Kanbur (1990). Using a survey of inequality in nutritional status in the Philippines, they found that neglecting intrahousehold inequality resulted in a significant underestimation of the level of inequality but did not drastically change the conclusions about the patterns of inequality—except between men and women.

[25] To simplify further, housework time is not taken into account.

$$Eq\text{-}Y = \frac{\left(w_f LM_f + w_m LM_m + NL\right)}{n_{eq}}, \tag{12.1}$$

where w is the earnings rate, LM the time in the labor market, and f and m identify females and males, respectively.

The standard approach assumes that $Eq\text{-}Y_f = Eq\text{-}Y_m$. This implies that any difference between $w_f LM_f$ and $w_m LM_m$ is counterbalanced by implicit transfers between the partners and that NL is received jointly or equally shared, and it assumes that the economies of scale are distributed equally between the partners. To take into account other neglected possibilities, the couple's total income, including the economies of scale (assumed separable), can be rewritten as

$$\begin{aligned} Eq\text{-}Y = & \left[a_1\left(w_f LM_f\right) + b_1(w_m LM_m) + a_2\left(NL_f\right) + b_2(NL_m)\right] \\ & + \left[\frac{(1-a_1)w_f LM_f}{n_{eq}} + \frac{(1-b_1)w_m LM_m}{n_{eq}} + \frac{(1-a_2)NL_f}{n_{eq}} + \frac{(1-b_2)NL_m}{n_{eq}}\right], \end{aligned}$$

where the first part of the right-hand side corresponds to the amount of incomes not pooled, and the a_is and b_is represent the share of income each partner holds back from the pool.

Compared with the standard approach, which assumes that any a_i, $b_i = 0$, and where any difference between w_f and w_m or LM_f and LM_m does not count since the incomes are fully pooled, leading to $Eq\text{-}Y_f = Eq\text{-}Y_m$, the second expression allows for a difference between $Eq\text{-}Y_f$ and $Eq\text{-}Y_m$ by an amount equal to $[b_1(w_m LM_m) - a_1(w_f LM_f)] + [b_2(NL_m) - a_2(NL_f)]$.

This amount illustrates the potential ignored inequality within a couple-household; it involves the degree of inequality between the partners' earnings, whether nonlabor incomes are received jointly or separately (which, in the case of capital income, raises the issue of asset ownership within multiperson households), and, of course, the share of his or her incomes each partner holds back from the pool. Whether this share is large or small remains unknown. However, the "pooling question" of the European survey "Intra-household allocation of resources" (EU Statistics on Income and Living Conditions [SILC] ad hoc module 2010) provides an order of magnitude of the proportions of individuals and households for which this share is not 0: over 21 European countries, the mean percentage of adults living in multiperson households who reported holding back at least some of their income from the pool was about 47%. At a household level and including one-person households (for which the assumption of full pooling is always true), this yields 38% of all the households in which at least one household member does not pool all his or her income (Ponthieux, 2013). Even though caution is necessary when interpreting the "pooling question" (see Section 12.2.4.2), this suggests a rather high risk of assuming full pooling when it could be unjustified. The next issue is that of the impact this may have on the measurement of economic inequality between men and women.

In the 1990s, several studies explored how men's and women's poverty rates would differ from the conventional measures under assumptions other than intrahousehold equality (Borooah and McKee, 1993; Davies and Joshi, 1994; Findlay and Wright, 1996; Fritzell, 1999; Phipps and Burton, 1995). The most general principle consists of applying an "unequal" distribution of income instead of the equal distribution assumed by the standard assumption; the "individual" income is then computed as if only the household nonlabor income was shared, using various assumptions about how it is distributed.[26] Whatever the year, country, or methodology, all these studies find that departing from the standard assumptions results in increased gender gaps in poverty (Table 12.2). In the case of married men and women, income poverty rates are dramatically higher for women and significantly reduced for men, instead of the equal poverty rates obtained with the conventional approach; when all households are included, the changes are less pronounced, mitigated by the relative share of one-person households for which the assumption has no effect.

Sutherland (1997) computed individual incomes assuming that all income is retained by the person who receives it, that the collective components of income are received by the head of household, and that family benefits are received by mothers—to whom Sutherland also allocates the responsibility for children. She shows that women are disproportionately represented in the bottom quantiles of the distribution of individual incomes, contrary to broadly equal shares of men and women in each quantile of the distribution of household income. A more recent study by Meulders and O'Dorchai (2010) suggested that the gap between conventional measures based on household incomes or "individual" incomes remains substantial. Using harmonized European data (EU-SILC) from 2006 for nine countries, they computed individualized incomes as the sum of the incomes received individually by adult men and women and, for those living in multiperson households, an equal share of the income components available only at the household level.[27] Then they compute a threshold at 60% of the median individual

[26] This is quite different from the approach developed in the literature on the "feminization of poverty," which focuses on households headed by single men and women, the argument being that couple households cannot, by definition, contribute to a gender gap in poverty. A limitation of these approaches is that they do not allow the effects of gender and the effects of the household composition to be sorted out (see Bennett and Daly, 2014, especially Section 12.5). The main results highlight that single mothers and single elderly women face higher-than-average poverty risks. Comparative work shows significant cross-country differences related to women's participation in employment and social policies (Barcena-Martin and Moro-Egido, 2013; Brady and Kall, 2008; Gornick and Jäntti, 2010; Kim and Choi, 2013; Wiepking and Maas, 2005).

[27] The income components that the data do not provide at individual level are capital income, net inter-household transfers, family benefits, taxes, and social contributions. Dividing equally the social contributions (which are based on labor incomes) is debatable, but the data do provide only an aggregate of taxes and social contributions.

Table 12.2 Sharing assumptions and poverty risks by gender

Sharing assumption **Authors, country, year, population**	**Equal sharing of household income**		**Other assumption on sharing**	
	Men	**Women**	**Men**	**Women**
Women get 30% of the couple's market income Borooah and McKee (1993), United Kingdom, 1985, married couples % below 2/3 mean equivalent income	33	33	14	66
Each adult keeps her/his own income[a] Phipps and Burton (1995), Canada, 1986, married couples % below 50% median equivalent disposable income	10.5	10.5	4.5	28
Each adult keeps her or his own income[a] Davies and Joshi (1994), United Kingdom, 1986, married couples % below 20th percentile equivalent disposable income	15	15	11	52
Women get 20% less than their equivalent income[a] Findlay and Wright (1996), United States, 1985; Italy, 1986; all adults % below 50% median equivalent disposable income				
Italy	17.5	16.8	15.4	27.1
United States	17.0	22.6	15.9	30.3
No sharing[a] Fritzell (1999), Sweden, 1991, adults aged under 65 % below 50% median equivalent disposable income	4	3.9	4.5	9.6

[a]The authors also present other assumptions or computations for other household demographic compositions than those reported in this table.

income and measure the risk individuals would face of falling below this threshold (called "financial dependency") if they lived only on their own financial resources.[28] The comparison of the two approaches shows that the conventional methodology has much more influence on women than men: over the nine countries, men's ratio of "financial dependency rate" to poverty rate ranges from 0.7 to 1.4 and women's changes from 1.7 to 3.3.

[28] This is not completely true because "individual" incomes are computed including an equal division of common income components, which are likely to be at least partly related to the current household composition (e.g., state transfers, taxes) and then change when the household composition changes. It is also perhaps not realistic to divide capital income equally because it is not necessarily common income. Another limitation is that, unless assuming that labor market status is totally independent of the individual's position in his or her household, the individual income is also likely to differ.

These results seem convincing enough to answer the question in the heading above: yes, neglecting intrahousehold inequality can be serious.[29] But while they show clearly that assumptions matter, it is more difficult to draw conclusions in terms of individual living standards; the main conclusion is that the living standard is a household-level notion and that household-level information fails to inform about individual situations within households.

12.2.5.2 The Standard Assumptions and the Assessment of Gender Economic Inequality

As exemplified above, by construction, the standard assumption of equality within households puts serious limits on the assessment of the extent of gender inequality. The crux of the problem is that the household dimension comes up entangled with individual characteristics, not only making an overall assessment of gender economic inequality virtually impossible but also obscuring the causal factors of gender inequality behind the household dimension. This is not to say that the household dimension has no effect on men's and women's economic outcomes—it certainly has strong effects, as will be obvious in the next sections—but the conventional measure of economic well-being conflates individuals and households, making individual situations intractable. The analytical challenge is to disentangle individual outcomes from household outcomes to understand how the "household dimension" both contributes to (because of decisions made in the household context) and obscures (because of assumptions about the absence of inequality within the household) gender inequality. This understanding may, in turn, have various implications in the perspective of public policies aimed at reducing inequalities.

The comparison of individual labor market status and outcomes and the risk of poverty is especially illuminating: in the working-age population, women, despite their lower participation in the labor market (see Section 12.3) and their disproportionate presence among low-wage workers when they do work (see, e.g., Grimshaw, 2011), do not face dramatically higher poverty rates than men: the gap (women − men) ranges from 2.2% to 2.9% points in English-speaking countries, between 0.9 and 2.1 in continental and southern European countries, and is negative in Nordic countries (figures are from Table 1 in Görnick and Jantii, 2010[30]). Moreover, Görnick and Jantii show that, among individuals of working age with low or no earnings, women are less likely to be poor than men. In a study including 22 EU countries, Maitre et al. (2012) found the same pattern among low-paid workers:

[29] The standard approach is also biased in a different way because the equivalent disposable income is measured directly for individuals who live alone and under strong assumptions for the others. These strong assumptions can themselves result in statistical artifacts, as can easily be illustrated by comparing the situation of two partners before and after separation (see Chiappori and Meghir's introduction to Chapter 16, in this volume).

[30] Their estimates are based on data from the early 2000s, but the order of magnitude remains comparable (for European countries) with most recent statistics from Eurostat (available from: http://epp.eurostat.ec.europa.eu/portal/page/portal/income_social_inclusion_living_conditions/data/main_tables).

men's poverty risk is notably higher than women's. A similar "gender paradox" is underlined in empirical studies of the working poor (Peña-Casas and Ghailani, 2011; Ponthieux, 2010). This, of course, has a lot to do with the fact that in the working-age population, a large proportion of men and women live in couple households, a configuration in which there is no inequality by construction. The measure of women's economic well-being then seems to be much less related to the outcome of their individual economic activity than men's. However, this is precisely because their earnings are, on average, lower than men's. Because of this inequality and the large share of adults who do not live alone, the influence of the equal sharing assumption is the greatest on the estimates of women's poverty rates.

What does this imply in terms of public policies? Many social transfers target the households (families, fiscal units) and assess their efficiency on the basis of outcomes measured at the household level. The implicit assumption is that meeting the needs of individuals is achieved by meeting the needs of households—another formulation of the unitary model. It is the same when individual benefits are conditioned by household resources, implicitly assuming that there cannot be needy individuals in nonneedy households. How this may affect the economic well-being of the individuals within households is, by construction, difficult to assess precisely because conventional measures of economic well-being and policy targets are derived from household-level information. While no statistical information allows for an assessment of the incidence of individual poverty in nonpoor, multiperson households, there are reasons to believe that neglecting the intrahousehold distribution of resources can contribute to the persistence of gender inequality. Policies that link what an individual is entitled to with the actions or resources of another member of his or her household can reinforce the imbalance of resources between men and women and women's economic dependence.

However, even accepting that intrahousehold transfers are such that equal living standards are achieved despite unequal personal resources, and that, contrary to what empirical results suggest, the imbalance of resources within households is not an issue, the equilibrium can be fragile. The trend of decreasing marriage in favor of cohabitation and increasing divorce or separation rates results in an increase in the number and types of households an individual may belong to over his or her life cycle. This suggests that resorting to household outcomes to assess individual situations may become increasingly irrelevant. From the perspective of measuring and analyzing gender inequality, this calls for a change of framework; as long as women's labor market outcomes are less favorable than men's, as is still the case, the standard approach, bypassing the issue of intrahousehold inequality, conceals gender asymmetries in the relation between the market and the household and inequality in terms of autonomy, risks, and opportunities.

12.3. THE GENDER WAGE GAP

Women's increasing participation in the labor market was a major trend in the second half of the twentieth century. At the same time, women's educational levels caught up with those of men—even overtook them, on average, in nearly all advanced countries—and women gained access to a greater number of occupations, favored by technological change. Since the 1970s, the effects of what Goldin (2006) describes as a "quiet revolution" have changed not only women's expectations about their careers and family lives but also public attitudes toward women's social role. Nowadays, in most industrialized countries, the participation of women, and especially mothers, in paid employment has become almost a norm; dual-earner families outnumber "male breadwinner" families; gender equality is an explicit policy goal, and gender discrimination is prohibited by law in many countries. But women's outcomes in the labor market still remain significantly lower than men's.

This section presents an overview of the analysis of gender inequality in wages, focusing particularly on the recent search for new explanations of its persistence. Over recent decades, this gap has narrowed in many OECD countries, but the trend of convergence now seems to be very slow, if not stationary (Blau and Kahn, 2006a,b). Since the early 1970s, the fact that men earn higher wages than women on average has usually been analyzed as the result of two main factors: a gender gap in productivity (due to women's lower levels of human capital and/or effort at work) and gender discrimination (cf. the survey by Altonji and Blank, 1999). With women's human capital (education and experience) catching-up men's, these variables become ever less relevant to explaining the gender wage gap. The stylized fact today is that gender wage inequality results from gender differences in occupations and from the lack of women at the top. This raises the question of why women still do not have similar careers to men. A vast literature competes in proposing explanations that are generally nonexclusive, complex, and of a scope far beyond standard human capital models. A growing strand of this literature incorporates psychological factors and social norms, shedding new light on the relationships between individual behavior and labor market outcomes (see a survey by Bertrand, 2010). But this does not rule out the central role played in the gender wage gap by the unequal share of unpaid work. Children are still at the heart of gender inequality on the labor market, and family constraints are largely responsible for career interruptions, part-time jobs, reduced working hours, and slow wage progressions. Before reviewing these developments, we start with a brief overview of the main trends and cross-country differences since the 1990s.

12.3.1 Main Trends and Cross-Country Differences in Gender Labor Market Outcomes

Wages are among the most available data on income by gender, but comparing wages (and the gender wage gap) over time and between countries presents a number of difficulties. Ideally, comparisons of the gender wage gap should be based on data covering all employees, sectors, and industries and a consistent concept of wage. Such data do not exist. National sources do not necessarily provide directly comparable information because of the variety of possible statistical sources (self-reported or administrative data), differences in scope (e.g., covering some or all sectors and industries, including part-time workers or not), differences in the concept of wage (especially whether it includes overtime, bonuses, etc.). Indicators of the wage gap can be calculated on the basis of hourly, weekly, monthly, or yearly wages, which of course do not yield the same result; they can cover all the employees or (and most frequently) only full-time workers; they can be calculated as a differential of the mean or median wages. It is therefore not surprising that the size of the gender wage gap can vary even within the same country and over a single year, making comparing gender wage gaps between countries even more tricky (on the importance of comparable data for the measurement of the wage dispersion in international comparisons, see Salverda and Checchi, 2014, Chapter 18, in this volume).

12.3.1.1 Narrowing, But at Different Speeds Across Countries, and Not Closing Completely

The overview of trends and cross-country differences presented below does not escape these limitations. We use the information available from the OECD. The information from the OECD has the advantage of scope and time coverage (1975 through 2011, although not for all countries); one drawback is that information is based on national definitions; another drawback is that it only covers full-time (or, in a few cases, full-time equivalent) employment, hence making it impossible to assess the impact of part-time work on the gender wage gap. Graphs are the easiest way to "see" trends over time, so Figure 12.2 displays the average gender pay gap over half-decades since 1975 for a sample of OECD countries, using a 4-year moving average to smooth the changes.

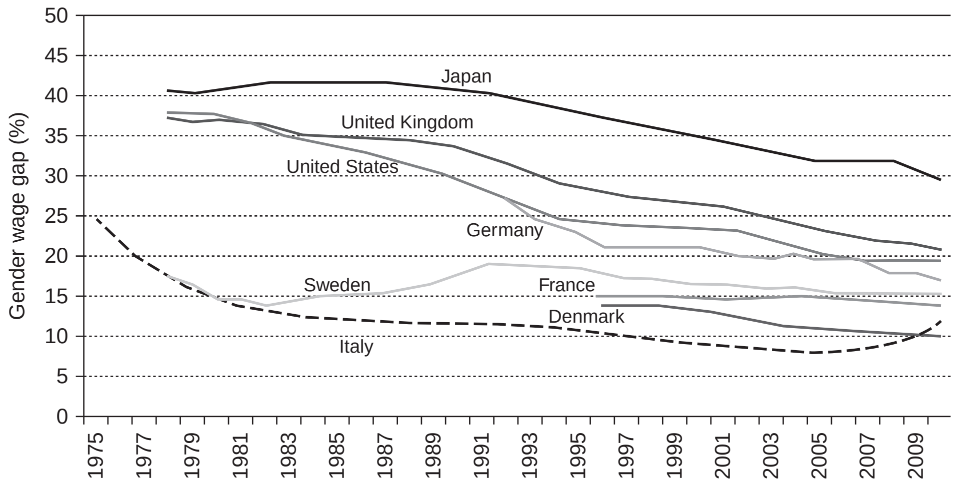

Figure 12.2 The gender wage gap in selected Organisation of Economic Co-operation and Development (OECD) countries from 1975 through 2007 (4-year moving average considering full-time workers). The wage gap is measured as the mean men's wage minus the mean women's wage divided by the mean men's wage. The gap is measured for various concepts of wage (annual, monthly, hourly), depending on the country. *Source: OECD, employment database 2012, national definitions and sources. Available from: http://www.oecd.org/employment/emp/onlineoecdemploymentdatabase.htm#earndisp.*

The general view of a wide gender pay gap narrowing fast and then more slowly is clearly verified for the United States, whereas the pattern is less uniform in other OECD countries. The United States experienced the most dramatic narrowing of the gender wage gap during the 1980s. This was particularly remarkable because it occurred during a period when the level of labor market inequality was rising sharply in the United States. This movement was called "swimming upstream" in a famous paper by Blau and Kahn (1997): women's improving qualifications, especially their experience and occupations, made up for the rising inequality. In the OECD countries, the gender wage gap has been decreasing more slowly since the late 1990s (except in the United Kingdom and Japan, where the narrowing has continued at the same pace) or stagnating, and even increasing in Italy.

Historically, the main factors behind the general narrowing of the gender wage gap have been the increases in women's educational levels (Goldin et al., 2006) and in labor market experience together with the associated returns (O'Neil and Polachek, 1993). Since the 1970s, the catching-up of women's educational levels and a reversal of the gender education gap have been observed in most OECD countries. Women now outrank men in 29 of the 32 OECD countries; in 2009, about 60% of all graduates with a university degree were women (OECD, 2012).[31] However, the specialty of degree remains highly gendered: only 26% of graduates in engineering, manufacturing, and construction are women, compared with more than 75% in health and welfare (OECD, 2011a). This has very important implications for occupational segregation (see below).

The increase in women's participation in and attachment to the labor market, and the corresponding increase in their work experience, is believed to result from changes in the demand for labor and in women's labor supply. Labor demand changes were driven mostly by major technological changes such as computerization[32] and the rise of the service sector. On the supply side, two sorts of technological change may also have contributed to women's increased attachment to the labor market by modifying their constraints: progress in domestic technology, reducing the time required for domestic chores (a debated factor; see Section 12.6), and the contraceptive pill, of which Goldin and Katz (2002) underline the central role in allowing women to postpone maternity, spend more time in education and at work, and "form their identities before marriage and family" (Goldin, 2006, p. 14), and which was a true cultural change. However, the impact of these changes (which occurred with varying delays and intensities outside the United States) is a sort of one-shot impact and cannot explain the lasting trend of convergence between women's and men's participation rates over the 1990s and

[31] OECD, http://www.oecd.org/edu/skills-beyond-school/49986459.pdf.

[32] Weinberg (2000) finds that computerization may account for more than half the increase in demand for female workers in the United States.

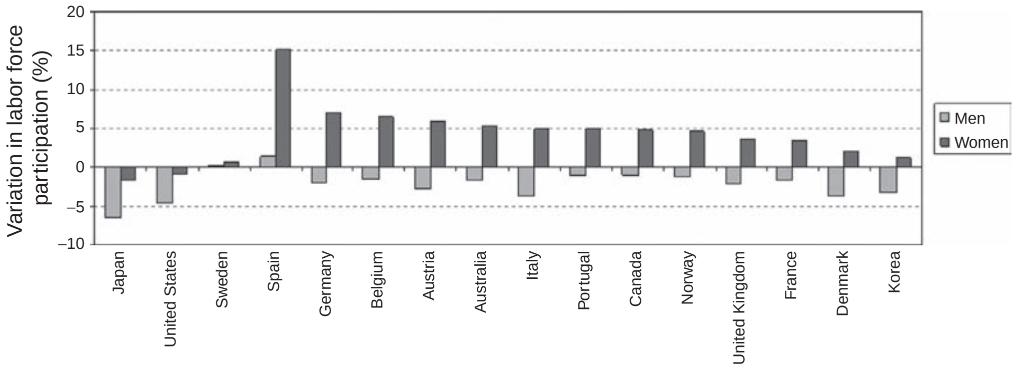

Figure 12.3 Variations in men's and women's labor force participation, 1990–2011. *Source: Organisation of Economic Co-operation and Development, employment database 2012, http://www.oecd.org/gender/data/harmonisedindicators.htm.*

2000s.[33] In most countries, this trend stems from the continuing increase in women's participation in the labor force, combined with a slight decrease in men's participation (Figure 12.3). The exceptions are Japan and the United States, where both participation rates have decreased (but men's more than women's); Sweden, which has hardly changed; and Spain, where men's participation increased, albeit far less than women's.

12.3.1.2 Gender Labor Market Outcomes: An Overview for OECD Countries

At the end of the 2010s, the average gender wage gap in the OECD countries is about 16%, but there are wide differences across countries: it is more than 25% in 3 countries, between 20% and 25% in 3 countries, between 15% and 20% in 9 countries, between 10% and 15% in 10 countries, and less than 10% in the remaining 7 countries (Table 12.3).

Several factors can help to explain these differences. The most important of these factors is the degree of inequality in the national wage structure. Other possible explanations, but at a lesser level, are gender differences in the employment rate, part-time work and the unemployment rate. We will briefly review differences across countries for these indicators.

12.3.1.2.1 The Wage Structure

Because women tend to be concentrated at the bottom of the wage distribution, a more compressed male wage structure reduces the gender pay gap, as shown by Blau and Kahn (1992, 2003): the average wage penalty resulting from women's unfavorable ranking in the male wage distribution is mechanically smaller in countries where the wage distribution is less widespread (Blau and Kahn, 1996). One striking example of this mechanism is given by Blau (2012, pp. 140–141), who compares Sweden and the United States. Gender earnings ratios (adjusted for hours) are 77.3% and 65.4%, respectively, and women's

[33] This continuous increase of women's participation rate is probably mostly driven by the expansion of work–family conciliation policies in most OECD countries (Blau and Kahn, 2013).

mean ranking in men's wage distributions[34] is 28.2 in Sweden and 32.3 in the United States; the less favorable position of women in the wage hierarchy in Sweden nevertheless results in a lower pay gap than in the United States because the wage distribution is more compressed in Sweden.[35] The wage structure compression itself depends essentially on differences in wage-setting institutions: highly centralized, unionized wage settings reduce the wage dispersion and have a positive effect on low-paid workers, who are predominantly women; similarly, the existence of a minimum wage raises women's relative pay by limiting its lowest possible level (on labor market institutions and wage dispersion, see Salverda and Checchi, 2014, Chapter 18, in this volume).

12.3.1.2.2 The Gender Gap in Employment

Despite the trend of convergence, women's employment rates generally remain significantly lower than men's (Figure 12.4), and it has been found that the gender wage gap could be negatively correlated with the gender gap in employment. For instance, the employment gap is much smaller in the United Kingdom than in Italy, and the wage gap is much smaller in Italy than in the United Kingdom (cf. Table 12.3). This is caused by effects of selection into employment, as shown by Olivetti and Petrongolo (2008): the

[34] Each woman is assigned a rank in the male wage distribution according to her wage. The mean female percentile in the male distribution is the mean of these rankings. If women's wage distribution were exactly similar to men's, the mean would be equal to 50. The lower the women's mean ranking, the more unfavorable their position in the wage hierarchy.

[35] Women's ranking in men's wage distribution is a useful indicator of gender differences in wage hierarchy and complements the average gender wage gap, which gives the monetary effect of the ranking inequality. Unfortunately, this indicator is rarely available in published statistics.

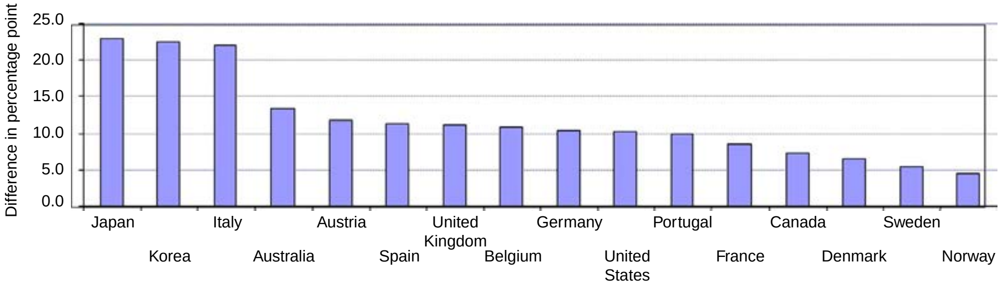

Figure 12.4 Gender gaps in employment in selected Organisation of Economic Co-operation and Development (OECD) countries, 2011. *Source: OECD Employment Outlook (2012).*

fewer women employed, the more they are positively selected and the higher their relative wage. In a study of the impact of reunification on former East Germany, Hunt (2002) reported a similar effect. She found that in the 4 years following reunification, the gender wage gap dropped by 10% points. But she also found that, because of a decrease in the demand for low-skilled workers, the employment rate of women had fallen by 6% more than men's and that this differential in exits from employment explained half the relative wage gain of women.

However, the relation between women's participation in employment and the gender wage gap is not uniform, as shown by the comparison between Italy and Japan, two countries that are very similar in their high gender employment gaps (the highest of the countries displayed in Figure 12.4) but are far from similar in their gender wage gaps (see Table 12.3). While employed women in Italy are becomingly increasingly skilled compared with "random" employed men, however, the gender gap in education remains pronounced in Japan, and employed women are mostly concentrated in part-time or short-term jobs, with men securing the best and best-paid jobs (see Chang and England, 2011, on the heterogeneity with regard to gender inequality within Asian industrialized countries).

12.3.1.2.3 Part-Time Work

Part-time work is a typical feature of women's employment. The percentage of part-time work among men is growing slightly, but at the end of the 2000s, it remains, on average, well below 10% in most OECD countries (with the noticeable exception of the Netherlands), while it represents anything from 15% to about 40% among women and up to 60% in the Netherlands. Comparing total employment or full-time employment may lead to very different views of cross-country differences. Figure 12.5 shows the gender gaps in employment in the OECD countries (OECD, 2013) using two measures: the gap in total employment and a gap measured in full-time equivalent employment (part time is defined as less than 30 weekly hours). The contrast between the two indicators reflects the difference in the share of part-time employment between women and men, which can be very large, as for instance in the Netherlands, Germany, and Switzerland and, to a lesser degree, in Austria and the

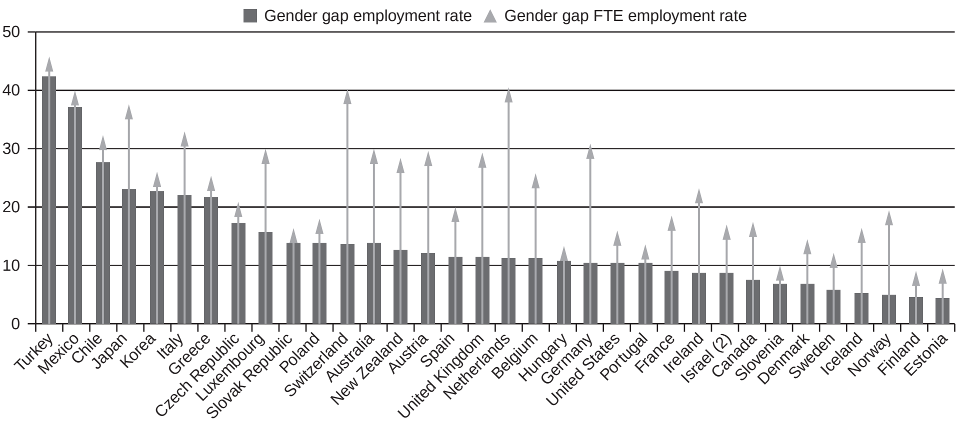

Figure 12.5 The gender gap in employment rate and in full-time equivalent (FTE) employment rate, 2011. *Source: OECD Family database www.oecd.org/social/family/database (2) The statistical data for Israel are supplied by and under the responsibility of the relevant Israeli authorities http://dx.doi.org/10.1787/888932315602.*

United Kingdom. Part-time employment, which contributes to women's participation in the labor market—especially by making it easier to balance work and family constraints (see Jaumotte, 2003)—may have adverse effects on women's careers and wages (see below). Unfortunately, as mentioned earlier, indicators of the gender wage gap, including part-time employment, are not available at the OECD level.

12.3.1.2.4 Gender Gaps in Unemployment

In most OECD countries, the unemployment gap has virtually disappeared as a result of women's increased labor force attachment (Albanesi and Sahin, 2013). In the United States there has been no difference between men's and women's unemployment rates since the 1980s —except during recessions, when men's unemployment rates exceed women's (but the recovery is also faster for men). In the European Union, unemployment rates have converged since 2000, and the gap can be said to be mostly residual (Eurostat), with the exception of southern countries (Greece, Italy), where women's relatively low attachment to the labor market makes them more at risk of unemployment.[36] Azmat et al. (2006) also found a prominent effect of women's participation rate on the gender gap in unemployment and explain cross-country differences by the interaction of gender differentials in labor market attachment and institutional factors—plus perhaps hiring. Institutions contributing to a more compressed wage distribution (minimum wage, unions) or to a reduction of labor turnover (firing costs and subsequent reduced

[36] However, we must bear in mind that the overall unemployment rate may influence the decision to participate in the labor market: expectations of a high risk of unemployment may discourage labor supply in the same way as other anticipated work interruptions. The resulting selection effect in labor supply may then reduce the gender unemployment gap.

hiring rates) as well as temporary contracts (making it difficult to stay in employment) increase the unemployment rate of low-skilled workers or workers with less attachment to the labor market. Women (whose outflow rates from employment are higher than those of men) are then more likely than men (more often employed in permanent jobs) to be affected by reductions in hiring.

To sum up: at the end of the first decade of the twenty-first century, the raw gender wage gap stands between 10% and 20% in most industrialized countries, but it has been at this level since the mid-1990s; men's and women's employment rates continue to converge, but women are still much more likely to work part time.

12.3.2 Gender Segregation on the Labor Market

Not so long ago, it was legal to offer women lower wages than men for the same job or to hire only men or women for certain jobs. In the United States, job advertisements could be published separately by sex until 1963, the year of the Equal Pay Act, which prohibited wage differentials based on gender. In Australia, the law allowed employers to pay women up to 25% less than men for the same work until 1969. It was the same in New Zealand, where the legal pay gap was set at 50% in 1903, lowered to 30% during World War II, and finally abolished in 1972. Equal pay for equal work is now the law in many countries, and the antidiscrimination legal framework has been reinforced in recent decades. In theory, pure wage discrimination is no longer possible.

The persistence of a gender wage gap between workers with similar productive characteristics but of different genders is therefore puzzling; it suggests that there is still a possible discrimination, but one different from pure wage discrimination (that is, unequal pay for equal work) and difficult to assess. Wage differentials between apparently comparable workers can result (and actually do result) essentially from the unequal distribution of men and women across occupations, firms, or sectors more than from differences in pay rates within occupations in a same firm (see Blau, 2012, specifically chapter 1, "Equal Pay in the Office"). In this section we start by briefly describing the tools of empirical research on the gender wage gap. Then we turn to analyses of the effect of gender segregation by firm, industry, and occupation. Finally, we present the important strand of literature devoted to vertical segregation and the debates around the "glass ceiling effect."

12.3.2.1 How to Analyze the Gender Wage Differential

Since the 1970s, numerous empirical studies of the gender wage gap have sought to quantify the contributions of various factors to pay differences between men and women or to the way they have changed over time. Fundamentally, this means distinguishing between the part of the gap that is due to differences in the observable productive characteristics of men and women and the part that is not.

The standard methodology used in this huge number of studies is decomposition of the gender wage gap, initiated by the seminal papers by Oaxaca (1973) and Blinder (1973). The basic principle is to rewrite the gender wage gap as the sum of two differences: a difference in the "quantities" of men's and women's productive characteristics (i.e., human capital variables) and a difference in the prices of these characteristics as measured by the difference in their estimated returns. The decomposition method has been developed and extended to explain changes over time in the unexplained wage gap (Juhn et al., 1991, 1993); to integrate quantile analysis (Albrecht et al., 2003; Machado and Mata, 2005); and to treat dichotomous outcomes (Fairlie, 2005), nonlinear models, censored outcomes (Bauer and Sinning, 2008), and nonparametric setups (Ñopo, 2008a,b). The case of distributional parameters other than the mean has been incorporated into this framework, and different methods have been proposed to study the entire conditional distribution (Chernozhukov et al., 2013; DiNardo et al., 1996; Firpo et al., 2009; Fortin and Lemieux, 2000). Decomposition methods still form a very active field of research in econometrics (see the survey by Fortin et al., 2011).

Decomposition methods provide a useful tool to assess the contributions of various factors to the gender wage gap and to diagnose which of these factors are the most quantitatively important, but they do not say anything about the underlying economic mechanisms. For instance, the variable "occupation" is responsible for a large part of the gender wage gap, but this difference may result from employer's discrimination toward women or from gender differences in the choice of occupations; clarification of this point requires further analysis.

Applied economists face some practical problems when decomposing the gender wage gap. One classic difficulty is that the measurement error of some key variables may be more marked for women than for men. This is particularly likely for the measure of actual labor market experience, which is not always available in individual data sets and in this case is replaced by a measure of potential experience (current age minus school-leaving age). Because women are more likely than men to experience career breaks, their potential experience is overestimated, biasing downward the returns to experience and so biasing upward the unexplained part of the wage gap (cf. Regan and Oaxaca, 2009, who used the 1979 National Longitudinal Survey of Youth and the Panel Study of Income Dynamics). Another difficulty in choosing the specification of the wage equation is the risk of omitting variables that could be correlated with the included variables; this bias can work in either direction (Neumark and Korenman, 1992).

Workers, especially women, are generally not a random sample of the working-age population. Certain unobserved factors may determine whether an individual is employed, and they may be correlated with the individual's productive characteristics and the wage. Following Heckman (1976, 1979), sample selection bias is treated by introducing a correction term (the inverse Mills ratio), obtained from a probit model of the probability of being employed, into the wage equation (Neuman and Oaxaca, 1998).

This method itself introduces a practical difficulty: the need to find at least one explanatory variable correlated with labor market participation but not with wage (i.e., an exclusion variable; see Vella, 1998).[37]

Another standard issue is that of the "norm" (price) to be used in the valuation of the difference between productive characteristics. In the initial formulations of Oaxaca and Blinder, the coefficients estimated for men were used as the price norm, which was arbitrary (technically, they could equally well have used the estimated returns to women's endowments) but fairly logical given the sign of the wage gap. However, using men's or women's coefficients as prices does not result in the same estimates of the explained and unexplained parts of the gap. Neumark (1988) and Oaxaca and Ransom (1994) proposed a generalized method using the coefficients obtained by estimating the wage equation over the pooled sample of men and women as the norm (alternative weighting schemes have been proposed by Cotton, 1988 and Reimers, 1983). Fortin (2008) updated the Neumark (1988) or Oaxaca–Ransom approach (1994) by including gender intercept shifts in the pooled regression with an identification restriction, so that the nondiscriminatory wage structure is such that the advantage of men equals the disadvantage of women.[38]

Such decomposition techniques have been widely used on data from different countries, periods, and samples of workers. Given all the possible variations in the data collected and the methodology adopted, the results are difficult to compare, even within a single country. A meta-analysis by Weichselbaumer and Winter-Ebmer (2005) using 263 published papers covering 63 countries between the 1960s and the 1990s[39] offers a useful overview of these findings and their sensitivity to the methods used. Ultimately, data restrictions (how wages are defined, which sample is studied, the quality of independent variables) were found to be more important than the choice of econometric methods in the decomposition of the wage gap. They found that the overall decrease in the total gender wage gap (from 65% in the 1960s to 30% in the 1990s) was mostly explained by the improvement in women's productive characteristics (education, experience). The decrease in the explained part is not surprising; as mentioned above,

[37] Blundell et al. (2007) proposed an approach for dealing with nonrandom selection when there are no obvious identification strategies; they developed bounds based on restrictions derived from economic theory (one of their restrictions is that the probability of working is higher for those with higher wages) and used their methodology to analyze changes in gender wage inequality in the United Kingdom.

[38] Another well-known problem in the Oaxaca–Blinder decomposition is that the portion of the explained part of the gender wage gap assigned to a categorical variable depends on the omitted category. To solve this problem, Gardeazabal and Ugidos (2004) suggested including all categories in the wage regression and imposing coefficients on a set of indicator variables to sum to zero. The method proposed by Fortin (2008) also includes this constraint for each categorical variable.

[39] All these papers used the Oaxaca–Blinder type decomposition. Because US papers were overrepresented at the beginning of the period (65% of the papers based on data for the 1960s), the authors applied a weighting scheme to correct for this bias.

women's education levels are comparable to those of men in OECD countries, and because their increasing participation in the labor market has given them similar levels of work experience,[40] the gender wage gap is less able to be explained by gender differences in basic human capital variables. The remaining component is predominantly due to occupational segregations: women and men do not occupy the same jobs (horizontal segregation) or have the same wage careers (vertical segregation). In both cases, these differences are unfavorable for women, but the gender gap in promotion and access to top jobs is generally considered the main cause of gender pay inequality.

12.3.2.2 Gender Differences in Occupations and Sectors

Occupational gender segregation in the whole economy is observed in all OECD countries: less than 10 occupations[41] accounted for half of the total employment of women in 2009, compared with 12 or more for men (OECD, 2012). A similar pattern is observed for the United States but at a lower degree than in most industrialized countries (Anker, 1998). Dolado et al. (2003) used a common detailed classification (108 occupations) to compare horizontal segregation in the United States and Europe in 1999. The degree of occupational concentration is smaller in the United States than in Europe,[42] but in both cases women are concentrated in similar types of jobs (salespersons, domestic help, personal care, secretaries, and teachers).

12.3.2.2.1 The Multiple and Complex Causes of Gender Differences in Occupations

The first explanation of this general finding is persistent gender differences in the field of study; in short, few women choose science or technology, and this has direct consequences on occupational segregation[43] and, consequently, on wages. The choice of subject of study is, then, a pre–labor market decision that has significant long-term consequences on earnings. The effects of college major on wages have been studied for the United States (Black et al., 2008; Brown and Corcoran, 1997; Loury, 1997; Weinberger, 1998, 1999); these studies concluded that it has a significant effect on early career wages. Including the field of study in the wage equation considerably improves the explained part of the gender pay gap. Similar results were obtained by Machin and Puhani

[40] The remaining gender differences in work experience are mainly due to family constraints: women are still more likely than men to have a discontinuous work life because they are more responsible for caring for children (or dependent adults). Part of the gender wage gap is then related to the impact of children on their work life and their chances of reconciling work and family. We return to the specific question of career interruptions and their impact on wages in the later section on the family pay gap.

[41] This indicator depends on the choice of classification of occupations and the degree of detail; here the 3-digit ISCO88 classification of occupations has been used, distinguishing 111 occupations.

[42] Two-thirds of female workers are concentrated in 21 occupations in the United States and 18 in the European Union.

[43] Even the link between field of study and occupation is weaker for women than for men: those who choose science, technology, or mathematics are less likely to pursue a science career than men (OECD, 2012).

(2003) for Germany and the United Kingdom: the choice of degree explains a significant part (between 8% and 20%, according to the specifications) of the overall gender wage gap among graduates. This raises the question of why women are so reluctant to choose science, given the well-known consequences on their future earnings and their high performance at school. Traditionally, differences in the choice of study subjects and their consequences on chosen occupations have been explained by taking into account the outside options for women, i.e., family responsibilities. Polachek (1981) argued that women choose occupations (and the corresponding investment in education and training) in which the cost of career interruptions is low. Because women's work attachment is stronger nowadays and their careers are more often continuous, this kind of explanation is less convincing. Economic analyses are turning toward more psychological approaches and gender stereotypes to explain this conundrum (see Section 12.3.3). The choice of field of study may also depend on the environmental conditions of schooling and peer effects. In line with educational studies research, recent economic papers test the causal impact of the gender composition of classes or teachers in the choice of field of studies. This is done using random variations in teacher gender (Carrell et al., 2010) or in the gender composition of classes (Schneeweis and Zweimüller, 2012). Results tend to show that exposure to a female-dominated environment encourages girls toward male-dominated fields.

In addition to investment in education, occupational segregation results from both supply and demand factors. On the supply side, women may prefer a given occupation because of nonmonetary advantages (flexible work hours, job amenities), in line with Adam Smith's compensating differentials theory, in which case they trade nonmonetary advantages for lower wages. For instance, Filer (1985) and MacPherson and Hirsch (1995) support the explanation of gender differences in preferences for occupational characteristics and found that taking into account occupational characteristics reduces significantly the unexplained part of gender wage differentials. But, as in the case of educational choice, women may also choose a given occupation to comply with social norms and stereotypes.

On the demand side, discrimination against women (taste discrimination) or the employer's perception that women are, on average, less productive or reliable than men (statistical discrimination) may affect the gender composition of occupations. Hiring discrimination has been estimated by correspondence testing (Booth and Leigh, 2010; Duguet et al., 2005; Petit, 2007; Riach and Rich, 2002) on the French financial sector) or audit studies (Neumark, 1996 on waiters and waitresses[44]). Correspondence testing shows that women are less likely to be selected for an interview in high-status jobs and in traditional male occupations; the opposite is observed in female-dominated occupations (secretary, for instance). Weichselbaumer (2004) extended correspondence

[44] They found that women have a lower probability of being interviewed for a job in high-price restaurants.

testing to investigate whether gender stereotypes affect the hiring process. She included personal characteristics given in curriculum vitae (hobbies, photographs) and did not find that a masculine identity for a woman (indicated by a masculine look and hobbies, such as motorbiking) reduces unfavorable treatment in masculine occupations; she concluded that discrimination is largely responsible for sex segregation. In that case, the proportion of women in a given occupation may change if the hiring process is modified and a fairer procedure is adopted. A famous example of this mechanism is presented by Goldin and Rouse (2000), who examine the effect of the adoption of "blind" auditions behind a "screen" to recruit musicians to American symphony orchestras. The blind audition procedure clearly increased the proportion of women in orchestras, suggesting that hiring discrimination was responsible for the previous quasi-absence of women in orchestras.

12.3.2.2.2 A Slow Decrease in Occupational Segregation

Occupational segregation has changed over time. The increase in women's education and labor market participation since the 1970s has modified the quality and quantity of the female labor supply. It is also possible that hiring discrimination decreased with the strengthening of antidiscrimination policies. Conversely, the expansion of the service sector, partly driven by the marketization of housework (Ngai and Petrongolo, 2013), and technological changes biased in favor of highly skilled workers have affected the occupational structure of female employment and their tasks (Black and Spitz-Oener, 2010).[45] Occupational segregation in the United States tended to decline slowly in the 1960s (Blau and Hendricks, 1979), and this trend accelerated over the 1970s (Bianchi and Rytina, 1986). It has continued to decline, but at a much slower pace, since the mid-1990s (Blau et al., 1998) or even stagnated (Hegewisch et al., 2010). The study of occupational segregation by gender in the United States from 1970 to 2009 by Blau et al. (2013), with a consistent set of occupational categories, confirmed the slowing decline of occupational gender segregation. This study also confirmed that the reduction in occupational segregation is positively correlated with education. The largest decrease is observed among college graduates, whereas there is a very limited change among high school dropouts. This result is in line with the results of Black and Juhn (2000), who observed, again for the United States, a strong increase in the percentage of college-educated women in high-paying professional occupations (increasing from 8% in 1967 to 23.5% in 1997). Their analysis was that women had positively responded to the increase in demand by firms and increasingly chosen "career jobs," either by

[45] Using a West German database, Black and Spitz-Oener (2010) examined changes in tasks consecutive to technological progress and the spread of computing. They found that women experienced a strong decline in routine tasks (with a positive effect on wages), contrary to men.

increasing their labor market participation or by moving away from traditional "female" occupations (nursing, teaching).

Occupational segregation is related to workplace gender segregation in a complex interaction. Using matched employee–employer data for the United States, Hellerstein et al. (2007) found a decrease in workplace segregation by sex between 1990 and 2000, contrary to workplace segregation by race or ethnicity. Interestingly, changes in the occupational distribution of men and women were not the main reason for the decline in workplace gender segregation. The main driving force was the change of occupational structure within firms, with a growing share of mixed occupations and the decline of female- or male-dominated occupations. Moreover, the rise of the service sector (in which women represent a large majority of the workforce) has slowed the decline of horizontal segregation.

12.3.2.2.3 Do Female-Dominated Occupations Systematically Pay Less?

What are the consequences of this occupational segregation for the gender wage gap? It is generally considered that female-dominated occupations pay less, following Bergmann's (1974) "overcrowding" model: the discriminatory behavior of some employers creates an excess supply of women, which depresses their wages for a comparable occupation. A wide empirical literature on the US case verifies this prediction: controlling for measured characteristics of workers, predominantly female occupations pay less than predominantly male occupations. Consequently, occupational gender segregation accounts for a part of the gender wage gap (Bayard et al., 2003; Groshen, 1991; Killingsworth, 1990[46]). For the United States, Groshen (1991) concluded that the importance of occupational segregation in the gender wage gap is an argument in favor of comparable worth policy (equal pay for work of equal value) as a powerful tool to reduce the gender wage gap. Amuedo-Dorantes and De la Rica (2006) also found a notable effect of female segregation into low-paying jobs on the gender wage gap in Spain. This effect can be amplified by gender segregation in firms (particularly small firms; see Carrington and Troske, 1995) and the corresponding wage penalty. Because women are more likely to be employed in low-wage workplaces, the unexplained gender wage gap is reduced when a workplace fixed effect is included[47] (Drolet and Mumford, 2012).

But the penalty attached to female-dominated occupations is not observed everywhere, or only to a lesser extent. In their comparative study of the United States and

[46] Bayard et al. (2003) found also a large within-occupation/within-firm gender wage gap; this results in part from using broader occupational categories compared with other studies.

[47] Note that the workplace-specific return may be different for men and women. Meng and Meurs (2004) for Australia and France and Drolet and Mumford (2012) for the United Kingdom and Canada found a higher workplace return for women than for men. In other words, firms' policies tend to narrow the gender wage gap. This effect is particularly strong for the private sector in Canada, which may be due to Canada's pay equity legislation.

Canada, Baker and Fortin (1999) found a small and not statistically significant effect of occupational gender composition on Canadian women's wages; they attribute this result to a higher unionization rate in Canada than in the United States. Jurajda and Harmgart (2007) studied the interesting case of former West and East Germany and did not find a wage penalty on female jobs in West Germany; in East Germany predominantly female occupations offered higher wages.[48] Female-dominated occupations often are associated with jobs providing care for others, such as childcare, nursing, teaching, or social work. Again, the wage penalty attached to these jobs is not uniform, nor is it observed in all countries. Barron and West (2013) examined the gender wage penalty in caring occupations in Britain and found that this penalty is located in occupations requiring lower levels of educational qualification (childcare workers, nursing assistants, auxiliaries) and not in highly qualified occupations (doctors, nurses, school teachers).

12.3.2.2.4 Female Overrepresentation in the Public Sector Tends to Reduce the Overall Gender Wage Gap

The question of wages in caring occupations is related to a well-known phenomenon of industrial gender segregation: women are overrepresented in the public sector. According to the OECD (2012), women accounted for about 58% of the total public sector workforce, and the public sector accounted for about 20% of overall employment in OECD countries. The overrepresentation of women in the public sector is explained by several nonexclusive factors (Blank, 1985): it offers traditionally female-dominated occupations (teaching, nursing, administrative tasks); it is often a family-friendly workplace with childcare, leave, and flexible hours, which are valuable to women; and employment security may attract more risk-averse workers (see Section 12.3.3.2).

Pay formation in the public sector is regulated (with variations across countries), and the public wage structure is more compressed than in the private sector (Gregory and Borland, 1999). As a result of this difference in wage structure, the gender wage gap is often smaller in public sector jobs than in the private sector (Arulampalam et al., 2007; Chatterji et al., 2011; Lucifora and Meurs, 2006). Another stylized fact is that the public–private sector pay gap is positive (with some exceptions, such as in Germany or Sweden; cf. Melly, 2005), particularly in the lower part of the wage distribution, but may be insignificant or negative at the top (Depalo et al., 2011). Because women are concentrated in the lower wage brackets, they are better off in the public sector (Meurs and Ponthieux, 2008); this is particularly true for the United Kingdom (Lucifora and Meurs, 2006) and Australia (Barón and Cobb-Clark, 2010). So, women's presence in the public sector tends to reduce the overall gender wage gap. However, this protective effect has

[48] It has been argued that this result comes from a positive selection of women in the labor market because only more highly qualified women stay on the labor market.

been receding with the trend of privatization since the 1980s and, more recently, with the budget crisis and its negative consequences on public wages (de Castro et al., 2013).

To sum up, horizontal gender segregation by occupation is often associated with a female wage penalty and is responsible for part of the gender wage gap in some countries (the United States), but this is not the case everywhere, nor is it the case in all female-dominated occupations. Labor market institutions and trade union density can reduce or reverse this penalty.

12.3.2.3 Vertical Segregation and the Glass Ceiling

As women gain education and experience, their relative absence in top jobs[49] is attracting growing attention (OECD, 2012) as a potential waste of human capital. More generally, vertical segregation—that is, the fact that women do not move up the career ladder at the same speed as their male counterparts—is considered today as the key factor for understanding the persistence of the gender wage gap.

12.3.2.3.1 Measuring the Gender Gap in Promotions and the Glass Ceiling

Women's disadvantaged position in the wage hierarchy can result from two different, nonexclusive mechanisms. The first is that women are promoted at lower rates than men. Since the publication by Albrecht et al. (2003), this has been called the "glass ceiling effect," evoking an invisible barrier between women and the highest positions in firms. A glass ceiling is suspected if the gap between the conditional wage distributions of men and women gets wider in the upper tail of the wage distribution. The second mechanism occurs when women are as likely as men to be promoted but gain less from their promotion than men do. This has been labeled the "sticky floor effect," following Booth et al. (2003)[50]; a sticky floor is suggested by a widening of the gender wage gap at the bottom of the wage distribution.

The detection of a glass ceiling effect, based on quantile regressions, has given rise to a large set of empirical work. The initial pattern of a continuous increase of the gender gap throughout the wage distribution and a sharp acceleration in the upper tail, as found in Sweden by Albrecht et al. (2003), was subsequently observed in many countries, but with differing intensities. The analysis of gender wage distributions in 11 European countries by Arulampalam et al. (2007) confirms the variety of patterns across countries and across sectors; this diversity is even more striking between the 26 European countries (Christofides et al., 2013). Kassenboehmer and Sinning (2014) examined changes in the US gender wage distributions over time, applying a decomposition based on the

[49] On average, across the OECD, only one-third of managers are female, with considerable variation across countries.

[50] Using a British household panel data set for 1991–1995, Booth et al. (2003) observed no differences between men and women in the likelihood of promotion, but rather smaller pay increases for women after promotion than for their male counterparts.

method described by Firpo et al. (2009). They confirmed the heterogeneity along the wage distribution, with greater narrowing of the gender wage gap at the bottom and small changes at the top. A glass ceiling effect is observed in the majority of countries, with the exception of Spain, but its magnitude varies substantially, depending on labor market institutions and the compression of national wage distributions. Countries with more "generous" work–family reconciliation policies have a lower unexplained wage gap at the bottom of the wage distribution and a wider one at the top—this is the case in Denmark and the Netherlands. Interestingly, a glass ceiling is observed in Spain only among educated workers (Amuedo-Dorantes and de la Rica, 2006; Del Río et al., 2011).

Gobillon et al. (2015) proposed another empirical tool for measuring the glass ceiling effect, based on a job assignment model. This measure is the probability ratio of getting a job for women and men at each rank of the wage ladder. An application to French full-time executives 40–45 years old in the private sector shows that the gender difference in the probability of getting a job increases along the wage ladder from 9% to 50%.

12.3.2.3.2 A Gender Difference in the Pace of Promotion Within Firms

We now turn to what happens inside the firm and the distribution of men and women across jobs. It has long been observed that pay rates tend to be equal in the same narrow occupational category within a firm (Blau, 1977, 2012; Groshen, 1991; Petersen and Morgan, 1995). This does not mean that there are no wage differences (and no discrimination) at the firm level, but rather that the observed gender wage differences at this level are mainly because of differences in the distribution of men and women in the wage hierarchy within the firm. This then raises the question of the extent to which gender differences in job-level assignment are due to labor supply factors, to firm discrimination, or to individual preferences.

To study precisely the internal mechanism of promotion requires access to personal data. These data are quite difficult to get, so there is a limited number of papers on gender differences in intrafirm mobility and job assignment. Overall, they conclude that there is a large part of job assignment that is not explained by observable individual productive characteristics. Malkiel and Malkiel (1973) studied the gender wage difference using a sample of professional employees in a single corporation for 4 years. When only individual variables are included in the Oaxaca–Blinder decomposition, a large part of the gender wage difference cannot be explained; adding the job level (defined in 13 categories) into the wage regressions makes the unexplained gender wage difference fall to a value close to zero. The authors showed that half the gender difference in job level cannot be explained, suggesting gender discrimination in job assignment.[51]

[51] Notice also that among the small and homogeneous group of US top executives, Bertrand and Hallock (2001) found that the huge gender pay gap (around 45%) is entirely explained by observable characteristics (age, seniority, firm size) and occupational segregation (women are less likely to be chief executive officers than men are). But this is not observed in every country. Smith et al. (2013) found a large unexplained gender gap in promotions to top positions in a cohort of Danish executives.

Pekkarinen and Vartiainen (2006) presented another approach to the glass ceiling effect by studying gender differences in the allocation of workers across jobs of different complexity among Finnish metalworkers. Women are less likely to be promoted than men, and women face a higher promotion threshold than men. Ransom and Oaxaca (2005) investigated intrafirm mobility and gender wage differences in a large grocery retailer in the United States over the 1976–1986 period. Importantly, for hourly wage workers, the wage rate in a given occupation is fixed for a given seniority by gender-neutral union contracts. Nevertheless, the employer had full control over job allocation and recruitment (in 1982, no woman held a top position). For hourly paid jobs (covered by union contracts), all gender difference in pay can be associated with the job assignment of employees, and women have less chance of promotion than men.[52] Dina et al. (2012) exploited two particularities of this case: there was no "pure discrimination"—union contracts were gender neutral—so the wage differential arose uniquely because of occupational segregation, and the firm was found guilty of discrimination, so the job assignment was proven to be discriminatory against women. The methodology developed in that paper extended the existing decompositions of the gender wage gap to isolate the contribution due to job segregation, even in the case where there is no overlap between men's and women's occupations.

12.3.2.3.3 Explaining the Gender Gap in Promotion

How can this gender gap in promotion within a firm be explained? Some studies argue that there is no unexplained difference once the exit rate has been taken into account; female executives exit the occupation at higher rates than men, and the executives who remain are promoted more quickly (Gayle et al., 2012). The promotion of young professionals also seems to be correlated with working longer hours (Gicheva, 2013), and women may be disadvantaged on account of their family constraints. These explanations of vertical segregation in terms of gender differences in labor market commitment are in line with human capital theory (Polachek, 1981). A model proposed by Lazear and Rosen (1990) formalizes the link between outside opportunities and wage careers. It assumes that wage differences are uniquely due to differences in promotions along a job ladder where top jobs require specific training. Men and women have the same distribution of labor market ability, but women have a higher ability in domestic work. Consequently, women have a higher probability of leaving the labor market, and, as a result, employers are reluctant to invest in their training and to promote them on an equal basis with men. Thus, a woman must have greater ability than a man to be promoted (and to be induced to stay at work by a higher wage). So their productive "advantage" in the labor

[52] When controlling for age, age squared, seniority, and seniority squared in a probit model, a male food clerk is more than six times more likely than a female food clerk to be promoted to a store-level salaried, managerial position.

market turns out to be a handicap in their wage career and prevents them from obtaining high-paid positions.[53]

This explanation does not, however, rule out the possible role of discrimination in job promotions (see the study on Austria by Winter-Ebner and Zweimuller, 1997, where a large part of gender differences in job positions remains unexplained even after taking into account expected job-separation probabilities). Statistical discrimination (Arrow, 1973; Phelps, 1972) is regularly advanced as a key notion for understanding inequality in careers and unequal access to higher positions. Models are based on workers' heterogeneity, imperfect information about their productive characteristics, and distinct distributions of unobserved productive characteristics between groups. This covers two situations: when women's level of ability is lower on average than men's (which is not true discrimination because workers are not equally productive) and when the ability levels are equal on average but the variance is larger within one group (see Aigner and Cain, 1977). The most common example of a case of statistical discrimination is when employers do not hire or promote women because they assume that women are more likely to interrupt their careers to have children and/or have a higher rate of absenteeism or be less available for late meetings and business travel because they are or will be mothers. This mechanism may be perpetuated by feedback effects: if women are systematically less often promoted than men because their employers anticipate career breaks, they may be less motivated to invest in their careers. They thus confirm their employers' preconceptions. The trouble is that such feedback effects make it difficult to distinguish between statistical discrimination—that is, unequal treatment due to employers' assumptions of labor supply behavior—and the human capital model of unequal promotions based on employees' work–family trade-off decisions.

These two lines of explanations both highlight the key role of career interruptions (effective or potential) in the gender gap in promotions. Other models complete these explanations based on family constraints by taking into account behavior at work and individual preferences on the gender composition of coworkers. This also implies that improvements in gender equality may be obtained by paying attention to the relationship between workers. Becker's model of taste discrimination was extended to unequal promotion by Baldwin et al. (2001), with the hypothesis that men have distaste for female supervision. Goldin (2013) presents a "pollution model" that combines the taste and statistical discrimination models: the entry of women into a male-dominated occupation is viewed as a negative signal on the value of this occupation and reduces the associated prestige. Consequently, male employees will oppose the recruitment of women to

[53] Note that one consequence of the higher productivity threshold to promotion is that women's average productivity in good jobs is higher than men's. In Lazear and Rosen's (1990) model, wages equal output in top jobs, so there is a female wage premium at this level, which is at odds with the empirical evidence, as underlined by Lazear and Rosen themselves.

protect their labor status. Empirical research also examines the role of interpersonal relationships within the firm to explain gender differences in promotion. Cannings and Montmarquette (1990) found that men use informal networks for career advice more often that women, whereas women rely more on formal bidding for promotion than men and wait longer for promotion.

12.3.3 Psychology, Social Norms, and the Gender Wage Gap

The persistence of the gender wage gap combined with the weakened explanatory power of standard human capital variables (education, experience) has led economists increasingly to integrate psychological factors and sociological approaches into their analysis of gender differences on the labor market (Bertrand, 2010). Psychosocial factors are used and tested to explain occupational segregation in the gendered choice of field of study, job, and sector. Also, because the gap in promotion to the top positions in the wage distribution is one of the most important gender inequality, it is not surprising that a large part of the psychological work applied to economics focuses on the reasons why women seem to be disadvantaged in labor market competition. The issue still being debated is the explanatory scope of these findings in the real world. These traits certainly play a role in slowing women's promotions, but their effect on the gender wage gap should not be overestimated.

12.3.3.1 Gender Differences in Risk Aversion and Competitiveness

Women's risk aversion and lack of competitiveness have been extensively studied in experiments (Croson and Gneezy, 2009; Eckel and Grossman, 2008), and these psychological traits are said to explain gender differences in earnings (see, e.g., Dohmen and Falk, 2011; Gneezy and Rustichini, 2004; Gneezy et al., 2009; Gneezy et al., 2003; Niederle and Vesterlund, 2007, 2011). Laboratory and field experiments concur that women are more risk averse and less competitive than men.

The reasons for these gender psychological differences are still being investigated in terms of the respective roles of culture (Gneezy et al., 2009 found that women in matrilineal societies are more competitive than men), social learning (Booth and Nolen, 2012a,b used variations in single-sex coeducational schooling and found that all-girl groups favor risk-taking attitudes), or biological factors (on the role of hormones see Wozniak et al., 2010). If psychological features are acquired, the next question is the age at which these gender differences in behavior appear, so experimental studies examine the attitude toward competition among the young (Dreber et al., 2011; Gneezy and Rustichini, 2004) or the very young (Sutter et al., 2013 extended the analysis to 3-year-old children). A gender gap in competitiveness is generally observed at young ages, except by Dreber et al. (2011), whose research is based on Swedish children, among whom no gender differences were observed. Again, the role of social environment, even in childhood, seems to be central in explaining gender differences in psychological traits.

A close and related question is the stability over time of these psychological traits. Risk aversion and the taste for competition often are considered as immutable when people reach adulthood. But new evidence suggests that it may still change over time and in different circumstances. To test this is not easy because it requires repeated information on individual preferences, but some recent empirical papers found that risk aversion is not time invariant: middle-aged people seem to be more risk averse than adolescents and elderly people (Tymula et al., 2013). Risk tolerance is also positively influenced by health (Hammitt et al., 2009), and unexpected negative shocks such as a disease change the attitude toward risk (Tison et al., 2012).

12.3.3.2 Occupational Segregation, Risk Aversion, and Gender Identity

Psychological approaches have been applied to the analysis of gender occupational segregation in many different ways. For instance, psychosocial traits such as self-esteem, impulsivity, or self-assessed intelligence may shape the choice of both study subjects and occupations (Antecol and Cobb-Clark, 2013). Risk aversion is also an important feature in the choice of occupation because it may lead to a trade-off in favor of more stable but less well-paid occupations (Bonin et al., 2007). Because the public sector offers more job security, it may attract more risk-averse workers (Clark and Postel-Vinay, 2009) and thus explain the overrepresentation of women in the public sector. The few empirical studies of this subject[54] confirm the influence of risk aversion on self-selection into the public sector (Bellante and Link, 1981 for the United States; Pfeifer, 2011 for Germany). The preference for team work may also explain industrial segregation. In laboratory experiments, Kuhn and Villeval (2013) found that women are significantly more likely than men to select team-based pay. They conclude that this preference may explain their overrepresentation in the nonprofit sector and helping occupations, where work often requires cooperative production (but provides few financial rewards).

However, the most widely used framework for understanding gender differences in choice of occupation is the model of gender identity developed by Akerlof and Kranton (2000, 2010). Their starting point is the idea that each individual is assigned a social category ("man" or "woman") associated with prescribed behaviors. Failing to comply with these prescriptions leads to disutility in oneself and in others (negative externalities). An action's payoff is then dependent on gender identity. So, men in female-dominated occupations (such as nursing) or women in male-dominated occupations (law) do not follow the behavior expected of their gender. They make their coworkers uncomfortable; in return, the latter may react negatively and not cooperate with them. These two negative payoffs (the disutility of deviating from social norms and the disutility brought by coworkers) may help to explain why women (or men) are reluctant about certain

[54] Few data sets provide a measure of individual risk aversion and the choice between public and private sectors.

occupations and why occupational segregation persists over time. This framework is extended from the choice of occupations on the labor market to the global question of the gender division of labor, particularly when the time of work within the household cannot be explained solely by specialization and also seems to be shaped by social norms (see Section 12.6).

12.3.3.3 The Impact of Women's Lack of Competitiveness on Wages

Two main psychological factors (reluctance to ask, lack of competitiveness) are put forward to explain women's disadvantage in promotion opportunities. Gender differences in the ability to negotiate have been studied by Babcock and Laschever (2003). In a US cohort of graduates from the same business school, they observed that men obtained a first job salary 7.6% higher than women; however, only 7% of women had tried to negotiate with their recruiter, compared with 57% of men. A large field experiment further clarified the difference between men and women in initiating wage bargaining (Leibbrandt and List, 2012). The authors collected 2500 responses from jobseekers to fictitious ads for administrative jobs in various cities in the United States; when the ads did not explicitly mention that wages were negotiable, men were more likely to negotiate than women, but if it was explicitly stated that wages were negotiable, this gender difference disappeared. Another important result of this testing is that male candidates preferred the rules of wage determination to be ambiguous.

In laboratory experiments, Gneezy et al. (2003) found that women are less effective than men in a competitive environment, particularly when they are in direct competition with men, but they perform equally well in noncompetitive environments. The findings of Niederle and Vesterlund (2007) corroborate this idea that women tend to avoid competition, unlike men (on aversion to competition and the choice of tournament see also Datta Gupta et al., 2013). The authors attribute these results to male overconfidence and gender differences in the taste for competition. This behavior reduces women's chances in competing for jobs or promotion, especially when they are in direct competition with men.

The question of whether experimental findings can be extrapolated to real life is discussed by Levitt and List (2007), and the contributions and limits of experimental designs to the understanding of gender differences in labor market outcomes are discussed by Azmat and Petrongolo (2014). Some studies affirm that the influence of women's aversion to competition in explaining gender differences in wage promotion should not be overestimated. Garrat et al. (2013) developed an interesting approach using the natural experiment of a footrace where the participants, both women and men, had to choose between two levels of competition (elite race and cash prize or "regular"). As expected, women were, on average, less interested than men in the elite race. But the very fastest women respond to financial incentives and were quite likely to try the elite race. It was in the midrange that the difference between women and men was the widest: in this range, men tended to overestimate their skills. The authors concluded that the economic consequences of aversion to competition for capable women are probably limited in the labor market. One example of discrepancy between behavior in laboratory experiments and behavior in the real world is given by Lavy (2012): in a case of performance-based pay for teachers, contrary to lab and field experiments, he did not find gender differences in performance when the financial rewards depended on a rank order tournament.

The last two examples are based on case studies, so it is difficult to extrapolate their significance to the whole economy. Manning and Saidi (2010) adopted a more general approach by using a large individual data set for Great Britain with detailed information on performance pay contracts. They tested the importance of differences in attitudes toward competition on the actual gender wage gap. They found that women are less likely than men to work on performance contracts, as predicted by experimental studies, but the final effect of performance pay on earnings is limited and does not differ much by gender. So, they concluded that the competition hypotheses do not provide a significant explanation of the observed gender pay gap. A similar conclusion (that a small part of the gender wage gap is explained by psychological factors) was obtained in a previous work on the gender gap in early career wage growth (Manning and Swaffield, 2008).

12.3.4 Family Constraints, Career Interruptions, and the Family Pay Gap

The more women participate in the labor market, the more they face the need to reconcile the constraints of motherhood and professional life. The unequal sharing of unpaid work and family responsibilities (see Section 12.6) probably contributes much more to gender income inequalities than women's lack of taste for competition. Fortin (2005) argued that culture, social norms, and inner conflict between work and family values may be considered a major cause of the slowdown (or, recently, the stagnation) of the gender convergence in pay.

Consequently, family situation and the composition of the household (particularly the number and age of children) are crucial to the gender wage gap. As Polachek (2004) argued, "the detrimental division of labor is at the root of almost all the wage gap" (p. 27). In the labor market, family characteristics have dissimilar consequences for women and men, even between women and men who are comparable in their productive characteristics. To what extent can women's adaptations to their family constraints—by choosing a family-friendly occupation with flexible hours, choosing a part-time job, or interrupting her employment—explain the average gender wage gap and differences in career? How large is the motherhood wage penalty between comparable women?

Men's wages also are affected by their family status, but in the opposite direction to women. Their earnings are not modified by the number of children they have (which is consistent with the fact that fatherhood does not change their work habits), but men enjoy a marriage premium, while there is no such positive wage difference for married women. There are two main explanations for this marriage premium: either married men are positively selected, or they are more productive thanks to specialization at home and the domestic chores done by their spouses. The earliest studies of this issue tried to distinguish between these two hypotheses; more recent studies focus on the expected changes in the marriage premium when the norm becomes a two-earner family, the benefits of specialization within marriage are receding, and the traditional type of married couple becomes less prevalent in OECD countries.

12.3.4.1 On the Demand Side: Lower Wages as a Result of the Inelasticity of Female Labor Supply

Because of their family obligations, (married) women often face multiple constraints in their choice of labor supply; this can give employers in monopsonic labor markets some market power. In this case, the employer exploits the inelasticity of the supply curve and pays workers below the competitive wage. The more inelastic the labor supply, the lower the wage (see Manning, 2003, on dynamic monopsony drawn from the search-theoretic framework of Burdett and Mortensen, 1998). In this approach, married women or mothers can suffer a wage penalty because they are less (or not at all) geographically mobile or because they need to work closer to their home to meet their domestic responsibilities. The female labor supply to a given firm may then be less elastic than that of men, and the employer may pay them lower wages than comparable men. Ransom and Oaxaca (2010) tested this framework in the case of a retail grocery store chain and found that the elasticity of labor supply to the firm differed between men and women; this difference was consistent with wage discrimination against women. Other studies from Germany (Hirsch et al., 2010) and Norway (Barth and Dale-Olsen, 2009) also found that women's labor supply is less elastic than men's and is linked with wage discrimination.

12.3.4.2 The Supply Side: Part-Time Work and Career Interruptions

Motherhood may also modify women's labor supply as a result of the gender division of labor within the household (see Section 12.6.3). Part-time paid work is a common way for mothers to reconcile work and childcare, and it may be considered a substitute for childcare facilities.[55] Part-time work usually leads to a pay penalty (in hourly earnings) compared to full-time work. In the United Kingdom, the penalty was about 25% and has widened over recent decades (Manning and Petrongolo, 2008). This penalty is partly due to individual characteristics (part-timers are less educated) and partly due to occupational segregation: women switching to part-time work often downgrade professionally (i.e., move to a lower-skilled job[56]). The risk of occupational downgrading is strongly

[55] In countries such as Australia, Germany, Japan, the Netherlands, and the United Kingdom, more than 40% of women work on a part-time basis (OECD, 2007).

[56] This phenomenon has been labeled as a "hidden brain drain" in a report by the UK Equal Opportunities Commission (2005).

dependent on the (lack of) part-time opportunities within a woman's current occupation (Connolly and Gregory, 2008).

Does this correspond to a willing choice by women, happy with this reduced time, making it possible to reconcile work and family? Or, does it rather correspond to a constraint on their labor supply? The answer depends greatly on the institutional context and on the social norms in the country considered. In three countries characterized by a high share of part-time work (Australia, the Netherlands, and the United Kingdom), Booth and Van Ours (2008, 2009, 2013) found that women report high levels of satisfaction with their reduced working hours, which are associated with a clear gender bias in the division of labor within the household. The case of the United Kingdom seems slightly different; women's satisfaction seems to be unaffected by their hours of work and remains "a puzzle."

Career interruptions are a radical way to meet family constraints but have strong and lasting negative effects on wages. Since the work of Mincer and Polachek (1974) and Mincer and Ofek (1982), employment interruptions are commonly responsible for gender differences in earnings because of the loss of experience and human capital depreciation (skills atrophy). Are the (negative) returns associated with career breaks different for men and women? Empirical evaluation is difficult for want of an appropriate data set with precise information on the duration of employed periods, time out of the labor market, and the reasons for career interruptions. It is therefore not surprising that the magnitude of the penalty associated with career breaks varies according to the study and methodology, but it is regularly found to be significantly negative. Kim and Polachek (1994) identified three possible biases in the estimates of penalties related to career interruptions: heterogeneity (unobserved characteristics such as motivation, influencing both labor market intermittency and earnings); endogeneity (low wages may explain intermittency and not the reverse); and selectivity. Taking into account these biases and using panel data (the Panel Study of Income Dynamics), they found a stronger effect of labor market intermittency on wages, but the effect was equivalent for men and women; the unexplained male–female wage gap was, therefore, very small. Albrecht et al. (1999) also analyzed the coefficients associated with the total time out using a rich Swedish data set that distinguishes different reasons for time out of the labor market (formal parental leave—an important component of the Swedish family policy—versus household time and other career interruptions). The penalty associated with parental leave for mothers was far smaller than that for fathers. The interpretation is that parental leave taken by the father is a rare event (compared with parental leave taken by mothers), so the signal was interpreted negatively by employers; for mothers, the negative coefficient reflects uniquely human capital depreciation. Finally, Hotchkiss and Pitts (2007) evaluated the total effect of labor market intermittency on gender wage differentials using a US sample of retirees with detailed information on their work history. They found that differences in intermittent employment represented 61% of the explained part, making the largest contribution to gender differences on observed characteristics[57]; but the sample was composed of retirees belonging to generations when labor market interruptions were very common.

12.3.4.3 The Family Pay Gap

Since the mid-1990s, increasing attention has been paid to the "family pay gap" or "motherhood wage gap," that is, the differential in hourly wage between women with and without children. This is because the wage dispersion between women with different family characteristics increased in some countries (the United States) while the gender wage gap was shrinking. As a result, marital status and children were making a larger contribution to the average gender wage gap (Korenman and Neumark, 1992; Waldfogel, 1998a), whereas the wages of childless women were closer to those of men. The family pay gap is generally negative, but its extent varies depending on the country, the period, and the methodology used to assess it.

Several nonexclusive explanations for the family pay gap have been advanced (see the detailed survey by Budig and England, 2001). First, working mothers are more likely than childless women to have spent time out of the labor market and, consequently, to have accumulated less human capital. In addition to the negative impact of career breaks on wages, having children to care for may influence mothers' allocation of effort (Becker, 1985). Mothers might limit their occupational choices to jobs and positions that are compatible with their family responsibilities—seeking "more convenient and less energy-intensive jobs" or just putting less effort into their work or being absent more often (Simonsen and Skipper, 2012, found some evidence of the role of absenteeism in the wage penalty in Denmark). These adjustments, under the form of working or having worked part-time jobs or in jobs or firms that are more "family friendly" (or simply closer to the home or school) may result in reduced work opportunities or, according to the theory of compensating differentials, lower pay to make up for better working conditions (Filer, 1985). Finally, mothers may be discriminated against if their employers assume that they are less productive and therefore avoid promoting them or putting them on fast tracks.

Empirical measurement of the effect of children on women's wages is not straightforward. One possible method is to include the number of children in a standard wage equation based on a cross-sectional data set; the motherhood penalty then corresponds to the estimated coefficient. However, this approach suffers from several biases, the most severe being the unobserved heterogeneity between mothers and nonmothers: less work-oriented women may have more children and cause spurious correlations of motherhood and wages. So, the most widely used method to measure the family pay gap is using panel regression models to control for cohort effects, individual unobserved heterogeneity, and, if possible, sample selection bias (working women are not a random

[57] However, the explained part represented only 30% of the total gender wage gap for this sample.

sample[58]). However, one problem with cohorts is that, by construction, one observes the results of past careers. Because there have been profound changes in education, job opportunities, and family policies over the past decades, the observed family pay gap may not be an accurate prediction for the next generations of women.[59]

Most of the evidence of the existence and extent of a family pay gap is based on Anglo-American research (Budig and England, 2001; Joshi et al., 1999; Lundberg and Rose, 2000; Viitanen, 2014; Waldfogel, 1998b). There are also some results for other countries, for example, Spain (Molina and Montuenga, 2009, using the European panel ECHP[60]) and Australia (Livermore et al., 2011, based on the Australian panel Hilda), and a few comparative studies: Harkness and Waldfogel (2003) studied seven industrialized countries; Davies and Pierre (2005) studied the European Union; Gangl and Ziefle (2009) studied the United States, the United Kingdom, and Germany; Sigle-Rushton and Waldfogel (2007) studied eight Western industrialized countries. Significant pay penalties associated with motherhood (around 2–10% for one child, 5–15% for two or more children) have regularly been found in all countries except the Nordic countries.

In the United Kingdom and the United States, the wage penalty is entirely explained by career interruptions, reduced work hours, and the concentration of mothers in low-paying part-time jobs (especially in the United Kingdom, where the family gap is particularly high). Joshi et al. (1999) found a penalty of 33% for the United Kingdom (comparing mothers and nonmothers at the age of 30), and Waldfogel (1998b) found a penalty of 20% (for women aged between 30 and 33 in 1991) in the United Kingdom and the United States. Interestingly, using a different method (propensity scores) on the same British cohort as Waldfogel (1998b), Viitanen (2014) found similar results for the United Kingdom and also found a long-lasting (but small) pay penalty 30 years after motherhood for the generation born in 1958 (the last wave observed was of women aged 50–51 in 2008–2009). For the United States, Kahn et al. (2014) found an attenuated effect of motherhood at older ages, except for women having three or more children, which is consistent with the work effort explanation (young children are more demanding than older ones). Anderson et al. (2003) proposed an alternative explanation; observing that medium-skilled mothers suffered a higher net wage penalty than low- and high-skilled mothers in the United States, they argued that medium-skilled workers face more time constraints (regular presence required during office hours, no possibility of taking work home), with negative effects on their wages.

[58] Variables used to correct for selectivity are generally household wealth and nonwage income (see, e.g., Datta Gupta and Smith, 2002).

[59] Another practical problem is the lack of national longitudinal data sets, which explains why most studies are done in the United States and the United Kingdom.

[60] The ECHP (European Community Household Panel) was a panel survey running from 1994 to 2001 that covered a wide range of topics concerning living conditions. It was replaced by the EU-SILC in 2003/2004.

A more recent debate concerns the relationship between the timing of births and the family pay gap, with the hypothesis that women postpone having children to accumulate work experience and build their careers; the fertility delay seems to be correlated with an increase in earnings (Caucutt et al., 2002).[61] The empirical difficulty is to identify the causal effect from delayed maternity to earnings and so to find convincing variables that influence the timing of motherhood and nothing else. Miller (2011) exploited biological fertility shocks in the US case and confirmed a positive effect of delaying the first birth on wages (as well as a flatter wage profile after motherhood).

There are few studies of continental Europe because of the lack of suitable data sets. One exception is Germany, where the GSOEP (German Socio-Economic Panel) allows studies comparable to those from the United States and the United Kingdom. A pure and high wage penalty against working mothers (i.e., an unexplained difference after taking into account labor market behavior) has been observed in Germany for cohorts born between 1955 and 1969 (Gangl and Ziefle, 2009). This finding was confirmed by Felfe (2012), who tested the influence of job amenities on the wage penalty in Germany. The motherhood wage gap can be partially explained by compensating wage differentials, but women who have neither changed jobs nor reduced their working hours still face a family wage penalty of 12%.

Nordic countries constitute a special case because the family gap is very limited (Harkness and Waldfogel, 2003, compared seven western countries including Finland and Sweden; Albrecht et al., 1999, studied Sweden; Datta Gupta and Smith, 2002, studied Denmark). One possible explanation of this singularity is that the generosity of Nordic maternity leave and family policies affects all women, mothers or not, since childless women are expected to become mothers and take parental leave; this leaves room for statistical discrimination against all women, however many children they have (Datta Gupta and Smith, 2002). Another important feature for understanding the small motherhood penalty in Nordic countries is the role played by self-selection into the public sector, which offers more favorable conditions to mothers.[62]

12.3.4.4 Opting Out: Do Highly Skilled Mothers Interrupt Their Careers?

The studies presented above generally found that the motherhood penalty increases with the education level (Anderson et al., 2002[63]), and that interruptions are less frequent

[61] However, the mechanism can be different for the access to the few top positions. Smith et al. (2013) found that having children at a young age increases the probability of being selected as chief executive officer among the pool of vice presidents. The interpretation could be that these women who were obliged to reconcile work and family have proven their high productive capacity.

[62] We will return to the adverse effect of Nordic family-friendly policies on women's wages.

[63] Using the US National Longitudinal Survey labor market experience of the Young Women 1968 cohort, they found that only highly skilled women suffer a wage penalty (much higher for those with two or more children), which is, for white mothers, entirely explained by years out of the workforce.

among highly skilled mothers, because this has a higher cost for them. However, the idea that highly educated women are increasingly "opting out" to care for their children as a consequence of "mother guilt" is receiving much more media coverage and has attracted the attention of economists as a possible effect of culture and norms on labor supply and a possible explanation for the small number of women in top jobs. To test this hypothesis, various studies have examined the careers of highly educated cohorts of women and their propensity to leave their job and the labor market, temporarily or permanently. No strong evidence of the opt-out revolution was found. On the contrary, Goldin and Katz (2008) even found evidence of a stronger labor market attachment in the most recent group of women from highly selective colleges (Harvard/Radcliffe classes) who graduated in 1970, 1980, and 1990, and no major change in fertility rates across cohorts (around 38% in each cohort were childless 15 years after graduating). Half of the mothers from these cohorts had not been out of the labor market for more than 6 months, and the most recent graduates had taken even less time off after childbirth.

However, highly skilled workers are heterogeneous with respect their work commitment. Focusing more specifically on women graduated from a top US business school between 1990 and 2006, Bertrand et al. (2010) found that MBA graduates seem to have more difficulty combining career and family than physicians, PhDs, or lawyers. This is consistent with a study by Herr and Wolfram (2009), who found that female graduates from Harvard are less likely to stay in the labor market if their workplace lacks a family-friendly policy. The phenomenon of opting out also seems to be more common among a specific group of women in highly visible job positions or working in particularly male-dominated occupations. The propensity of the media to focus on this group may explain the discrepancy between common perception and empirical evidence (Antecol, 2011). The second implication of these findings is that family constraints matter for the labor supply, even for some highly educated women. Pursuing these analyses, Goldin (2014) explains the heterogeneity among highly qualified women by differences in the allocation of working hours and the nonlinearity of earnings with respect to hours worked. People working in corporate, financial, and legal occupations are considered not substitutable and are required to work long hours (and are paid accordingly). Lack of flexibility makes the life of women with young children too difficult and incites them to leave their jobs. On the contrary, pharmacists are perceived as being interchangeable and can modulate their working time, so women are not disadvantaged in such occupations.[64]

12.3.4.5 On the Men's Side: A Marriage Premium

Family situation also influences men's wages, but in the opposite direction. There is generally no direct effect of children on men's wages, and there are few studies of this issue

[64] Notice that Goldin (2014) deduces that gender convergence in wage may come from a firm's changes in pay structure, with more linearity in paid hours of work to favor temporal flexibility.

(Loughran and Zissimopoulos, 2009), but a differential of 10–20% has been regularly observed in married men's earnings compared with unmarried men (mostly in the US literature), and there is an abundant literature to elucidate the reasons for this wage advantage.

The two main hypotheses tested are productivity and selection. More precisely, men's marriage premium may result from greater productivity resulting from more effort (Becker, 1974b) or more time spent at work (Korenman and Neumark, 1991), thanks to their wives being specialized in home production. Employers might also favor married men over unmarried men because they think they are more stable (Hill, 1979a). The marriage premium may also result from a selection mechanism: more productive men in the labor market are also more valued in the marriage market (Cornwell and Rupert, 1997; Nakosteen and Zimmer, 1997). Bonilla and Kiraly (2013) recently proposed a model in which the marriage premium results from search equilibrium in frictional labor and marriage markets, but they have not tested it empirically.

Empirical analyses provide mixed evidence on selection versus productivity hypotheses, which is not surprising given the endogeneity problem, the sensitivity of results to the methodology, the variety of identification strategies, and the fact that the two hypotheses are compatible. For the United States, Nakosteen and Zimmer (1997), observing earnings before the marriage, and Dougherty (2006), using panel data and taking into account the duration of marriage,[65] conclude there is a selection effect. On the contrary, Chun and Lee (2001) found no effect of selection and a positive effect of the degree of specialization within the household.[66] Mehay and Bowman (2005) came to a similar conclusion, exploiting personal data and observing performance reviews and promotions of US naval officers. Korenman and Neumark (1991) used a fixed-effects model and found that the marriage premium seems to be due to married workers being in better-paid positions within the company and receiving higher performance ratings from their supervisors, lending support to the productivity effect explanation. Ginther and Zavodny (2001) exploited shotgun weddings (marriage because of premarital conception) as a potential exogenous cause of marriage to identify the selection effect and concluded that selection does not explain the marriage premium, as did Antonovics and Town (2004), who used data on monozygotic twins. In addition to these results from the United States, Petersen et al. (2011) found an opposite result in Norway, where the marriage premium resulted from sorting into higher-paid occupations and occupation-establishment units before marriage. More important, the marriage premium seems to be decreasing over recent decades (Blackburn and Korenman, 1994), and

[65] Dougherty also found a small and temporary but positive wage premium for women, which is incompatible with the specialization hypothesis.

[66] Chun and Lee used a switching regression model with endogenous marital selection; the identifying variable was local marriage market tightness (the relative differences between male and female adults by state).

marriage may even negatively affect the wage growth of men in the United States for recent cohorts (born in 1979) when unobserved heterogeneity has been taken into account (Loughran and Zissimopoulos, 2009). This would be consistent with the idea that marriage—and dual-earner families—impose constraints on men's careers, too.

So far we have not considered the impact of changes in family status and the increasing share of cohabitation on the marriage premium. Does this premium differ according to the legal status of the couple? Datta Gupta et al. (2007) examined the situation in the United States and Denmark and found in both countries that marriage is a more selective state than cohabitation[67] and that it is therefore important to control for cohabitation when estimating the marriage premium. They also observed a small but negative effect of fatherhood on wages in Norway—the wage growth is lower for fathers than nonfathers—and explained it by the hypothesis that fathers may devote more time to childcare and less to training. For Germany, Barg and Beblo (2009) used a nonparametric matching model to differentiate between wage premiums for married and cohabiting men compared with single men. A wage premium exists for cohabiting and married men and seems to be due to positive selection into both marriage and cohabitation. Finally, Killewald (2013) considered different types of family (coresidential or not, biological father or not) in estimating the marriage premium and found a vanishing marriage premium in less normative family structures (unmarried fathers, nonresidential fathers, or stepfathers). Moreover, married residential fathers also received no statistically significant wage premium when their wives worked full time.

12.3.5 Institutions and Policies Matter

Almost all OECD countries have legislation ensuring equal pay for equal work regardless of gender (OECD, 2007). However, there is evidence of wage discrimination on the labor market, as proved by the persistence of an unexplained part of gender wage differentials. Policies against wage discrimination, and more generally against gender inequality at work, can be classified into two broad categories: those aiming to regulate firms' behavior (firm-targeted policies) and those aiming to change women's labor supply and facilitate the conciliation between work and family.

Policies seeking to change firms' hiring and promotion behavior do not seem to be very effective on the whole because they do not address the major source of inequality on the labor market, namely family constraints. Consequently, public policy, especially family-friendly policies, is now considered to be the major lever in reconciling work and family (OECD, 2007, 2012) and in reducing gender inequalities on the labor market. Public policies encouraging women's labor market participation also are considered important for economic growth and the fight against poverty and to maintain fertility rates in OECD countries. These public policies cover monetary incentives to work

[67] But there is also a wage premium for cohabitation.

(tax/benefit systems, childcare benefits) and work–family conciliation policies (parental leave, public childcare services). They are effective enough in increasing female labor market participation (with differences across countries according to the bundle of policies), but family-friendly policies that are too generous may have a "boomerang effect" and jeopardize women's careers. Ultimately, involving fathers in childcare through paternal leave incentives is increasingly viewed as a way to directly address the source of gender inequality, but empirical evidence is still rare and does not show any dramatic changes in childcare sharing.

12.3.5.1 Firm-Targeted Policies

In addition to enacting antidiscrimination legislation, changing the behavior of firms toward working women can be done in two opposite ways: first through the pressure of competition, and second by regulating the composition of the workforce (affirmative action, quotas). Both have been scrutinized in numerous works. In both cases, there is empirical evidence of their effects on gender inequality, which are generally positive but of a limited extent and sometimes dubious.

12.3.5.1.1 Does More Competition on the Product Market Reduce Wage Discrimination?

According to Becker's (1971) theory of taste discrimination, discrimination is costly for firms, and gender discrimination should spontaneously regress with increased competition: discriminatory employers cannot survive in a competitive market because they have to pay higher wages than their competitors to obtain their preferred type of worker. The policy recommendation is then simply to let the market clear discriminatory employers. In recent years, a number of empirical studies have tested this hypothesis by studying the evolution of the gender wage gap in contexts of increasing competition. This could be the result of deregulation in a given industry, as for the US banking industry (Black and Strahan, 2001); they found that men's wages decreased more than women's and that women's occupational status improved. Using a difference-in-difference approach, Heyman et al. (2013) also found that takeovers and product market competition have a positive (but limited) impact on the relative position of Swedish female employees. A more common way to study the effects of a competitive shock on the gender wage gap is to observe the consequences of the opening up of an economy to international trade. Examining the relationship between globalization and changes in the gender wage gap across industries in the United States, Black and Brainerd (2004) found that the decrease in the residual gender wage gap was faster in concentrated industries after the shock of competition than in already competitive industries. Similar findings were obtained for other developed countries. According to Klein et al. (2010), exporting firms exhibit less wage discrimination than nonexporting firms in Germany. Meng and Meurs (2004) also found a smaller unexplained gender wage gap among firms more exposed to competition in France and Australia. These papers are based on national case studies.

Zweimüller et al. (2008) gave a more general view by adding to the meta-analysis described above (Weichselbaumer and Winter-Ebner, 2005) a proxy for the degree of competition in each country (the "Economic Freedom Index"). They observed a negative correlation between competitive markets and gender wage gap residuals. They acknowledged, however, that they could not tell whether these reduced gender wage gaps resulted from wage increases for women or wage decreases for men, and the effect on employment was not considered. The general conclusion of these diverse studies is that competition actually reduces the gender wage gap (generally by reducing men's wages), but the effect is not strong enough to profoundly change firms' discriminatory behavior.

12.3.5.1.2 Affirmative Action and Quotas: Their Effect on Gender Equality

Another means of reducing discrimination on the labor market that has been investigated is directly regulating firms' labor demand and compelling them to observe certain rules in their workforce composition. The famous US affirmative action programs of the early 1907s[68] fall into this category of antibias policy and have been extensively discussed in the literature (Fryer and Loury, 2005), mainly based on Coate and Loury's (1993) theoretical framework, in which it is argued that positive discrimination policies do not systematically eliminate negative stereotypes. A large strand of research on the effect of this policy is devoted to the employment of racial minorities in the United States,[69] but it also has been extended to women's employment. Leonard (1989) concluded that affirmative action has been more effective in increasing job opportunities for minorities than for white women, whose employment would probably have increased without the program. However, Holzer and Neumark (2000) have a more positive assessment of affirmative action policy; they argue that the firms adopting this program change their process of hiring and training, reducing statistical discrimination, and attract more minority and female job applicants. Eberts and Stone (1985) focused on the effect of Equal Employment Opportunity Commission on promotion in the education sector in the 1970s and also concluded that discrimination against female teachers had decreased. Finally, experimental evidence concludes that affirmative action may increase women's willingness to compete (Niederle et al., 2013) and their self-confidence (Villeval, 2012).

[68] Title VII of the Civil Rights Act of 1964 bars private employment discrimination on the basis of race, color, religion, sex, or national origin. The policy was enforced with the Equal Employment Act of 1972; since then, all federal contractors have been required to maintain written affirmative action plans for women.

[69] One strand of empirical literature studies access to self-employment status by US black minorities (Fairlie, 1999) and changes in access through this affirmative action policy on subcontractors. Blanchflower and Wainwright (2005) concluded there are few changes despite the existence if various programs, and Chatterji et al. (2013) concluded there is a more positive effect of small business set-aside programs on minorities' employment than affirmative action programs.

More recently, attention has been centered on gender quota policies in top management and their effect on gender inequality. This is consistent with the analysis that the persistent imbalance in top positions is now the most important mark of the inequality between men and women on the labor market. It has led to public policies imposing an increase in the proportion of women on corporate boards in many OECD countries (Pande and Ford, 2012), with the notable exception of the United States, which is very hostile to this kind of regulation. Norway is a leader in this field, requiring 40% women on corporate boards since 2003, but now it is also the case in France, Italy, the Netherlands, and Belgium, which have mandatory quotas from 30% to 40%. A European directive imposing a quota of 30% on corporate boards for all member states in 2015, and 40% by 2020, was adopted in 2012.

The percentage of women on boards of directors is usually analyzed from the point of view of firms' financial performance, with mixed evidence, more often positive (for the United States see Carter et al., 2007; Erhardt et al., 2003; Miller and del Carmen Triana, 2009; Shrader et al., 1997, via a positive effect on innovation; see also Smith et al., 2005, on a panel of Danish firms; Adams et al., 2011 found a positive reaction of shareholders to female director appointees in Australian firms). The problem with this empirical evidence is that variations in the percentage of women on boards of directors are endogenous, so causal effects are difficult to prove. In Norway, firms were obliged by law to change their board composition, so it offers an interesting natural experiment. Exploiting this case, Ahern and Dittmar (2012) found negative effects of the shock on board composition: stock prices and firms' performances (measured by Tobin's *q*) both decreased. They interpreted these results as a consequence of the lack of experience of new female directors replacing old and experienced male directors. This suggests that the negative effect may be transitory if women accede to positions enabling them to acquire managerial skills.

This raises the question of the effect of gender quotas in boards of directors on human resource practices. Does the reinforced presence of women at the top trickle down to the lower grades? The expected mechanism behind this hypothesis is double: women at the top may directly favor the promotion of women and/or act as positive role models. There are still few econometric studies testing the effects of top managers on the female proportion of executives because of the dearth of suitable data. The few studies of US panel data found a positive association between an increase in the proportion of women on boards of directors or among top managers and a reduced gender wage gap (Cohen and Huffman, 2007), better pay for executive women (Bell, 2005), or a higher share of women among top executives (Matsa and Miller, 2011; and for Norway, Matsa and Miller, 2013; Kurtulus and Tomaskovic-Devey, 2012). However, a positive association between the proportion of women among top executives and positive outcomes for women is not observed everywhere; for example, in Denmark, Smith et al. (2013) did not find that having more women in the management board favors the promotion of women. Therefore, the link between the proportion of women involved in the hiring process and a break in the glass ceiling effect is probably not as straightforward as these findings may suggest. Bagues and Esteve-Volart (2010)[70] showed that a higher proportion of women on a recruitment committee plays in favor of male candidates, whose relative quality is overestimated. Other studies (based on correspondence testing) did not find gender difference in the recruiters' bias in favor of men for hiring in science research positions (Moss-Racusin et al., 2012). This sheds doubt on the efficacy of quota policies for helping women in their careers. To sum up these mixed findings, the presence of women in top positions does not guarantee that promotions will be fair or that the lack of women at the top will quickly dissipate.

The mitigated results of voluntary policies to equalize career prospects between men and women are partly due to the timing of childbearing. Some policy programs directly address the difficulty women have in combining a career and childbearing ("the overlap between biological and tenure clocks"), especially in academia. The "Stop the Clock" policy, which delays promotion review under certain circumstances, was introduced in 1971 at Stanford University and is now widely adopted in US academic institutions. Manchester et al. (2010) found no empirical evidence of the effectiveness of this policy and even proposes that Stop the Clock policies may exacerbate the gender pay gap in academia. This last example suggests that the effects of equal opportunity programs are limited when they do not directly address issues related to labor supply.

12.3.5.2 Public Policy and Women's Participation in the Labor Market

The particularities of the labor supply of (married) women have been extensively studied in labor economics (Heckman, 1974; Killingsworth and Heckman, 1986). Basically, it depends on the choice between market activities (and the corresponding wages) and household production. The mechanisms behind this choice, however, seem to have evolved dramatically. As underlined in the first part of this section, the increase in the female labor supply since the 1970s has been outstanding, and this trend was mainly due to changes in the behavior of married women with young children; the traditional pattern of withdrawal from the labor market to take care of children has receded in recent decades. Olivetti (2006) explained this impressive change by the relative increase in (married) women's returns to experience. As a result, work interruptions are penalized more highly, especially for young women in their early careers. These changes shifted the elasticity of married women's labor supply in two directions (at least for 1980–2000 in the US case): their wage elasticity decreased by half and became quite similar to men's, and their labor supply became less responsive to their husbands' wages (Blau and Kahn, 2007).

The general increase in total hours worked by women may be the result of greater participation in the labor market (extensive margin) and/or of an increase in the intensity

[70] These findings are based on evidence provided by Spanish public examination for judiciary occupations (magistrates). The 150,000 candidates were randomly assigned to juries of varying gender composition.

of work on the job (intensive margin). In two companion papers, Blundell et al. (2011a,b) decomposed the evolution of total hours worked in three countries (the United States, France, and the United Kingdom) into extensive and intensive margins for the period 1975–2008. One striking result is that while the extensive labor supply for married women with children is similar in the three countries, the intensive margin differs: US married women increased their mean annual hours of work, contrary to women in France and the United Kingdom, who tended to reduce their hours worked. These differences between industrialized countries are related to differences in institutions and policies, for instance, whether part-time work for mothers is encouraged.

We focus here on the two main policy tools influencing the female labor supply: earnings taxation and family-friendly policies (cf. OECD, 2007). First, we briefly sum up the debates about the response of the labor supply to income tax. To what extent does the current fiscal structure determine the labor supply of men and women? Second, maternal and parental leave, childcare subsidies, and family-friendly public policies in general have been expanding over the past few decades in OECD countries, but at different speeds in different countries. A growing corpus of studies details their impact on the labor behavior of mothers. The positive impact of these policies on female labor participation is widely recognized, but various studies highlight the possible negative effects of some of these policies—especially parental leave—on female wage careers. The parental leave taken by fathers has more recently been viewed as a possible lever to change attitudes at work and to improve equal gender opportunities, but the (still) scarce empirical evidence on this issue does not really support this view.

12.3.5.2.1 Marriage, Taxation, and the Labor Force Supply

Does it pay for the second earner in a household to work in the labor market? The answer greatly depends on the tax system for families and on the average effective tax rate and the marginal effective tax rate (METR).[71] The OECD (2012, Chapter 4) provides an overview of the METR for test cases in OECD countries. The designed test cases are the transition from inactivity to part-time employment, then from part-time to full-time employment, for couples with two young children (aged 4 and 6). The financial incentive to take a part-time job in single-earner couples is very low in 16 of 29 countries (particularly Sweden, Switzerland, Ireland, and Norway, where the METR is >100%), whereas the incentive to transition to full-time work is strong. In both cases (transition to part-time or to full-time work), the incentives are stronger for dual-earner couples.

These test cases assess the effect of national tax systems on family income without differentiating between incentives within the household. In fact, income tax may be applied

[71] The average effective tax rate is the proportion of gross earnings lost by taking up employment (extensive margin). The METR measures the proportion of any increase in earnings lost to taxation and/or benefit income reductions for those already working (intensive margin).

to individuals or to households, and the choice between joint taxation and individual taxation is the subject of considerable theoretical debate, with strong implications for female labor force participation. A large majority of authors support the individual tax unit through the Ramsey (1927) rule: an optimal tax system ensures that individuals with high labor supply elasticity face a lower marginal tax rate than those with low elasticity. Applied to dual-earner married couples and when the income tax is progressive, this means that it is preferable to tax individual earnings rather than the household income (Boskin, 1975); in the case of individual taxation, the secondary workers of the household, whose labor supply elasticity is high, are taxed at a lower marginal rate than the primary workers, whose labor supply elasticity is low. Following this reasoning, the US system, in which husbands and wives have been allowed to pool their income and file a joint return[72] since 1948, is generally considered not optimal (Rosen, 1977) because it discourages second earners (in practice, wives) from working.

The Boskin and Sheshinski (1983) model of taxation of married couples relies on individual and cross–labor supply elasticities and the joint distribution of wage rates to design optimal taxation; their numerical example, based on US parameters, suggests that the optimal rate for husbands would be approximately twice that for wives. One of the difficulties with this scheme is that individual taxation counteracts the objective of redistribution: if the government values redistribution, two married women with the same labor income ought not to be treated identically if their husbands' incomes are different. Kleven et al. (2009) studied how the tax rate of one individual should vary with the earnings of the spouse, taking into account the objective of redistribution. They propose a sophisticated model of optimal income taxation of couples where the second earner has to decide whether to work (a binary choice). The optimal tax formula is a function of labor supply elasticity, the redistributive tastes of the government, and the distribution of earning abilities and work costs among the population. As a result, the optimal tax (or subsidy) on secondary earnings decreases with primary earnings and converges to zero asymptotically.

The idea that a tax system based on individuals rather than households is more efficient has been challenged by Piggott and Whalley (1996) by adding household production to the model of optimal taxation. In this case, the optimal tax design should not distort the input of family members in household production. The underlying intuition is that moving from an individual to a household-based income tax reduces the supply of secondary work but increases time for household production and leisure and can improve welfare.[73] Apps and Rees (1999, 2007) disagree with this model. They also include household production in their optimal taxation model and find, contrary to Piggott

[72] In this case, the taxation is calculated as if they had each earned one-half of the income.

[73] Note that in this model, the household is treated as a single optimizing agent.

and Whalley (1996), that it is still optimal to tax individuals separately, as in the Boskin and Sheshinski (1983) model.

Another lively debate of the optimal taxation of married couples concerns the idea of gender-based taxation (GBT), whereby women have a lower tax rate because of their higher elasticity of labor supply. Alesina et al. (2011) argued that such a reform would increase the bargaining power of women within the family, endogenize labor supply elasticities, and narrow the gender labor elasticity gap. Their idea is to replace the various policies in favor of women, such as quotas, affirmative action, or subsidized childcare facilities, with this tax advantage for women. Saint-Paul (2008) strongly disagreed on the grounds that it is discriminatory and GBT would be perceived as unfair because it does away with equality before the law. He argued in favor of a gender-neutral system (the second earner not necessarily being a woman) with the same rate of taxes on individual earnings. Guner et al. (2012b) brought an empirical perspective to this debate. They tested the introduction of GBT in the US context and found that it would improve welfare, but welfare gains would be higher if the US tax system were replaced by a proportional, gender-neutral income tax.

There are relatively few empirical studies of the effect of fiscal policies on the actual female labor supply. Guner et al. (2012a) used a dynamic model with heterogeneity and quantified the effects of two possible tax reforms in the United States: a proportional income tax and a reform in which married individuals file taxes separately. Their model indicates that the effect on married women's work hours is stronger in the second case—labor force participation increases more than twice as much as it does under a proportional income tax reform (+10% and +5%, respectively). The effect is even more pronounced for married women with children, with men's hours being nearly constant in both cases. Kabátek et al. (2014) studied the French case, which is characterized by the joint taxation of married couples (but not for cohabiting couples at the time of the survey), using an individualized data set with information on each member of the couple. Once again, a simulation of separate taxation concluded that the labor supply of wives increases, but only to a limited extent.

Japan offers an interesting case because the tax system is such that the primary earner (usually the husband) has a spousal deduction (Allowance of Spouse) if his spouse earns income below a threshold level. As a result, an increase in the wife's earnings decreases the amount deductible from the husband's income. Akabayashi (2006) exploited this particularity to assess the labor supply response of women and found that it is a strong disincentive to women's labor supply because they value more the loss of the spousal deduction than the potential gain of their own paid work. Consequently, the intrahousehold allocation of labor supply is inefficient.

As in Japan, Italian tax policy does not encourage women to participate in the labor market: a tax credit for dependents is paid to the main earner of the family, which encourages one-earner families. Figari (2011) studied the potential effects of abolishing the existing tax credit and replacing it by in-work benefits, inspired by the UK Working Tax Credit, which is an income supplement for all individuals working 16 or more hours a week. The first scenario envisaged is an in-work family-based benefit; the second is individual based. Using EUROMOD (the tax benefit microsimulation model for the European Union),[74] Figari found an increase in the labor supply of women in both cases; the larger effect was obtained with the individual-based benefit, and the labor supply changes are particularly marked for the poorest households.

Figari et al. (2007) proposed comprehensive comparative research on the effects of the tax and benefits system on the labor supply of married women for nine European countries. As in the case study for Italy, the simulations were based on the EUROMOD model, which allows for calculations on the basis of the actual social and demographic characteristics of each national population. The first aim of this comparative work was to quantify the difference in independent income brought into households by male and female partners in couples and to measure how far the gap is closed by the national tax and benefits system.[75] In all nine countries, the average share of couples' pretax benefit income received by women is far less than half, with the lowest in Greece (18%), mainly because of its low female rate of participation, and the highest in Finland (37%). But the case of women with a higher income than their partners is not so rare (around 25% of couples in Finland and the United Kingdom). The tax benefit system reduces within-couple income inequality on average in all countries: more so in Austria, Finland, the United Kingdom, and France (countries where non-means-tested benefits[76] have an equalizing effect), and less so in Greece (the system makes little difference to the women's share before and after tax benefit). The equalizing effect is small in Germany and Portugal. The second aim of this study was to assess the incentives of women in couples with an earning partner to increase their earnings by working more or at a higher wage rate (intensive margins) or by taking on paid work themselves (extensive margins). As expected, comparative analysis indicates that joint taxation (France, Germany, and Portugal) is the system with the most important negative impact on incentives for the second earner to work (assessed based on marginal effective tax rates).

12.3.5.2.2 Family Policy Instruments and Labor Market Participation

After this overview of the debates about the effect of the tax system on female labor market participation, we now turn to public family policy and its impact on the female labor

[74] Note that the paper is based on a unitary model of household behavior (pooled income constraint).

[75] Independent incomes are allocated to the member of the household who earns or receives them. Benefits received by an individual to compensate for individual risks (maternity, unemployment, disability) are allocated to the individual concerned. Family or child benefits are divided equally between the two partners. The convention is questionable, but the authors assume that it is more transparent to adopt this assumption in the absence of information about the actual sharing.

[76] These benefits are composed of parental benefits, unemployment benefits, and child and family benefits (equally shared by assumption).

supply. Family policy instruments cover a wide variety of programs (OECD, 2013; Thévenon, 2013). Typically, they combine three kinds of measures: entitlements to maternity and parental leave after the birth of a child, which provide employment protection and often are covered by public income support; childcare services adapted to the working hours of parents with young children; and a tax benefit system that contains incentives to work.

All countries have developed these policies over recent decades, but to different extents and in different combinations, so it is not easy to obtain an overall picture of the bundle of policies. One convenient way to classify types of family public policy is to use the Esping-Andersen (1999) framework. Broadly speaking, countries can be categorized into three groups (Thévenon, 2011, 2013). Nordic countries (Denmark, Finland, Iceland, Norway, and Sweden) favor the model of the dual-earner family. These countries are characterized by comprehensive support for working parents with very young children. They offer generous birth-related leave conditions for working parents and provide childcare and services out of school hours. English-speaking countries (Ireland and the United Kingdom, the United States, Australia, Canada, and New Zealand) provide less generous in-kind support to working parents with very young children and more cash benefits, often targeted to low-income families. Continental countries form a heterogeneous group: southern European countries provide limited support for working families, but France is a particular case, providing strong support for working women to combine work and family. Interestingly, the type of welfare state regime (which can also be categorized as sociodemocratic, liberal, and conservative in the order of presentation above) also shapes the division of labor at home (Geist, 2005; see Section 12.6 on unpaid work in the household).

12.3.5.2.2.1 A Positive Effect of "Family-Friendly" Policies on Female Labor Market Participation The expansion of "family-friendly" policies in Europe (and in the other OECD countries, except for the United States) over the past two decades has largely contributed to the increase in female labor force participation, contrary to the recent stagnation of the US participation rate[77] (Blau and Kahn, 2013). The diversity of policies within Europe has attracted numerous studies seeking to evaluate their effect on female labor participation in a comparative framework. In general, macroeconometric analyses of OECD panel countries found a positive effect of family-friendly policies (especially when combined with female education, low unemployment, and favorable cultural norms) on female labor market participation; the exception is child benefits, which tend to reduce female participation because of an income effect (Jaumotte, 2003). Thévenon (2013) developed a macroeconometric analysis of the responses of female labor participation to changes in policies for 18 OECD countries from 1980 to 2007. His results confirm the key role of childcare services as a driver of female

[77] The US female participation rate has nevertheless stabilized at quite a high level (75%).

participation in the countries' labor forces. Taking into account complementarities with other policies, he showed that this effect is enhanced in countries with high levels of employment protection, longer paid leave, and other measures supporting working mothers. Using the European panel ECHP, Del Boca et al. (2009) found that part-time work opportunities (when well paid), childcare, optional parental leave, and child allowances are a greater determinant of the participation choices of women with lower levels of education. They also concluded that differences in social policies across European countries are responsible for a large part of the differences in female labor market participation across these countries. Gutierrez-Domenech (2005) studied the influence of national policies on a precise event in work life—women's transition from employment to nonemployment after a first birth—and compared five European countries over 1973–1993. During this period, Spanish mothers increased their probability of employment after giving birth, contrary to West Germany. The author points out the shift towards a separate taxation system, the increase in education and part-time employment to explain this divergence across countries.

12.3.5.2.2.2 Maternal and Parental Leaves: What Effect Do These Have on the Participation Rate? Maternity and parental leaves (generally taken by the mother) are one key component of family policy in all OECD countries (Thévenon and Solaz, 2013). However, national policies differ in their objectives and in the resources allocated. A first group of countries (Nordic countries) favor short, well-paid leave as a way to preserve mothers' work attachment; other countries consider parental leave as a substitute for formal childcare services and propose long leaves at a flat rate (if any); the US case is particular because it was one of the few countries that had no national maternity leave policy until 1993 (since then, 12 weeks' unpaid leave have been granted under the Family and Medical Leave Act).

How do women react to maternity leave entitlement with regard to their work commitment? The general findings are that maternity leave encourages labor market participation before pregnancy to qualify for leave benefits and reinforces work attachment and return to the former employer (Ruhm, 1998; Waldfogel, 1998a). But the empirical problem in studying the effect of maternity leave on mothers' labor supply is to find exogenous variations in taking maternity leave. The identification strategy usually exploits either an institutional difference across countries on a parameter of the policy considered or a sudden change because of a reform in a given country. The US case has been largely studied because, despite the absence of national coverage, it was possible to get differentiated coverage through state policy, unionized firms, or voluntary employer provisions. These studies then compare the behavior of women with and without maternity leave entitlement and measure their respective probabilities of returning to paid work.[78]

[78] There is still a selection problem, however, because this advantage is not offered randomly by firms.

Women entitled to maternity leave are more likely to take leave up to the maximum period allowed but return more quickly after 12 weeks than mothers with no entitlement. They are also more likely to return to their previous employer after childbirth (Berger and Waldfogel, 2004)[79] and to receive a wage premium that offsets the negative effects of having children (Waldfogel, 1998b). Positive effects in terms of job continuity were observed by Baker and Milligan (2008), who exploited the variability of maternal leave eligibility across Canadian provinces, and by Joshi et al. (1996) in work with the British 1958 birth cohort, which was the first generation to be offered statutory maternity leave; the gains of maternity leave and other family-friendly policies were unevenly distributed and more pronounced for educated women.

Parental leave policy (after maternity leave) has complex effects on the probability of returning to work after childbirth. Two statutory components—the length of job protection and payment during the leave period—produce opposite effects on the return to work. A longer period of job protection increases the probability of returning to work; paid leave increases the probability of taking the leave and then staying at home (Pronzato, 2009). So, the overall effect of parental leave varies according to the generosity of the conditions. Lalive and Zweimüller (2009) provided causal evidence of the impact of parental leave on employment and earnings[80] using two opposite changes in Austrian parental leave policy. The 1990 reform increased the duration of parental leave from 1 to 2 years, whereas the 1996 reform reduced it to 18 months (there was no change in the benefit paid during the parental leave, equal to 40% of net median female earnings). They found that extended leave led to significant short-run reductions in employment and earnings and delayed the return to work, even after the parental leave had expired. But they did not observe any negative effects of the parental leave extension on earnings 5 years after the birth, even for highly qualified mothers (contrary to a general view that longer parental leave has a negative effect on women's careers; see Section 12.3.5.2.3). Dustmann and Schonberg (2012) used a change in maternity leave coverage in Germany[81]; as in the work by Lalive and Zweimüller, they found that the extension of leave actually delays mothers' return to work.

12.3.5.2.2.3 The Effects of the Costs of Childcare on Mother Labor Supply We have already mentioned the general consensus that access to childcare is crucial to enabling parents to be in paid employment. The costs of childcare may be a serious barrier against labor market participation. When they are taken into account, the financial

[79] Notice that Klerman and Leibowitz (1999) argue that the effect of the Family and Medical Leave Act (1993) on job continuity is small and that the new law did not change the practice.

[80] Fertility responses to Austrian parental leave reforms are also thoroughly examined by Lalive and Zweimüller (2009). We do not report their results on this issue, which are beyond the scope of this section.

[81] Their study focused on children's long-term outcomes after a longer period of staying with their mothers.

incentive to work decreases, especially for lower-income families.[82] The disincentive effect is particularly strong in Anglophone countries, Japan, Israel, and Switzerland (OECD, 2012). Consequently, lower childcare costs increase female employment, but estimating the price elasticity of childcare presents serious methodological difficulties (Blau, 2003). Natural experiments offer a convenient way to identify the effects of childcare subsidies on labor supply. Baker et al. (2005) studied a new childcare policy of reduced fees in Quebec, Canada, and found a large and positive impact on the labor supply of mothers with preschool children.[83] On the contrary, such an effect was not found in Sweden after a considerable reduction in childcare prices (Lundin et al., 2008). The interpretation here is that highly subsidized childcare already existed before the reform, so further reductions had limited impact (not significant). Some studies underline that the effect on labor supply also depends on availability (see Kreyenfeld and Hank, 2000, for Germany) and on the quality of childcare (see Hansen et al., 2006, for the United Kingdom). Finally, out-of-school care is also an important factor in reconciling full-time work with motherhood when children are in primary school, but this public policy is not yet very developed in OECD countries.

12.3.5.2.3 The Boomerang Effect of Family-Friendly Policies

The evidence that family-friendly policies boost the female labor participation rate seems to be solidly established by numerous empirical studies. However, this does not imply any improvement in women's position in the labor market or any reduction in gender wage inequality. Blau and Kahn (2013) completed their observation of the relative advantage of OECD countries over the United States in female labor market participation (see above) with a relative disadvantage in the quality of work: US women are more likely than women in other OECD countries to work full time and to be managers or professionals.

The most controversial family policy is long parental leave, which is regularly associated with a wage penalty for mothers in various countries (Ruhm, 1998, describes nine countries in a seminal work; Misra et al., 2011, describe European countries; Phipps et al., 2001b, describe Canada; Beblo et al., 2009, describe Germany; Lequien, 2012, describes France). Although parental leave preserves the ties between women and their employers and thereby encourages women's participation in the labor market, it reduces their commitment to a career.

These negative effects of family policy seem predominantly to affect highly qualified workers through a "boomerang effect" (Datta Gupta et al., 2006, 2008). The extension of family-friendly schemes[84] seems to have a negative effect on the wages of women

[82] The advantage of reduced childcare costs for low-income families does not make up for limited income gains.

[83] But the authors also found negative effects of this policy on children's health and behavior.

[84] In the Danish case, this factor is reinforced by female segregation in the public sector, where family-friendly policies are the most generous. This partly explains the observed stagnation (or even a tendency to increase) of the gender wage gap (Datta Gupta et al., 2006).

(with children) because it leads to a higher probability of long career interruptions and penalizes their careers, particularly for the most highly qualified. The same conclusion was reached by Mandel and Semyonov (2005, 2006) in their comparative analysis of industrialized countries: the welfare state facilitates women's access to the labor force but not to managerial occupations. More generally, family-friendly policies may deter women's (mothers or not) career progression (see Albrecht et al., 2003; Arulampalam et al., 2007; Christofides et al., 2013). They also attract disproportionate numbers of women to the public sector, which offers more favorable working conditions at the expense of their wage career (Simonsen and Skipper, 2006). Datta Gupta et al. (2008) concluded that "extensive family-friendly schemes may even have created a 'system-based glass ceiling' hindering women's career progression" in Nordic countries.

12.3.5.2.4 Does Paternity Leave Change Parents' Behavior?

Paternity leave has recently attracted attention as a policy that directly addresses the main cause of gender inequality on the labor market, namely the time devoted to childcare by mothers. The expected effects are twofold: first, to shorten maternal leave by sharing parental leave; second, to change mentalities in the hope of obtaining a fairer division of housework over the long term (Huerta et al., 2013; OECD, 2012, Chapter 18). The finding by Nepomnyaschy and Waldfogel (2007) that the length of paternity leave has a positive influence on fathers' involvement in childcare constitutes an argument in this direction. However, the country studied was the United States, where there is no paternity leave policy, even though a large proportion of fathers take some (unpaid) time off work after a birth, so it could be argued that the fathers who take longer paternity leave are a selected group.

Contrary to the US case, European countries have adopted various measures in favor of paternal leave in the past two decades. The Nordic countries (Norway, Sweden, Finland, and Iceland) are the most advanced in this field, with well-paid paternity leave and a strong incentive to take it because part of the total parental leave is lost if not taken by the father. For instance, Iceland is often exemplified for its system of 3 + 3 + 3, meaning that a third of the parental leave is reserved for the father (13 weeks), a third is reserved for the mother, and the last third can be taken by either the mother or the father (in practice, usually by the mother).

What are the actual changes in fathers' behavior induced by this policy? Highly educated fathers are more likely to take parental leave (Sundström and Duvander, 2002); large parental leave benefits and longer duration of exclusive parental leave for fathers seem to be positively correlated with fathers' childcare time (see Haas and Hwang, 2008, for Sweden; Boll et al., 2013, for a cross-country comparison based on time-use data). But these findings are descriptive and do not establish a causal effect of paternal leave on fathers' behavior. Ekberg et al. (2013) took advantage of a natural experiment in Sweden (the 1995 "daddy-month" reform offers 1 month of parental leave for the fathers of children born after January 1) to study the short- and long-term effects on fathers' behavior. They observed a strong short-term effect of the incentives on male parental leave but no behavioral effects over the long term (measured by sick days taken to look after sick children younger than 8 years old). It is possible that this persistency in behavior was due to the limited scope of the observed change (only 1 month). A similar pattern was observed in Germany; the natural experience exploited by Kluve and Tamm (2013) was the introduction of more generous parental leave benefit and 2 "daddy months" in 2007 (the "Elterngeld reform"). Like Ekberg et al., they found no significant changes in the time fathers devoted to childcare among those subject to the reform (measured by the fathers' relative contribution to childcare during the children's first year). Generous paternal leave attracts fathers and so has an effect on the duration of maternity leave, but it has little effect on childcare sharing.

To sum up the findings on the gender wage gap, the most salient fact is that the gender wage has stopped decreasing in OECD countries since the late 1990s, after a sharp decline in the 1970s and 1980s. The reasons for this decline have been clearly identified: rising education levels and increasing participation in the labor market have brought women's human capital closer to men's. The reasons for the recent stagnation are nowhere near as clear cut. From a descriptive point of view, men's and women's occupational structures differ considerably, and women are less successful than men in their careers. A huge number of studies have tested a large range of sophisticated explanations that are not exclusive and are difficult to rank in terms of explanatory power. First, firms may discriminate against women, and testing, natural experiments, and econometric studies show that women are not treated equally in the hiring process or in promotions. Second, women's psychological features may impede them from being as aggressive as their competitors or from choosing certain occupations. Once again, there are laboratory experiments proving the existence of gender differences in risk aversion and competitiveness, but the external validity of psychological explanations for the gender wage gap is still open to question. Finally, family constraints and the issue of children and housework appear to be central to understanding the gender wage gap: young mothers are penalized in their careers, especially when they are highly qualified; women may choose family-friendly places at the expense of their careers; if firms think that childless women may become mothers in the future, they may be reluctant to train and promote them. As a result, national public family policies play a major role in explaining national differences in the gender gap. The new paradox is that a generous system in favor of parents of young children has positive effects on female participation but a negative impact on their careers.

12.4. THE CASE OF SELF-EMPLOYMENT

Self-employment is a two-faced concept in labor economics. On the one hand, it is considered the basis of economic dynamism and the soul of capitalism. In line with Schumpeter's theory, the entrepreneur is the prominent figure of capitalism: an individual capable of perceiving economic opportunities, combining various resources, and taking risks. The belief that small business is essential to the growth of the capitalist economy has policy implications, especially in Europe. One of the priorities defined by the Lisbon Strategy (March 2000) was to foster start-ups. More recently (January 2013), the European Commission proposed the Entrepreneurship 2020 Action Plan "to reignite the entrepreneurial spirit in Europe" and to address the structural, administrative, and cultural obstacles to entrepreneurship.

On the other hand, self-employment is presented today as a way of mitigating the human consequences of the economic crisis by diminishing the unemployment rate (even artificially). More generally, self-employment is considered a route out of poverty for unemployed or marginal populations. The flexibility allowed by self-employment is also seen as a convenient way to accommodate constraints on the labor market: it allows flexible hours and schedules, can often be done at home, and so offers an intermediate situation between inactivity and salaried work. It is therefore not surprising that the European plan in favor of entrepreneurship suggests that policy should aim "to promote specific actions for reaching out to groups that are [. . .] under-represented within the entrepreneurial population" (OECD 2013, p. 4): migrants, seniors, the unemployed, young people—and women.

Gender studies on self-employment lie at the crossroads between these two approaches. The gender gap in self-employment is analyzed in terms of the characteristics required to become an entrepreneur. Since Cantillon (1755) and Knight (1921), the entrepreneur has been viewed as a risk-taker or bearer of uncertainty; to this risk attitude, Lazear (2005) added balanced skills and varied backgrounds as personal characteristics that influence the choice of entrepreneurship. Thus many studies test gender gaps in human capital, risk aversion, and self-confidence as the main explanatory factors for the lack of women in small business. Once women are self-employed, however, the analysis focuses on this situation as a means for women to reconcile work and family. Studies of women's performance compared with that of men explain the observed differences, mainly in working hours and, more generally, in the business objectives: profit for men, work–life balance for women. Like the gender wage gap, gender differences in earnings then tend to be related to differences in labor supply and family constraints.

In this section, we present the statistics available on self-employment rates in OECD countries,[85] showing that women are less likely to be self-employed than men in all OECD countries. Why do self-employment rates for women differ from those for men? A growing strand of research examines the role played by psychological

[85] We do not consider female self-employment in developing countries. There is a lot of debate about microcredits and self-business as an efficient way for women to gain economic independence, but the issues are too far removed from the scope of this chapter, which is centered on gender inequalities in OECD countries.

characteristics (risk aversion, self-confidence, and perception of economic opportunities) in explaining this gap. Then we turn to studies of differences in the way men and women run businesses. Some studies examine the possibility that women face discrimination in the access to credit. But most analyses are centered on gender differences in family constraints as the main reason for differing performance between men and women.

12.4.1 Stylized Facts

12.4.1.1 The Fuzzy Scope of Self-Employment

Self-employment covers a wide and heterogeneous range of economic activities: traditional farmers, regulated professions in law or health, small business, start-ups, and so on. To measure it, the OECD has adopted a comprehensive definition: "Self-employment is a form of employment in which people work in their own business, farm or professional practice and receive some economic benefit for their work, such as wages, profits, in-kind benefits or family gain (for family workers). Volunteer work is excluded from this definition" (OECD, 2013, p. 32). Self-employed people can work on their own (i.e., own-account self-employment) or have employees. Business owners are excluded if they are not involved in the day-to-day operations of the business activity.

As Ahmad and Seymour (2008) emphasized, entrepreneurship should not be confused with the above measure of self-employment. Entrepreneurial activity is defined as "the enterprising human action in pursuit of the generation of value, through the creation or expansion of economic activity, by identifying and exploiting new products, processes or markets" (OECD, 2007). Consequently, entrepreneurship is not limited to small business units, but includes innovative large companies. In practice, studies often confuse self-employment and entrepreneurship. This has consequences on gender analyses, which tend to confuse the relative dearth of self-employed women with the lack of female entrepreneurship.[86]

In practice, comparable statistics on self-employment are based on national labor force surveys. The Global Entrepreneurship Monitor (GEM) measures entrepreneurship activities through annual household surveys of the adult population in 54 countries and includes a set of questions on motivations and aspirations. GEM is also the main source

[86] Another statistical problem is the inclusion in self-employment statistics of people who are falsely self-employed ("bogus self-employment" or "economically dependent workers"). This corresponds to an employment arrangement in which the worker has only one customer and is registered with tax authorities as a self-employed worker rather than an employee on the employer's payroll. The extent of bogus self-employment is, of course, difficult to assess. According to Oostveen et al. (2013), it is marginal in the 27 European Union countries, representing less than 1% of the workforce. It seems more important in certain countries such as Italy and the Czech Republic (Geissler 2012; Oostveen et al., 2013), where it may represent more than 10% of the self-employed (2% of the employed workforce). There are no significant differences between men and women in the incidence of this form of "self-employment."

of information on nascent entrepreneurship (businesses started less than 42 months and more than 3 months ago).

12.4.1.2 The Gender Gap in Self-Employment

In all developed countries the self-employment rate—the proportion of self-employed people relative to all employed people—is lower for women than for men, whatever the average level of self-employment.

In the 27 European Union countries in 2011, the self-employment rate was 9.7% for women and approximately the double for men (18.3%); the average rate was 15%, with great variations across countries (OECD, 2013). Some countries, such as Denmark, France, and Germany, have a much lower female self-employment rate (around 5%) than the EU average, whereas others, such as Italy and Greece, have much higher rates (around 20%). There are large contrasts in the evolution of these figures within each country. Over the 2000–2011 period, 13 EU countries experienced an increase in female self-employment rates; the most significant increases were observed in Slovakia, the Czech Republic, and the Netherlands. The other 13 EU countries saw a decline (or a stagnation in Latvia), and the most significant declines were in Lithuania, Portugal, and Romania (OECD, 2013).

The United States has a relatively low rate of self-employment, equal to 11% in 2009 (based on Bureau of Labor Statistics figures in Hipple, 2010) and stable since 2003.[87] The female self-employment rate is, as expected, nearly half the male rate (8% and 14%, respectively), and the gap is particularly large in incorporated self-employment (2% and 5%, respectively).

In all countries, gender segregation by industry in self-employment seems similar to the segregation in salaried employment. Women are relatively absent in manufacturing and building, which account for approximately 25% of male self-employment. Self-employed women are more likely to work in consumer-orientated services (health, social work, arts, education). These sectors represent around 40% of female self-employment (OECD, 2013).

12.4.2 Why So Few Women in Self-Employment?

The lower propensity of women to start businesses is well documented (see Allen and Langowitz, 2013; Koellinger et al., 2013; Langowitz and Minniti, 2007; OECD 2013, Chapter 2; for the most recent references based on the GEM database; Anderson and Wadensjo, 2008 on the Swedish case; Furdas and Kohn, 2010, on the German case). Once a business is started, in general there are no significant differences in survival rates

[87] This stability results from the combined impact of a decline in unincorporated self-employment and an increase in the rate of incorporated self-employment.

across genders when economic characteristics are taken into account (for the United States, see, e.g., Perry, 2002).

Why do women start fewer businesses than men? Gender differences in observed human capital are not sufficient to explain the gender gap in self-employment (Minniti and Nardone, 2007; Wagner, 2007). Furdas and Kohn (2010), using a detailed individual data set on start-up activity in Germany, decomposed the probability of starting a business by sociodemographic variables and personality traits. They found that men opt for start-ups more often than women with comparable sociodemographic variables (age, education, professional status, region, immigrant background, and family environment). Much of the gender difference is explained by the distribution among women of personality traits (risk tolerance, openness, emotional stability, creativity, need for achievement, etc.) that are less favorable to entrepreneurship.

A large strand of literature has sought to explain the lack of self-employed women in terms of psychological and social factors, which can be classified in three broad categories: risk aversion, perception of economic opportunities, and preferences for self-employment. According to the model developed by Kihlstrom and Laffont (1979), in which individuals make their occupational decision by comparing the risky returns of entrepreneurship with the nonrisky wage in the competitive labor market,[88] gender differences in risk aversion are a natural candidate for explaining the gender gap in self-employment. Risk aversion may also play a role by discouraging access to financial resources to start a business; using the English Household Survey of Entrepreneurship 2003, Sena et al. (2012) found that women are more reluctant than men to borrow from banks, and this gender difference in the search for external funding reduces their probability of becoming self-employed. In addition to risk aversion, perception of opportunities (see Kirzner, 1979), self-confidence, and knowing other entrepreneurs are crucial characteristics for starting a business. Consequently, the lack of self-confidence among women, the gender difference in perception of the economic environment (women tend to perceive themselves and the entrepreneurial environment in a less favorable light than men do), and the higher fear of failure lower the propensity to start a business (Langowitz and Minniti, 2007; Minniti and Nardone, 2007; Koellinger et al., 2013; Wagner, 2007). In addition, gender stereotypes (Gupta et al., 2009) and preferences for self-employment may contribute to the gender gap in self-employment transition and also have given rise to a large number of studies combining psychology and economics. For instance, Verheul et al. (2011), using a representative data set of more than 8000 individuals in 29 developed countries, distinguish two stages in the process of starting a business: the general preferences for self-employment—whatever the actual work status of the individuals

[88] For instance, Ekelund et al. (2005) tested the role of risk aversion on self-employment using a Finnish psychometric data set and found a sizeable negative effect of this psychological feature on the probability of being self-employed.

surveyed—and the actual involvement in self-employment. They find that a lower inclination for entrepreneurship among women explains a large part of the observed differences in the self-employment rate and conclude that general preferences appear to be the key factor behind the low self-employment rate of women.

However, some recent studies have argued that the importance of social and psychological factors and gender stereotypes should not be overestimated, and that the decision to be self-employed also depends on economic opportunities for both women and men. A macroeconometric analysis of longitudinal UK data, estimating the extent to which women are influenced by economic factors, shows that economic factors (gross domestic product [GDP], interest rates, house prices, employed and self-employed incomes) influence equally the self-employment choices of both women and men (Saridakis et al., 2013). The impact of economic factors on the decision to be self-employed also has been studied using microanalysis by comparing the behavior of individuals with similar human capital. Generally, the behavioral difference between men and women in the propensity to become self-employed may be strongly mitigated when the population is homogeneous. Analyses restricted to professional and managerial self-employment indicate that women choose self-employment to pursue a careerist model and to obtain work autonomy as men do (for the United States see Budig, 2006a). Leoni and Falk (2010), who analyzed the propensity to be self-employed among Austrian university graduates, find that age and the field of studies explain two-thirds of the gender gap observed in self-employment. When the group studied is limited to medical graduates, they no longer observe any gap between men and women in the propensity to be self-employed.[89] But it could be argued that medical graduates are a self-selected group that attracts women prepared to exercise as licensed professionals.

12.4.3 Self-Employed Women: Family Constraints and Gaps in Working Hours and Earnings

Given the lower propensity of women to start businesses, what factors might encourage women to become entrepreneurs? One motivation for women to become self-employed could be to avoid the gender wage discrimination they face on the labor market[90] and to be rewarded according to their productive characteristics. Evidence, however, is not very convincing: empirical work tends to find a small unexplained part in the gender earnings gap of self-employed workers, once productive characteristics and work hours have been controlled for (for the United States see Clain, 2000; for Canada see Leung, 2006).[91] But

[89] In general, however, women still have a lower probability of being self-employed in other fields of study.

[90] Note that self-employed women may suffer from consumer discrimination if the customers do not like being served by women.

[91] One exception in this set of studies is Lechmann and Schnabel (2012), who obtained a larger unexplained part for the self-employed than for salaried workers in the German case.

despite these results, which suggest that women have higher returns on their human capital when they are self-employed, the role of gender wage discrimination in the transition toward self-employment is not firmly proved (Leung, 2006; see Williams, 2012, for a set of European countries).

On the contrary, there is a general consensus that familial responsibilities play a dominant role in women's choice of self-employment and that this status is often chosen by (married) women as a way to achieve a better work–life balance, given their family constraints (Carr, 1996). The family status and the presence of young children is therefore a key variable explaining the choice of self-employment because the flexibility in working hours allows parents to reduce the cost of childcare (Connelly, 1992). Empirical studies have regularly found a positive influence of fertility on women's selection into self-employment (Boden, 1999; Macpherson, 1988). Women with young children are more likely than men to declare flexibility of schedule and child constraints as main reasons for becoming self-employed (for the United States, see Boden, 1999). Therefore self-employment seems to be a close substitute for part-time work and labor market inactivity, especially in countries where there are few public childcare services (see Georgellis and Wall, 2004 on the US case). To be covered by their husband's health insurance is also a positive factor of women's self-employment, especially in the US case (Devine, 1994). Lombard (2001) presents a careful econometric study of the choice of self-employment over wage/salary employment by married women in the United States. The women's requirements in terms of monetary (wages) and nonmonetary job attributes (flexibility and a nonstandard work week) were estimated in a first stage, and these estimates, together with husbands' health insurance, were used to explain the self-employment decision. The conclusion is that these three factors—the relative earnings potential when self-employed, the demand for flexibility and a nonstandard work week, and the husband's health insurance—positively affect the probability of women being self-employed.

Another way to demonstrate the key role played by work–family time in self-employment is to compare the use of time by self-employed people and employees. According to a study based on the Australian Time Use survey (Craig et al., 2012), self-employed mothers spend more time on domestic work and childcare and their paid work hours are shorter than those of salaried mothers, whereas the fathers' time does not vary much across employment types. Some studies also have found positive nonmonetary outcomes for women (mothers) who have opted for self-employment: self-employed married women report greater job satisfaction, less occupational burnout, and less negative spillover from work to home (based on a 1997 US survey; Hundley, 2001).

Given these differences in work commitment and working hours, it is therefore not surprising that self-employed women are regularly found to perform worse than men. The raw gender earnings gap (defined as the difference between male and female average self-employment incomes divided by the male average self-employment income) is around 35% for OECD countries as a whole, with large variations between countries.

Portugal and Poland (countries where farms are still important) have the largest gap (60%), Nordic countries (Iceland, Sweden, Denmark) the smallest (10%), and the US and most European countries are at around 40% (OECD, 2013, gender data portal).[92] But, as mentioned above, the unexplained part of this gap is small: in most countries this gender difference in earnings generally vanishes quite entirely when structural differences (human capital, financial capital, sectors of activity), and particularly women's reduced working hours and their commitment to children and housework, are taken into account (for the United States see Budig, 2006b; Fairlie and Robb, 2009; Marshall and Flaig, 2014; see Du Rietz and Henrekson, 2000, for Sweden; see Young and Wallace, 2009, for Canadian lawyers). Hundley (2000) analyzes this male/female earnings gap in self-employment in terms of their different reasons for being self-employed (compared with salaried work). The starting point is that self-employment offers a broader range of options of work organization than salaried work: self-employment is not bounded by minimum work hours (and corresponding minimum pay), nor by maximum hours, contrary to salaried work. Combined with the gender division of labor (see Section 12.6), this implies that self-employed married women will do more hours of housework than salaried women (and less market work), and conversely self-employed men will do less hours of housework than salaried men (and more market work). As a result, the gender earnings gap is greater in self-employment than in salaried work. Empirical analysis based on the US Panel Study of Income Dynamics survey confirms that marriage, family size, and hours of housework have a negative effect on self-employed women's earnings and a positive effect on those of self-employed men. Hundley (2000) also suggests that this pattern may operate as a barrier to entry into business by ambitious women, as they may fear that self-employment will oblige them to do the lion's share of the housework.

12.4.4 Are Women Discriminated Against in Their Access to Credit?

Another well-documented stylized fact on gender differences in entrepreneurship is that self-employed women make less use of bank loans than men do. Are women discriminated against by banks, experiencing more credit denials or higher interest rates than men? Or do they simply apply for less credit? This issue has been largely studied in the United States (Blanchard et al., 2008; Blanchflower et al., 2003); it is regularly found that women do not face discrimination in terms of access to loans, unlike ethnic or racial groups. Asiedu et al. (2012) confirmed these results using the latest Survey of Small Business Finances in 2003. The 2003 database allows them to extend the analysis to loan renewals (and not only new loans). Loan renewals, compared with new loans, are

[92] There are specific methodological difficulties in collecting data on self-employment earnings: how to distinguish between the return on capital and the payment for hours worked, how to treat negative earnings, the bias due to incomplete declarations, etc. (see Section 12.2). However, these biases are assumed to affect men's and women's earnings equally.

interesting because there is less information asymmetry, so unexplained differences in denial rates (with white men as the reference group) can be attributed to discrimination with more certainty. After controlling for selection bias and nonlinearity (i.e., the possible different impact of some of the control variables according to the level of applicants' credentials), Asiedu et al. found discrimination against ethnic minorities, but not against (white) women; they even found that women tend to pay a slightly lower interest rate than white males.

Then the limited use of banking credit may stem from gender differences in behavior. Although there may be no gender differences in the granting of bank loans, differences in the perception and expectation of their banking relationship may negatively affect women's demand for credit. Saparito et al. (2013) studied gender differences in the perception of banking relationships; their research was based on a survey of 696 matched pairs of business owner/managers and bank managers and that included qualitative variables. They found that gender influences the quality of the relation between business owner and banker: the male pairs (a male firm owner and a male bank manager) have the highest level of trust and satisfaction with credit access, and the female pairs have the lowest level of these indicators. Interestingly, an influence of gender is also observed in women's access to angel capital. In general, women are less likely to seek angel financing, although they have an equal probability of obtaining funding from this source; they are also more likely to seek and obtain financing from women angels (Becker-Blease and Sohl, 2007).

However, the role of behavioral variables should not be overestimated in explaining gender differences in access to credit; the differences in structural characteristics explain a large part of this gap. Using Survey of Small Business Finances over two decades, Cole and Mehran (2009) summarized the major characteristics of female-owned firms as follows. These firms are smaller, younger, more likely to be in retail trade and business services, and more likely to be organized as proprietorships rather than corporations. Female owners are younger, less educated, and less experienced than male owners. Econometric analysis indicates that these structural differences explain why female-owned firms are less likely to obtain credit than male-owned firms.

The above findings on the absence of gender banking discrimination are for the US case. There is no certainty that the result is valid in other OECD countries. In fact, Alesina et al. (2013) offer a counterexample in the case of Italy, where the share of self-employment is high and a lot of microfirms are owned by women. They find robust evidence that women pay more for credit than men, even after taking into account a large number of characteristics relating to the type of business, the borrower, and the structure of the credit market. The disadvantage is higher in male-dominated industries. The authors suggest two explanations for this result: a taste-based discrimination against women, as Italian society still has very traditional values concerning the place of women in society, and asking for a loan could be considered unsuitable, and a lower ability to negotiate good deals with banks because women are more averse to competition and more reluctant to ask.

To sum up, some features already highlighted in the analysis of the gender wage gap also seem to be relevant to gender differences in self-employment, namely the choice of field of study, industrial segregation, and (once again) family constraints and the need for flexible work hours to reconcile childcare and professional activity. The possibility of combining work with staying at home seems to be contradictory to the relative scarcity of self-employed women. Gender differences in risk aversion seem to provide a solid basis for explaining this paradox, but their importance should not be overestimated. Finally, self-employment is a very heterogeneous field, with huge differences in types of business (how can one compare the behavior of lawyers and farmers?) and across countries, and for which data are still too limited (compared with those for wages) to provide a comprehensive picture of gender inequalities.

12.5. THE GENDER GAP IN PENSIONS

Pensions are the main source of retirement income for the elderly, and it is well known that older women receive far less individual pension income than older men. All countries have adopted various mechanisms to take into account the wages lost by women because of their family constraints and to reduce their risk of poverty in old age. However, before 1990, the gender pension gap was a blind spot, virtually invisible in the economic literature (Ginn, 2001), and it has only recently attracted attention (see Jefferson, 2009, for a survey; Folbre et al., 2005). There were two reasons for this invisibility. First, because pensions were based on past earnings, their less advantageous careers automatically led to smaller pensions for women, and the gender pension gap was viewed as a simple outcome of this fact. Second, it was considered that nearly all women were married, and married women shared the benefits from their husband's entitlements, and this occurred even after his death through survivor's pension schemes. In other words, the hypothesis of income pooling within the family was explicitly assumed for retiree couples and there was no point in studying gender inequality. Consequently, the gender aspect of pensions was covered from the perspective of the living standard of widows and spinsters, as the people most at risk of poverty. The policy issue was that of a safety net for old people and poverty (mainly women poverty) and/or the more or less generous way to transfer pension rights to the survivor (wife).

The recent growing interest in the gender pension gap stems from three concurrent social evolutions. First, the end of the male breadwinner model in the 1960s has led to the current massive entry into the retirement system of generations of women with their own past work lives and their own pension entitlements. The usual analyses of the gender wage gap can then be transposed to the gender pension gap, with similar issues. Should we expect a narrowing of the gender pension gap similar to that observed for the gender wage gap? To what extent do part-time, incomplete careers, occupational segregation, wage discrimination, and so on have adverse consequences on the level of individual pensions? Second, changes in family history with the decline in marriages, the rise in divorces, and the increase in cohabitation and celibacy have a direct impact on the gender pension gap. The typical figure of a single retired woman is now less likely to be a widow and more often a divorcee or spinster. This change calls into question the rationale of survivor's pension schemes inherited from the past, when there was only one (male) breadwinner.

Last but not least, population aging and the corresponding increase in the dependency ratio are exerting pressure on retirement schemes in all countries. The general trend in reforms is to reduce the level of pensions and to align pension benefits more closely with career trajectories. A pure contributory system—defined as a system where the total sum of pensions received by a pensioner is proportional to the discounted sum of contributions made during his or her working life—creates gender inequalities because of the previous gender inequalities in careers. The more the pensions system is based on contributions, the more it is disadvantageous to women. However, all countries have kept or expanded diverse mechanisms to counterbalance these (negative) gendered effects, such as noncontributory pensions, the use of unisex mortality tables to calculate contributions, and benefits or additional family rights.

In this section, we present the (few) statistics on the gender pension gap. We will see that it is even more difficult to obtain comparable international figures of this indicator than it is for the gender wage gap. Then we discuss the main mechanisms that determine the actual level of pensions and the extent to which the same rules may have a different impact on men's and women's pensions. Finally, we turn to family history and its consequences on the gender pension gap. The main issue here is how to compensate for unpaid work such as caring for children or other family members and the emerging transition toward family rights and away from spouse's rights.

12.5.1 Sparse and Noncomparable Statistics

There is general agreement on the existence of a considerable gender pension gap, but there are no harmonized international statistics to compare the situation between countries. Some figures are available by country, but the way they are calculated is heavily dependent on the specificities of each national pension scheme.

One of the problems in obtaining comparable figures, which is also encountered for the gender wage gap, is the question of which population is considered. Is it limited to private pension recipients or not? Are social security pensions included or not? But there are also problems related to the variety of national pension schemes and the way data on pensions are collected. Is the gender pension gap measured at the household level, with information on the composition of earnings (direct pensions, derived pensions, savings income) or based on individual administrative data without information on the composition of the household? Finally, there is a difficulty specific to the gender issue. Unlike wages, which are defined on an individual basis and are a remuneration for hours worked, pensions may include rights derived from the spouse (pensions paid to the spouse or ex-spouse, survivors' pensions) or from the family situation (family rights).

There are very few comparable international statistics, even fewer than for the gender wage gap. One exception is the recent document published by the European Commission (2013) presenting comparable tables based on the EU-SILC 2010 database. To the best of our knowledge, these are the only published statistics comparing countries available in 2014 and, by construction, the United States is not included in the comparison. The population surveyed is defined as people over 65 years old not living in collective households[93] and receiving a pension. Because of the way the data are collected, the first "two pillars" of pensions—state pensions, based on societal solidarity and pay-as-you-go financing, and occupational pensions (OPs), based on occupational solidarity and prefunding—are not distinguished; only the third pillar (individual pension schemes) can be isolated. Another particularity of these figures is that survivor's pensions are mixed with other pensions.

According to this study, the average gender pension gap[94] in Europe was 39% in 2009, approximately twice the average gender wage gap for these countries.[95] Germany, the United Kingdom, and the Netherlands have a gender pension gap of more than 40%, whereas it is less than 25% in Nordic countries (Finland, Denmark), and Eastern European countries (Figure 12.6).

For the United States, scarce figures are given separately for the social security system (the first pillar in the United States) and for the private system. In both cases there is a gender pension gap, equal to 35% for the social security system (which includes spouse's benefits) and stagnant over the past 50 years, despite the increase in the labor force attachment of women. This stagnation is mainly due to the US spousal benefits system: additional social security earnings have no effect on social security benefits because they replace the spousal entitlement (see below). The picture is different for private pensions: between 1978 and 2000, the ratio of women's to men's benefits increased from 0.23 to 0.29 (Even and Macpherson, 2004).

An additional difficulty in obtaining pertinent figures is that the population of retirees is far from homogenous in terms of work history and accumulated entitlements, so the average pension is not very informative, particularly for women: recent cohorts have had

[93] This excludes people living in nursing homes, who represent a sizeable percentage of old people.

[94] The average gap is equal to 1 minus the average women's pension/average men's pension.

[95] The comparison should be treated with caution because the average gender wage gap is measured at a given point in time, whereas the average gender pension gap is based on the cumulated gender gap for the whole working life.

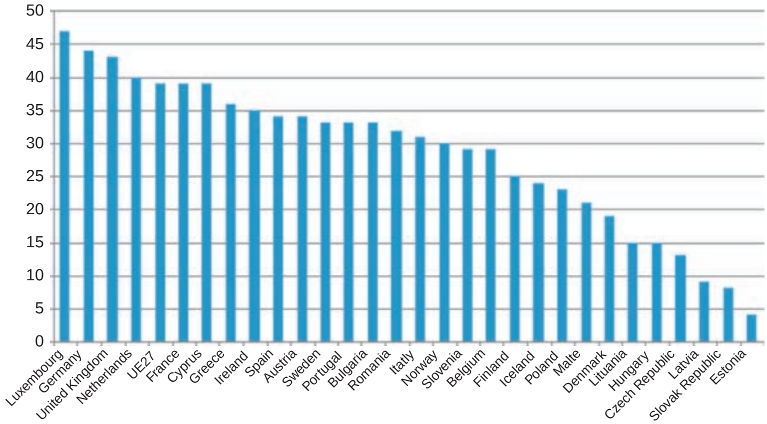

Figure 12.6 Average gender pension gap in Europe (pensioners aged over 65 years). *Source: Bettio et al., 2013 – Based on EU-SILC UDB data 2010.*

a longer working life than the older cohorts, for whom the past norm was the one-earner family. This implies a narrowing of the gender pension gap, reflecting the dramatic growth in female participation in the labor market. For instance, in France in 2008, women's own pensions were 44% of men's for the 1924–1928 cohorts and 56% for the 1939–1943 cohorts (Andrieux and Chantel, 2011). However, the picture is not really so clear cut and depends on the viewpoint one adopts. Because the SILC statistics on pensions are not limited to personal entitlement pensions but include survivors' pensions, the gender gap in total pensions by cohort does not indicate narrowing (Bettio et al., 2013). Comparing cohorts older than 80 years with the cohort aged 65–79, it can be seen that the younger groups face considerably wider gender pension gaps (41% vs. 33%). This surprising result is due to a combination of large proportions of widows who receive survivors' pensions among the eldest women and selection effects (life expectancy is higher for former qualified workers, so pension benefits are relatively higher and the group is more homogeneous). Consequently, changes in women's labor market participation result in attenuated changes in benefits for women; the benefits derived from spousal rights are replaced by benefits linked to individual careers.

12.5.2 The Gendered Effects of Pension Regulations

The individual gender pension gap mirrors work life inequality: women's lower labor force participation, more part-time work, more career interruptions, and lower pay all have consequences on their pension entitlements and levels. Most studies (Even and Macpherson, 2004, for the United States; Bonnet and Geraci, 2009, for France) conclude that higher labor force participation and the narrowing of the gender wage gap will not suffice to produce pension equality in the future and there will be still a need to compensate for child-related career interruptions. Differences in regulations (the extent of noncontributory schemes, the coverage of individual pension schemes, the minimum period of contributions required to establish entitlement, and the retirement age) and in the method of calculating pension benefits may amplify the gendered impact of work life differences (on international differences in pension progressivity see Aggarwal and Goodell, 2013).

12.5.2.1 Coverage and Contributions: The Gendered Impact of Current Reforms

Old-age pension schemes generally include a first minimum level with wide coverage, less demanding conditions, and a benefit level close to that of welfare benefits. Noncontributory schemes are a powerful way to loosen the link between career earnings (and associated contributions) and benefits (Bonnet and Geraci, 2009). They are one of the major tools to fight women's poverty in old age. The Scandinavian countries propose the most generous scheme, with universal pensions for all residents. Most countries offer a kind of safety net but one with conditions and usually income tested; for instance, Canada's "old age security," the United Kingdom's basic state pension (but with very low benefits), the "*minimum contributif*" in France (which is proportional to the duration of the career and is intended to compensate more for low wages than interrupted careers), or the "age pension" in Australia. Women constitute the majority of beneficiaries because of their interrupted careers and low wages.

Beyond these minimum pensions, the retirement income system is generally a mix of publicly administered social insurance (financed by employer and employee contributions) and private pension schemes supplemented by individual savings. The minimum length of employment required for entitlement to a pension may affect women more than men, given their shorter working lives. Pension reforms tend to lengthen the required period, but in some cases the higher labor participation of women has counterbalanced this negative effect, and the gender coverage gap is generally expected to narrow. For instance, the US public scheme (social security) now requires 40 quarters (15 in 1971), but the percentage of women entitled to social security benefits increased from 57% to 65% between 1980 and 1999 (Even and Macpherson, 2004). In most countries, pension reforms tend also to increase the legal age for full retirement benefits; in the United Kingdom, for instance, the state pension age, currently 60 for women and 65 for men, is being gradually equalized to reach 65 for both sexes in 2020. This can be more prejudicial to women than to men because the increase in the length of working life may not be sufficient to keep pace with the increase in the retirement age. OECD pension reforms also tend to align the legal age of retirement of men and women. In the past, the legal age of retirement for men has often been higher than that of women as a way of compensating women for unpaid care work. In 1995, 15 OECD countries applied the same retirement age for men and women and 8 applied different ages; in 2013, only 2 countries (Israel and Switzerland) applied different retirement ages (64 for women, 65 for men) (OECD, 2013). The equalization of the legal age of retirement was favorable for women in higher-paid, full-time jobs, enabling them pursue their careers and to acquire more pension rights (and higher pension benefits), but it can increase income insecurity for women in precarious forms of employment (Luckhaus, 2000).

Another salient trend in pension reforms is to give a larger weight to individual private pension schemes provided through employers, that is, largely OPs, in other words, a switch from first to second pillar pensions (Behrendt, 2000). The link between contributions and the level of benefits is stronger than in public schemes (first pillar), and private pensions are viewed as the main source of the gender pension gap (Bardasi and Jenkins, 2010). This is particularly the case in the United Kingdom, where only 33% of women over 65 years old received a private pension in 1993–1994, compared with 61% of men (Ginn et al., 2001, p. 52). Because the schemes are provided voluntarily by employers, people in part-time employment, precarious jobs, and small organizations are less likely to be covered by OPs. Bardasi and Jenkins (2010) estimated the effects of different variables on the probability of being covered by an OP and found significant correlations between women's OP probabilities and labor status (part-time employment, time out of the labor market); marriage and children have only indirect effects through work history.

In the United States, the correlation between wage rates and pension coverage weakened after enactment of the Employment Retirement Income Security Act in 1974, which limits tax preferences for employer plans for which all workers, including the low paid, are eligible. However, women still tend to have lower rates of coverage because they are more likely than men to work in small firms and in low-paid or part-time jobs (Bajtelsmit, 2006). Similar regulations have been introduced in Europe: two judgments of the European Court of Justice in 1994 stipulated that the exclusion of part-time workers from OP schemes contravenes equal pay laws and may represent indirect discrimination against women.

Another possibility for rectifying gender gaps in pension coverage and entitlements is the policy of matching government contributions for low-income workers (Jefferson, 2009). For instance, Australia has experimented with government cocontributions to personal superannuation accounts. A large proportion of women participate in this scheme, and it has been considered successful in encouraging women to build their private pension savings, although not enough to improve significantly the economic situation of old women (Olsberg, 2006). Moreover, there is doubt about whether it is possible for low-income earners in low-income households to save. It is likely that these savings came from high-income households (where women are in part-time, low-paid jobs), which can take advantage of these profitable cocontributions. In that case, first the policy target is missed, and second, it is not an individualization of private pension savings but a form of pooling savings at the household level (with predictable difficulties in case of divorce).

12.5.2.2 Benefit Calculation Methods

Benefit calculations are identical for men and women, but structural differences in working lives and life expectancies have different consequences on the level of benefits for men and women. Here we examine the consequences of three main characteristics in calculation methods: reference earnings years, defined benefits versus defined contributions, and the choice of annuity tables.

Women are more likely to have low earnings years in their careers, so the longer the reference periods used for benefit calculations, the more they are disadvantaged. For instance, France's 1993 reform gradually increased the number of reference years from 10 to 25 in 2008. Using a microsimulation model, Bonnet et al. (2006) calculated that this reform would reduce the reference wage (which is used to determine the level of benefit) by over 20% for more than 30% of women, compared with 12% of men. Another consequence of this reform is that it increases pension disparities between women.

The pension reforms that shift the focus from the first pillar to the second pillar often are combined with a change from defined benefit to defined contribution schemes (Mackenzie, 2010; Orenstein, 2013). In defined benefit schemes, the benefits are calculated using a fixed formula, and the risk of the amount to be paid is shared by employer and worker. In defined contribution schemes, the payout is dependent on both the amount contributed to an individual account and the performance of the investment vehicle.[96] The expansion of defined contribution schemes is analyzed as a transfer of risk from the employer and the worker to the beneficiary. The majority of pensions provided by private employers in the United States are now based on defined contributions (more than 85% in 2001), and they are expanding in OECD countries. In the United States, they are essentially tax-free saving accounts (i.e., a tax deferred account—retirement plans like the 401(k)), where employees choose whether to participate and how much to save for their retirement; it does not penalize quitters, unlike defined contributions.

Defined contributions offer the advantage of portability, which is appreciated by workers. This can be important for women because of their weaker attachment to the labor market. It is also likely, however, that women will not accumulate sufficient savings over their working lives—they tend to have lower amounts accumulated in their defined contribution plans (because of their lower wages) and therefore lower financial returns. In the event of a separation from their employer, they are more likely to use the lump sum to meet their urgent financial needs rather than roll it over into another tax-qualified savings plan (Bajtelsmit, 2006).

Another growing problem with this shift toward defined contributions is that participants have to be active in their employer's pension plan. Actually, the general observation is that employees are passive and do not change the default rules proposed by employers (see Duflo and Saez, 2003). For women, the negative effect of this passive behavior may be exacerbated by their lower financial literacy compared with men (Van Rooij et al., 2011; see Fonseca et al., 2012, on financial literacy within the couple) and their higher risk aversion.

[96] However, the difference between the two systems has been blurred by the sovereign debt crisis, which led to numerous cuts in pension payments in defined benefits systems.

12.5.2.3 Life Expectancy, Gender, and Pensions

The gender gap in life expectancy also has an impact on individual contributions and benefits in defined contribution schemes, according to the way the benefits are designed. Calculations based on unisex mortality tables have a redistributive effect away from those with lower life expectancy (men) and toward those expected to live longer (women). If the calculations of pensions were based on sex-based actuarial factors, women's pensions would tend to be lower than men's or their contributions would be higher (10–15% higher) (Shilton, 2012). Whether benefits should be calculated on sex-based actuarial factors or unisex tables is an ongoing debate; insurance companies are pushing to be able to discriminate by gender (and their associated mortality tables) and apply gender-based contributions or benefits. The 1978 US Supreme Court ruled in favor of unisex tables, judging that differences in compensation based directly on sex are unlawful as a matter of statutory policy (Luckhaus, 2000) and that contributions and life annuities must be calculated from unisex mortality tables. The underlying rationale is that this ensures equity in the amount the employer pays to the employees, rather than equity in the lifetime value of that benefit to the employee (Jefferson, 2005). A similar debate was held in Europe in the 1990s, and the prohibition of sex-based mortality tables was imposed on insurance companies on the basis of antidiscrimination laws and reaffirmed in 2004 and then 2011 (Shilton, 2012).

12.5.3 Family Matters for Pensions, Too

So far we have examined the gender differences in individual pensions. The big picture is that the individual gender pension gap is due to differences in work history and that the narrowing of labor market participation and wage gaps is not sufficient to reduce gender inequality in pensions "as long as combining paid work and parenthood (or other caring responsibilities) affects women more than men" (Bajtelsmit, 2006). The role of career differences in the gender pension gap has been quantitatively estimated by Bardasi and Jenkins (2010). Using a regression-based decomposition of the average gender private pension income gap in the United Kingdom for people aged 66 and older,[97] they found that differences in returns to personal characteristics account for at least four-fifths of the private pension income gap among recipients. They conclude that this result is probably because of the nature of the jobs taken by these cohorts of workers (part time and of shorter duration). But they also suggest that women in these generations may have chosen not to contribute to private pensions in the expectation that they can rely on their husband's entitlements.

There are strong associations between marital and fertility decisions, pensions coverage, and the level of benefits. Derived entitlements from marital status or family rights are an important component of women's pensions and explain why the gap in living

[97] The data set used is the British Household Panel Survey 1991–2000.

standards during retirement is relatively small compared with the individual gender pension gap. In France, for instance, the median standard of living of elderly women was 10% (single)[98] to 19% (widowed) lower than that of couples in 2009 (Bonnet and Hourriez, 2012).

There is a wide variety of pension entitlements derived from marital status. The US system is particularly generous from this point of view. The social security system includes a spousal retirement benefit, equal to 50% of the pension benefit of the spouse (or former spouse), subject to the condition of at least 10 years of marriage, and a survivor's benefit equal to 100% of the husband's actual benefit. Women's eligibility to these benefits is based on their own earnings history; they receive whichever is higher between their own benefits and the derived pensions. One side effect of this system is that the couple's replacement rate decreases mechanically with the labor market activity of women: one-earner couples have a maximum replacement rate (with a ceiling on monthly earnings) equal to 60% (40% for the husband plus an additional 20% for the spouse); two-earner couples, with individual benefits calculated on their own careers, have a maximum replacement rate by social security of 40% (there is no additional benefit for marital status). Actually, the replacement rate for married households is decreasing across generations from 50% (generations born in 1931–1935) to 45% (generations born in 1948–1953); this decline is being driven by the increase in the frequency of dual-earner couples with their own benefits (Wu et al., 2013). The eligibility condition of 10 years of marriage has a side effect on the duration of marriage: using American social security data, Goda et al. (2007) showed that couples tend to delay divorce decisions from year 9 to year 10.

In Germany and the United Kingdom, there is another type of spousal entitlement whereby pension rights are divided equally between spouses in the event of divorce. The mechanism is intended to remedy the low level of women's own rights (because of unpaid work) and corresponds to a perfect pooling of the pensions rights acquired by the husband and wife during the marriage (Bonnet and Geraci, 2009). Denmark offers an interesting case study in adopting a completely opposite reform in 2006: private pension savings (which form the basis of pension incomes) were no longer regarded as community property in the event of divorce, but as private property. This reform should lead to a substantial decrease in divorced women's pension income because men's pension savings are 30% higher. Amilon (2012) exploited the natural experiment constituted by this change and the period of 7 months, during which couples could divorce without being affected by the reform, and she observed a significant increase in the probability of getting divorced and a rise in women's savings within couples. As in the US case, this tends to prove the sensitivity of family status to the legal pension scheme.

[98] The relatively low gender pension gap for single women is also the result of a composition effect; divorced and unmarried women retirees are, on average, more educated and have accumulated more individual pension rights.

Last, the survivor's pension (defined as a percentage of the deceased spouse's pension) is still used to guarantee the living standard of widows in most OECD countries. It is intended to compensate for the loss of the spouse's pension and to reduce the gap in living standards between couples and widows by compensating widows for the loss of economies of scale within the couple. In a society where couples are stable, this survivor's scheme equalizes the living standards of men and women in retirement (provided retired couples pool income).

However, there is increasing debate about the legitimacy and effectiveness of these spousal rights, especially the survivor's pension, and a decline in these derived benefits. In Sweden, survivor's pensions have been gradually abolished and, more recently, survivor's benefits have been reduced in the Netherlands and Germany (OECD, 2007). Changes in marital history, with the increasing number of divorces and the decline in marriage, explain the need to reexamine the rationale of survivor's schemes (see Bonnet and Hourriez, 2012). There are fewer widows and more spinsters and divorced women in elderly one-person households, so the effectiveness of survivor's pensions in guaranteeing a decent living standard for older women is compromised. As a matter of fact, nowadays single mothers raising children seem to be more at risk of poverty than widows.

Because children and their consequences on mothers' careers are at the core of the gender pension gap, family rights are gaining significance as a way to improve the situation of women in old age, in place of survivor's schemes. Family rights have been extended in various European countries over the past 20 years (Bonnet and Geraci, 2009; D'Addio, 2013). In Italy, Germany, and the United Kingdom, family rights are limited and initially open only to parents who have not worked. France has a more generous system that combines different mechanisms: contribution credits for mothers,[99] old-age insurance for nonworking parents, and pension bonuses for parents of three or more children (this last measure is not aimed specifically at women). The tendency of a shift from marital rights to family rights reflects the decline of marriage and the shortening duration of couples but also recognizes the persistent family-related gender wage gap.

12.6. NONMARKET WORK, THE GENDER DIVISION OF LABOR, AND GENDER INEQUALITY

Together with women's increasing participation in the labor market and commitment to employment, another major and related trend of the second half of the twentieth century was the reduction in the hours of housework, the time women spend at home doing

[99] Contribution credits for mothers are an advantage for women when pension reforms increase the number of quarters that must be worked for entitlement to a full pension, but not when the reforms involve raising the minimum retirement age.

domestic tasks and caring for children or other family members. In the United States, for example, Bianchi et al. (2012) reported a decline in the time dedicated to housework by women aged between 25 and 64, from an average of 30 weekly hours in 1965 to about 16 h in 2010.[100] In this same period, the time spent by men rose from 4.9 to 10 weekly hours. Similar trends have been observed in other Western/industrialized countries (Gershuny and Robinson, 1988; Sayer, 2010; Sullivan and Gershuny, 2001), but with differences in magnitude and timing. The decline in women's share of housework was initially sharper in Anglo-American and Nordic countries than in continental Europe, and since the 1990s the change due to men's participation in housework seems to have been greater in "traditional" countries than in "egalitarian" ones (Geist and Cohen, 2011; Treas and Lui, 2013), as has an increasingly positive social perception about men's participation in housework (Geist and Cohen, 2011).

Despite these trends, cross-country differences remain large and, at the end of the 2010s in OECD countries, the remaining national gender gaps in housework were still impressive, even in the most egalitarian countries: the minimum ratio of women's to men's hours of daily housework, in Sweden, is about 1.3; it stands between 1.5 and 1.8 in many other countries, exceeds 2 in some countries such as Ireland and Italy, and it reaches about 5 in Japan.[101] Beyond housework, women also do more other non-market work such as volunteer work and care for nonhousehold persons (Miranda, 2011). All in all, the share of nonmarket work in women's total hours of work (paid and unpaid) was between 60% (Canada) and 74% (Italy) at the beginning of the 2000s. This means that the major contribution to household production of nonmarket services results from women's unpaid work. The reduction in women's housework time (and the fact that this reduction was far from counterbalanced by the increase in men's time) also results in a much lower total time spent on housework, and in turn in the household production of nonmarket services, than 50 years ago. To sum up: Women still do a higher share of unpaid work than men—albeit of a reduced total amount of unpaid work, and men still do a higher share of paid work than women and have increased their participation in housework. There is very little difference between men's and women's total time of work (Burda et al., 2013; Folbre 2009) but still a significant gender difference in the composition of this total amount of work.

That women carry out the lion's share of nonmarket work is not only well documented in statistics and academic literature; it also seems to be a shared perception, as

[100] Time-use indicators are highly sensitive to definitions and methodology, so the figures provided in this introduction for illustrative purposes are not necessarily comparable between different references. Measurement issues are discussed later in this section.

[101] These figures are computed using the OECD data on time-use available from http://www.oecd.org/gender/data/balancingpaidworkunpaidworkandleisure.htm. The original data, from national time-use surveys, are from various years between 2001 and 2011.

suggested by Burda et al. (2013). In a small ad hoc survey,[102] they asked researchers and students in economics and sociology to give a spontaneous estimate of the difference between men's and women's total work in the United States (including paid work and any activity they related to nonmarket work). About 57% of the respondents estimated that men's total work was at least 5% lower than women's, and 25% thought it was roughly equal (differing by less than 2.5%). Since the question started by recalling that men do more market work than women, this means that the respondents estimated the quantity of women's nonmarket work to be large enough to balance out their lower quantity of market work.

As for the gender gap in total work, Burda et al. (2013) found it close to nonexistent over a sample of 27 countries (the positive difference "in favor" of women is statistically significant but small). They identify this state of things as "iso-work," hence "iso-leisure." However, they wonder about "iso-leisure" when men still work more in the market and their earnings, which are expected to determine their relative power in decision making, are still significantly higher than those of women. "Three logical possibilities present themselves. Men have more power, but are altruistic toward their spouses and toward women generally, and do not take advantage of it. Another is that economists' modeling of the household has been incorrect, and market earnings do not generate power in the household. A final alternative is that earnings do generate power, men are not altruistic, but the average man's utility from his market and home work exceeds that of the average woman's from the same total amount of work" (Burda et al., 2013, p. 258). Another source of puzzlement is that "iso-work" and hence "iso-leisure" somewhat contradict the decline in women's subjective well-being observed by Stevenson and Wolfers (2009), especially its decline relative to men while men's and women's relative opportunities have converged rather than the contrary. This decline in women's perception of their well-being relative to men's is itself consistent with Krueger's "U-index,"[103] showing no real trend over the past 40 years except for "a shift away from activities associated with unpleasant feelings" among men (Krueger, 2007, p. 205).[104] These results, together with the final alternative proposed by Burda et al., suggest that men benefit from a better combination of market and housework than women and perhaps, as we explore later in this section, a better quality of leisure.

Beyond iso-work, which means that men's and women's contributions to productive activities are equal, it is then necessary to consider that the structure of "work" remains

[102] The respondents (far from representative) included 663 faculty labor economists, 255 other economists, 210 researchers and graduate students in sociology, and 533 students in an introductory microeconomics class.

[103] The "U-index" basically measures the share of time spent in activities associated with an "unpleasant state."

[104] Note that Aguiar and Hurst (2008), for the United States, found a decline in women's hours of leisure between 1985 and 2005 and that the trend of increasing leisure time for both women and men since 1965 occurred before 1985.

very unequal, with men allocating a much greater amount of time to market work than women. This may matter a lot: a fundamental difference between market work and nonmarket work is that the former provides incomes in money, whereas the latter does not. The time allocated to unpaid (nonmarket) work relative to paid work, resulting in different outcomes for men and women, therefore has important implications in terms of gender inequality.

This section reviews how the gender division of labor is analyzed today, with a focus on unpaid work. We start by examining the productive dimension of households' nonmarket activity, and the way it appeared at the same time around the 1960s in parallel streams of research on household behavior and on the measurement of economic performance. This leads us to examine some of the methodological difficulties encountered when it comes to measuring and evaluating what happens outside the market and how it may affect estimates of gender inequality. Then we review the effects of nonmarket work—mostly women's time—on the economy and on inequality. The remainder of the section is centered on the analysis of specialization within the household, reviewing how recent empirical research analyzes this very persistent dimension of gender inequality.

12.6.1 Nonmarket Work/Household Production

Standard consumer theory considers households as consumers allocating their resources to consumption and leisure and their members as participating in the labor force to obtain the income they will spend on consumption; standard statistics measure the "economy" on the basis of hours of work, monetary incomes, and the volume of goods and services exchanged on the market. Households and the market interact through labor supply and consumption. These representations changed considerably at the turn of the 1960s with the conjunction of two "revolutions"—a new approach to households as producers and recognition of nonmarket activity as a significant dimension of the economy—at a moment when time-use data started to become available on a regular basis (see Juster and Stafford, 1991). This resulted in notable changes in the conception and analysis of economic performances at macro level, in the analysis of individuals' and households' behavior at a micro level, and in the approach to economic inequality, with particular implications for gender inequality. Whether at macro or micro level, accounting for households' nonmarket production (or its counterpart: individuals' nonmarket work) requires time-use data. This raises specific methodological issues, especially the need to define which nonmarket activities are considered as production or leisure and to find a method of evaluating the time devoted to these activities.

12.6.1.1 Two Conceptual Revolutions

The first revolution, founding the "new home economics," concerns the approach to household behavior with a focus on the productive dimension of this activity. In the 1960s, the interest in home productive activity was not new—early research dates back to the 1930s[105]—but the turning point was Becker's (1965) theory on the allocation of time, in his own words: "a basic theoretical analysis of choice that includes the cost of time on the same footing as the cost of market goods" (p. 494). Instead of the household as a consumer, Becker's theory presents the household acting as a small firm, producing a set of commodities obtained by a combination of time (including time spent on consumption) and market goods; it is these commodities, not goods or time themselves, that provide utility. This approach, which turns consumption into production (and utility maximization into cost minimization), also departs from the traditional approach in terms of a trade-off between work and leisure[106]: substitutions between nonmarket and market time and between time and goods are possible, and "leisure" disappears into a general category of nonmarket time. The agent's constraint, or full income, is then a global resource integrating a goods constraint and a time constraint, and time is allocated depending on its cost relative to the cost of goods in the production of commodities. In multiperson households, the allocation of the household's total time includes an additional dimension, since the time also has to be allocated between the household members, but this allocation remains determined by the same principle of cost minimization in the production of commodities. It is then the relative market efficiency of the household members that determines how they will be assigned to market or nonmarket activity, entailing reallocations if there are changes in the household members' relative market efficiency. Becker's approach was criticized on various points,[107] especially for the lack of a distinction between housework and leisure, "a good approximation of the role the husband plays in the production activity of the household but does gross injustice to the wife (. . .) the wife's allocation of time should therefore be analyzed in terms of a three-way division of work in the market, work at home, and leisure" (Gronau, 1973, p. 634).[108] The new "standard" model of household production finally distinguishes leisure from housework within nonmarket time, following Gronau, basing the allocation of

[105] Zick et al. (2008) provided four references from between 1929 and 1954, including Margaret Reid, who is most often cited for her "Economics of Household Production" (1934).

[106] Mincer (1962) had already underlined the need to take nonmarket activity into account to understand the trend in women's labor supply, which he described as "the most striking phenomena in the history of American labor force [. . .] the continuing secular increase in participation rate of females, particularly of married women, despite the growth in real income" (p. 64); this is actually a trend in total contradiction with the standard theoretical prediction.

[107] See Pollak and Wachter (1975) on the additional assumptions needed for the theory to hold, particularly the need of absence of direct utility from the activity of production itself (or "process benefits"; see Juster et al., 1981). Gronau (1977) also argued that Becker's model was about consumption technology, not household production.

[108] Mincer (1962) had underlined the need to consider "the home-market dichotomy within the world of work" in the analysis of women's labor supply and the family context of decisions regarding labor supply, home production, and leisure.

time within the household on a principle of comparative advantage; we examine later in this section what this implies in terms of the division of labor between men and women.

The second "revolution" happened in the measurement of economic activity, with the recognition of the need to complete conventional measures focused on market goods and market time to take into account households' nonmarket activity. Another limit to conventional aggregates, underlined in gender studies, is that conventional measures neglect a large share of women's contribution to the economy.[109] The revolution took some time, from the 1960s and a growing concern about the shortcomings of the GDP (gross national product [GNP] at the time), to 1993, when the revision of the System of National Accounts introduced the idea of satellite accounts to "enlarge the concept of production to include household production of services for own use" (UN Statistical Commission, 1993). The idea became an explicit recommendation at the UN Conference of Beijing in 1995 (UN, 1995).

The shortcomings of conventional measures of economic activity were the focus of a conference on "The measurement of economic and social performance" held by the National Bureau of Economic Research (NBER) in 1971. In the introduction to the volume of contributions, Moss (1973) speaks of the GNP as "under attack" for neglecting the negative externalities of growth or failing to provide "appropriate measures of economic performance of households and governments." One of the propositions emerging from this conference, and much debated, was to develop accounts for households' nonmarket productive activity based on the measurement and evaluation of households' time. Gronau (1973) proposed an evaluation of "housewives' time." Nordhaus and Tobin (1973) proposed a more encompassing extension, integrating nonmarket time, including leisure, into a "measure of economic welfare." For 1965 in the United States, their lowest estimate for nonmarket activity represented about 42% of the GNP, and their lowest estimate for leisure was about equal to the GNP (Nordhaus and Tobin, 1973, p. 518). Forty years later, the debate is still open, as illustrated by the recent report of the "Commission for the Measurement of Economic Performance and Social Progress" (Stiglitz et al., 2009). Referring to the same shortcomings of the conventional measures as the NBER conference of 1971, the 2009 report recommends "broaden[ing] income measures to non-market activities." The extensions discussed are still intended to provide a better account of well-being, moving a step further "towards a notion of 'full income'" (Stiglitz et al., 2009, p. 126), especially with the valuation of leisure (p. 131) or the development of measures of subjective well-being.[110] The report specifically recommends

[109] This asymmetrical effect of conventional measures had been underlined by Hill (1979a,b), who explained that the types of nonmarket activities typically carried out by women are not taken into account in the "production for own account" conventionally included in the GDP; hence, as he remarks, "the textbook joke" that the GDP goes down when a housekeeper marries her employer because the output is no longer counted, while the output is counted when a mechanic replaces the family car's engine.

[110] See Fleurbaey (2009) and Decancq et al. (2014), Chapter 2, in this volume .

taking into account the "services that households 'deliver to themselves' such as child care, cooking or parent's education services to children" (Stiglitz et al., 2009, Recommendation 5, p. 14). The 2009 report is, however, not a repetition of the NBER conference of 1971, and at least two points go further: First, it underlines the need to address gender differences in time use and the issue of the distribution of unpaid domestic work within families—a view that was absent from the debates of 1971. Second, it includes an investigation into subjective well-being, a strand of research that has attracted increasing attention since the 1990s and goes beyond GDP not by developing extended indicators, but by changing the units of measurement to account for individual perceptions and affects—this is the idea behind "well-being accounts" or "national time-use accounting" (Kahneman et al., 2004; Krueger et al., 2009).

12.6.1.2 Measurement and Valuation Issues

The two revolutions differ in their scope and implications, but they are connected by the same "subject": housework or its output, that is, the services that households provide to themselves. But nonmarket work is not captured by the usual indicators of participation in the labor force. Being unpaid, it does not appear in individuals' or households' money income; its output is consumed but there is no market transaction, and hence it does not appear in households' expenditure. No market hours, no wage, no money income, no price and a product in unobservable quantity: economists and statisticians, then, are deprived of their favorite measurement kit. Basically, the problem is to define which nonmarket activities should be considered as productive, to measure the time spent on them,[111] and to convert it into money. These questions have been debated for decades, with a focus on the evaluation of "productive" time outside the market—our focus here.[112]

[111] A general difficulty in measuring time is how to obtain detailed and reliable information. Time-use survey practice is beyond the scope of this chapter, but discussions can be found in Juster and Stafford (1991), Hamermesh et al. (2005), and in international guidelines (Eurostat, 2008; UN, 2005). One important issue is the mode of data collection (diary versus other methods); there is a long-standing consensus among experts that the former is preferable (see a recent comparison in Kan, 2008). Sampling is another issue: It is possible to obtain aggregate estimates by surveying only one person per household, but this does not provide useful data for the analysis of intrahousehold allocation of time (see Apps, 2003). Finally, time-use estimates, and hence gender gaps in time use, are very sensitive to the type of household (individuals living alone or in a family, presence of children), age group, and occupation, as well as whether gender gaps are measured between men and women on average or between men and women within the households.

[112] Measurement methodology has been especially debated in experimental accounts of household production (see, e.g., Chadeau, 1992; Landefeld and McCulla, 2000). See a review of various options by Eurostat (2003) and a discussion of these methodological options by Poissonnier and Roy (2013). Note that households' satellite accounts include measures of nontime inputs (contribution of capital services). We also concentrate on "domestic" work rather than "unpaid work" (see Miranda, 2011), which includes nonmarket activity outside the household (volunteer work or services provided to persons outside the household).

12.6.1.2.1 Perimeter

Which nonmarket activities are "productive"? There is no clear theoretical definition, and practice depends on whether measurement is implemented to analyze individuals' (households') behavior or in a national accounting perspective. In the first perspective, the focus is on individuals' (households') activity, especially in terms of choices of time allocation; in the second it is on the product of this activity.

When focusing on individuals' activity, the problem is to distinguish leisure from productive activity within nonmarket time. A first approach is that of the household production model—in Gronau's (1977) revisited version,[113] since Becker's did not distinguish leisure within nonmarket time: "An intuitive distinction (. . .) is that work at home (like work in the market) is something one would rather have somebody else do for one (if the cost were low enough), while it would be almost impossible to enjoy leisure through such a surrogate" (p. 1104). In this view, nonmarket work is different from leisure because, unlike leisure, it does not provide utility directly but only through its outcome (provided the absence of process benefits is assumed, as underlined by Pollak and Wachter [1975]). Other approaches to the contrary, in welfare economics or time-use research, emphasize the "emotional" content of various activities, that is, whether the time spent on it is enjoyed or found pleasant, precisely process preference. Stiglitz et al. (2009, p. 135) evoke this research as a promising way to be able to distinguish between leisure and production in household activities.[114] Folbre (2004) proposes a more encompassing approach to nonmarket work, arguing that the valuation of time does not fully account for the positive externalities—not only within but also outside the household—that can result from it.

The accounting perspective does not rely on a notion of preference or pleasantness but adopts a reference to the output and the market; nonmarket work is generally identified by the fact that it provides services that could have been purchased in the market. According to the literature (e.g., Ironmonger, 1996, 2000; Juster and Stafford, 1991; Zick et al., 2008), Reid (1934) is considered to have been the first to propose what is referred to as "the third party" (or person) criterion: "If an activity is of such character that it might

[113] Gronau's (1977) objective was to explain why changes in wages did not affect husbands and wives work/leisure trade-off in the same way, suggesting that other factors operate: "A wage increase may result not merely in a shift from work at home to work in the market but also in a reduction of leisure—employed women having less leisure than the not employed (. . .). A natural question is to what extent will the labor supply function of married women resemble that of their husbands once they reach similar labor force participation rates. Right now any answer to this question should be regarded as sheer speculation, since so much depends on changes in role differentiation and reallocation of work at home within the family" (p. 1117).

[114] It is debatable whether this is operational as an aggregate because it would involve moving work/leisure boundaries between individuals. It may also be difficult to combine with material aspects of well-being, for example, to account for the double benefit of enjoying the time spent on market work *and* being paid for it.

be delegated to a paid worker, then that activity is deemed productive" (cited by Ironmonger, 2000, p. 6). This leads to the identification of a set of nonmarket activities broadly including preparing meals, cleaning and laundering, caring for children or other household members, managing the home, repairing the home, gardening and caring or pets, and related shopping and travel.

The various approaches are not necessarily incompatible, and none is completely straightforward.[115] Economic or time-use studies sometimes restrict the perimeter of nonmarket work, for instance, by only keeping routine or "core" domestic work, excluding gardening and pet care (which may have a leisure character) or shopping (its direct relation with the productive activity can be difficult to check). Childcare is often treated separately (one reason being that time cannot be spent on childcare of one's own children in childless households) and sometimes is refined into "active" and "passive" childcare (or primary and secondary, depending on whether another activity is performed simultaneously; see Allard et al., 2007).

Of course, variations of the perimeter (often related to the perspective of the analysis or the issue addressed, as well as to the accuracy of the information on time use) have a significant impact on the "quantity" of nonmarket productive time measured and on the estimate of men's and women's contributions to this quantity or gender gaps in time use. Using the French Time Use survey from 2010 on the population aged 11 and older, Poissonnier and Roy (2013) compared three perimeters. Starting with a restrictive definition limited to core activities (cooking, washing, cleaning, active care of children and dependent adults and related travel time, household management), they obtained a daily average of 2 h 7 min; an intermediate definition, adding shopping, home repair, gardening, and playing with children—or "productive leisure"—results in almost one more hour (3 h 4 min), and an extensive definition, adding driving oneself and pet care, adds about 50 min more (3 h 53 min). In these daily averages, the share of women's time decreases significantly when the perimeter is extended, with values of 72%, 64%, and 60%, respectively. Using the American Time Use survey from 2010 on the population aged from 25 to 64 years, Bianchi et al. (2012) obtained a similar pattern in the ratio of women's to men's time, which falls from 2.9 when the perimeter is restricted to "core" housework to 1.6 for total housework.

These differences reflect the fact that, on average, men and women do not do the same sorts of housework. In short, "women cook, clean and care while men build and repair" says the OECD (2011b, p. 22). Beyond averages, the time spent on housework and care by men and women varies with the composition of the household. Of course, the presence of children has an important effect on the total time spent on care,

[115] Chadeau (1992, p. 89) discusses "borderline cases" that the third party criterion does not solve, for instance, care activities, which are considered productive when performed for a sick or disabled person but not for oneself, although it is the same service.

but it is not the only factor; in the United States, married men and married women spend more time on total housework than the average, and even more on core housework, and women spend more than men; the gender ratio (women's time to men's time) for this perimeter is 3.4 versus 2.9, on average (Bianchi et al., 2012). Parents naturally spend more time on childcare, and mothers spend more than fathers (the ratio is 1.9), but they also both spend more time on core housework than the average married men and women—again mothers spend more time than fathers, signaling that the presence of children tends to reinforce the unequal gender division of nonmarket work (Bianchi et al. 2012). The difference is also pronounced in the detailed activities related to childcare: 60% of mothers' childcare time is devoted to physical care and supervision versus only 45% of fathers' childcare time; conversely, 41% of fathers' time is spent on educational and recreational childcare compared with 27% of the mothers' time (Bianchi et al., 2012). In addition, men's and women's "specialization" within nonmarket work may be weighted differently because of the routine versus occasional nature of the core or other housework (Sayer, 2010) or because of a difference in the emotional content of the activities—a direction explored by Stevenson and Wolfers (2009). "Women's" housework may also be more intensive than men's if several activities can be carried out simultaneously (e.g., cooking and doing the dishes and looking after the children) or interrupt their leisure time (Bittman and Wajcman, 2000; Sayer et al., 2004). Such differences do not count in an accounting perspective but may count in the perspective of measuring and analyzing gender inequality—hence the interest of going beyond the simple measurement of quantities of time.

12.6.1.2.2 Valuation

Once the relevant activities have been defined and the time spent on them measured, the next step is to obtain a value of the time or product. There are two main approaches to this valuation. The "replacement cost" method consists of estimating the price the household would have paid to obtain the same service on the market (or the money saved if the service is produced at home instead of purchased on the market). The "opportunity-cost" method estimates the earnings the person (or the household) would have received if the time devoted to housework had instead been spent working in the market. As in the perimeter definition problem, there is no generally agreed best method, and either might appear more or less appropriate depending on its application.

The opportunity-cost method is generally used in the analysis of intrahousehold organization and decision making and inequality within the household; it is consistent with the methods used for the valuation of leisure. But it is problematic in the accounting perspective because it results in the same output having different values depending on who produced it (Eurostat, 2003; Landefeld and McCulla, 2000). Using the opportunity cost can also be problematic when the producer of the service does not work in the market. This problem has been discussed at length. Gronau (1973) tested two estimates under the alternative assumptions that women who do not work in the market are more efficient in the home sector or less efficient in the market sector, resulting in a price of time respectively higher or lower than the potential wage rate. Bonke (1992) used the individual wage rate in the case of working men and women and the reservation wage for those who do not work in the market. Another direction of discussion is that the opportunity-cost method assumes that the individual would work for pay instead of doing housework, but this approach neglects the fact that market work is often not offered by the hour. The choice may then be between taking a job or not, or between a full-time or part-time job, and then giving up more hours of market work than the number of hours actually spent on nonmarket work. We cannot exclude the possibility that at the individual level, housework might cost more in terms of foregone leisure time than in terms of foregone earnings; while this does not change the valuation at the household level, it maybe not be so in terms of individual well-being.

The replacement cost method has the advantage of being consistent with the "third person criterion": the cost of what is available on the market does not depend on the wage of the person buying it (while of course, this wage is relevant in the choice of doing versus purchasing). Eurostat (2003) distinguished two main approaches to the replacement cost: the "specialist" cost (using the wages of specialized wage workers—a cook in a restaurant, a nurse at a daycare center, etc.—or the cost of specialized services at home—e.g., a private nurse, cleaning person, plumber[116]) and the "generalist" wage (sometimes referred to as the "housekeeper's" wage). In addition, there is the option of using the minimum wage (when there is one). None of these solutions is fully satisfying (see also Landefeld and McCulla, 2000), first, because in the household, several tasks can be carried out simultaneously, while the corresponding service would require several specialized workers; second, some tasks cannot be carried out by "generalist" workers (e.g., fixing the roof). Another possible drawback of the replacement cost method is the need to find market substitutes for all the services the household provides to itself.[117] It is possible that some of these services are specific to the point of not having market equivalents; more generally, market substitutes can be of poorer (or better) quality than homemade products (not to mention the emotional dimension of some domestic or care tasks; see Folbre, 2004).

As with variations of the perimeter, choosing one or another method of valuation can result in wide differences. The opportunity cost always yields a higher value for household production of nonmarket services than any other method. Over a sample of

[116] This may result in higher estimates than in the case of wage workers because it includes other costs than wages.

[117] Gronau (1980, p. 414) also objected that using market prices can be irrelevant when the household does not consume the market service because it assigns to the household production prices that are rejected by the household.

25 countries, it is at least twice as high as the replacement cost (housekeeper rate) in 7 countries, between 1.5 and 2 times as high in 10 countries, and between 1.1 and 1.5 as high in the 7 remaining countries (Ahmad and Koh, 2011; link to data in OECD, 2011b). Landefeld et al. (2009, p. 219) estimated the value of nonmarket household services in the United States using various options. For 2004, the lowest value is obtained using the minimum wage; compared with this value, the "housekeeper's" wage gives an estimate 54% higher, the "specialist" wage gives an estimate twice as high, and the opportunity cost gives an estimate five times higher.[118] At the individual (household) level, the difference between the two values (market price vs. opportunity cost) illustrates the possibility that the increase in money earnings from working for pay instead of producing nonmarket services could be higher than the decrease in the value of home production.

12.6.2 Taking Households' Production and Productive Time into Account: What Does It Change?

As mentioned earlier, one of the aims of measuring household production—responding to long-lasting debates on the limitations of conventional aggregates measuring economic activity,[119] income, or consumption—was to provide a full account of economic and social progress and an accurate basis for the measurement of inequality. At a micro level, the conventional approach, which considers only money income (or expenditure), does not provide a satisfying estimate of the household well-being either because it neglects the actual access to goods and services, which is enhanced by household production. Given the average contribution of men and women to the production of nonmarket services, taking household production into account also allows one to take full stock of the impact of women's work, especially its distribution between paid and unpaid work, on economic well-being. This impact is rather different depending on the perspective: unpaid work reduces inequality among households but, because it is mostly women's work, it contributes to gender inequality.

12.6.2.1 Household Production and the Markets

At the macro level, it has been shown that household production of nonmarket services represents significant shares of GDP: in 2008, from 15% in Canada to 26% in the United Kingdom, with a replacement costs valuation, and from 40% to 68%, respectively, with the opportunity-cost method (Ahmad and Koh, 2011). The shares of household production tend to be negatively linked to participation in paid work in general (see Miranda, 2011), if only because total time is constrained. Very basically, more time in paid work is

[118] The differences between the various options of valuation were less pronounced in 1985, showing that the choice of an option can also affect comparisons over time.

[119] Gronau and Hamermesh (2006) also remark that the interaction between time and goods and its variations (in other words, the demand for more or less goods-intensive commodities) may have additional implications in the relative demand for traded goods at the international level.

associated with more market goods, and less time in paid work (hence more time in nonmarket production) is associated with more household production—even more if one concentrates on women's participation. So as long as there are significant cross-country differences in the distribution of time between work and leisure and, within work, between market and nonmarket work, taking household production into account tends to have an "equalizing" effect in cross-country comparisons of economic well-being. For instance, the disposable income per head is higher in the United States than in France by 21% points, but only by 16 points when corrected for household production (in 2005; figures from Stiglitz et al., 2009, p. 131). Comparing Finland, France, and the United States between 1995 and 2006, Stiglitz et al. (2009) also remarked that the annual growth rates of households' extended income, that is, corrected for household production, are significantly smaller than those obtained without this correction—in other words, not correcting for household production results in overestimating growth in well-being. The same was found by Landefeld et al. (2009) over a longer period (1965–2004) when comparing the growth rate of US GDP and an extended measure including nonmarket household services; they interpreted this as reflecting women's entry into the labor market, which resulted in an increased growth rate of market production, but neglecting its counterpart in terms of reduced household production overestimates the increase in production.

The relationship between household production (i.e., the unpaid time spent on housework and care) and market products depends first on how the population is distributed by household type (especially singles versus families) and on the degree of substitutability between household products and market products. It also depends on whether men's and women's nonmarket time are perfect substitutes in the household utility function, and it has been found that this is not the case. This is one implication of the tests rejecting the unitary model and a result of other precise tests (see, e.g., Browning and Meghir, 1991, who find that the assumption of substitutability is strongly rejected). Previous analysis of labor supply also had shown that men trade market work for leisure, whereas women trade market work for both housework and leisure (e.g., Killingsworth and Heckman, 1986). This may have changed—as we have seen, men's housework time tends to increase (albeit slowly), but all in all, this points to women's allocation of time as the main driver of changes in both labor supply and the relative shares of household products and market products in the consumption of commodities. In turn, changes in the demand for market products have employment effects in the sectors producing market substitutes for home production.

This is the question addressed with the "marketization hypothesis": Freeman and Schettkat (2005) linked the larger amount of time worked in the United States than in the European Union with a more pronounced departure from household production in the United States and the shifts it induces in terms of both "freeing" time and increasing the demand for market substitutes—hence the employment in the sectors producing these substitutes. In turn, the jobs created in these sectors contribute to the increase in women's employment (although this is primarily low-skill employment; see Section 12.3). Freeman and Shettkat showed that the difference between the United States and European countries is mostly attributable to women's allocation of time to paid work versus housework; as the authors remark, "substitution of male for female time in housework is modest" (p. 37), and, in the case of men, the trade-off is essentially between paid work and leisure. A striking difference is the time spent by women on childcare, which is much lower in the United States, where the proportions of children younger than 3 years old in formal daycare is more than twice higher than the average in their sample of EU countries. Other studies (Del Boca, 2002; Jaumotte, 2003; Wrohlich, 2004) showed that childcare availability could be more important to the trade-off between market work and household production than its cost (together with other arrangements that help to reconcile work and family responsibilities; see Section 12.3).

There is also an ongoing debate in time-use research on the interaction between women's entry into paid employment, that is, a departure from housework, and expenditure on time-saving domestic appliances (the "mechanization" hypothesis) or reliance on market substitutes (the "buying out" or "outsourcing" hypothesis). New technologies, assumed to increase the productivity of housework, should allow women to devote more time to paid employment. But various studies have found that, contrary to the intuition, either the time spent on housework remained constant, or "the more technology, the more time spent" (Gershuny and Robinson, 1988, quoting themselves, 1972). Likewise, using the Australian Time-Use Survey from 1997, which also provides information on household equipment, Bittman et al. (2004) did not find a significant effect of ownership of appliances on housework or on its division between genders (it even seems to go with more pronounced gender specialization within housework). As for time-saving services (food away from home, childcare, paid domestic services, laundry services, etc.), Bellante and Foster (1984) found a positive association between women's participation in paid work and buying out, but no relation with the number of hours worked, and most of all a strong relation with the family income. With time use data but a small sample of dual-earner couples, Killewald (2011) found that the relation between the use of market substitutes and housework time (excluding childcare) is, at best, very small (e.g., an increase of 1% point in expenditure on market substitutes was associated with a reduction of 1 min per week spent on cooking and cleaning). All in all, studies provide inconclusive results (see a review by De Ruijter et al., 2005)—probably partly because of differences in data quality and methodologies.

12.6.2.2 Household Production and Inequality Between Households

Across households, studies have regularly found home production to be less unequally distributed than money income (Aslaksen and Koren, 1996; Bonke, 1992; Frazis and Stewart, 2011). This is consistent with theoretical prediction: provided there is no process preference, high opportunity-cost individuals will turn to more goods-intensive consumption and, conversely, low opportunity-cost individuals will turn to more time-intensive commodities and therefore spend more time on household production. Taking into account nonmarket production then tends to result in lower estimates of economic inequality than those obtained with conventional measures of income.

The "equalizing" power of nonmarket work might have somewhat declined over time, as has been suggested over the last decade or so.[120] Returning to the main link between women's allocation of time to market or nonmarket work, it seems obvious that the increase in women's participation in market work goes together with a decrease in household production. However, this may not be completely obvious; one must assume that nonmarket time was not initially totally allocated to leisure (time-use evidence confirms this) or that the increase in market time was not just added to an unchanged amount of nonmarket work (time-use evidence confirms this, too, contrary to what the notion of the "second shift" suggested[121]). Zick et al. (2008) found that, in the United States, the correction due to household production was larger in the 1970s than in the early 2000s. They argued that the shift in women's time from unpaid to paid work has two opposing effects: on the one hand, women's entry into the labor market has slowed the increase in money income inequality; on the other, high-wage women have reduced their housework time more than low-wage women, hence creating an increased inequality across households, which is partly limited by the increase, even if small, in time spent on housework by men in high-income couples. These changes have been reinforced by marital homogamy (high-wage men marrying high-wage women), contributing to inequality between couple households. At the same time, changes in family composition, especially the increase in single-parent households (most often headed by women), have reinforced inequality (see a discussion by Kollmeyer, 2013). These results are consistent with those obtained by Gottschalk and Mayer (2002); comparing the 1970s and 1980s, they also showed an equalizing effect of household production for both periods, albeit larger at the bottom of the distribution.

This highlights the fact that the size of the equalizing effect also depends on the level of inequality in the distribution of households' money income, which is itself influenced

[120] Most comparisons of the distribution of income versus extended income do not take into account household size, or they only consider couples. But some provide estimates for households of different composition (e.g., Aslaksen and Koren, 1996); the size of the "equalizing" effect is larger than that, on average, for multiperson households and households with children. This adds a demographic dimension to the trend of the declining equalizing effect of household production. Note that including household production in a measure of extended income may impact the equivalence scale. This has been examined mainly through the cost of children (see Apps and Rees, 2002; Craig and Bittman, 2008); Couprie and Ferrant (forthcoming) estimate economies of scale in the time allocation of the household.

[121] *The Second Shift* is the title of the very influential book by Hochschild and Machung (1989). Drawing attention to the addition of paid work to domestic work in the 1970s, it nevertheless somewhat overestimated the gap between women's and men's total work.

by women's earnings (a counterpart of the decline in women's unpaid work). This influence is essentially studied through counterfactual experiments: what if women had no earnings, or if their earnings were not unequal? Comparing couples' earnings in 1979 and 1989 in the United States, Cancian et al. (1998) found for both years that including wives' earnings reduced the inequality in family money incomes, that is, inequality would have been larger if wives had no earnings. However, the level of inequality would have been lower than observed in the absence of inequality in wives' earnings.[122] Comparing income inequality in 16 countries in the early 2000s, Harkness (2013) found that first, despite large differences in households' employment structure and the incidence of part-time work among women, the contribution of women's earnings to household income is quite similar across countries—with the exception of the United States, where this contribution is the largest at close to 30% of gross income. Three counterfactuals are examined. If no women worked, household earnings inequality would increase in all countries, most of all in the United States. If all women worked, there would be a decline in earnings inequality. The third counterfactual consists in closing the gender gap (all else unchanged); here, the results are mitigated, with a decrease in inequality in some countries and an increase in others—especially in Nordic countries—but it would decrease among couples. The analysis also underlines the varying effect of women's earnings in different types of households, especially between one- or two-earner couples and between couples and one-person households, especially single women. Beyond the general result, a case study of Italy (Del Boca and Pasqua, 2003) also shows that the "correcting effect" of women's earnings is highly dependent on the level of married women's participation in paid work. Working on a counterfactual "if no women worked," Del Boca and Pasqua found that income inequality would have been much higher than observed (in 1977, 1989, and 1998) in northern Italy, where wives' employment is higher, whereas it would have been comparable in southern Italy, where fewer married women work. They underlined the fact that southern Italy lacks many of the factors facilitating women's access to employment, especially opportunities for part-time work and childcare facilities, resulting in large inequalities in women's earnings. It would be especially interesting to combine these results with an analysis of the correcting effect of nonmarket work because Italy is one of the OECD countries where women's participation in the labor market is the lowest and the amount of housework is the highest (see OECD, 2011b). Unfortunately, no such study yet exists.

[122] Men's earnings also play a role. Juhn and Murphy (1997) explained that the wives of high-wage men significantly increased their participation in employment in the 1970s and 1980s compared with the 1960s, while at the same time low-wage men's earnings decreased sharply and their wives' participation in the labor market slowed (on the contrary, it was faster in the 1960s when their husbands' earnings were also growing quickly).

Nevertheless, despite its probable decline, the equalizing effect of household production remains quite large. Folbre et al. (2013), who compared couples' market earnings and a measure of extended earnings including nonmarket work (valued at the minimum wage[123]) over nine countries, showed that the Gini coefficients with the measure of extended earnings are reduced, in most countries, by about one-third compared with those for the earnings. There is some variation between countries, but the rankings remain fairly stable—except for the United States,[124] where the equalizing effect is the lowest because of the combined effects of a relatively low share of nonmarket work in total work and a low minimum wage (the lowest of the nine countries relative to average earnings).[125]

12.6.2.3 Housework and Gender Inequality

We turn now to the influence of housework on gender inequality. The issue is not only its unequal distribution between men and women per se, but also its consequences on other socioeconomic outcomes. One, pointed out by Becker (1985), is that it may affect women's earnings: "(. . .) the earnings of men and women would not be equal even if their participation [in paid work] were equal" (p. S35). This is not because of discrimination in the workplace but the fact that housework and childcare demand so much energy from women that little is left for market activity—a hypothesis that would save human capital theory from the "embarrassment," in Becker's words ("failure" in the terms of England, 1982), of not explaining gender earnings differentials. Another is that the "pressure of time" may affect women, who have to combine paid work and family responsibilities, more than men; the "dual burden" or "second shift" would then result in a gender gap in leisure (Hochschild and Machung, 1989; Bryant and Zick, 1996). While this gap is almost closed (on average) in terms of overall quantity, recent work points at a gender gap in the quality of leisure time. Ultimately, both approaches suggest that housework and family responsibilities influence the capacity to focus on and/or benefit from what one is doing when not doing housework. If this is so, it may affect gender inequality in ways that conventional measures of individual living standards or well-being do not capture and may contribute to women's disadvantage in economic and social outcomes.

[123] Using the minimum wage is debatable: it may result in under- or overestimation of the value of time, depending on its level; as mentioned earlier, no method of valuation has yet been proved to be better than another, but, because the purpose is to compare households, it would be interesting to test whether other methods (e.g., opportunity costs) might change the rankings.

[124] Finland, France, Germany, Italy, Poland, Spain, Sweden, the United Kingdom, and the United States.

[125] This and Harkness' (2013) results suggest that there can be large differences between what is observed in the United States and what is observed in the rest of the world. Given the large share of US-based evidence in the literature, it is an invitation to be cautious about whether the trends observed in the United States are representative of more general trends, not in terms of a "big picture" but in terms of the magnitude and timing of changes.

12.6.2.3.1 Housework and Wages

According to Becker (1985), women's family responsibilities affect their potential for effort at work because these tasks drain their "energy." The more energy spent on child-care and housework (which he describes as being highly demanding in energy), the less left for the job. Hence, a choice of less demanding and, accordingly, less well-paid jobs or those with lower career opportunities, as analyzed in the literature on the family pay gap since the mid-1990s (see Section 12.3). However, strictly speaking, the family pay gap is an effect of the family status, especially motherhood, not an effect of housework (even if the time spent on housework is not independent from the family status); moreover, the focus is on differences between women. Then arises the question of whether there is an effect of housework that is distinct from the effect of motherhood or family status and of its impact. Following Becker, such an effect should be negative on women's wages; what is slightly unclear, however, is whether this effect operates indirectly, by influencing the choice of hours and type of job (work effort), or directly, by the performance at work (effort on the job) once the occupation, hours worked, and so on have been controlled for. As emphasized by Bielby and Bielby (1988), the notion of "energy" refers not to the quantity of time or the occupation but to the intensity of physical or mental effort required on the job. As for men, the logical complement to Becker's proposition is that married men (or, more generally, men living in couples) should be able to allocate more energy to their work because they do not suffer the same energy-draining home activity as women and they benefit from their wives' housework.

Testing the assumption of an intrinsic impact of housework on wages is difficult because one must be able to measure the expenditure of energy on both housework and paid work, or to control for the jobs' actual requirements (e.g., concentration, precision, availability), and to combine this with accurate information on housework. It also poses various estimation problems, particularly because of the potential endogeneity of wages (wages have regularly been found to influence negatively the time spent on housework) and unobserved heterogeneity (a detailed review of the econometric problems is provided by Maani and Cruickshank, 2010).

A first question concerns the impact of housework on the expenditure of "energy" at work; this was the question asked by Bielby and Bielby (1988). Their test used an index of work effort based on self-reported information on the demands of the job (physical and mental) and whether the actual effort made goes beyond what is required. Their index was designed to avoid a potential gender bias, for example, exhausted women overreporting the job's requirements. However, the authors argue, the sociopsychology literature suggests that women tend rather to understate their performance, so that if there is bias, it is more likely to be in the other direction. Their main result is that, controlling for education, occupation, age and family composition, working time and pay, family responsibilities (responsibility for child, childcare hours, domestic work hours), and whether the spouse works, women did not allocate less effort to work than men. Married women or mothers allocated less effort than single women, but this reduction in effort left them at the same level as men. In the case of men, on the contrary, the hours of housework seem to reduce slightly their effort at work, suggesting a trade-off that did not occur in the case of women: Women's efforts in paid work do not depend on their hours of housework, but men's do. However, the result for men could be a case of reverse causality, that is, men's effort in housework might depend on whether they work in more or less demanding jobs. Another limitation, more likely to affect the results for women, is that the estimation (by a sample of men and women working at least 20 h per week) did not account for possible selection into paid work; it could well be that the most exhausted women do not work in the market. This study by Bielby and Bielby remains, to date, the only study directly tackling the issue of the allocation of effort.

Hersch's (1991) study of the United States was one of the first to examine the effect of housework on wages. Controlling for various job attributes (hardship, autonomy, stress), she found substantial differences between men and women in the frequency of these attributes but no significant difference in the returns to them. Housework (self-reported) had a negative effect on women's wages (not men's), but only as long as the job attributes were not controlled for. Moreover, the negative effect was found only for housework on work days. Since then, almost all empirical studies have found a negative relation between housework and women's wages (see a detailed review of empirical work from the 1990s to the 2000s in Maani and Cruickshank, 2010). Hersch and Stratton (2002), also studying the United States, also found that including housework in a decomposition of the gender wage gap substantially increases the explained part of the gap. However, the size of the effects found is highly sensitive to the estimation strategy; the review of results by Maani and Cruickshank (2010) shows that using ordinary least squares (OLS) yields the highest effects, using instruments and two-stage estimation seriously reduces the effect (but satisfactory instruments are difficult to find), and using fixed effects reduces the effect even more. Moreover, some results differ substantially from the dominant evidence, finding no effect of housework on wages. McLennan (2000) found no significant effect once the endogeneity of time spent on housework was controlled for (using the ideal number of children in her instruments—information that is seldom available); but this result could also be because her results were obtained from a sample of younger men and women (mean ages of 34 and 33, respectively) than in comparable US studies. Hirsch and Konietzko (2013), studying German data, found "no impact at all" of housework on wages; contrary to the majority of other studies relying on self-reported housework time, they used detailed diary data matched with register data on earnings.

A number of studies from the 2000s also examined whether the type of housework tasks, especially their frequency, flexibility, and timing, has different effects on wages. Noonan (2001) and Hersch and Stratton (2002) found that frequent tasks or inflexible tasks—that is, those that cannot be postponed (and are mostly performed by women)—are the main drivers of the negative impact of housework on wages and of its stronger effect for women than for men. When the tasks are not disaggregated, Noonan (2001) did not find any gender difference in the negative impact. Bonke et al. (2005), using Danish data, showed that the timing and flexibility of housework have an impact on wages; using quantile regressions to estimate the wage functions they also found a surprising positive relation between housework and women's wages in the 90th quantile of the wage distribution and a negative effect on men's wages—contrary to their result for the rest of the distribution. The impact of housework also seems to be different depending on the type of working time; for instance, Bryan and Sevilla-Sanz (2011), using British data, found a negative impact of housework on wages except for women working part-time, and Bonke et al. (2005) found a stronger effect for workers whose working time schedule is not flexible.

As for the relation between housework and men's wages, it is less clear, and, when an effect is found, it is weaker than for women. Moreover, Hersch and Stratton (2002), for instance, found that men's hours of housework do not influence the "marriage premium" (see also Section 12.3); but Gray (1997) and Chun and Lee (2001), both using US data, found a negative relation between the hours of wives' paid work and men's marriage premium. At first view, these results seem to be conflicting; on closer examination, they suggest that men's wages are influenced by the amount of housework done by their wives rather than by themselves, which would fit with the view that women's specialization in housework boosts men's productivity in market work. This would also be consistent with the difference in the composition of housework performed by men and women: daily, repetitive tasks (most often women's) can result in more constraints than occasional tasks (most often men's) or tasks that can be postponed. But there is also unsupportive evidence of such an effect. Lincoln (2008) did not find a relation between men's marriage wage premium and the division of housework. More precisely, neither the hours of market work nor the hours of housework performed by wives significantly affect the husbands' wages, but Lincoln found a small positive effect of the hours of housework performed by husbands on wives' wages.

Finally, is there an effect of housework on wages? Empirical results suggest a negative impact of housework on women's wages rather than no impact, and Maani and Cruickshank, 2010 argued that the bulk of results cannot be suspected of being driven only by endogeneity bias and unobserved heterogeneity. Housework would then be a useful dimension to take into account in explaining the gender wage gap. But beyond the issue of econometric problems, the main limitation of existing studies is that most of them, including those published in the 2000s, are based on US data from the 1980s or early 1990s. Evidence from more recent data, and from other countries, would help to clarify the issue. It would also be particularly interesting to analyze more systematically the relation between men's housework and wages, now that they seem to participate more in housework, as well as the impact of housework among younger men and women. The fact that, as mentioned above, no impact of housework was found by Bryan and Sevilla-Sanz (2010) or Hirsch and Konietzko (2013) in countries (Germany and the United Kingdom) where the incidence of part-time work in women's employment is especially high, also call for further investigation.

12.6.2.3.2 Market Work, Housework, Leisure, and Well-Being: Is ISO-Work Equality?

Most of the literature on the effects of housework on time use has stressed that paid work on top of domestic work particularly increases women's burden; this was the message in *The Second Shift* (Hochschild and Machung, 1989), attracting attention to the fact that women's additional hours of paid work were not counterbalanced by an equal reduction in their hours of domestic work, even though the figure they provided of women's weekly hours of total work (paid plus unpaid) exceeding men's by about 15 h on average is highly unlikely, as underlined by Sayer et al. (2009). Whether performed in the market or in the home, work has the same effect of reducing the amount of free time remaining, but some analyses suggest that domestic work (housework and childcare) may affect this remaining time, and thereby men's and women's subjective well-being, in ways that do not appear in the amount of leisure. A first issue is that of the reality of unequal or equal total work. Using the most recent data available from the OECD,[126] it seems that many countries are actually close to iso-work (Table 12.4); in the 16 countries examined, only 5 had a gender gap in total work of more than 15 min per day (in Sweden, the Netherlands, and Denmark, total work seems to be greater among men than among women). However, iso-work covers highly different gender gaps in paid and unpaid work. Japan, where the gap in total work is the lowest, is also the country where the gender gaps in paid work and domestic work are the highest. On the contrary, large gender gaps in paid work do not necessarily result in large gaps in total work, as illustrated by the case of Italy versus Ireland. The next point that can be made from this sample of countries is that the gender gap in leisure is negative in all the countries examined, that is, women have less leisure than men (by only a very small amount in the case of Japan and by an amount smaller than the gap in total work in the Netherlands). Burda et al. (2006) also found lower amounts of leisure for women using data from the early 2000s and, distinguishing between weekdays and weekends, much higher gender gaps in leisure on weekends.

First, this suggests that, contrary to what was implicitly acknowledged earlier in this section (and with all necessary caution, because the computation is based on second-hand data), iso-work does not necessarily mean iso-leisure; in other words, on average, women derive less leisure from each hour of total work than men (see Figure 12.7). Second, the difference between weekdays and weekends (which cannot be examined in the data from the OECD) also suggests that comparing total amounts of time does not reveal all the dimensions of gender differences in time use.

[126] Data available from OECD (2012), updated March 2014.

However, these results "on average" may not precisely capture the notion of "double burden" or "second shift" because this notion refers not to average men and women but to couples and especially to parents—hence only a fraction of the populations examined above. One might expect the gender gaps in work and in leisure in these cases to be more pronounced than on average; in the United States, married women (with or without children) perform more core housework than women on average, and married men perform more noncore housework than men on average (Bianchi et al., 2012). Both married fathers and married mothers carry out not only more childcare than average married men and women but also more core housework (women more than men). The presence of children also has been found to affect mothers' allocation of time to paid and domestic work more than fathers'. Maume (2006), using US data, or Sayer et al. (2009), using Australian and US data from the late 1990s, show that men do not adjust to their partners'

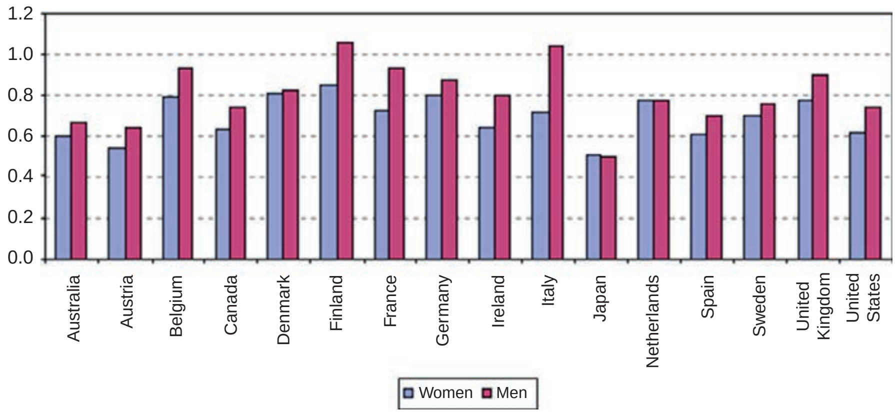

Figure 12.7 Ratio of leisure to total work by gender in selected Organisation of Economic Co-operation and Development countries.

hours of employment; Gershuny et al. (2005), however, using panel data from the United Kingdom, Germany, and the United States, suggest that men gradually adjust their participation in housework to changes in their spouse's employment, even though this does not result in a complete reallocation of housework. Finally, various studies have found that parenthood reinforces a traditional division of labor between spouses (Sayer, 2005 on the United States; Craig, 2006 on Australia; Hallberg and Klevmarken, 2003 on Sweden; Régnier-Loilier, 2009 on France; or Craig and Mullan, 2010 on the United States, Australia, Denmark, France, and Italy). Comparing the United States and three European countries, Anxo et al. (2011) observed that having children causes the "greatest revolution in the time that individuals spend in unpaid work." Change may be underway: Dribe and Stanfors (2009) find a change in the effect of children between the 1990s and the 2000s in Sweden. In a comparison of 20 countries from 1965 to 2003, Hook (2006) found significant changes in men's housework and care that were positively associated with women's participation in market work, and cross-country variations were influenced by the share of women working part-time, the length of parental leave (longer parental leave discourages men's participation), and whether parental leave is available to men. Yet, for the time being, all studies found that women's use of time is more affected by their family status than men's.

In addition to gender differences in the amount of time spent on housework and the possible impact on a gender gap in the amount of leisure, several studies underline that women's leisure time could also be "less leisurely" than men's (Bittman and Wajcman, 2000), or more fragmented and "contaminated" by other tasks (Mattingly and Blanchi, 2003). Multitasking is also more prevalent among women than men and substantially increases the time spent on housework (Craig 2007; Offer and Schneider, 2011); while it makes it possible to squeeze more activities into a same span of time, it may contribute to feelings of time stress. All these analyses point to the pervasive nature of "family responsibilities"—still, today, more incumbent on mothers than fathers—which fits quite well with Becker's view of energy-draining activity, but more in the sense that women (mothers) do not benefit fully from their leisure time than that it prevents them from participating in market work.

Analyzing the quality of leisure requires detailed data not only on the primary use of time but also on secondary activities to detect simultaneous activities and whether leisure is actually a time free of constraints; it also requires reliable measures that are available only from detailed individual data (see a comparison of measures, and subsequent invitation to caution, by Lee and Waite, 2005). Bittman and Wajcman (2000) resorted to notions of "pure" and "adult" leisure, that is, excluding a secondary nonleisure activity, and measures of the length and number of leisure episodes and whether children are present during these episodes. Using Australian diary data from 1992, they found that men have an advantage in all of their indicators of leisure quality, most of it related to the presence of children, and the fact that parents specialize in different types of care: mothers in primary care and fathers in more leisurely care (see Miranda, 2011). Mattingly and Blanchi (2003) obtained similar results using US diary data from 1999. They also observed that men's leisure time with children is more often spent in the presence of others, whereas women's is more often a time spent alone with their children, and that free time is more correlated with reduced feelings of time pressure among men than among women. Focusing on multitasking, Offer and Schneider (2011), using US data collected using beepers,[127] argued that it may allow spouses in dual-earner families to spend more time and more enjoyable time together with their children but, again, that mothers are more likely than fathers to multitask in the presence of children. Their data do not accurately represent all families in the United States (and constitute a rather small sample), but they have the advantage of including measures of emotional state over the day being surveyed. Controlling for work and family characteristics, they found that subjective well-being is positively affected by multitasking in the presence of one's spouse and that feelings of work–family conflict among mothers are reduced when multitasking in the presence of children.

Finally, does housework affect perceived well-being differently for men and women? Very few data sets provide reliable measures of both time use and information that allow one to compute any measure of subjective well-being (feelings of stress, perceived time pressure, or dissatisfaction). Consequently, empirical results are obtained using rather unreliable measures of either the dependent or the key independent variables, making it difficult to answer the question of the impact of housework. Among the small number

[127] This method of data collection (the experience sampling method) consists in providing participants with programmed beepers that randomly ask the respondents to indicate what they are doing, where, and with whom, and in this case how they were feeling, several times per day over 7 days.

of studies addressing the issue, two use a measure of time stress (how often the respondent feels rushed or pressed for time), and obtain quite contrary results despite very close methodologies: Hamermesh and Lee (2007) studied couples with at least one partner in the labor market (they mention the same results for two-earner couples) in Australia, Germany, the United States, and Korea, using data that provide self-reported (not diary) hours of market work and housework. They find that more hours of domestic work only increases time stress for women, but the effect is only significant in Australia and Germany; the same was found for the effect of the partner's market work. One's own market work increases time stress for both men and women. Time stress also seems to be correlated between the partners.

Using the same dependent variable (time stress) on Danish data for two-earner couples, Bonke and Gerstoft (2007) found no significant effect on time stress of either one's own and partner's hours of housework or of one's own and partner's hours of market work. However, hours of domestic work have a negative coefficient for both women and men, which Bonke and Gerstoft interpreted as a sign that housework acts as a destressor. They used an additional control variable, which they call the "rush hour," measured as the length of time between market work and housework at the end of each day (excluding commuting time); a short length of this time is interpreted as a sign of time pressure. When this variable is introduced, hours of housework become significant for women; they analyzed this rather unexpected effect as possibly reflecting women's "preferences" for housework because of their "more family-oriented perspective" (p. 58) and speculated that it gives support to the idea that the work–family conflict affects women more than men. The nature of this time between market work and housework, excluding commuting time, seems at first rather unclear; it is not free time—in this case, the results would only imply that less rushed women (or women who have more leisure) feel less rushed by housework; the only other possibility is that it corresponds to "physiological time" (e.g., a shower or a snack).[128]

All the other studies examined (MacDonald et al., 2005, on Canadian data, using a measure of time stress and a measure of satisfaction with work–family balance; Boye, 2009, comparing 25 European countries and using a composite measure of psychological well-being; Mencarini and Sironi, 2012, comparing 26 European countries and using a measure of satisfaction with life) found a negative effect of housework on women's measure of subjective well-being. Overall, with the exception of Bonke and Gerstoft (2007), the studies examined regularly obtain a significant coefficient (of the expected sign according to the dependent variable) on the hours of housework. The results also strongly suggest that while hours of paid work increase time stress (again, except Bonke and Gerstoft, 2007), they are positively associated with psychological well-being or life

[128] This analysis could be an invitation to question the classification of activities between leisure and physiological time.

satisfaction for women, although none of these effects are significant for men. Another interesting result is that once the hours of housework have been controlled for, the presence of children has no significant effect (MacDonald et al., 2005; Mencarini and Sironi, 2012) or a positive effect (Bonke and Gerstoft, 2007, in their specification with the "rush hour"). However, one weakness of these studies is either their dependent variable (time stress is only a partial approach to subjective well-being or satisfaction with life) or their measures of housework (the last three studies reviewed do not use information from diaries but derive their measure of housework from information given by one respondent on the hours of housework in the household and his or her share of it). Here again, more research using appropriate data on both the dependent and independent variables would provide more precise results.

12.6.3 Within the Household: The Persistent Gender Division of Labor

So far, gender inequality in the time allocated to paid and unpaid work has just been taken as given. At the end of this section, we turn to a last but no less important question: Why do women do more unpaid work than men? We start with an overview of the economic and sociological approaches to the division of labor within the household and then examine how empirical research has, since the 1990s, also focused on the question of why, when so much has changed in women's market activity, so little seems to have changed in men's domestic activity. A last part addresses the issue of the "quiet" but unfinished revolution using comparative research.

12.6.3.1 An Overview of the Theoretical Background: Approaches to the Division of Labor Within the Household in Economics and Other Social Sciences

There is no shortage of theoretical tools to analyze the division of labor: economic theory uses rationality, other social sciences focus on power relations, and both use social norms. Whether grounded in economic theory or other social sciences, they are not mutually exclusive; beyond the difference of perspective there is a strikingly large number of common features—and predictions.

12.6.3.1.1 The Economic Approach: Specialization and the Allocation of Time to Paid and Unpaid Work

In economics, the basic framework was introduced by Becker's theory of household production (see Section 12.6.1), in which the household members (henceforth we speak indifferently of spouses or partners) allocate their time according to their relative market productivity to maximize the household's full income. How time is allocated is not a question of gender (Becker, 1985) but of efficiency—a choice of technology (Lundberg, 2008; Pollak, 2013; Pollak and Wachter, 1975). Each spouse specializes in the activity (market work or housework) in which they have a comparative advantage. Moreover, Becker (1965) argued, no more than one member of the household should work in the market. This is a rather extreme view of specialization, which may have been an idea of the American family back in the early 1960s, but is not very operational nowadays (in particular, it is very difficult to interpret part-time work in this conceptualization: Is it specialization or nonspecialization? Is it expected to be efficient or inefficient?). Comparative advantage is in principle not "gender," but Becker's analysis is somewhat unclear when it comes to women's "intrinsic" advantage, their "biological commitment to the production and feeding of children," completed with a rational consumer's behavior—that is, expecting returns to one's investment and adding a productivity argument: it is quite easy to produce additional children while nursing those already born (Becker, 1991, pp. 21–23).

Becker's approach to the family has been criticized at length (see Section 12.2), and we will not develop the argument further. However, one particularly problematic aspect is that, depending on the point of view, spouses are sometimes assumed to be perfect substitutes (if they are equally productive in the market) and sometimes not (because of the "natural" advantage women have in childcare). A critical point in the perspective of gender (in)equality[129] is that, in principle, how time is allocated to market work or housework does not depend on whether the person is a man or a woman, and that the link between the allocation of time and efficiency is conceived at the level of the household as a whole. From an individual point of view, is it rational to specialize in housework? It depends essentially on whether income pooling and sharing is such that each household member gets their fair share and whether they stay together—or move to another household. Marriage as a formal commitment is then an important condition of stability; the distribution of income within the household is another. Grossbard-Shechtman (1974), in line with Becker (1973), proposed a view of marriage as an exchange of housework based on the comparative advantages of the partners; Grossbard-Shechtman (2003) introduced a notion of quasi-wage as a means to share the gains of specialization; at the equilibrium, the husband's supply of market work equals the wife's demand, which depends on the opportunity-cost of her time in housework.

In nonunitary models, earnings (precisely, wages as prices; see Pollak, 2005) and relative earnings are among the determinants of the spouses' bargaining power or threat point, depending on the model (see Section 12.2); power relations are made explicit instead of technology. Introducing household production does not fundamentally change the underlying principle (Apps and Rees, 1997; Browning and Chiappori, 1998; Chiappori, 1997), but unpaid work can be analyzed as a source of bargaining power exchanged for consumption/resources. This is difficult to test, however, because there are no data on individual consumption/expenditure. An empirical alternative is to

[129] Another is that of the necessity of specialization for the outcome to be efficient. See a discussion by Pollak (2013).

consider leisure as the outcome (e.g., Beblo and Robledo, 2008; Browning and Gørtz, 2012; Couprie, 2007; Datta Gupta and Stratton, 2010).

To sum up, the main prediction of the economic approach is that, one way or another, wages and housework should be negatively correlated, either because an increase in a spouse's earnings results in a reallocation of time from unpaid to paid work (time-consuming commodities become more costly and household production decreases) or because an increase in a spouse's earnings results in an increase in his or her relative power. This relation from wages to housework, together with the possible relation from housework to wages (see Section 12.6.2.3.1) looks like a chicken-and-the-egg question: If domestic work impairs labor market outcomes and poor labor market outcomes imply more housework, this is rather depressing from the perspective of gender equality. The issue has been addressed in a few theoretical models (e.g., Albanesi and Olivetti, 2009; Attanasio et al., 2008; Cigno, 2008; Francois, 1998; Ishida, 2003), all of which conclude that policy interventions can break the vicious circle.

12.6.3.1.2 Sociological Approaches to Housework Time: Dependence, Power, and Gender

A major difference between the economic approach and other social science approaches is their scope; while the economic approach provides a framework to analyze the allocation of time between paid and unpaid work, these approaches seek to explain the time of housework. Two main theoretical approaches are generally identified in the literature: "time availability" and "resource exchange" theory.

The approach in terms of time availability (Coverman, 1985; Hiller, 1984; Shelton, 1992) considers that housework time depends on the time left available to each spouse after deduction of their time of paid work. It therefore takes paid work to be quasi-exogenous. The underlying model is a unitary model, that is, the spouses are motivated by the interest of the family. One weakness is that the time spent in paid work may depend on factors that contribute to the division of housework, especially children.

Resource exchange theory basically posits that the organization of the household depends on the relative power of the spouses, which is itself determined by the resources they bring to the marriage (Coleman, 1988; Kamo, 1988; Safilios-Rothschild, 1970, 1976).[130] This approach allows for an unbalanced interdependence; in other words, A's utility may depend on B's resources more than B's utility depends on A's resources. Moreover, this unbalanced relationship allows B to impose decisions on A. Sticking to the perspective of the distribution of housework, resource exchange means that the spouse who brings in more money income (or other resources) is expected to provide

[130] The focus here is on the allocation of time to housework. Resource exchange theory is not limited to this issue and has many other applications in sociological approaches to family organization and marital power, in feminist theory, and in gender inequality in general, which are beyond the scope of this chapter.

economic support and to obtain, in exchange, more housework from the other spouse—this is the basis of the approach in terms of "dependence" (Brines, 1994) and a formulation of the "male breadwinner" model.

While the scope of the resource exchange approach is not the same as that of the economic approach, resources exchange, rational specialization, and the collective model all link the domestic sphere and the market in one way or another. The underlying principle of interdependence brings the collective approach and the resource exchange approach especially close together, and both rest on two basic principles: first, that the allocation of time (housework) is related to the partners' bargaining power, and second, that a form of income (earnings, wages, possibly assets) plays an important role in determining the spouses' respective bargaining power. As for the explanation of housework time, the three approaches predict a direct or indirect interaction between the spouses' relative resources, more precisely that the amount of domestic work carried out by one spouse should decrease if his or her wage/earnings/bargaining power increases and vice versa. This prediction has not systematically been obtained in empirical work, leading research in a third direction: the influence of social norms.

12.6.3.1.3 Social Norms: Doing Gender and Identity

Since the widely cited article by Akerlof and Kranton (2000), using social norms to explain economic behavior has become increasingly frequent (Davis, 2006). The concept of identity helps to explain behavior that may at first seem to deviate from economic rationality in the sense that individuals make choices resulting in apparently poorer outcomes than if they had made other possible (rational) choices (see Section 12.3). From the perspective of housework, their identity model allows for an asymmetrical relation between the share of paid work and the share of unpaid work carried out by spouses if social norms prescribe that a man should earn more than his wife—and should not do a woman's work (i.e., housework). In this framework, the cost in terms of "male identity" of earning less than one's wife (a deviation from the norm) helps to explain why lower-earner men do less housework than their wives (and conversely why higher-earning women nevertheless do more housework than their husbands).

The same idea, albeit not in terms of utility function, was developed earlier by West and Zimmerman (1987) in an influential article entitled "Doing Gender"—almost a trademark in time-use research on wages and housework time (see the survey by Coltrane, 2000). West and Zimmerman highlighted the social dimension of gender roles and used the example of housework as typical of an activity socially perceived as "women's work"; hence, for a woman, doing the housework is conforming to the social norm of what a woman should do—whatever her wage might be (South and Spitze, 1994, provide one of the first quantitative applications). "Doing Gender" posits that gender (understood as socially defined gender roles) can have an effect even in the absence of unequal resources in the same way as the identity model suggests that individuals can choose actions that seem irrational from the point of view of their economic outcome. It is only recently that both articles have started to be cited in the same articles—another case of parallel strands of literature addressing the same questions but not communicating with each other.

A last approach related to social norms, known as "gender ideology," links intrahousehold arrangements to attitudes about work and family roles.[131] The distribution of housework resulting from these attitudes defines various categories ranging from "traditional" to "egalitarian" and predicts essentially a positive relation between traditional gender ideology (i.e., the male breadwinner model) and women's housework time (and, conversely, a negative relation with men's housework time).

12.6.3.2 An Overview of Empirical Results

As we have seen, the theoretical toolkit available for empirical work offers many options. However, this multitude of options can be a problem because of the similarity of many of their underlying ideas. Sociological approaches in terms of relative resources, gender ideology and time availability seem to find support in research on the US (Davis and Wills, 2013); but explanations in terms of economic dependence seem challenged in cross-country comparisons (Davis and Greenstein, 2004). All posit that spouses' allocation of time to housework should vary according to their relative market productivity (measured by their relative wages) or their relative power (measured by their relative earnings or bargaining power) following a unique pattern: more housework should indicate less power, more power should result in less housework, and partners' behaviors should be symmetrical. But beyond the broad pattern, things can be less straightforward. First, from an economic point of view, a change in the relative wage rates or relative earnings of the partners has not only an effect in terms of power but also a substitution effect and an income effect; second, the relation from wages/earnings to housework can be mitigated by gender or identity effects.

12.6.3.2.1 Some Methodological Issues

Beyond broad similarities, empirical studies differ considerably in their methodologies (see Table 12.5), including the dependent variable, which most often is hours of housework but sometimes the share of housework. Housework is defined in more or less inclusive ways; however, most studies exclude childcare. The explanatory variable of main interest can be the partners' relative earnings or a measure of the woman's contribution to the couple's earnings, most often as a measure of economic dependence (following the

[131] A related approach is developed in Hakim's (1998, 2000) "preference theory", but this mostly aims to explain women's participation in paid work. In particular, she suggests that preferences may explain why, despite different social structures and social policies across European countries, the patterns of women's participation in the labor market are so similar. She provides a classification of women in three groups (home centered, adaptive [the majority], and work centered), which has led to much debate (e.g., McRae, 2003).

Table 12.5 Methodological differences in investigations of the determinants of housework time

Author (year), country	Data	Hours	Population	Perimeter	Measure of hours	Main independent variable
Brines (1994), United States	CS 1983–1985	Self-report	Couples Age ≥18 in 1983	No childcare	Amount weekly	Dependence[a] (current and long-term)
Greenstein (2000), United States	CS 1987–1988	Self-report	Couples Age <65	No childcare	Amount weekly	Dependence

[a]Sorensen and McLanahan's (1987) measure.

measure proposed by Sorensen and MacLanahan, 1987),[132] or absolute earnings, or relative wages. The sample of couples can be more or less restricted according to age or employment status; sometimes, it is not a sample of couples but a sample of married men and women. Most data sets are cross-sectional or use a cross section of panel data.

As always with time-use data, measurement is a serious issue (see earlier in this section), especially considering the difference between self-reported hours and diary data and the definitions of housework (e.g., Coltrane, 2000; Sullivan, 2011). Measurement error is also very likely because few (if any) data sets provide reliable information on both time use and earnings or wages. In particular, many results are based on self-reported housework time,[133] and it has regularly been found that this results in under- or over-reporting. Finally, issues of unobserved heterogeneity are also very likely to arise.[134] A last point to be clarified is that most empirical work describes variations across couples, not changes within couples[135]; the effect of relative power or wages is inferred on the basis of the observed distribution at one point in time.

12.6.3.2.2 The Case of "Doing Gender"

Most of the existing empirical work can be related to Brines' (1994) finding of a nonlinear relation between partners' relative resources and their hours of housework. Basically, wives' hours of housework are negatively related to their relative resources (i.e., the larger their contribution to the couple's earnings, the lower their hours of housework), and husbands' hours of housework are not really affected, but only up to the point where their wives' relative resources become larger than their own, that is, the point where they become dependent on their wife. Past this point, husbands do less housework than their wives. Brines analyzed this asymmetry as "gender display." Since then, a large strand of research has focused on what happens when a wife has greater resources than her husband, confronting the "dependence"/"relative resources" approach and the "doing gender"/"gender display" approach. The type of pattern observed by Brines has been found quite regularly for the United States (Bertrand et al., 2013; Greenstein, 2000; Evertsson and Nermo, 2004; Schneider, 2011), in Spain (Alvarez and Miles, 2003; Sevilla-Sanz et al., 2010), in Australia (Baxter and Hewitt, 2013; Bittman et al., 2003), and in Sweden (Halleröd, 2005). The interpretation is that a deviance-neutralization

[132] (Woman's earnings − Man's earnings)/(Woman's earnings + Man's earnings).

[133] Sometimes even reported by only one spouse for both partners.

[134] For instance, the marital status. Various studies show that married or cohabitant couples do not adopt the same financial organization (see Section 12.2); cohabiting and married couples also have been found to differ in the division of labor (Baxter, 2005; Davis et al., 2007; Domínguez-Folgueras, 2012; South and Spitze, 1994), as have couples married after cohabitation (Batalova and Cohen, 2002; Baxter et al., 2010). This suggests selection effects (see Barg and Beblo, 2012) that are most often not accounted for.

[135] This would mean being able to observe whether, within couples, changes in one partner's resources result in changes in the distribution of housework time.

process occurs, with the wife exaggerating her "woman's work" or the husband reducing his contribution—"inflection points" have been found from 50% to 75%—and husbands, or wives, contribute more or less in neutralizing the deviance. For the United States, Brines and Greenstein found that it is rather husbands who contribute, but Schneider found that it is mostly wives; for Australia, it seems to be wives.

The broad picture is that husbands' and wives' housework time is believed to result from the combined effects of relative resources and gender; as long as wives remain the lower earners, relative resources operate, but more strongly for women than for men (men's housework time is generally found to be rather flat). Past the point of deviance, gender talks, and men, or women, act to neutralize the gender deviance. But it seems that this result is not systematic. For instance, Evertsson and Nermo (2004) obtained the standard result for the United States in 1991 but not in 1999. For Sweden, they did not find that higher-earner wives did more housework, but among two-earner couples with children, Halleröd (2005) found that dependent husbands tended to do less housework; moreover, a significant share of husbands with lower market productivity than their wife nevertheless had higher earnings: instead of doing more housework, they worked longer hours.

The scope of a "gender-deviance neutralization effect" has been much questioned since the mid-2000s on other grounds than (sparse) cross-country evidence, starting with serious methodological drawbacks highlighted by Sullivan (2011). England (2011), drawing on later research on the United States and Australia, argued that focusing on the point where the wife out-earns the husband resulted in "missing the big picture." Several limitations have been underlined.[136] First, the "gender-deviance neutralization effect" is at best very small, both in magnitude and because of the small share of couples above the inflection point (for instance, only 4% in Australia, according to Baxter and Hewitt, 2013). Second, the neglect of absolute earnings leads to confusion between higher-earner wives and high-earning women (Gupta, 2007). Third, related to the neglect of absolute earnings, the relation between earnings and housework is not the same for low-earning wives and high-earning wives, partly because high-earning wives have already reduced their hours of housework and outsourced many basic tasks (Killewald and Gough, 2010).

12.6.3.2.3 Changing Patterns?

Contrary to the broad picture conveyed by the previous results, with husbands either not responding to changes in the economic status of their wives or husbands or wives resisting their threatened gender identities through the performance of housework, other research based on longitudinal data or using wages instead of earnings provides a more nuanced picture.

[136] Including methodological drawbacks (measurement first), but also mis-specification, which can account for spurious results (see Sullivan, 2011).

Comparing Denmark, the United Kingdom, and Spain, Esping-Andersen et al. (2013) found a significant relation (with the expected sign) between spouses' relative wages and men's paid and unpaid work in the United Kingdom and Spain but not in Denmark. The division of labor across couples is also more heterogeneous in Spain and the United Kingdom than in Denmark. Rather than lending support to an interpretation in terms of "doing gender," they suggested that this is an indication of more or less stable and widespread equilibrium related to different stages of the "ongoing revolution of women's roles." The ongoing revolution involves adaptations in men's roles, too. Gershuny et al. (2005), using longitudinal data, analyzed whether spouses' allocation of time to housework responds to a change in employment status; they found that, when the wife starts a full-time job, both wives and husbands (but more slowly) adjust their time of housework, resulting in an increase in the housework carried out by the husband. Also using longitudinal data, Evertsson and Nermo (2007) found that changes in spouses' relative resources between 1991 and 2000 had a small negative effect on wives' share of housework, mainly because of an increase in husbands' time spent on housework, resulting in men doing a larger share of the (smaller) total amount of housework.

Studying French parents' simultaneous time adjustments to differences in wages, Bloemen and Stancanelli (2014) found that for fathers and mothers, own market and nonmarket hours are related in the expected way to their own wages. They also found a negative relation between the father's wage and the mother's market hours, but no significant relation between the father's wage and the mother's nonmarket time. Mothers' hours of paid work then seem to depend on the partners' relative market productivity, but their hours of housework depend only on their own market productivity, and their parental time does not seem affected by their wage. Father's parental time, however, seems responsive to their wife's wage; in other words, mothers cannot increase their housework/childcare hours further, but fathers can, suggesting that a continuing trend of reduction of the gender wage gap could result in a reduction in the gender housework and childcare gap. Focusing on childcare in the United States, Connelly and Kimmel (2009) found that both spouses seem to adjust their childcare time to their partner's paid hours or relative wage on weekdays—but not on weekend days—suggesting substitution effects. In the United Kingdom, Kalenkoski et al. (2009) do not find such an effect: men's time use seems rather unresponsive to their wife's and even their own wage, but there is a significant positive association between their own wage and their time of primary childcare on weekend days.

Taken together, these results suggest that another social norm, under which housework or childcare is not a marker of gender identity, could be emerging. This is a possible interpretation of results from research into the divergence between spouses' reports of their own and partner's hours of housework. As mentioned earlier, self-reported housework time is particularly likely to be biased by overreporting, and it has regularly been found that both men and women are prone to overreporting (Coltrane, 2000; Kamo, 2000). Comparing self and partner's reports in 35 countries, Geist (2010) showed that there are considerable cross-country differences in the disparities in reports of both men's and women's housework time, including for the division of housework in specific tasks. She found that discrepancies are stronger for men's housework hours than for women's: men self-report more hours of housework than their partners say that they do, whereas the difference is much less pronounced in the case of women. Kamo (2000) argued that such discrepancies are related to frustrations and social desirability, which brings us back to norms. Geist (2010) suggested that men overestimate their own contributions to "fit better the model of a supportive husband, even though they may not do much work at home"; however, she also found that discrepancies are greater in countries where the overall time of housework is higher. Treas and Tai (2012) also found that men emphasize shared household management but that shared decision making is more prevalent in more egalitarian countries, where women's participation in the labor market is also higher. These findings fit rather well with the analysis by Gershuny et al. (2005) or Esping-Andersen et al. (2013) in terms of lagged adaptation and changing equilibrium.

12.6.3.2.4 Changing Contexts

While most of the empirical research on intrahousehold organization has focused on individual-level (or household-level) explanations, as soon as a comparative perspective is adopted it is obvious that contexts matter. There are actually few reasons to think either that what happens within households is completely unrelated to a broader environment or that "gender" talks universally. Many researchers share the idea that comparative perspectives—across comparable countries—is central to a better understanding of what shapes the patterns of labor division within households. Some even argue that it is more important than individual-level factors (Treas and Lui, 2013). Whether it is more or less important can be debated; however, virtually all comparative research observes that patterns of the division of labor in couples differ across countries, generally according to welfare regimes and the impact of public policies on the work–family balance (Aassve et al., 2014; de Henau et al., 2013; Fuwa and Cohen, 2007; Geist, 2005; Gornick and Meyers, 2003; Hook, 2010; Ruppanner, 2010; Sayer, 2010). Whether referring to Esping-Andersen's (1990) typology of welfare states or another type of clustering, all found that greater gender equality, in terms of labor market participation and access to individual rights not mediated by the family structure, is associated with more equal/less unequal sharing of housework within couples.

In terms of policies, the main focus is on those that facilitate mothers' participation in employment, essentially the provision of public childcare,[137] parental leave policies, and

[137] High-cost childcare raises two different issues. The first involves inequality between high-income and low-income families because the former but not the latter can sidestep the issue. The second is a lingering question about who pays for childcare (the same question can be raised more generally about outsourcing); in terms of opportunity costs, the outcome of women's labor supply is implicitly weighted as their wage net of childcare costs. To what extent do women actually pay for the arrangements that allow them to do paid work?

policies aiming to increase fathers' participation in childcare (see Section 12.3).[138] On average, childcare is not the largest component of housework time, but having children, in addition to the immediate changes induced (see Anxo et al., 2011), has probably the most pervasive effects in shaping routine housework organization. Childcare policies are therefore a means of influencing what happens within the private sphere both directly—and policies aimed at fathers may reinforce their impact—and indirectly, by their effect on mothers' participation in employment and access to full-time employment.

However, childcare policies are only but one factor contributing to gender equality in the home. Analyzing the case of Portugal—in a rare comparison of southern European countries—Tavora (2012) showed that a high employment rate such as that in Portugal (one of the highest among European countries) can remain associated with very unequal sharing of housework(see Section 12.6.2). In addition to childcare policies, taxation and tax schemes—through their effect either on access to an independent income (de Henau et al., 2013) or on the labor market participation of a "second earner"—also influence how housework is shared within the household by changing the partners' relative resources. However, even though the sharing of housework depends on gender (in)equality in general (Fuwa, 2004), even in the most egalitarian countries, housework does not seem to be equally shared (Aassve et al., 2014; Geist and Cohen, 2011). Whether this is a case of lagged adaptation (Gershuny et al., 2005), incomplete revolution (Esping-Andersen, 2009), or stalled revolution (England, 2010) remains an open question. As for the impact of State policies, Dex (2010) underlines that the main changes seem to have produced policy changes rather than the contrary.

This section has examined gender inequality in nonmarket work, the other side of the considerable changes related to the rise in women's participation in the labor market and increased commitment to paid work over recent decades. On the one hand, these changes have generated tensions referred to as "second shift," "dual burden," and then, increasingly, "work–family balance" (or work–family reconciliation). On the other hand, they also result in increased economic independence, which has transformed women's opportunity sets within and outside the household and the economic foundations of marriage because there are fewer economic incentives to marry (see Lundberg and Pollak, 2013). These changes have also—to a greater or lesser extent in different countries—transformed the terms of gender (in)equality in general and the basis of intrahousehold allocations of time and money, with several broader social and economic consequences. Breen and Cooke (2005) proposed a game theoretical model in which threat points can be divorce or fertility within marriage; the outcome depends on whether men

[138] Another related issue, not addressed in this chapter, is that of eldercare, which has been variously found to affect women's participation in employment and working time (e.g., Kotsadam, 2011; Lilly et al., 2007; Spiess and Schneider, 2003). We have not examined it here because eldercare is rarely identified in time-use research (and often not measured as housework because it is often provided to people who do not live in the household).

prefer to live with an economically independent woman at the price of doing more housework or divorcing. Several researchers have pointed out the consequences of gender inequality in terms of fertility (e.g., Craig and Siminski, 2011; de Laat and Sevilla-Sanz, 2011; Haan and Wrohlich, 2011).

Picturing couples as battlefields, with each partner fighting to maintain or increase their relative power/earnings (possibly resulting in both of them overworking) is no more realistic than picturing them "doing gender" over the dishes. One possibility is that women have changed faster than contexts, norms, and conceptual tools. As underlined by Gregory (2009): "With women's progress in the labor market already undermining the basis of the Beckerian approach to the division of labor within the household, economic analysis will increasingly need a new paradigm for analyzing gender inequality" (p. 307). The same applies to sociological analysis.

It is a challenge, involving analysis of the difficult level of observation of the "intrahousehold" and conceptualization of the interactions between men and women within the household, between social norms and individual behaviors and contexts. The increasing availability of time-use data will be crucial for such progress, under two conditions: one, which is essential, is that time-use surveys include more than one respondent per household; the other is to find ways to improve non-time-use information, especially about incomes and wages, to escape the trade-off between reliable time-use information or reliable information on market wages.

12.7. WEALTH AND GENDER

Wealth inequality is an important dimension of economic inequality and an increasingly important driver of inequality (Piketty, 2013). Yet economic research has seldom considered wealth inequality between men and women, at least until recently[139]—so seldom that, in their review of empirical work on the distribution of wealth up to the late 1990s, Davies and Shorrocks (2000) cited only one study mentioning a gender differential (an analysis of the composition of wealth portfolios by Shorrocks, 1982). This reflects that research on wealth inequality considers essentially household wealth and hardly ever ownership within households. But does ownership matter within a household? Some assets such as a home or a car are a direct source of utility, whereas others, such as savings invested in interest-bearing assets, are a source of income; all are also a security—selling or drawing on one's savings helps to cope with variations in income. Then, one might answer that who owns what does not matter much because any member of the household can benefit from the assets held by the others—at least insofar as the household stays together—and the issue of ownership matters less than that of income sharing. But the distribution of assets between spouses may affect their relative power in decision making and the intrahousehold distribution of income, and household disruptions can make who owns what matter a great deal.

[139] See an overview of existing research, including in law and history, in Deere and Doss (2006).

What can be expected about a gender gap in wealth? In the perspective of wealth accumulation,[140] inequalities can result from inheritance and persistent differences in the levels and combined effects of incomes (which determine the capacity to save), preferences (which affect the savings rate), and investment choices (which determine the returns to savings). Considering the gender gap in earnings, the unequal labor market attachment of men and women, and a possible difference in investment behavior leading women to make less risky investments than men, resulting in lower returns to their financial savings, it is reasonable to expect a gender wealth gap in favor of men on average. However, because large proportions of men and women live in couples, there is also a "marital" dimension in the process of accumulation that somewhat complicates both the prediction and the assessment of the gender gap in wealth. As for transfers received, while inherited wealth is an important factor of wealth inequality in general, there is nothing in the empirical results examined to suggest a gender differential in the effect of inheritance (including expected inheritance).[141] But this is not the case for other types of transfers related to family disruptions such as divorce and widowhood, the latter "favoring" married women because they tend to outlive their husbands. This illustrates some of the complicated marital dimension of wealth accumulation and gender.[142]

This last section examines the main results from empirical work on gender inequality in wealth. Most of this empirical work is hampered by the lack of information about "who owns what" within households—with a few exceptions. As we will see first, data on individual wealth are imperfect and imprecise, a default that seriously limits the ability to assess the gender wealth gap. The section goes on to examine the main results of analyses of wealth inequality between men and women, and the last part reviews a few results on the distribution of wealth within couples.

[140] On models of accumulation see Davies and Shorrocks (2000).

[141] One could expect that it should not favor men (sons) any more or less than women (daughters), at least nowadays in most rich/Western countries; in continental Europe the prevalent regime is that of egalitarian inheritance (cf. Pestieau, 2003); in the United States and the United Kingdom there is freedom of bequest, but Cox (2003, p. 170) argues that the majority of bequests are shared equally between children. However, there could be less visible differences in gifts, financial support, and so on favoring sons more than daughters (see, e.g., Cox, 2003), but such inter vivos transfers are particularly not well covered by statistics.

[142] The effects of the marital dimension are complex. At the household level, living in a couple enhances the capacity to save and invest (especially in dual-earner couples) because of the economies of scale; therefore, a couple-household is likely to accumulate more wealth than two single households. At the individual level, between spouses/partners, wealth ownership is conditional to the marital status and premarital arrangement, which determine the degree of community/separateness of the assets, women's property rights, and divorce and inheritance law. In addition, "who owns what" may be influenced by the tax regime; dividing wealth within families to escape or reduce taxation may have contributed to the upward trend observed until the 1960s in women's share of wealth in the United States (Harbury and Hitchens, 1977), and, in countries where taxation is separate (e.g., Canada, the United Kingdom) it can be advantageous to divide the assets among spouses.

12.7.1 Who Owns What Within Households?

"Who" owns what within households is rather difficult to identify because, with very few exceptions, surveys collect information on household wealth[143]; surveys typically ask the respondent whether he/she/another member of the household owns such or such an item (and associated debt), then the value of each item if it was sold at the date of interview or elements allowing a value to be imputed.[144] Few surveys provide detailed information about the assets of all household members or whether the assets are owned individually or jointly.

The lack of data on individual wealth is probably one of the most serious limitations to research on wealth inequality between men and women. This is why most of the existing empirical work is based on household-level information and either compares men and women in different types of households (distinguishing single households headed by a man or a woman), divides the household wealth between its members, or combines partial information about ownership (when available) and computes a measure of "individualized" wealth. In our review of recent empirical work (1999–2013) addressing the question of the gender wealth gap,[145] we found very few studies able to make relatively precise individual imputations without making the assumption of equal ownership of all the assets.

In addition to surveys, there are other sources of information on wealth, either register data from taxes on wealth (when such taxes exist) or from estate tax records, but they are not really suitable for the analysis of gender inequality for several reasons. First, because of exemption thresholds, they only cover the upper part of the wealth distribution, possibly biasing estimates by gender if men and women are not evenly represented

[143] The most general approach to wealth is the "net worth", that is, the gross value of all the assets held minus associated debts. The assets generally covered include current bank accounts, saving accounts and saving plans, any type of financial product, life insurance, pension plans, owner-occupied residences and other real estate properties, business assets, durables (e.g., a car) and other tangible assets (such as art collections, jewelry, etc.). Debts include mortgage and other property debts, leasing contracts, consumer credit, etc. In most studies, these items are aggregated in four groups: financial assets, housing wealth, business wealth, and pension wealth.

[144] Measurement error caused by nonresponse and misreporting is an important issue (see detailed reviews by Davies and Shorrocks, 2000; Juster and Kuester, 1991); respondents may be reluctant to disclose information, omit reporting some assets or understate their value, or have difficulties in assessing the value of the assets held (e.g., a house, a financial portfolio). To help with this assessment, questionnaires often allow the respondent to report bracketed values instead of amounts—hence a choice between lack of precision and missing responses (see Chand and Gan, 2003). To avoid "don't know" answers from respondents who have little or no knowledge of the assets held in the household (or by whom, if this information is collected), surveys often start by identifying the household member who is most likely to have such knowledge (the "best financial respondent" or "best knowledgeable respondent").

[145] Thus excluding studies that consider only women's wealth (e.g., Gornick et al., 2009; Sanders and Porterfield, 2010). Also striking in this review is the small number of studies on non-US empirical work.

over the distribution (survey data, on the contrary, tend to underrepresent this upper part, but this is generally corrected by oversampling the top of the distribution). In addition, taxes on wealth are levied on fiscal units that are not necessarily individuals. The major drawback of estate tax records, which provide information on individual wealth holdings, is that the information only covers dead people. However, using estimates derived from this information,[146] a small number of studies from the 1970s and early 1980s provide some evidence on the distribution of wealth by gender in the United Kingdom and the United States.[147] They observed that women held less wealth than men but that there was a larger gap at the top of the wealth distribution (Atkinson, 1971; Atkinson and Harrison, 1978; Smith, 1974), a greater concentration of wealth among women than among men (Atkinson and Harrison, 1978), differences in the composition of assets, fewer debts in the richest women's wealth than in the richest men's (Smith, 1974), differences in the origin of the assets (Harbury and Hitchens, 1977), and differences in the influence of age and wealth on the composition of men's and women's portfolios (Shorrocks, 1982). However, these results, while they provide valuable indications of differing patterns of wealth accumulation (albeit among a population limited to the wealthiest), describe generations from before "the quiet revolution" (the estimates are derived from estate data in the 1960s and 1970s), when women's wealth was more likely to depend on their fathers' or husbands' wealth than on "self-made" wealth (see Harbury and Hitchens, 1977), fewer women had independent incomes, and marriages were more stable than today. In the case of the United States, a recent estate-based study by Edlund and Kopczuk (2009) shed some doubt about the actual effect of the change in women's economic status. They showed that the share of women among the very wealthy, after peaking at the end of the 1960s, returned to its prewar level by 2000. Their analysis of this evolution is that the share of women at the top of the wealth distribution reflects the share of inherited wealth in an inverse relation with technological change: the information technology revolution (in which men made new fortunes) coincides with the turning point, in the 1970s, in the share of women among the very wealthy. Among the most wealthy, the trends Edlund and Kopczuk outlined ultimately point out the continuing gender gap in entrepreneurship.

[146] These methods (mortality multipliers and estate multipliers) basically expand the information on the deceased to estimate wealth holdings among the living. These methods are presented and discussed by Atkinson and Harrison (1978) and Davies and Shorrocks (2000).

[147] These studies aimed firstly to analyze the distribution of wealth, its concentration and intergenerational transfers. In a way, the data obliged researchers to consider men and women separately. One of the problems was to obtain estimates of family wealth starting from information on men's and women's individual wealth (see Atkinson and Harrison, 1978, p. 241), quite the opposite of the problem research on gender inequality faces today, which is to separate men's and women's wealth starting from information on household wealth.

12.7.2 Investigating the Gender Gap in Wealth

Facing the unanswered question of "whose asset is it?" in couple households (and multi-person households in general), researchers have adopted strategies that, one way or another, sidestep the issue of the distribution of wealth within the household. We first describe these strategies and their limitations, then the main results.

12.7.2.1 Strategies and Limitations

There are two main ways to avoid the issue of intrahousehold distribution of assets. One (the most frequent) is to compare the net worth of men or women living in couple households and those in "not-couple" households (i.e., households in which the head/reference person has no partner or spouse at the time of survey) and use the gender and other characteristics of the household's head as explanatory variables of the household's wealth. Another strategy consists of imputing "individualized" levels of wealth (either per capita net worth, assigning equal shares to each partner in couple households, or using combined estimates, adding individual assets for which individual-level information exists and equal shares of the other assets[148]). Alternatively, some studies focus on one sole type of asset for which their data provide individual-level information. The selection of studies referred to in the review of results is presented in Table 12.6.

While better than nothing, none of these options is satisfying. First, comparing couples and single individuals obviously conflates gender and family/household composition. Most studies focus on the gap between single men and women heading households, but men and women are likely to head different sorts of households[149]—most households headed by women contain no adult man, and single men heading households are more likely to be young and/or childless. Households headed by single women can also be more heterogeneous than those headed by single men, as underlined by Conley and Ryvicker (2005). Single women heading households are more likely to have children or to be older (and widowed), hence conflating not only gender and family composition but also life cycle effects. The "individualization" option is very likely to result in biased estimates of individuals' wealth holdings.[150] For couple households,

[148] This methodology is close to that used by Meulders and O'Dorchai (2010) to compute individual incomes (see Section 12.2).

[149] Despite cross-country differences, the determination of the head of household in surveys is such that it results most often in identifying a man if there is one in the household (see the review of statistical practices by Cowell et al., 2012).

[150] Per capita estimates raise the issue of a pertinent equivalence scale to use in comparisons of wealth among households of different size; see the discussion by Sierminska and Smeeding (2005). Because studies based on household-level information compare households of different sizes, using the household net worth or a per capita or other individualized measure should reduce the wealth gap between couples and other types of households, depending on the size of the other households. Schmidt and Sevak (2006) used a variant of the per capita measure that actually affects the level and significance of the coefficients; they mentioned having tested various alternative equivalence scales with similar results.

Table 12.6 Research strategy, units of analysis, and wealth measure

Author (year)	Country, data source, years	Units of analysis (age group)	Wealth components	Wealth measure
A. Household wealth				
Conley and Ryvicker (2005)	United States, PSID, 1984–1989	Single heads of household (aged ≥18)	Pension wealth excluded	Household net worth
Lupton and Smith (2003)	United States, HRS wave 1992 (cohort born 1931–1941)	Couples versus single (aged ≥18)	Total net worth (not pension wealth)	Household net worth
	United States, PSID, 1984–1989–1994			
Ozawa and Lee (2006)	United States, SCF, 1998	Couples versus single heads of household (age 25–61)	Household net worth	
Sedo and Kossoudji (2004)	United States, SIPP, 1996	Individuals (reference person for the housing) (age ≥25	Only housing wealth Household housing wealth	Gross value and net worth
Schmidt and Sevak (2006)	United States, PSID, 2001	Individuals (married versus single) (age ≥18 and the younger cohort age 25–39)	Pension wealth excluded	Household net worth Variant: per capita
Ruel and Hauser (2013)	United States, WSL wave 2004	Individuals (best financial reporter), cohort graduating in 1957		Household net worth
Ulker (2009)	United States, HRS wave 1992	Couples versus single heads of household (cohort born 1931–1941)		Household net worth
Yamokoski and Keister (2006) US, *NSLY1979*		Couples versus single heads of household (cohort born 1957–1964)		Household net worth
B. Household wealth individualized				
Denton and Boos (2007)	Canada, SFS, 1999	Individuals (age ≥45)		Per capita net worth
Warren (2006)	United Kingdom, FRS, 1995–1996	Individuals (age ≥18)		Single: Household net worth Couple: own pension wealth + half the couple's financial and housing net worth
Wilmoth and Koso (2002)	United States, HRS wave 1992	Individuals (cohort born 1931–1941)		Per capita net worth

FRS, Family Resources Survey; HRS, Health and Retirement Survey; NLSY1979, National Longitudinal Survey of Youth 1979 cohort; PSID, Panel Survey of Income Dynamics; SCF, Survey of Consumer Finances; SFS, Survey of Financial Security; SIPP, Survey of Income and Program Participation; WLS, Wisconsin Longitudinal Survey.

dividing the couple's assets equally entails the assumption that all assets are owned jointly and that each partner holds an equal share. This is a strong assumption in the case of cohabiting couples and a very simplifying assumption in the case of married couples; some assets may indeed be equally owned, but there is no reason for joint ownership to be systematic, and the partners' shares of assets may differ depending on the marital status and marriage agreement. Hence, allocating couples' wealth between spouses under the assumption of joint ownership and equal share of all assets is very likely to conceal within-household inequality and, in turn, to bias the comparison between men and women living in different types of households. Frick et al. (2007), using appropriate data, showed that wealth is more unequally distributed between individuals when measured on the basis of individual-level information than when measured per capita on the basis of household-level information.

Finally, comparing men's and women's wealth over only one type of asset obviously provides a partial measure of the extent of gender wealth inequality. It is an attractive option for analytical purposes (e.g., selection in ownership; cf. Sedo and Kossoudji, 2004), but it does not account for the choice between alternative investments or the influence of total wealth and family composition on the composition of assets.

This review of obstacles and limitations may seem somewhat discouraging. However, working within these limits provides some indications of the influence of marital status and history in the process of wealth accumulation between men and women and points to some gender differences in wealth ownership. For simplicity, we talk of "married" men and women for couple households (including cohabiting couples unless results distinguish between marital status) and of "single" men and women for single households.

12.7.2.2 Evidence: Gender and Composition Effects

As might be expected, the result regularly obtained is that, once relevant characteristics have been controlled for (the minimum set includes age, education, inheritance, race, a measure of income, and/or current labor market status[151]), married men and women have an advantage in the accumulation of wealth over single men and women, that is, a "marriage effect" (Denton and Boos, 2007; Lupton and Smith, 2003; Ozawa and Lee,

[151] Assessing the impact of gender/household composition on the wealth differential leads to problems of estimation. In particular, income, labor market status, marital status, and marital history can be influenced by the ownership of assets and the level of wealth. For income, a number of studies use only the earnings, nonasset income, or a proxy for "permanent income." Issues of endogeneity are mentioned in relation to divorce (Ulker, 2009) or marriage (Ruel and Hauser, 2013) but are not dealt with because of data limitations. Wealth is also much more unequally distributed than income or earnings (as illustrated by the large gaps between the mean and median values of wealth holdings when descriptive statistics on the dependent variable are provided), resulting in other biases that are not systematically acknowledged. Many empirical results face one of these econometric problems. We have chosen not to dwell on these limitations.

2006; Schmidt and Sevak, 2006; Wilmoth and Koso, 2002; Yamokoski and Keister, 2006). The second general result is that single men have an advantage over single women (Conley and Ryvicker, 2005; Denton and Boos, 2007; Lupton and Smith, 2003; Ozawa and Lee, 2006; Schmidt and Sevak, 2006; Wilmoth and Koso, 2002). Finally, virtually all the results point to single parents (mostly women) as the most disadvantaged group compared with any other combination of gender and household composition.

Beyond this general hierarchy related to household composition, there are some discrepancies. One is between wealth levels: the marriage effect is larger in the upper part of the distribution, and the gap between single men and single women disappears at the 75th percentile (Schmidt and Sevak, 2006). Using a measure of savings, Lupton and Smith (2003) found a larger advantage of married couples at higher levels of net worth and discuss a possible impact of sorting into marriage (i.e., "prudent" individuals would be more likely to marry and to stay married or to remarry after a divorce because they also find that divorced and remarried individuals have better outcomes than divorced people).

The other discrepancy is between cohorts. When they restrict their sample to a cohort aged between 25 and 39 in the early 2000s, Schmidt and Sevak (2006) no longer obtained statistically different effects of household composition or gender, indicating either a cohort effect or a life cycle effect. In the first case, this could result from the closing of other gender gaps; in the second, it would indicate that, because wealth inequality builds over time, these young households have not yet accumulated enough for a gender and a family differential to appear. These results do not entirely converge with those obtained from another cohort of about the same age at the same period: Yamokoski and Keister (2006) found almost no difference between never-married men and women and no significant difference between divorced women and men with children, but they found a strong marriage effect. There is also a marriage effect among older cohorts, although it is mitigated by marital history. In short, any disruption from continuous marriage has a negative impact on accumulated wealth and any past marital dissolution has a negative impact (Ulker, 2009; Wilmoth and Koso, 2002; both used data on the wealth of a cohort born between 1931 and 1941 and collected in 1992). However, the effects differ for men and women depending on the type of disruption and the current marital status; compared with continuously married men, the effect of having never married, having divorced once or twice, or being separated after a second marriage (the worst case) are significantly larger for women than for men (Wilmoth and Koso, 2002).

Ruel and Hauser (2013) studied a cohort of men and women who graduated in 1957 (wealth was measured in 2004). Among those not currently married, they found no real gender effect on the accumulated net worth—the difference between men and women is essentially explained by labor market history, past income (nonasset income), and current earnings (controlling for education, social origin, and inheritances). Nevertheless, divorce has a small negative effect on women's net worth, but the major factor is the gender earnings gap over the work-life cycle. Among the currently married, and compared with continuously married men, continuously married women have a significant disadvantage, as do divorced men and, even more so, divorced women. But their full model explains a rather small portion of the accumulated wealth, suggesting unobserved heterogeneity (e.g., different preferences in savings and investment). For currently married men and women, they discussed a possible effect of comparing men and women as the "best financial respondent": if men are more likely to be the couple's best respondent in wealthy couples and women in less wealthy couples, the gender of the respondent depends on the household's level of wealth.[152]

In addition to the effect of the interaction of gender and household composition, other studies have investigated more specifically the effect of the labor market dimension. Women's lower earnings affect their capacity to save, and they have less continuous careers. They are therefore likely to accumulate fewer assets than men (Denton and Boos, 2007) and less pension savings (Warren, 2006). Other occupational differences also determine different opportunities to accumulate assets. For example men, who are more often self-employed than women (see Section 12.4), are more likely to hold business assets. In the United States in 1998, households headed by single men owned about three times the net worth owned by those headed by single women (Ozawa and Lee, 2006). In Germany in 2002, the ratio of men's to women's business assets (gross value) was about 5.5 (Sierminska et al., 2010). In their full model of married men and women, Ruel and Hauser (2013) obtained large and significant coefficients for self-employed men (among the largest coefficients, together with past incomes).

Empirical work based on household-level information on wealth suffers from several limitations but provides two main results: virtually all the results show strong effects of marital status (understood as a type of household/family)—but mitigated effects of marital history—and significant differences related to labor market outcomes, that is, the two essential dimensions of gender economic inequality, but not independent of each other. The main limitation is that the results are unclear about the exact unit analyzed because the dependent variable is a household variable and the independent variables are those of one person in the household.[153] This mixing of gender and marital status/household composition and finally parenthood (a second best justified by the absence of appropriate data) has many limits.

[152] This would be consistent with findings on money management within households, showing that women are more likely to manage tight resources (e.g., Kenney, 2006; Vogler et al., 2008). This raises an issue of measurement error if, for whatever reason, there is a systematic gender bias, as suggested by Zagorsky (2003). Using US data, Zagorsky found significant differences in the value of a couple's net worth reported by the wife or her husband because of husbands reporting a higher gross value of the assets than their wives and wives reporting higher levels of debt than their husbands.

[153] This problem is very similar to that underlined in Section 12.2 about the working poor.

12.7.3 Measuring the Gender Gap in Wealth and Its Components

So far, only two studies, those by Sierminska et al. (2010) and Bonnet et al. (2013), have measured and investigated the gender wealth gap using data that allow a gender gap in wealth to be computed, that is, considering men and women in any type of household. While the data they use (the German Socio-Economic Panel 2002 and the French Household Wealth Survey "Enquête Patrimoines" 2003–2004, respectively) do not provide directly individual wealth variables, they do provide information allowing individual wealth to be computed (on the basis of questions about the share of common property held by couples' partners) rather than assuming equal ownership. Both these studies found a substantial gender wealth gap: men's net worth is higher than women's by 45% in Germany and by 16% in France. Accounting for at least some of this huge difference between the two countries, Bonnet et al. did not include business assets in their definition of wealth; in Germany, the gender gap in business wealth is the highest of the gaps by component[154] (the men-to-women ratio is 5.5). In particular, the total gender gap is higher in the subsample of married couples than on average in Germany (similar in France), higher in the subsample of cohabitant partners than among the married subsample—suggesting different financial arrangements—and lower than the average in the subsample of singles living alone (and nonexistent in France in 2009–2010).

OLS regressions show all the expected associations between wealth, marital status, and labor market characteristics, controlling for education, permanent income, and social origin.[155] The most interesting results are, for both countries, the decomposition of the gender wealth gap, even more so because the two studies use the same methodology (DiNardo et al., 1996), although they are not fully comparable because Sierminska et al. (2010) only analyzed the composition of the gap in their sample restricted to married/cohabiting men and women, and Bonnet et al. (2013) decomposed the gap of their full sample of men and women. In both countries, the main contributions to the gender wealth gap were income and a set of labor market characteristics, especially at the median and upper deciles of the distribution.[156] But the most striking result is the relatively large share of the gender wealth gap that is not explained by the characteristics, especially in the lower part of the distribution (and larger in Germany than in France) and its sign (negative) in both countries.[157] These results suggest that, with given characteristics, women obtain

[154] The self-employed not only hold business assets that employees do not accumulate but also invest more in private pensions because they are not covered by the social security regime.

[155] Using a pooled sample of men and women, Bonnet et al. (2013) obtained very comparable results in 2003–2004 and 2009–2010; the sign and significance level of almost all variables remains the same, except for "cohabiting," which was significant only in 2009–2010.

[156] The 75th percentile in the decomposition for Germany (Sierminska et al., 2010) is puzzling; contrary to any other point, education and intergenerational characteristics are negative and the unexplained gap is positive.

[157] This result is obtained at any point of the distribution in France but not in the lower half of the upper distribution in Germany (the restriction of the sample could account for this difference).

more wealth than men, that is, they get better returns to their characteristics. But men have, on average, "better" characteristics than women and therefore own more wealth.

In both papers, the authors speculate about these "better returns" along two main tracks. One is the "marital" track: women benefit from the relatively better characteristics of their partner/husband (and perhaps deceased husband); this line, consistent with the "male breadwinner model," is especially attractive for Germany (the results are for married men and women); the results for France do not allow anything more than speculation, but it could be less relevant given that one of the major differences between the two countries is the higher degree of gender inequality in terms of labor market characteristics and outcomes in Germany.

The other line of inquiry concerns gender differences in "preferences," involving risk preferences and their effect on savings and investment choices. Risk preference determines the share allocated to risky assets, which are assumed to yield better returns; income depends on the allocation of savings to more or less risky investments and in turn determines the potential for future investment. A gender difference in risk preference could then, in the long run, help to explain a wealth gap between men and women who are otherwise comparable. The question of a gender effect on risk tolerance/aversion has been investigated extensively (see Section 12.3), providing indications that women are more risk averse than men or that men are overconfident (e.g., Barber and Odean, 2001). However, risk preferences might explain very little of the gender gap in wealth. Estimating the choice of risky assets (the share of stocks in older Americans' individual retirement accounts), Neelakantan (2010) found that the gender differential in risk tolerance accounts for 10% and the gender gap in earnings for 51% of the difference between men's and women's accumulated retirement accounts. Barasinska and Schäfer (2013) also showed that between men and women with similar risk preferences (measured by the presence of risky assets in their financial portfolio), there is no significant difference in the allocation decision (measured by the share of risky financial investments), except in Italy—a result that they related to a choice of identity in a context of high gender inequality. Other research invokes a possible effect of a differential in financial literacy (e.g., Van Rooij et al., 2011). Dwyer et al. (2002) found that controlling for financial knowledge significantly reduced the impact of gender on investment decisions but that this effect was difficult to assess among representative samples.

The effect of gender differences in the choice of investment could be more complicated to assess in the case of men and women living together (a large share of the adult population); savings and investment decisions may result from the interaction of partners' preferences. Finally, the issue of investment choice raises the issue of wealth inequality and power in decision making within the household.

12.7.4 Wealth and Gender Within the Household

Given the lack of information on individual wealth, intrahousehold (intracouple) wealth inequality and the role of partners' preferences in saving and investing decision making have seldom been analyzed. A first question is that of the pattern of ownership (joint/separate) and the distribution of wealth between spouses/partners. Grabka et al. (2013), using the German Socio-Economic Panel 2007, found a large within-couple gender wealth gap; on average, women's assets represent about 37% of the couple's wealth—a quite different picture from the assumed equality—and the gap tends to increase with the wealth level. Men hold more wealth than women in 52% of couples, women hold more in 29% of couples, and the shares are equal in the remaining 19%. Kan and Laurie (2013), using the British Household Panel Survey (HPS) (which collected data on savings, financial investments, and debts at the individual level in 1995, 2000, and 2005), found that savings are more often jointly held than investments or debts and, controlling for ownership, that the likelihood of joint ownership of the three types of assets is lower among cohabiting couples—a pattern already identified for income pooling (e.g., Vogler et al., 2006; see also Section 12.2).[158]

The next issue concerns the relation between gender, preferences, financial decision making, and wealth within couples. The general pattern that emerges from various empirical results is that there is a relation, but it is mediated by the level of income, wealth, and context. In the Netherlands, Barasinska and Schäfer (2013) found that in couples who reported that they make financial decisions jointly, gender has no effect on the probability of ownership of risky assets but the differential in risk tolerance between the spouses has an effect: any level of risk tolerance of one spouse has a reduced effect if the other spouse is more risk averse. Such an effect of mitigation is illustrated by Love (2010). Studying allocations after a divorce, he showed that men choose riskier investments than women and that transitions from divorce to marriage have opposite effects. In the United States, Neelakantan et al. (2009) found support for the prediction of the collective model: the household portfolio is determined by the risk preference of the spouse with more bargaining power. This result is somewhat contradicted by Gibson et al. (2006) in Australia; they found that the level of accumulated wealth among preretirement couples is not higher when women have more bargaining power (measured by a power index combining age, education, inherited wealth, and income); the reason is that the public pension system in Australia better replaces preretirement income for women than for men. In Canada, Phipps and Woolley (2008), using various measures of control over money, found that women's greater control is associated with lower probabilities of contributions to a private savings plan both for men and women. However, women's control is more frequent at lower-income levels, and savings are primarily associated with income. Finally, in Germany, Grabka et al. (2013) found that the wealth gap tends to be higher in couples where the financial decisions are most often made by the man and that men are more likely to make financial decisions in wealthier couples (a question also

[158] They also observed a downward trend in joint ownership between 1995 and 2005, consistent with the trend in marriage versus cohabitation observed in the United Kingdom and other countries.

addressed by Ruel and Hauser, 2013). All in all, things are rather difficult to disentangle—especially because joint ownership is almost never controlled for, "who makes decisions" is self-reported, and there may be divergence between each spouse's view of "who decides" (for retired couples in the United States see Elder and Rudolph, 2003) or about the couple's financial difficulties (see Breunig et al., 2007, with Australian data). Further research taking into account a possible difference between what happens in married *and* cohabiting couples would also be useful.

What conclusions can be drawn from research on the gender wealth gap in the past decade? First, it seems that there really is a gender gap in wealth, but there are far too few empirical studies that can provide an assessment of its full extent. For the time being, one could say that the gender gap in wealth seems easier to explain than to measure. As for the explanations, they converge on a strong effect of gender earnings differentials mitigated by strong effects of marital status and history, complicated by additional effects of cohorts and total wealth. In addition, a large share of the existing empirical work consists of research on the United States, with a particular household structure[159] and based on inappropriate data. It is an understatement to conclude that more research—and comparative work—is needed to allow for common methodologies to build up.

Identifying who owns and controls assets within households is a prerequisite to gaining knowledge that has important implications for the analysis of gender inequality, as underlined by Deere and Doss (2006). Gaining knowledge is conditioned by the availability of appropriate data. This is a challenge for statistics, a challenge seldom acknowledged to date, as exemplified by the recent initiative of the European Central Bank aimed at developing harmonized data on wealth. On the model of the Canberra Group, the Central Bank seems to have adopted the standard unitary approach; the questionnaires available online[160] show no intention to collect any details on individuals or ownership status. The Luxembourg Wealth Study,[161] a project aimed at building a data set based on harmonized national data, seems to have missed the issue, too (see Barasinska and Schäfer, 2013, who mention that individual information is lost through data standardization [p. 8]). As mentioned in Section 12.2 in our discussion of income statistics, the increased financial independence of women and changing patterns of families and households provide good reasons to argue that statistics must change as well.

12.8. CONCLUSION

Gender economic inequality encompasses a large field of study, far beyond the gender wage gap (even though this issue is central); the related literature is overabundant and

[159] As shown by Bover (2010) in a comparison between Spain and the United States.
[160] http://www.ecb.europa.eu/home/html/researcher_hfcn.en.html.
[161] Luxembourg Wealth Study (2003); http://www.lisdatacenter.org/our-data/lws-database/.

still growing, driven by the conjunction of dramatic demographic and economic shifts in the past decades and the puzzle of persistent gender inequalities. Delayed maternity and marriage have transformed women's economic opportunities relative to men's: education is no longer a key factor of gender inequality, and motherhood is less incompatible with paid work. Family structures have changed in several ways. A majority of couple families count two earners, but marriages have become less stable than in the past, and cohabitation is an increasing arrangement. Consequently, women may rely less on a husband's incomes, as in the traditional "male breadwinner" model, and more on own their economic independence.

But the "quiet revolution" does not seem to have changed market and nonmarket work to a comparable extent, and the gender wage gap has remained basically unchanged in the past two decades. More than an academic puzzle, this is also a major policy issue. There is a general consensus that this persistence is related to occupational segregation and a gender gap in promotions, but the underlying causes are still debated. Whether the explanation focuses on employer discrimination, gender psychological differences and social norms that disadvantage women in the labor market, or family constraints on work hours, a common denominator is the gender division of labor, especially of unpaid childcare, as reflected by the importance given to the issue of work–family balance. As Craig (2006) remarks: "In the absence of adequate support, there is a sticking point in the revolution: taking care of the kids. An implication of this is that the marker of the most extreme difference in life opportunities between men and women may not be gender itself, but gender combined with parenthood" (p. 146).

While the time dedicated to housework has decreased dramatically since the 1960s, women still make the major contribution to nonmarket work within households, and the need for flexible work hours when they are mothers affect their labor market outcomes in many ways, from less favorable careers to smaller pensions—a delayed expression of the gender asymmetrical effects of family life. So, it is not surprising that recent public policies addressing gender wage inequality point out the need for making men and women more equal in terms of family constraints, adding incentives to get fathers more involved in childcare to usual measures of work–family reconciliation for mothers.

All throughout this chapter, various limitations in the knowledge of gender inequality have been underlined, pointing at the lack of appropriate data on individual incomes. Work incomes are quite well identified at individual level, but this is not so for other income components, which in many data sets are available only at the household level. It is quite the opposite with time-use surveys, which provide individual-level information but do not always allow reliable household-level variables to be computed because very often there is only one respondent per household. Another problem with data is that the possibilities for researching the relations between time use, labor market outcomes, and issues of power within the household are limited. Time-use data, on the one hand, are a precious resource for analyzing the allocation of time, but variables describing earnings and other incomes often lack of precision, whereas data on income and labor market status, on the other hand, most often provide imprecise—if any—information on the time not spent at work. Finally on wealth, an emerging strand of research on gender inequality, the need for appropriate statistical sources is blatant. Cross-national perspectives are needed also to better understand the various dimensions of gender economic inequality. This entails discussing and adopting common methodologies allowing meaningful international comparisons - and harmonization is clearly an issue, but also the agreement on basic principles, especially of the pertinent level of information.

A better understanding of gender economic inequality is not only a question of data (although more large scale and comparable data would not hurt), but also a question of concepts and indicators allowing to compare men and women economic outcomes. Women's economic and social status have undergone enormous changes over the last decades, and this is challenging many theoretical approaches. A concern is that the reference remains of the household as a stable unit of pooling and sharing, an increasingly irrelevant conceptualization while households are less stable than in the past and individuals are more likely to experience diverse family configurations over a lifecycle. These are serious incentives to depart from a paradigm which limits the analysis of inequality between individuals in general and between men and women in particular.

CHAPTER 13

Attitudes to Income Inequality: Experimental and Survey Evidence

Andrew E. Clark*, Conchita D'Ambrosio†

Contents

Abstract

We review the survey and experimental findings in the literature on attitudes to income inequality. We interpret the latter as any disparity in incomes between individuals. We classify these findings into two broad types of individual attitudes toward the income distribution in a society: the normative and the comparative view. The first can be thought of as the individual's disinterested evaluation of income inequality; on the contrary, the second view reflects self-interest, as individuals' inequality attitudes depend not only on how much income they receive but also on how much they receive compared to others. We conclude with a number of extensions, outstanding issues, and suggestions for future research.

13.1. INTRODUCTION

A number of areas of research in economics might sometimes be thought not to pass the "So what?" test: Do we really care about this issue? This would not seem to be the case for inequality, which looks like it passes the test with flying colors. Income inequality might be thought to occupy something like the same kind of place in the economic Pantheon as unemployment: It is almost taken as an axiom that it is a bad thing.

Given this sense of unanimity, it might seem to be churlish in the extreme to want to write a chapter about individuals' attitudes to inequality; surely they are negative aren't they? We believe that the situation is not quite as simple as might be imagined. First, we have to ask the rather fundamental question of what we mean when we talk about income inequality, and then why would we expect any measure of such inequality to be correlated with individual well-being. Following on from this setting-out of the scene, there are a number of open questions. Is inequality equally bad for everyone? And on an extremely practical level, how can we tell? Last, the term *inequality* is used perhaps rather loosely in the empirical literature. It is of interest to ask which measures of the distribution of income are the most important (to individuals) in this context: Is it (as is commonly assumed) the Gini coefficient, or rather something else? As we will discuss later, recent work using experimental and survey methods has allowed considerable progress to be made in answering some of these questions.

To set the stage, we first ask under which circumstances others' incomes should affect our own well-being.[1] We use the term *income inequality* to refer to any disparities in incomes between individuals (i.e., there is income inequality when some individuals have different incomes than others). As opposed to many of the other variables that have been related to individual well-being, the distribution of income does not exist at the individual level: income inequality is rather measured only at an aggregate, often societal, level. The key axiom in the measurement of inequality is the Pigou–Dalton principle of transfers, according to which inequality increases whenever a transfer of income from a poorer to a richer individual takes place.

[1] We limit ourselves here to discussion of individuals' evaluations of the inequality of income. Inequality in the distribution of other variables is of course of interest as well, including that of subjective well-being (as in Clark et al., 2014).

We believe that people do indeed have preferences over inequality. It is helpful to consider two broad types of individual attitudes to the distribution of income in a society. The first can be thought of as the individual's disinterested evaluation of income inequality: If I see two distributions of income in some society, which do I believe is better? We will call this the normative evaluation of inequality.

In addition to this disinterested reaction to income inequality, the individuals who we analyze when we carry out experimental or survey analysis do actually live in the society in question: Their own income then forms part of the income distribution in which we are interested. This second inequality effect is at the individual level: income inequality will directly impact both the absolute income that individuals receive, and how much richer and poorer they are compared to others. The attitude to inequality here is not disinterested but rather self-interested, with the additional assumption that individuals care not only about how much income they receive but also about how much they receive compared to others. We will call this the comparative evaluation of inequality.

The effect of the distribution of income on individual well-being will likely run through both of these channels. Even though income inequality as such in a society is not an individual-level concept, any distribution of income will have individual-level effects due to the way in which it changes the individual's own income and their standing with respect to those who are richer and poorer, as will be discussed later.

In the context of relative standing or comparisons, individual attitudes to inequality will depend critically on the *reference group* that the individual has in mind. This term was first used by Hyman (1942) in work on the evaluation of the rankings that individuals assign to themselves and refers to the group or individuals to which or with whom they compare themselves for the purpose of self-appraisal. The term has subsequently been refined and expanded in numerous contributions across the social sciences, with various definitions of the term now being proposed. Kelley (1965) distinguished between two roles that any such reference group can play and hence proposed separate definitions of the *comparative* and *normative* reference groups.

The first of these, the *comparative* reference group, is in the spirit of the original interpretation given by Hyman, whereby the reference group acts as the standard of comparison for self-appraisal. The *normative* reference group is the source of norms, attitudes, and values of the individuals concerned. Both groups can be further distinguished according to whether the individual in question *is* or *is not a member* of the reference group. Reinterpreting Shibutani's (1955) proposed conception of the terms, a comparative reference group is the point of comparison allowing the individual's own status to be calculated when the individual is part of the group (as in Hyman). However, the individual need not (yet) be part of the reference group. When the individual is not part of the group, but aspires to be, the reference group acts as a relative aspiration, that is, as the group of which the individual desires to be a member. A normative reference group is that whose perspectives constitute the frame of reference for the individual, and again a distinction between membership and nonmembership can be effected. In the latter case, individuals may adopt the behavior of the group as a result of anticipatory socialization (see Merton and Kitt, 1950).

Regarding the subject matter of this chapter, the reaction of an individual to income inequality will depend on both the role assumed by the reference group and membership status in the group. In a comparative reference group, of which the individual is a member, individual well-being is commonly assumed to be negatively affected by those who earn more than the individual, but positively affected by those who earn less. We say that the individual experiences *relative deprivation* from the income gaps with respect to those who are richer than she is in the reference group, but *relative satisfaction* from the income gaps with respect to those who are poorer. Both *relative deprivation* and *relative satisfaction* will very likely depend on the degree of income inequality within the reference group.

Comparative reference groups may also matter even if the individual is not currently a member of the group. If the individual aspires to be part of the group in question, then comparisons with respect to richer individuals in the group may give rise to positive feelings, as the individual anticipates being as rich as the group members once they join the group. This idea of a comparative reference group to which the individual aspires is akin to that of the tunnel effect in Hirschman (1973), which will be referred to in Section 13.2.1.

The rationale behind this comparative view of reference groups is that one's own position relative to others matters. We do not imagine that this is the only way in which others' outcomes may be viewed by the individual. It is very likely indeed that some groups will not be considered comparatively, but instead viewed with some kind of extended sympathy. The individuals to whom one compares and those for whom one feels sympathy are probably not going to be the same. As such, we may well see individuals whose position relative to their neighbors or work colleagues is paramount, but who at the same time vote for social programs for those in need or give money to international charities. Here individuals have a preference for making some others better off. We will explore this idea of empathy or altruism a little more in Section 13.4.4.

As opposed to the comparative view of reference groups, inequality in the normative view of reference groups is evaluated by the individual irrespective of where she appears in the distribution, or even irrespective of whether she appears in it at all. Concretely, a given distribution of income will be evaluated in the same way by an individual regardless of whether she is in the top or bottom quartile of the distribution, so that there is no role for comparisons to the richer and poorer in the normative reference group. Equally, we can all now have a normative opinion about the distribution of income in our own countries in the nineteenth century, even though we do not appear in that distribution ourselves. The normative evaluation of an income distribution can also be thought of as a mirror of preferences over inequality under the veil of ignorance (where the individual does not know where she will eventually be situated in the distribution).[2]

Both the normative and comparative views of income inequality will likely depend on how the distribution of income came about. We expect individuals to be more tolerant of the income gaps that result from effort than those that come about by luck. We will consider some of the work on the fairness of the income distribution further in Section 13.4.3.

The remainder of this chapter is organized as follows. Section 13.2 considers empirical evidence for an impact of income inequality in the context of a comparative reference group. We appeal to two different ways via which we can evaluate whether income inequality does indeed reduce the well-being the individuals who are exposed to it. The first approach relies on various measures of subjective well-being as proxies for individual utility: these are used to establish whether income disparities are indeed significantly associated with measures of individual well-being (such as happiness or life satisfaction).[3] The second is to see whether individuals behave as if they wish to avoid income inequality. This is tantamount to a revealed-preference argument. As it is anything but obvious to obtain clean measures of behavior and match these to income inequality in the field, we turn to experimental techniques in the laboratory to make progress here. Section 13.3 then follows the same structure, but this time with respect to the normative evaluation of income distributions. We propose a number of extensions, outstanding issues, and suggestions for future research in Section 13.4. Last, Section 13.5 concludes the discussion.

13.2. THE COMPARATIVE VIEW

When the reference group is viewed comparatively, individuals are not indifferent to others and compare to them to evaluate their own status in society.[4] If the individual is a member of this reference group, then higher incomes for others will reduce her well-being, whereas lower incomes have the opposite effect. Alternatively, if she is not in the reference group, but would like to be, then others' higher incomes will have a positive effect on her well-being. In both cases income disparities among others will be correlated with individual well-being.

[2] Considering only the level of one's own income, a richer-than-mean-income "impartial observer" will be more inequality averse when she is not involved in the distribution of income (this is the pure normative preference) as compared to the case in which she is present in it.

[3] This kind of subjective well-being literature has grown very quickly over the past couple of decades. As an example, three of the four top-cited articles published in the *Economic Journal* over the past 20 years have the word *happiness* in their title.

[4] Very generally, an individual's perception of inequality may depend on where she stands in the income distribution. An early contribution in this respect is Van Praag (1977).

We first consider evidence for the importance of such comparisons to others based on the measures of subjective well-being that are by now commonly available in many sources of survey data, before turning to the complementary work in experimental economics.

13.2.1 Subjective Well-Being and Others' Income

Arguably inspired by the salience of the Easterlin paradox[5] (Easterlin, 1974), and the increasing availability of information on various measures of subjective well-being in large-scale (including panel) data sets, there is by now quite a considerable stock of work on the relationship between income and well-being. One of the key questions in this literature has been "Does money buy happiness?" In standard economic theory, individual utility is not supposed to be affected by the behavior or income of others, unless these latter impose an externality on the individual.

In the context of the comparative reference group evoked earlier, however, the incomes of others in the reference group do indeed impose just such an externality. An increase in the income of others reduces the individual's well-being, through either greater relative deprivation or lower relative satisfaction (depending on whether the others whose income rises earn more or less than the individual in question), whereas analogously a reduction in others' income increases the individual's well-being.

There are any number of ways of attempting to show that individual well-being depends negatively on others' income. These were surveyed in Clark et al. (2008), and as such this chapter will only provide a shorter run-through of some of the relevant findings. Of course, comparisons need not be restricted to income and may well refer to comparisons of consumption, as initially suggested by Veblen (1949) and demonstrated empirically by, among others, Bloch et al. (2004), Brown et al. (2011), and Heffetz (2011). Comparisons could also cover leisure (Frijters and Leigh, 2008) or arguably almost any other observable economic attribute.

Some of the empirical work on the comparison of income has used a revealed-preference approach, in which observed measures of labor supply or consumption are argued to be more consistent with a relative utility function, in which either income or some consumption goods are compared to those of others in the reference group. A number of pieces of evidence along these lines can be found, for example, in Frank (1999), Layard (2005), and Schor (1992).

[5] This paradox is based on an opposition of the cross-section and time-series estimates of the relationship between subjective well-being and income. At any point in time, richer individuals are typically happier than poorer individuals. But as per capita GDP rises over time, Easterlin suggested that average subjective well-being remains flat in many countries. The extent to which subjective well-being is actually flat over time is the subject of quite heated debate (for example, Easterlin et al., 2010; Stevenson and Wolfers, 2008). The comparison of my income or consumption to that of others (or to myself in the past) has often been proposed as an explanation for this paradox.

It is always difficult to convince skeptics that any such correlations do indeed reflect spillover effects within the utility function, rather than learning, a hidden common factor within the reference group, or endogenous selection into the reference group. The tightest evidence in this respect may well come from natural experiments, in which either reference group income or consumption randomly changes. A small number of these experiments are described here.

Card et al. (2012) appeal not to expected outcomes but rather the revelation of information on others' earnings. The natural experiment here is a court decision that made the salary of any California state employee public knowledge. A local newspaper set up a website making it easy to find this information. Following this website launch, Card et al. informed a random subset of employees at three University of California campuses about the site. Some days later, all employees on the three campuses were surveyed. Comparing those in the treatment group (informed about the website) to others reveals the impact of information regarding others' salaries. The reference group in this work was defined as coworkers in the same occupational group (faculty vs. staff) and administrative unit in the university. Finding out about others' earnings should reduce the well-being of those who find themselves to be relatively less well-paid than others in the reference group and increase it if they find themselves to be better paid. The survey did indeed find lower job satisfaction for those with pay below the reference group median and a greater intention to look for a new job. The effect on both of these variables for those who were relatively well paid was insignificant. There is in addition some evidence of an actual quitting effect on those who were found to be in the bottom earnings quartile in the reference group.

Kuhn et al. (2011) consider observed large changes in close neighbors' incomes, which result from the design of the Dutch postcode lottery. Each week, this lottery randomly selects a postal code and allocates a prize of €12,500 per lottery ticket purchased within the postcode. In addition, one participating household in the winning postcode receives a new BMW. These postcodes are small, comprising on average about 20 households. Individuals who do not live in the winning postcode area, and those who do but did not buy a ticket, receive nothing. Households in winning postcodes were surveyed 6 months after the prize was won. One of the paper's key findings is that lottery nonparticipants in winning postcodes (who live next door to winners) are significantly more likely to have purchased a new car since the date of the lottery draw than are other nonparticipants, as if individuals do indeed compare their own car to that of their near neighbors.

A last example of a natural experiment is one in which comparisons to a reference position or an expectation (rather than comparison to other individuals) affect observable behavior (rather than subjective well-being). In New Jersey, police unions bargain over wages with their municipal employer, and in cases of dispute, an outside arbitrator has the final say. Mas (2006) found that the per capita number of crimes solved (cleared) is 12%

higher when the unions win their case compared to when they lose. He concluded that "the change in performance of police officers following an arbitration loss depends not only on the amount of the pay raise, but on the counteroffer that was demanded but never implemented as well" (p. 785).

Natural experiments of this kind are relatively rare. A great deal of work has instead appealed to survey data and modeled subjective well-being as a function of both the individual's own income and the income of a plausible reference group. This latter reference group is almost always imposed by the researcher as some measure of the income earned by those who are of the same age, sex, and education, for example, or who live in the same region, or (in the case of linked employer–employee data, as in Brown et al., 2008; Clark et al., 2009b) who work in the same firm. Direct information on who is in the individual's reference group in survey data is very rare (an exception is Clark and Senik, 2010).

Some of the by now large body of empirical literature is surveyed in Section 3.1 of Clark et al. (2008). For the income of "people like you," Clark and Oswald (1996) used the first wave of British Household Panel Study (BHPS) data to show that the estimated coefficients on income and others' income in a job-satisfaction equation are statistically equal and opposite, which is compatible with the Easterlin paradox. An early contribution by Cappelli and Sherer (1988) considered workers in the airline industry. The authors appealed to an occupational definition of others' earnings and showed that individual pay satisfaction is negatively correlated with an outside "market wage," which is average pay by occupation in other airlines. Ferrer-i-Carbonell (2005) related life satisfaction in the German Socio-Economic Panel (SOEP) to average income defined by sex, age, and education; Luttmer (2005) also considered life satisfaction, which is shown to be negatively correlated with average income by local area identified in a number of waves of the U.S. National Survey of Families and Households.

Instead of modeling reported subjective well-being as a function of own and others' income, an alternative is to ask how much income individuals need to attain a certain level of well-being. This is the method used in the Welfare Function of Income, associated with the Leyden school in the Netherlands. In this project, individuals are asked to assign income levels (per period) to a number of different verbal labels (such as "excellent," "good," "sufficient," and "bad"). It is then possible to estimate an individual lognormal Welfare Function of Income using the responses for each individual; this function shows how much income each individual needs to hit a certain level of well-being. The estimated means (μ_i) of these lognormal functions can then be used as the dependent variable in regressions seeking to explain which types of individuals require a higher level of income to be satisfied. The mean μ was found to be positively correlated with reference-group income (average income by age, education, and certain other individual or job characteristics); see Hagenaars (1986) and Van de Stadt et al. (1985). In other words, when the income of the reference group is higher, individuals need more money to attain a certain stated level of utility.

To date we have discussed empirical results that are consistent with a comparative reference group of which the individual is a member. The discussion in Section 13.1 revealed a possible counteracting effect when incomes rise in a comparative reference group to which the individual aspires, but of which she is not yet a member. Some work has indeed found that individual well-being is *positively* correlated with reference group income and has attempted to interpret this correlation in the light of aspirations and future outcomes. A positive correlation between my own well-being and others' income is consistent with Hirschman's tunnel effect, where others' earnings provide information about my own future prospects. In the terminology of Manski (2000), these are expectations interactions, where the individual updates their information set based on others' outcomes. The tunnel effect relates to the literature on the "prospect of upward mobility" (POUM), where both current and future income matter. This will be discussed further in Section 13.4.3.

Clark et al. (2009b) make the point that the estimated coefficient on others' earnings in a typical subjective well-being equation will likely mix together the comparison element (comprising relative deprivation and relative satisfaction, as discussed earlier) and the relative aspiration effect of the group to which the individual aspires. In the associated literature, this latter is often called an information or signal effect (whereas the former is called a jealousy or status effect). Positive subjective well-being effects from others' income are found, for example, in Senik (2004), Kingdon and Knight (2007), and Clark et al. (2009b). In each of these, the case can be made that the retained measure of others' income contains some element of my own likely future outcomes: An information or aspiration role for others' income is more likely the greater my probability of accession to the reference group in question. As will be discussed in Section 13.3.1, the inversion in the correlation between satisfaction and overall income inequality in Grosfeld and Senik (2010) in Poland can be interpreted in the light of such a tunnel effect. Individuals were initially happy with others' higher incomes (toward the top end of the income distribution), as this was thought to reflect their own future opportunities. Once it became clear that only relatively few people were actually going to be able to accede to these incomes, the correlation with satisfaction became more comparative, with a net negative effect in the later years of their sample.

Before describing the results of this literature any further, it is useful to set out the models of income comparisons formally. There is a set $N=\{1,\ldots,n\}$ of $n\geq 2$ individuals whose incomes are recorded in an income distribution $x=(x_1,\ldots,x_n)\in\mathbb{R}^n_+$, where $\mathbb{R}^n_+$ is the set of n-dimensional vectors with nonnegative components. The mean of x is $\lambda(x)$. For $x\in\mathbb{R}^n_+$, $B_i(x)=\{j\in N|x_j>x_i\}$ is the set of individuals with income greater than that of i, known as the better-off set; analogously, $W_i(x)=\{j\in N|x_j<x_i\}$ is the set of individuals who have an income that is lower than that of i, the worse-off set.

In the income-distribution literature, the most significant role of relative standing is in the determination of deprivation and satisfaction, which is related to inequality measurement as we will see later. As opposed to measures of income inequality, deprivation and satisfaction are defined at the individual level and aim to capture individuals' reactions when they compare their situation to that of others who have different levels of income (or of some other variable). Deprivation "involve(s) a comparison with the imagined situation of some other person or group. This other person or group is the 'reference group,' or more accurately the 'comparative reference group'" (Runciman, 1966, p. 11). In this literature, it is generally assumed that the reference group is the entire society.

The definition of relative deprivation adopted is the following: "We can roughly say that [a person] is relatively deprived of X when (i) he does not have X, (ii) he sees some other person or persons, which may include himself at some previous or expected time, as having X (whether or not this is or will be in fact the case), (iii) he wants X, and (iv) he sees it as feasible that he should have X" (Runciman, 1966, p. 10). When we consider income as the object of relative deprivation, which is the X in the preceding citation, then individual deprivation is simply the sum of the gaps between an individual's income and the incomes of all individuals richer than her.

Formally, Hey and Lambert (1980) specified the deprivation felt by someone with income x_i with respect to a person with income x_j as:

$$\begin{aligned} d_i(x) &= \left(x_j - x_i\right) \text{ if } x_i < x_j \\ &= 0 \text{ else} \end{aligned}.$$

In this case, as also suggested by Yitzhaki (1979), the deprivation function of an individual with income x_i is the sum of all the gaps to those in the better-off set divided by the number of individuals in the society:

$$D_i(x) = \sum_{j \in B_i(x)} \frac{x_j - x_i}{n}.$$

Aggregate deprivation, that is deprivation at a societal level, is then given by the average value of all of the individual deprivations. This aggregate deprivation turns out to the absolute Gini coefficient, which is given by the most popular index of income inequality (the Gini coefficient) multiplied by mean income.

Following on from these early contributions, Chakravarty (1997) proposed the inclusion of mean income in the measurement of individual deprivation. The latter now becomes the gap as a fraction of mean income, $d_i(x)/\lambda(x)$. This normalization is argued to be more appropriate for the comparison of the same society at different points in time, or different societies. When we use this formulation, aggregate deprivation is equal to the Gini coefficient, which is the absolute Gini index divided by mean income.

Analogously, income can be compared to those who are poorer than the individual in question (i.e., those who are in the worse-off set). This comparison yields the relative satisfaction function of an individual with income x_i, $S_i(x)$, given by:

$$S_i(x) = \sum_{j \in W_i(x)} \frac{x_i - x_j}{n}.$$

These measures of deprivation and satisfaction are called disadvantageous and advantageous inequality in Fehr and Schmidt's (1999) utility function. On this point Runciman (1966, p. 9) wrote: "If people have no reason to expect or hope for more than they can achieve, they will be less discontent with what they have, or even grateful simply to be able to hold on to it. But if, on the other hand, they have been led to see as a possible goal the relative prosperity of some more fortunate community with which they can directly compare themselves, then they will remain discontent with their lot until they have succeeded in catching up".

Although Fehr and Schmidt imagine that individuals are averse to both kinds of inequality, in the income-distribution literature it is most often implicitly assumed that individual well-being depends negatively on relative deprivation but positively on relative satisfaction. One of the main reasons for individuals not being inequality-averse, as will be set out in the following section, is that real income is not manna from heaven, and how that income comes about matters for individual attitudes.

This same concept of deprivation, which is at the core of the Gini coefficient, is also found in the literature of polarization (see Chapter 5). Deprivation is there called alienation. In general, alienation is assumed to be symmetric, whereas only the comparison to better-off individuals matters for deprivation. The interaction between alienation and identification is at the basis of the measure of polarization proposed by Esteban and Ray (1994). Bossert et al. (2007) reinterpret alienation and (the lack of) identification in terms of deprivation in a multivariate setting where functioning failures are analyzed. In this setting, individual deprivation is a multiple of the product of the share of agents with fewer functioning failures than the agent under consideration (the lack of identification) and the average of the functioning-failure differences between the individual and those who are better off (the alienation component).

The empirical subjective well-being literature described in this subsection has arguably made a key contribution in reminding social scientists (and maybe especially economists) that there are spillovers in individual income. The more you earn, the less happy I am, if you are in my reference group. Unless you are in a reference group to which I aspire, in which case my subjective well-being may well be higher (your position today provides me with an idea of what I can aspire to tomorrow).

The news is not only good, however. It can be argued that there are a number of drawbacks in this literature. In particular, the pertinent reference group is only a guess at who really matters in terms of the individual's own specific group that counts for income comparisons. In almost all cases, the best that we can do is use a series of likely reference groups and show that the effect of others' incomes seems to be consistent across them. An arguably useful piece of additional information comes from the identification of reference groups to which the individual aspires (for which there is an information or signal effect): We expect the correlation between individual subjective well-being and others' income in these groups to be less negative, or even positive. Even so, in both cases we can only guess at the correct reference group, with obvious implications for the accurate measurement of the relevant income gaps. As noted earlier in this subsection, we practically never ask individuals about their comparative reference group and have to our knowledge never asked about the reference group to which the individual aspires.

In the context of contributing to the analysis of relative deprivation and relative satisfaction described earlier, this literature has also not been an overwhelming success. Almost every paper here appeals to one single measure of the centrality of others' incomes, independent of whether the individual in question finds herself above or below that level. As such, there has been little attempt to distinguish relative deprivation from satisfaction.[6] Equally, knowing both my own income and the mean (or median) of my reference group income actually tells me fairly little about the gaps between me and others. Someone who has an income of 1000 euros above the mean or median reference-group income, say, can have widely varying values of relative deprivation and relative satisfaction.

The set of empirical subjective well-being work explicitly appealing to deprivation and satisfaction is not entirely empty. D'Ambrosio and Frick (2007) provided an empirical counterpart to the theoretical measures given earlier by exploring the relationship between self-reported income satisfaction and relative deprivation. Using panel data from the SOEP, they showed that subjective well-being depends more on a measure of relative deprivation than it does on absolute income because the correlation between income satisfaction and absolute income is 0.357, whereas that between satisfaction and relative deprivation is larger in absolute value at –0.439. As predicted by the income-distribution literature, the effect of relative deprivation on well-being is negative. This finding holds even after controlling for other influential determinants of well-being in a multivariate setting. Cojocaru (2014a) also estimated an individual well-being regression as a function of advantageous and disadvantageous inequality in the reference group, using 2006 data from the Life in Transition Survey (LiTS). Disadvantageous inequality is associated with lower life satisfaction, but advantageous inequality is not significantly so.

Bossert and D'Ambrosio (2007) introduced time as an additional dimension in the determination of the level of deprivation felt by an individual. They suggested that, as is usual, an individual's feeling of relative deprivation today depends on a comparison

[6] One exception, which arguably does fall into the group of survey work on satisfaction, is Loewenstein et al. (1989). Here individuals evaluate a series of hypothetical scenarios involving disputes between two people, where they are told to assume the role of one of the individuals and evaluate how satisfied they are with the final outcome in each situation. These satisfaction scores are shown to be related to both own and the other person's payoff. The correlation between satisfaction and advantageous inequality is much weaker than that with disadvantageous inequality.

with those who are better off today. They then proposed an additional consideration: The feeling of deprivation relative to someone who has a higher income today is more pronounced if this someone was *not* better off than the individual in question yesterday. In other words, relative deprivation is more keenly felt relative to those who, between yesterday and today, have passed the individual in question in the income distribution. Individual relative deprivation in this framework is then determined by the interaction of two components: the average gap between the individual's income and the incomes of all those who are richer than her (this is the traditional way of measuring deprivation), and a function of the number of people who were ranked below or equal in the previous period's distribution but who are now above the individual in question in the current distribution. A similar modification can be effected for the measurement of relative satisfaction, with the latter rising with the number of people that the individual has passed in the distribution between yesterday and today.

In a similar spirit to Bossert and D'Ambrosio (2007), D'Ambrosio and Frick (2012) proposed a utility function including dynamic-status considerations, which is tested on SOEP data. Individual well-being, measured in the SOEP by individual income or life satisfaction, depends at time t on four different elements: (1) the absolute component (i.e., the standard of living of the individual at time t); (2) the absolute dynamic component (i.e., how the individual's own income changed between $t-1$ and t); (3) the relative component, which is the individual's income at time t compared to others' incomes at time t; and (4) the relative dynamic component, which reveals how the result of the individual's income comparison in (3) changed between $t-1$ and t. This utility function is a generalization of that proposed by Fehr and Schmidt (1999), with the addition of individuals' income histories.[7]

This separation of income comparisons into those with respect to richer and poorer individuals, and explicitly distinguishing the others who have passed (or have been passed by) the individual in question, can be argued to shed some light on the debate regarding the potential status and signal effects of comparison income.

Individual well-being being negatively affected by comparisons to those who are permanently richer (and positively affected by comparisons to the permanently poorer) is completely in line with the standard empirical findings in the literature on relative income. At the same time, the presence of newly richer and poorer individuals can be argued to play the informational role described in Hirschman's (1973) tunnel effect. Someone who is today richer than me, but was yesterday poorer than me provides me with a positive signal about my own future prospects. And indeed in the empirical application, D'Ambrosio and Frick (2012) showed that individual satisfaction is positively

[7] Senik (2009) uses 2006 LiTS data, covering 28 post-transition countries (plus Turkey). She concluded that dynamic income comparisons (to oneself in the past) are more important than a number of other comparison benchmarks.

correlated with the income today of such people. Analogously, the income gap with respect to those who are now behind the individual but who were ahead of her reduces the individual's satisfaction, which is consistent with a negative signal that the individual could well be one of this group tomorrow. Finding such an effect in an advanced stable economy such as Germany is new and perhaps unexpected, in that previous work in the literature had rather underlined the relevance of the tunnel effect in societies that were either volatile or in earlier stages of economic development.

The broad conclusion from this work, which is by now far too voluminous to be listed in detail, is that others' incomes often do play a role in determining an individual's well-being. As the income of others to whom I compare rises, my well-being falls, but this status effect may be diminished or even entirely neutralized by a signal effect if what happens to others today informs me about what may happen to me in the future.

In general, however, the link between the formal models of income gaps (which are behind the measurement of inequality) and empirical work in the subjective well-being literature has been weak. The subjective well-being spillovers in society consist of a many-to-many mapping. As incomes in a society change, we need to know both who is affected by a movement in the income of individual *i* and who is in individual *i*'s reference group. We then have to identify the nature of the relationship between each pair: relative deprivation, relative satisfaction, or rather aspirations? Put in this light, it is obvious that we are asking a great deal of the information that is contained in standard surveys, all of which contain significant lacunae in this respect. To complement our understanding of how my well-being depends on my comparison to your income, we turn to experimental economics, where all the relevant parameters of the comparison process can arguably be controlled.

13.2.2 Experimental Economics

Experimentalists appeal to the notion of interdependence in preferences to explain the behavior of subjects who repeatedly violate game-theoretic predictions. Extensive surveys of work in this area can be found in Fehr and Schmidt (2003), Sobel (2005), and Camerer and Fehr (2006).

Interdependent preferences, that is, preferences that depend directly on the situation of others, were modeled formally for the first time in the theory of consumer demand. The phenomenon whereby individual utility functions depend on other people's income or consumption is known generically as the relative income hypothesis (Duesenberry, 1949). This can be further differentiated into "Keeping up with the Joneses," where the preference interaction with others depends on current consumption, and "Catching up with the Joneses," where it depends on lagged consumption. Leibenstein (1950) was the first to introduce demand functions that explicitly took into account the desire to be "in style," bandwagon and snob effects, and conspicuous consumption. Since then the literature has advanced to a considerable degree of sophistication, exploring the implications of such preferences on the theory of asset pricing (Abel, 1990; Campbell and Cochrane, 1999; Galí, 1994), Pareto optimality (Collard, 1975; Shall, 1972), the theory of optimal taxation (Abel, 2005; Aronsson and Johansson-Stenman, 2008; Boskin and Sheshinki, 1978; Dupor and Liu, 2003; Ljungqvist and Uhlig, 2000), the determination of work hours (Bell and Freeman, 2001; Bowles and Park, 2005), public spending (Ng, 1987), and the allocation of resources in general (Fershtman and Weiss, 1993), among others. A theory of social interactions has been proposed using varying formulations, where preferences are either defined over general consumption goods or an individual's identity. See Becker (1974) and Stigler and Becker (1974) for the first group and Akerlof and Kranton (2000) for the second. Sobel (2005) provides a thought-provoking discussion of the similarities and differences between these two strands of the literature.

Experimental work has made significant contributions to this area, in particular in considering the distribution of income across players, and distinguishing between doing better than others and doing worse than them.

13.2.2.1 Models of the Distribution of Income

The experimental economics literature fully incorporated distributional concerns into the utility function for the first time in Bolton (1991), with the modeling of *inequity* or *inequality aversion*. The two terms are very often used as synonyms in the literature to refer to the single phenomenon: that "people resist inequitable outcomes; i.e. the fact that they are willing to give up some material payoff to move in the direction of more equitable outcomes" as Fehr and Schmidt (1999, p. 819), to whom the definition of inequity aversion is due, put it.

The effect of inequality clearly results from some comparison being made to the reference group. On this point Fehr and Schmidt (1999, p. 819) continued by explaining that "Inequity aversion is self-centered if people do not care per se about inequality that exists among other people but are only interested in the fairness of their own material payoff relative to the payoff of others".

Fehr and Schmidt (1999) incorporated inequality into the individual utility function via the inclusion of all the pairs of the differences between the individual's own income and others' incomes. Bolton and Ockenfels (2000), who refined the earlier work of Bolton (1991), proposed an inequality-averse utility function that depends on the individual's own income and their share of the total income. The survey in Engelmann and Strobel (2007) compares these two approaches, together with that of Charness and Rabin (2002). Charness and Rabin's model is more related to social welfare than to inequality aversion and will not be analyzed in what follows: preferences in Charness and Rabin are a combination of the individual's own payoff and the payoff of the worst-off individual only.

Fehr and Schmidt (1999), who we henceforth call FS, proposed a utility function for individual i, $i=1,\ldots,n$, which depends on the individual's own outcome, and the gaps to those in the better-off set and the worse-off set, as defined in Section 13.2.1

$$U_i(x) = x_i + \alpha \sum_{j \in B_i(x)} \frac{x_j - x_i}{n} + \beta \sum_{j \in W_i(x)} \frac{x_i - x_j}{n} \tag{13.1}$$

where $\alpha \leq \beta \leq 0$ In this formulation, the utility of an individual depends positively on their own income, but negatively on both their levels of disadvantageous inequality (the gaps to those who earn more than them: the second term in Equation 13.1) and advantageous inequality (the gaps to those who earn less than them: the third term in Equation 13.1). According to Fehr and Schmidt, individuals dislike inequitable distributions. "They experience inequity if they are worse off in material terms than the other players in the experiment, and they also feel inequity if they are better off. (...) (H)owever, we assume that, in general, subjects suffer more from inequity that is to their material disadvantage than from inequity that is to their material advantage" (Fehr and Schmidt, 1999, p. 822). As such, α is larger in absolute terms than is β.

In the approach taken by Bolton and Ockenfels (2000), individuals are motivated by both their own pecuniary payoff and their relative payoff standing. They propose a theory of equity, reciprocity, and competition (ERC) in which the individual utility function is given by $U_i(x) = U_i\left(x_i, \frac{x_i}{\sum_{j=1}^{n} x_j}\right)$. The derivative of U_i with respect to the second argument is nonmonotonic, exhibiting a hump shape. This utility function satisfies a number of properties and, in a two-player game, with player i and j, one example of such an additively-separable utility function is

$$U_i(x) = a_i x_i + \frac{b_i}{2}\left(\frac{x_i}{x_i + x_j} - \frac{1}{2}\right)^2 \tag{13.2}$$

where $a_i \geq 0,\ \ b_i < 0$. In Equation (13.2), the utility of player i rises with her share of income when her share is under 50% and falls with her share when this share is over 50%.

In most experiments, these two models (FS and ERC) yield similar predictions. However, the predicted outcomes can differ for games where there are three or more players because ERC is not sensitive to all the inequalities in payoffs. In the ERC formulation, individuals want the average payoff of others to be as close as possible to their own but do not dislike the presence of richer and poorer individuals per se; in Fehr and Schmidt, individuals dislike inequality in all the outcomes. The experiment conducted in Engelmann and Strobel (2000) is designed to compare the performance of these two models: their results suggest that the formulation proposed by Fehr and Schmidt performs better than the ERC. A similar conclusion was reached by Dawes et al. (2007): Humans appear to be strongly motivated by egalitarian preferences.

The various contributions to the experimental literature measure inequality aversion via a number of alternative methods, which we will describe later. We believe that the appropriate term that should be used here is indeed inequality aversion, and not the original one proposed of inequity aversion. All the empirical contributions here are based on the assumption that the equality of payoffs is the fair, and hence equitable, outcome. But this need not necessarily be the case. If the distribution of income is not random, but depends (or is thought to depend) on individual effort or some other kind of meritworthy individual characteristic, the individual's view of what is equitable will depend on her own moral standards and the normative reference group. Opinions regarding what distribution of income is equitable will then very likely differ among subjects (see the discussion in Güth et al., 2009; Tyran and Sausgruber, 2006).

Experimental work has tested for the presence of inequality aversion and its consequences for economic outcomes in a number of different settings, such as ultimatum games, dictator games, dynamic bargaining games, public-good games with punishment, and redistribution games.[8]

13.2.2.2 Experimental Evidence from Ultimatum, Dictator and Dynamic-Bargaining Games

In the ultimatum game, some subjects, the proposers, are asked to suggest a division of a certain sum of money, say 100, between themselves and the other subjects, the responders. The proposer suggests a division, which the responder can either accept or reject. If the latter accepts the proposal, both the proposer and the receiver receive the money in accordance with the proposed division; if the responder refuses, neither player receives anything. Both the proposer and the respondent are fully aware of the rules of the game. The standard economic prediction based on subgame perfection is that the resulting outcomes will be very unequal: the proposer should make an offer of just over zero, and the responder should accept any positive offer that is made to them (as something is always better than nothing).

This prediction is not borne out by the behavior that is actually observed in the lab. The experimental results reveal a far more equal division of the pie, with responders frequently rejecting offers that are under 25% of the total sum (see Camerer, 2003; Levitt and List, 2007; see also Thaler, 1988, for a more comprehensive discussion of the general anomalies of these results). Bellemare et al. (2008) provide representative estimates of inequality aversion for the Dutch population. They found considerable differences between socioeconomic groups. Inequality aversion, in particular advantageous inequality, rises with age and falls with education level. Young and highly educated participants are one of the most selfish subgroups of the population under consideration. Fehr and

[8] More unconventional experiments have also been carried out showing preferences for fair redistributions (in experimental settings where effort can be controlled for) among Capuchin monkeys (Brosnan and de Waal, 2003) and 19-month-old infants (Sloane et al., 2012).

Schmidt (1999), in their survey of experimental results from the ultimatum game, noted that the vast majority of offers are consequently between 40% and 50% of the total sum, and no offers are below 20%. These results seem to hold regardless of the size of the sum that is to be divided, and in particular are also found in high-stakes games.

The second type of experiment used to reveal preferences over inequality is the dictator game. This is a simple variation of the ultimatum game, with the advantage of being nonstrategic. Here, as the name suggests, the proposer behaves like a dictator in proposing a split of the sum to be divided, with the responder having to accept the offer and thus having no decision to make. Experiments using the dictator game yield, as perhaps might be expected, distributions of income between the two players that are less egalitarian than those from the ultimatum game described earlier, with the proposer offering lower amounts. Even so, and despite the proposer running no risk of rejection, positive amounts of money are still offered. The survey of 616 such experiments in Engel (2011) concludes that dictators give on average 28.35% of the sum of money to be split to the responder, which is far from the self-interested economic prediction of no money being offered at all.

Abbink et al. (2009) also considered dictator games, but in the novel context of the destruction of others' income. This destruction is both negatively and positively framed. In the latter, individuals can decide to award their partner 50 points, and by doing so gain 10 points themselves. The decision not to make this award is analogous to the destruction of 50 of their partner's points at a cost of 10 points to themselves (and this is how the decision appears in the negative framing). Abbink et al. found destruction rates of about 25% with both framings. One surprising finding is that initially equal income distributions are actually more likely to be burnt, and the authors conclude as to the presence of a certain amount of equity aversion. One potential reading of this result is that, in their setup, the initially equal distribution is the only one from which the individual can gain rank by burning money (see their Table 1). We will return to the question of the rank comparisons of income in Section 13.4.2.

Last, in dynamic bargaining games, the evolution of bargaining proposals over time and the reasons that individuals provide for their behavior during the bargaining process can be examined jointly. In this framework, the experiments in Herreiner and Puppe (2010) show that Pareto-inferior solutions pertain due to the players' inequality aversion. For example, it is found that a majority (51%) of bargaining partners will reject the unequal payoff distribution of (46, 75) in favor of the Pareto-inferior equal split of (45, 45).

13.2.2.3 Public-Good Contributions and Punishment

In the public-good game, players are given an endowment and then secretly choose how much of this endowment they wish to put into the public pot (in order to finance the supposed public good, which will benefit everyone) and how much they would like to keep for themselves. Once the donation decisions have been taken by all players, the total sum of money in the public pot is multiplied by a factor of greater than one, and the resulting amount is evenly divided among all players. The Nash equilibrium in this game is for each player to contribute nothing to the public good. However, in experiments subjects are found to contribute an average of 40–60% of their endowment (Camerer and Fehr, 2004).

The public-good game can be refined by introducing a second stage in which information on others' contributions is provided, and players can punish each other. Introducing potential punishment in this second stage causes a sharp jump in cooperation in the first stage public-good game, as shown in Fehr and Gächter (2000). Masclet and Villeval (2008) assessed the role of inequality aversion in determining individuals' decisions to punish. They showed that individuals will punish others even when this punishment does not immediately affect the distribution of payoffs (in some situations the cost of one punishment point to the punisher is the same as the cost of this point to the target). Consistent with previous work, punishers are not primarily motivated by a desire to increase equality. Interindividual comparisons of outcomes do play a decisive role in the punishment decision in all treatments; the intensity of punishment is strongly correlated with the size of the difference in contributions and earnings between the punisher and the target. This result indicates that, irrespective of the willingness to directly reduce payoff differences, individuals may be willing to punish those whose decisions give rise to payoff differences, and that this inequality arouses emotions that trigger punishment. Punishment is shown to reduce inequality over time, as potential free-riders are incited to increase their contributions.

An open question in this literature is why individuals decide to spend their own resources to punish others. This decision could be self-centered, as today's punishment enhances my own future interests, or carried out altruistically in order to confer an advantage on my kin or group (see Van Veelen, 2012). Of course, any prosocial behavior can be self-interested if we include nonpecuniary moral preferences in the utility function (Levitt and List, 2007).

The sequential public-good game can be used to estimate separately the advantageous and disadvantageous inequality aversion suggested by Fehr and Schmidt (1999). In this game with two players, the first mover chooses his contribution to the public good under strategic uncertainty, as he does not know what the second mover will decide. The second mover does know what the first mover has decided and can choose to contribute either the same amount as the first mover or zero. Teyssier (2012) confirmed the theoretical predictions: First movers with greater risk aversion or disadvantageous inequality aversion contribute less to the public good than do others, and second movers with a sufficiently high degree of advantageous inequality aversion contribute more than do others. (For an analysis of risk aversion in the experimental literature see Section 13.3.2.).

Inequality aversion as in Fehr and Schmidt has been also applied to the analysis of the results of voting over redistribution. Although traditional economic models predict no redistribution, Tyran and Sausgruber (2006) showed that inequality aversion can predict the opposite result in their experiments, in which subjects have different endowments and decide how to redistribute from the rich to the poor by majority vote. On this point see also Farina and Grimalda (2011). In taxation games, Bolton and Ockenfels's ERC can predict the opposite allocations to those in Fehr and Schmidt, as shown by Engelmann and Strobel (2004), because the middle class would no longer be in favor of redistribution.

13.2.2.4 Deservingness: The Source of Income

One of the critiques of inequality aversion models and the experiments used to test them is that they often neglect the procedure that is behind the money to be allocated. Money appears here out of nowhere as "manna from heaven"; see, on this point, Bergh (2008) and Güth et al. (2009), among many others. In the majority of experiments, income is an allocation, so that having more than others is not seen as being deserved. However, in many real-world applications individuals likely believe that they earn more than others because they deserve to do so. As might be imagined, when income is considered to reflect effort rather than luck, the results do change. For example, Hoffman et al. (1994) reported that when the role of proposer in the ultimatum game is earned, rather than being randomly assigned, proposers offer less and respondents are more likely to accept unequal offers. Similar results are found in Cherry et al. (2002) when the asset of the dictators in the bargaining game is legitimate. We will return to this point in Section 13.4.3 when describing some evidence from the income-distribution literature on the fairness of outcomes. Another critique refers to the size of the stakes, with the suggestion that inequality aversion may be lower when the stakes are high. See on this point the discussion in Eckel and Gintis (2010), who concluded that this fact does not refute the theory but is rather a proof of the rationality of subjects who take the costs of their behavior into account.

A more general criticism of FS, which calls the scientific basis of their method into question, is contained in the various contributions of Shaked, and Binmore and Shaked. The details can be found in the January 2010 special issue "On the Methodology of Experimental Economics" of the *Journal of Economic Behavior & Organization*. This special issue includes the critique by Binmore and Shaked (2010a), the replies by Fehr and Schmidt (2010) and Eckel and Gintis (2010), and the rejoinder by Binmore and Shaked (2010b).

A novel test of the desire to change the income distribution and the provenance of the income in question appears in Zizzo and Oswald (2001). Rather than taking money from one person and giving it to another, participants in this experiment are allowed (at a cost to themselves) to destroy each other's earnings. This is the "negative framing" of the destruction described in Abbink et al. (2009) above. Participants played in groups of four. Each participant has the same amount of money to start with and can attempt to increase it by 10 rounds of betting on a number (1, 2, or 3) that is randomly chosen by a computer. A maximum amount per round can be wagered. This betting stage creates an unequal distribution of income. In the second stage, players can pay to burn each other's earnings, at a price to themselves of 0.01, 0.02, 0.05, and 0.25 of a money unit per money unit burnt.

Although the initial distribution of income is equal, two of the four players in each group are favored. These players can bet more than the others in each round of the betting stage, and they in addition receive a cash bonus between the betting and burning stages. This is public knowledge.

The results in Zizzo and Oswald show a remarkable amount of destruction. Just under two-thirds of players burned some money, and the average player had just shy of half of their earnings burned. The destruction rates here are higher than those in Abbink et al. (2009), which may well reflect that the average burning price here is lower. There is little evidence of a price elasticity of burning, except at the top burning-cost rate of 0.25. In the context of the current paper, richer players were burned more, but especially the two players who had received an unfair advantage were burned more.

13.2.2.5 Hypothetical Preferences and Neuro Evidence

Inequality aversion runs counter to the hypothesis that individuals are status seeking, as noted by Bolton and Ockenfels (2000, p. 172). The concern for relative standing is the focus of another set of contributions in experimental economics (see Alpizar et al., 2005; Johansson-Stenman et al., 2002; Solnick and Hemenway, 1998; Yamada and Sato, 2013). The approach here is to allow individuals to make choices over hypothetical states of the world to understand how important absolute and relative outcomes are to them. In income terms, these are couched in terms of own income and average societal income. The greater the importance of relative income, the more the individual will be willing to give up own income to achieve a better relative standing.

For example, in Solnick and Hemenway (1998), individuals are asked to choose between states *A* and *B*, as follows:

A. Your current yearly income is \$50,000; others earn \$25,000.

B. Your current yearly income is \$100,000; others earn \$200,000.

It is specified that "others" refers to the average of other people in the society and emphasized that "prices are what they are currently and prices (the purchasing power of money) are the same in States *A* and *B*."

The key in this hypothetical-choice literature is that respondents choose between one state in which they are better off in absolute terms and another in which they are better off compared with others. All of the cited papers find evidence of strong positional concerns over income, in that individuals report that they are willing to give up absolute income to gain status (choosing *A* over *B*). The percentage who exhibit "relative" preferences can be large: Half of the respondents said that they preferred to have 50% less real income but higher relative income (i.e., they preferred *A* to *B*; see Solnick and Hemenway, 1998, 2005).

Such choice experiments are easy to couch in terms of consumption or other life domains, rather than income, as well. The taste for relative standing in Solnick and Hemenway (1998) is found to be strongest for attractiveness and supervisor's praise and weakest for vacation time; in Alpizar et al. (2005) it is stronger for cars and housing and weaker for vacations and insurance. A useful extension in Corazzini et al. (2012) is to take the approach outside of only rich countries; in their work, respondents in high-income countries are more concerned by relative standing than are those in lower-income countries.

Most of these experiments have been conducted with students, which is the standard practice in experimental economics. Carlsson et al. (2007) is the first study that is based on a random sample of the population as a whole. Their results are comparable to those in Alpizar et al. (2005), who found that on average about half of the utility obtained from an additional dollar comes from relative concerns. Carlsson et al. (2007) reported that, on average, 45% of the utility increase from a small income increase arises from enjoying a higher relative income, a result that is halfway between 100% (corresponding to the hypothesis that only relative income matters) and 0% (where only absolute income matters).

A final set of experimental results comes from the recent NeuroEconomics literature. Fließbach et al. (2007) appealed to MRI techniques to measure the brain activity of pairs of individuals who carry out identical evaluation tasks in different scanners. If the individual succeeds in the task (remembering the number of blue dots on a previous screen, which they see for one and a half seconds), they obtain a monetary reward of a certain size, as indicated on their computer screen. The outcome of the other player (their success, and the amount won if the answer was correct) is shown at the same time. Fließbach and colleagues manipulated both the amount the individual won if correct and the amount the other player won to create a number of contrasting conditions. For example, in their conditions C6, C8, and C11, the individual always won 60 euros if his answer was correct (all participants were men), but the other player won, if correct, 120, 60, and 30 euros, respectively. One of each individual subject's many trials was randomly picked for payment after the end of the experiment.

The results show that relative incomes matter. Holding the subject's own earnings constant, the amount earned by the other player is significantly correlated with blood oxygenation level-dependent (BOLD) responses in the ventral striatum, one of the regions of the brain known to be involved in the processing of rewards. Wu et al. (2012) also found evidence of social comparisons in brain activity and suggested that it mostly appears in later cognitive appraisals and reappraisals, rather than in the initial evaluation stage. Recent follow-up work by Fließbach et al. (2012) repeated their 2007 experiment, but this time with both men and women, and distinguished between advantageous and disadvantageous inequality. Disadvantageous inequality is shown to have a much larger impact on brain activity in the ventral striatum than does advantageous inequality.[9] Dohmen et al. (2011) also used the same experiment and showed in a regression analysis that the effects of own and others' income on activation in the ventral striatum are equal and opposite (which was also true in the 2007 experiment). This holds for both men and women, although the estimated effect of both income variables is larger in size for men.

Somewhat similar in intent, although the experiment here consisted of individuals reading written reports on (fictitious) others who were superior or inferior to the respondent and the good or bad events that happened to them, is Takahashi et al. (2009).

Dawes et al. (2012) explicitly considered redistribution and brain activity. They considered individual decisions to pay a cost to change the distribution of income within a group, where this latter distribution was determined randomly. Redistribution was correlated with brain activation in an area known to reflect social preferences. In addition, this brain activation was shown to be correlated with survey measures of egalitarian preferences that were elicited outside of the scanner. Zaki and Mitchell (2011) showed that inequitable decision making (choosing to favor a smaller reward for oneself rather than a larger reward for the other player in a modified dictator game) is associated with brain activity in a region associated with subjective disutility. Last, Tricomi et al. (2010) explicitly addressed advantageous and disadvantageous inequality by randomly assigning individuals in pairs to be rich (with \$50) or poor (no dollars) after both received an initial allocation of \$30. Brain activity in areas known to be related to the valuation of stimuli was then measured via MRI as further transfers to both pairs were carried out. The results showed that the "poor" responded more strongly to transfers to themselves than to the other person, whereas the "rich" evaluated transfers to others more strongly than transfers to self. This is argued to show that individuals have social preferences over both advantageous and disadvantageous inequality.[10]

The discussion in the current section has shown that there is by now a considerable body of evidence consistent with individuals comparing their incomes with each other. Income is, in this sense, a social good. A certain amount of work has suggested something

[9] In a completely different setting, Cohn et al. (2014) also concluded that disadvantageous inequality matters more for effort decisions in a laboratory experiment than does advantageous inequality. Specifically, in a field experiment, individuals who reported that they were underpaid at an initial base wage increased their performance as the hourly wage rises; there was no such effect for those who reported being adequately paid or overpaid. Cohn et al. further showed that this distinction in the effort response to wages is only found for subjects who display positive reciprocity in a laboratory experiment.

[10] A novel contribution in the broad area of physiological reactions to income distribution is Falk et al. (2013). This paper first shows in an experimental setting that perceived wage unfairness (as in unmet expectations about the share of a reward to be received) is associated with measured individual heart-rate variability. It is also shows that the answer to a question on unfair pay in the 2009 wave of the SOEP is correlated with self-reported health outcomes and in particular with cardiovascular health.

of a loss aversion with respect to these comparisons, in that doing worse than others is more important in a well-being sense than doing better than others.

Any movement in the distribution of income will therefore affect societal well-being both directly, via changes in individuals' own incomes, and in a comparative manner, via the various gaps between individual incomes. Imagine a rise in inequality caused by an increase in some top incomes. Those who benefit from higher incomes will have higher well-being, both because they are richer and because their gaps to others have risen (although this effect may only be secondary). On the contrary, those whose incomes have not risen and who compare to the fortunate few who are richer are now relatively worse off, which reduces their well-being. The overall effect is a priori ambiguous.

Alternatively, inequality may fall due to a rise in the incomes of those at the bottom of the distribution (via an uptick in the minimum wage, say). Again, the well-being of those who benefit rises, both via greater own income and smaller gaps to the richer others. But the well-being of those who do not benefit falls as their advantageous gaps to the poorer are now smaller in size. If we continue to believe that this latter effect is of second order, then we may expect societal well-being to improve here.

Unfortunately, most of the changes in the distribution of income that we see are not this stylized. To make any kind of welfare statement, we need to know who compares to whom, how much the different kinds of income gaps matter, and how much relative income matters compared to absolute income. We have little reasonable hope of measuring these magnitudes with any degree of accuracy in existing data.

Even so, we do believe that the comparative reference group exists and represents one central constituent of attitudes toward inequality in an economy. The other main part of such attitudes comes from the normative view of inequality in the income distribution (as defined in the Introduction). Although there is a substantial amount of work devoted to the comparative reference group, it arguably turns out to be rather more difficult to evaluate normative attitudes toward inequality. It is to this question that we turn in Section 13.3. In this section we will also review some of the work that has tried to disentangle the various motivations behind individuals' actions.

13.3. THE NORMATIVE VIEW

In the normative view of the reference group, an individual evaluates the overall degree of income inequality in the reference group, but without making any comparisons to individuals who are richer or poorer than she is. Depending on the attitudes and social norms prevailing within a group, the individual can evaluate these income disparities as fair or unfair.

As in Section 13.2, regarding the comparative view of the reference group, there is evidence on the normative view of the reference group from both subjective well-being research and experimental analysis.

13.3.1 Inequality and Well-Being: What Do People Say?

We are interested in this chapter, as the title suggests, in individuals' attitudes toward or opinions about inequality. There are a number of ways in which these can be elicited, including direct questioning, experimental approaches, or inference from observed behaviors. In this subsection, we consider the contribution of "happiness economics," in which some measure of income inequality is related to the individual's self-reported well-being. In general, an equation similar to the following is estimated:

$$W_{ijt} = \alpha + \beta X_{it} + \gamma \text{Ineq}_{jt} + \varepsilon_{it}. \tag{13.3}$$

In this approach, we collect survey information on the subjective well-being of an individual i, living in some aggregate area j (where j is often, but not always, a country) at time t. This subjective well-being is related to a vector of standard demographic variables (age, sex, education, labor-force and marital statuses and almost always the individual's or the household's income) through the vector β. Of most interest to us here is the conditional correlation (i.e., controlling for all the variables in the vector X) between well-being and the aggregate measure of inequality in area j, Ineq_{jt}. The estimated value of the parameter γ shows us whether individuals, ceteris paribus, tick up or down their self-reported well-being scores in areas with higher or lower levels of income inequality.

The estimation of an equation like Equation (13.3) allows the "value of inequality," as it were, to be inferred from the empirical relationship between the observed inequality around the individual and their reported level of subjective well-being. This latter is most often measured by questions about the individual's happiness, life, and income satisfaction or some other measure of general psychological functioning. Multivariate regressions allow not only the sign of the conditional correlation between income inequality and subjective well-being to be established (γ shown earlier), but also the economic importance of any relationship that is identified (via the comparison of γ to some of the estimated β coefficients on other variables, such as income or unemployment).

This "happiness" approach to valuing public goods has now appeared a number of times in the subjective well-being literature. Some well-known pieces of work in this respect have considered inflation and unemployment (Di Tella et al., 2001), aircraft noise (Van Praag and Baarsma, 2005), and pollution (Luechinger, 2009), although there are by now many other applications.

Cross-section and panel data allow the happiness or satisfaction of tens or even hundreds of thousands of individuals to be measured. It is perhaps easy to get carried away by the sheer number of degrees of freedom here. Except that, as we suggest later, this is largely illusory: Although it is theoretically possible for each individual to be confronted with a different income distribution, the most common approach has been to take cross-country data, often repeated cross-section, and include the country-level Gini coefficient (or something else) on the right-hand side of a satisfaction regression. In this case, the effective number of degrees of freedom in the empirical estimation remains for the most part at the two-digit level.[11]

Although there are by now many thousands of empirical contributions across the social sciences that relate individual income to some measure of individual well-being, it remains true that only a small fraction of this existing work has considered any role for income inequality. Even so, it seems that the ease of access to large-scale data sets has led to relatively consistent growth of research in this area over time. A necessarily incomplete but hopefully somewhat-representative sample of some of the work that has been carried out in the area of income inequality and subjective well-being appears in Table 13.1. This table broadly reflects the growth in interest in the subject, but also considerable disparity in the estimated value of γ, as revealed by happiness data.

Perhaps the earliest contribution in economics is Morawetz et al. (1977), which contrasts two different Israeli communities and shows that the level of happiness is higher in the community with the more equal income distribution. Although interesting, the result essentially relies on two observations and does not control for all of the other factors that might differ between the two communities. A contribution that is more in the regression framework is an innovative article by Tomes (1986). This uses data (from the 1977 Quality of Life Survey) on individuals in approximately 200 Federal Electoral Districts in Canada. Matching in census data on income distribution, it is shown that the share of income received by the bottom 40% of the population is negatively correlated (at the 10% level) with both satisfaction and happiness for men. The same correlations are insignificant for women. Inequality is thus positively correlated with men's subjective well-being.

Hagerty (2000) is the first of a number of contributions to use U.S. General Social Survey (GSS) data. In his GSS sample from 1989 to 1996, maximum community income and the skew of community income are, respectively, negatively and positively correlated with happiness scores. Hagerty also used aggregate data from eight different countries to show that average happiness is lower in countries with wider income distributions. More recent work using the GSS has, however, come to a variety of results. Whereas Blanchflower and Oswald (2003) and Oishi et al. (2011) both concluded that there is a negative relationship between life satisfaction and income inequality, Alesina et al. (2004) and Di Tella and MacCulloch (2008) both found no significant relationships in GSS data. Alesina et al. (2004) is of interest here, as they explicitly compare long-run U.S. and European data, from the GSS (1972–1997) and Eurobarometer (1975–1992), respectively. Over the whole sample, inequality reduces reported subjective well-being among Europeans, but not Americans. The authors suggested greater (perceived) social mobility in the United States as one potential explanation of this difference.

[11] As one of the right-hand side variables in these kinds of regression is aggregated at a higher level than the dependent variable, the standard errors are underestimated and should be corrected as in Moulton (1990); it is not always clear that this correction is carried out in this literature.

Table 13.1 Income inequality and individual subjective well-being

Authors	Country	Data	Inequality measure	SWB measure	Inequality and SWB?
Morawetz et al. (1977)	Israel	Two different communities	Gini at community level	Happiness	Negative
Tomes (1986)	Canada	1977 Quality of Life Survey	Census data on share of income received by the bottom 40% in 200 Federal Electoral Districts	Satisfaction and happiness	Positive correlation for men
Hagerty (2000)	USA	GSS (1989–1996)	Maximum and skew of community income	Happiness	Negative
Hagerty (2000)	Cross-country	Eight countries	Gini	Happiness	Negative
Ball (2001)	Cross-country	1996 World Values Survey	Gini by country	Life satisfaction	Positive in raw data, positive and insignificant with controls
Blanchflower and Oswald (2003)	USA	20 Years of GSS	D5/D1 by state and year	Life satisfaction	Negative (but only significant for women, young, and the less educated)
Clark (2003)	UK	BHPS waves 1–11	Gini by region and year	Life satisfaction	Positive, especially for those who are more income mobile
Helliwell (2003)	Cross-country	WVS waves 1–3	Gini by country and year	Life satisfaction	No relation
Senik (2004)	Russia	5 Years of RLMS	Gini by region and year	Life satisfaction	No relation
Alesina et al. (2004)	USA	GSS (1972–1997)	Gini by year	Life satisfaction	No relation
Alesina et al. (2004)	Cross-country	Eurobarometer (1975–1992)	Gini by country and year	Life satisfaction	Negative
Graham and Felton (2006)	Cross-country	Latinobarómetro	Gini by country and year	Happiness	No relation
Schwarze and Härpfer (2007)	Germany	SOEP	Gini by region and year	Life satisfaction	Negative

Continued

Table 13.1 Income inequality and individual subjective well-being—cont'd

Authors	Country	Data	Inequality measure	SWB measure	Inequality and SWB?
Biancotti and D'Alessio (2008)	Cross-country	European Social Survey	Interquartile range by country	Happiness	Negative for those with more inclusive and moderate values
Bjørnskov et al. (2008)	Cross-country	WVS wave 3	Gini by country	Life satisfaction	No relation
Di Tella and MacCulloch (2008)	Cross-country	Eurobarometer and GSS (1975–1997)	Gini by country and year	Life satisfaction	No relation, but depends on other variables included in the regression
Ebert and Welsch (2009)	Cross-country	Eurobarometer (1978–1997)	Gini, Atkinson and hybrid measures by country and year	Life satisfaction	Negative
Knight et al. (2009)	China	2002 National household survey	Gini by county	Happiness	Positive
Berg and Veenhoven (2010)	Cross-country	World Database of Happiness (2000–2006)	Gini by country and year	Happiness	Slightly positive
Grosfeld and Senik (2010)	Poland	CBOS repeated cross-sections (1992–2005)	Gini by cross-section	Country satisfaction	Positive and then Negative as transition takes place (break in 1996). Positive effect only for right-wingers
Oshio and Kobayashi (2010)	Japan	Japanese General Social Survey (JGSS: 2000, 2003 and 2006)	Gini by prefecture and year	Happiness	Negative
Winkelmann and Winkelmann (2010)	Switzerland	Swiss Household Panel 2002	Gini by municipality/canton/region	Financial satisfaction	Negative

Oishi et al. (2011)	USA	GSS (1972–2008)	Gini by year	Happiness	Negative. Effect significant only for those in the bottom two quintiles of the income distribution. Effect is moderated by the perceived fairness of others, and whether the individual believes that others can be trusted
Verme (2011)	Cross-country	WVS waves 1–4	Gini by country and year	Life satisfaction	Negative
Van de Werfhorst and Salverda (2012)	Cross-country	ESS round 4	Gini by country	Happiness	Negative
Bjørnskov et al. (2013)	Cross-country	WVS waves 2–5	Gini by country and year	Life satisfaction	Effect more Positive the more the individual perceives society to be fair
Brodeur and Flèche (2013)	USA	BRFSS (2005–2010)	County-level percentage in poverty	Life satisfaction	Negative for all three of percentage of people of all ages in poverty, the percentage of related children age 5–17 in families in poverty and the percentage of people under age 18 in poverty in the county. Conditional on own income and neighborhood median income
Rozer and Kraaykamp (2013)	Cross-country	WVS waves 1–5	Gini by country and year	Average of Life satisfaction and happiness	Positive
Cojocaru (2014a)	Cross-country	LiTS wave 1	Gini by census enumeration area level	Life satisfaction	No relation

Schwarze and Härpfer (2007) calculated inequality in gross household income at the region and year level in 14 waves of German SOEP data. Life satisfaction is found to be negatively correlated with inequality (although a measure of income redistribution is not significant). Other work establishing a negative correlation between inequality and well-being includes Biancotti and D'Alessio (2008), Brodeur and Flèche (2013), Ebert and Welsch (2009), Oshio and Kobayashi (2010), Verme (2011), Van de Werfhorst and Salverda (2012), and Winkelmann and Winkelmann (2010), using data from a wide variety of different countries.

On the opposite side of the court, a number of contributions have instead concluded for a positive correlation. Along the same lines as the finding in Canadian data in Tomes (1986), Ball (2001) also found that happiness and inequality are positively correlated in raw data from the 1996 World Values Survey (WVS), although the introduction of a number control renders this positive correlation insignificant. The estimated value of γ in the first 11 waves of the British Household Panel Survey (BHPS) is positive (Clark, 2003), as is that in the first five waves of the WVS (Rozer and Kraaykamp, 2013). Last, in one of the relatively rare contributions entirely outside the OECD, Knight et al. (2009) found that county-level income inequality is positively correlated with happiness in the 2002 Chinese national household survey.

One recent intriguing contribution to this empirical debate comes from Grosfeld and Senik (2010). In contrast to a number of the contributions in Table 13.1, their identification is purely within and not between countries, as they consider data from Poland over its transition period. Using repeated CBOS cross-section data over the 1992–2005 period, they identified a turning point in the estimated relationship between inequality and subjective well-being. This correlation is positive and significant in the first years following transition, but then turns negative and significant. The break point that best fits this split in the data is 1996. The interpretation that the authors give is in terms of inequality first being regarded as providing opportunities for future higher incomes, which consequently turned into more negative comparative evaluations of disparities as it became clearer that not everyone would be able to benefit from any opportunities that this greater inequality promised.

As well as the sign and significance of the estimated effect, we are also interested in the size. Some of the work cited in Table 13.1 does contain explicit statements about marginal effects. For example, Tomes (1986) wrote that "an increase of 10% in the share of the poor reduces satisfaction by approximately 0.6 of a point. In order to maintain satisfaction unchanged, own income would have to be increased by \$4200 for every 1% increase in the share of the poor" (p. 435). This latter figure is larger than the annual income of 3860 Canadian dollars in his data set (although it should be noted that the confidence intervals around these estimates are quite large). Alesina et al. (2004) found that a one percentage-point rise in the Gini is compensated by a rise in annual income of 2950 dollars in the United States (8.7% of annual income) and 474 dollars in Europe (4.2% of annual income). The effect size in the SOEP in Schwarze and Härpfer (2007) seems more moderate: "If income inequality would be reduced by a half household income could be reduced by around 10% without changing life satisfaction" (p.244).

Although this kind of compensating differential is attractive in that it is easy to understand, it also obviously depends critically on the size of the estimated income coefficient in a subjective well-being equation. It is easy to believe that the coefficient on own income is actually an underestimate here, for standard endogeneity reasons, leading to trade-offs of income against inequality that are too high.

As an alternative, we consider the well-being effect of a one-point rise in the Gini coefficient, with the effect size being expressed as a percentage of the range of the subjective well-being measure. For example, the 0–10 life-satisfaction scale used in the SOEP has a range of 10; the corresponding 1–7 scale in the BHPS has a range of 6. It is not possible to calculate a standardized marginal effect using this metric across all of the work in Table 13.1. In the first instance, a number of the contributions here use ordered probit or ordered logit estimations, so that there are as many marginal effects as one minus the number of subjective well-being categories. Restricting ourselves to linear estimation techniques using the Gini, which yield significant estimates, cuts the sample down to five: Hagerty (2000), Schwarze and Härpfer (2007), Knight et al. (2009), Winkelmann and Winkelmann (2010), and Rozer and Kraaykamp (2013). These papers use five different data sets, with subjective well-being measured on a variety of scales.

Expressed as a percentage of the scale range, a 10% point change in the Gini coefficient mostly produces a movement in well-being of between 2% and 8% of the scale range (the exception being Schwarze and Härpfer, 2007, where the figure is smaller). In the SOEP, the standard deviation of life satisfaction is about 18% of scale range (1.79 for a scale of 0–10), with an analogous figure for the BHPS of 21% (1.29 for a 1–7 scale). A broad conclusion is that this very large movement in the Gini has an effect of between 0.1 and 0.4 of a standard deviation in life satisfaction. By way of comparison, the effect of unemployment on life satisfaction in the SOEP and the BHPS is somewhere around 6–10% of the scale range, or 0.3–0.5 of a life-satisfaction standard deviation.[12]

[12] It is arguably misleading to compare the size of the coefficient on inequality to that on individual unemployment. If half of the population are in the labor force, then a rise of 1% in the unemployment rate corresponds to one more person out of 200 in the population being unemployed rather than employed. Assuming that unemployment only affects the individuals who are unemployed (so that there are no spillovers) a one percentage point rise in the Gini index is roughly equal to a ten percentage point rise in the unemployment rate. For example, consider that subjective well-being is on a 1–10 scale, and the estimated coefficient on the Gini is –5: this ensures that a ten percentage point rise in the Gini will lead to a fall in predicted well-being of 0.5, which is 5% of the scale range (the midpoint of the figures mentioned in the text). If individual unemployment leads to an effect on individual well-being of 8% of the scale range (which is again the midpoint figure), then its estimated coefficient will be –0.8. A 1% rise in the Gini reduces well-being by 0.05 ($=0.01 \times 5$). A 1% rise in the unemployment rate will lead to a change in average well-being in the society by $-0.8/200=-0.004$. In this calculation, assuming no spillovers from the unemployed onto the nonunemployed, a rise in unemployment of over ten percentage points (12½ points, exactly) produces the same effect on societal well-being as a one percentage point rise in the Gini.

Some of the work on inequality and happiness here has explored the role of mediating variables or subgroup regressions to establish the subjective-groups for which the correlation with inequality is the largest to shed some light on the circumstances under which inequality affects subjective well-being. In the perhaps absence of a clear central tendency, it is arguably useful for policy purposes to know where and when inequality might be harmful in subjective well-being terms.

One of the best-known findings in this respect comes from Alesina et al. (2004): In Europe, inequality hurts the poor and left-wingers more (in the sense of having a greater negative effect on their well-being scores) than it does richer and right-wingers. This finding has recently been corroborated on more recent (2009–2010) Eurobarometer data by Vandendriessche (2012). Along the same lines, in Grosfeld and Senik (2010) the initial positive correlation between well-being and inequality was found only for right-wingers.

Other work has considered the mediating role of individual income. Oishi et al. (2011) found that the effect of inequality on happiness is negative and significant only for those in the bottom two quintiles of the income distribution. Schwarze and Härpfer (2007) found that only those in the first income tercile are negatively affected by post-government income inequality. In Clark (2003), the correlation between regional income inequality and individual well-being is more positive for individuals whose own income has been more mobile over time.

Oshio and Kobayashi (2010) carried out a number of tests of mediating variables and concluded that the correlation between happiness and inequality is more negative for women, the younger, those who have unstable positions on the labor market, and those who are politically in the center (rather than being progressive or conservative).

Some work has considered a mediating role for individual values, rather than observed demographic characteristics. In Biancotti and D'Alessio (2008), inequality has a more negative effect for individuals who report more inclusive and moderate values. Rozer and Kraaykamp (2013) found that the effect of Gini on well-being is more negative (actually less positive) for Europeans, those with more egalitarian norms (from a question on the relative preference for incomes being made more equal as opposed to needing larger income differences for incentive reasons), and those with greater levels of social and institutional trust. Last, as might be expected if the income distribution reveals information about the individual's own potential future position, in Ferrer-i-Carbonell and Ramos (2014) the effect of inequality is greater for those with higher (self-reported) measures of risk aversion in 1997–2007 SOEP data. The marginal effect of the Lander-Year Gini coefficient on life satisfaction is twice as negative for those with the highest risk-aversion score (on a 0–10 scale) as compared to the effect for those who report the modal score of 5.

One important individual value in the terms of this chapter, and one to which we shall return later, is the perceived fairness of the market system (i.e., the system that transforms individual inputs into individual outputs). In Oishi et al. (2011), the effect of inequality on happiness is moderated by the individual's perceived fairness of others and whether the individual believes that others can be trusted. Along the same lines, Bjørnskov et al. (2013) found that the perceived fairness of the income-generation process affects the association between income inequality and subjective well-being.

This burgeoning work on inequality and happiness has then revealed a number of intriguing findings. But perhaps one of the most striking aspects of Table 13.1 is the sheer variety of empirical correlations that have been uncovered. Is there any way of making sense of the variety of different estimated results here, or does sample variability rule the day (with as many positives as negatives as zeros)?

A first point, apparent from the fourth column of Table 13.1, is that there is no empirical agreement on the most appropriate measure of inequality. Although the majority of work refers to the Gini coefficient (a point to which we shall return in Section 13.4), it is also true that no consensus has been reached regarding the geographic level at which this coefficient should be evaluated.

Most of the empirical analysis has been carried out using data that contains only coarse-grained information on the distribution of income (i.e., at a very aggregated level, such as the country). Some work on British, Japanese, German, and Russian data has appealed to measures of inequality at the regional level (respectively: Clark, 2003; Oshio and Kobayashi, 2010; Schwarze and Härpfer, 2007; Senik, 2004). One of the few contributions to use large-scale data with more local-level inequality measures is Brodeur and Flèche (2013), who appeal to county-level information in the American BRFSS. Another is Winkelmann and Winkelmann (2010), who match in measures of inequality at all of the (in increasing order of size) municipality, region, and canton levels in the 2002 wave of the Swiss Household Panel. The research in Knight et al. (2009) combines more local-level measures of the distribution of income with data from a non-OECD country (China), finding a positive effect of the county-level Gini on respondents' happiness (see also Jiang et al., 2012).

One of the reasons why the degree of aggregation matters is that the Gini often moves only a little over time, a point made by Graham and Felton (2006), who noted that the Gini coefficient in Chile in the 2000s is not substantially different from that which pertained in the 1960s, despite the considerable social and economic changes that have taken place over the intervening period. Econometrically, it is then difficult to introduce both the Gini and country dummies into a regression, leading to the possibility that the Gini may be proxying for some other fixed country characteristic that is correlated with subjective well-being.

In general, this lack of variation in the measure of inequality does not help us to assuage the doubt that it is strongly correlated with some other variable that is important for happiness. For example, income inequality at the regional or country level could reflect industrial structure or the unemployment rate, both of which may well have independent effects on subjective well-being. Given a sufficient number of observations, it should be possible to tease out the independent contributions of inequality and other variables. But at the aggregate level it is anything but sure that sufficient observations are available. In general, the list of potentially important aggregate-level variables is often perilously close to the number of degrees of freedom in the analysis. In Di Tella and MacCulloch (2008), for example, income inequality attracts a negative but insignificant coefficient in their analysis of Eurobarometer and GSS data. They noted that this occurs "in part because there is some degree of co-linearity between the included variables. For example, if we do not include unemployment benefits, a variable that is highly correlated with inequality, we find that the coefficient on inequality becomes negative and significant" (p.36). Verme (2011) concurred that the lack of variability in survey measures of the Gini coefficient makes it particularly susceptible to multicollinearity with other aggregate-level variables (a problem he tackled via a number of robustness tests in which the other aggregate explanatory variables are dropped in turn).

An additional drawback to the empirical analysis of the relationship between individual well-being and aggregate income inequality is that it does not adequately distinguish between the comparative and normative aspects of the reference group. Even though some of the empirical analyses in Table 13.1 (although far from all) do introduce some measure of the mean of the income distribution into the analysis, they are unable almost by construction to calculate measures of relative deprivation and relative satisfaction from the survey data used. As such, any partial correlation between aggregate income inequality and individual subjective well-being very likely mixes together aspects of the comparative and normative reference groups, which perhaps explains the variety of estimated coefficients in Table 13.1.

Given the perhaps natural limits on the analysis of the relationship between aggregate inequality and individual subjective well-being, any evidence from this type of analysis will probably have to remain suggestive. This is arguably not the case for experimental work, where the reference group and the degree of inequality can be exactly manipulated, and it is to this that we now turn. Experimental work is of course not free of problems, in that what people say in a controlled setting may well differ from the way in which they would actually behave in reality, and their perceptions of inequality will likely be influenced by many factors. For a thorough discussion of these aspects and problems with experiments regarding social preferences, see Levitt and List (2007).

13.3.2 Experimental Economics

The experimental economics contributions to inequality aversion from the more aggregate perspective have appealed to two different approaches: (1) inequality and risk aversion with a parametric social welfare function; and (2) general social welfare functions. In the first of these, two types of experiments have been run. The first is similar to that adopted in the experiments on status or relative income discussed earlier in Section 13.2.2, that is the choice between alternative societies with different income distributions behind the veil of ignorance. The second type is based on the leaky-bucket experiment, which we introduce later.

Johansson-Stenman et al. (2002) carried out hypothetical-choice experiments. An individual's relative risk aversion is interpreted as the social inequality aversion from a utilitarian social welfare function's perspective. Inequality aversion is evaluated via individuals' choices between two types of society, from behind a veil of ignorance. Individuals are asked to choose the society that would be the best in terms of the well-being of their imaginary grandchild (in order for choices to be abstracted from the respondent's own circumstances and environment). The income distributions in the two societies, A and B, are uniform, and the respondent is told that their grandchild has an equal probability of receiving any income level within the range.

For example, Society A has a uniform income range of 10,000 to 50,000 Swedish kroner, whereas Society B has a uniform income range of 19,400 to 38,800 Swedish kroner. The student subjects in the experiment are told that prices are the same in the two societies, that there is no welfare state, and that there are no growth effects of the different income distributions.

An individual who is risk neutral will prefer Society A, in which expected income is higher. Someone who is indifferent between the two societies will have a relative risk-aversion parameter, η, that can be calculated by assuming a CRRA utility function[13] (see their Equation 5). In the example given earlier, indifference between societies A and B implies a value of η of 0.5; equally, an individual who prefers A (B) over B (A) will have a value of η of $<$ ($>$) 0.5. There are eight different conditions in their experiment. Society A always remains as described earlier, whereas there are eight society Bs, ordered such that indifference between A and B implies increasing risk aversion (see their Table 1). The higher is the value of η, the more income society is willing to give up to bring about a more egalitarian distribution of income, corresponding to a more concave social-welfare function.

The median value of inequality aversion in these experiments is in the interval between two and three. The respondents were fairly evenly distributed between the categories, with 43% of the respondents having inequality aversion of between one and five. Furthermore, a considerable number of respondents (17%) exhibited zero or negative inequality aversion. In addition, 19% of respondents exhibited extreme aversion compatible with the Rawlsian maxi-min strategy, which is the case of maximum aversion in the experiment. In a similar experimental setting, Carlsson et al. (2005) confirmed a median value of relative risk aversion of between two and three, and found a larger fraction of respondents (63%) with a value of relative risk aversion between one and five. In their experiment, 8% of respondents were found to be risk-lovers.[14]

[13] Such that $U = y^{1-\eta}/(1-\eta)$ if $\eta \neq 1$, and $U = \ln(y)$ if $\eta = 1$.

[14] It is notable that the values of the degree of inequality-aversion found in this experimental literature are far higher than those used in practice for the measurement of inequality: The U.S. Census Bureau uses a value of less than 1 (see http://www.census.gov/prod/2000pubs/p60-204.pdf), whereas the key inequality measures reported on the Luxemburg Income Study website as their "key figures" only use values of 0.5 and 1.

Some work in this area has tried to distinguish further between two types of inequality aversion: the first is the individual's level of risk aversion, as explained earlier, whereas the second is the individual willingness to pay to live in a more equal society. The estimation of individual inequality aversion only via risk aversion disregards any preferences that individuals may have regarding inequality per se.

To separate out these two attitudes, two types of experiments are carried out, one for each type of aversion. To this end, Carlsson et al. (2005) extended the analysis of Johansson-Stenman et al. (2002). The first experiment concerns the traditional imaginary grandchild, as described earlier, where the respondents do not know the position of their grandchildren, but only the income distribution and hence also the probability distribution in each society. In the second experiment, subjects choose between pairs of hypothetical societies with different income distributions, where the grandchild's income is known and is set equal to the mean income in the society. In other words, "In the first experiment individuals choose between hypothetical lotteries, where the outcomes determine their grandchildren's incomes in a given society. This experiment allows for the estimation of the individual's risk aversion in a setting where the level of social inequality is fixed. In the second experiment individuals choose between hypothetical societies with different income distributions, where the grandchildren's incomes are known and are always equal to the mean income in each society. This experiment enables us to estimate parameters of individual inequality aversion in a risk-free setting" (Carlsson et al., 2005, p.376).

In the second experiment, with a value of inequality aversion of zero, the individual is indifferent to income inequality; with a value of one, a 1% increase in own income yields as much utility as does a 1% fall in inequality. The median value of inequality aversion is found to be in the interval between 0.09 and 0.22, and most responses reflect positive inequality aversion. Only 7% of respondents appear to be inequality-lovers, in the sense that they are willing to sacrifice their own income to make society more unequal, whereas 6% are found to be extremely inequality-averse. Kroll and Davidovitz (2003) also found that subjects prefer more equal income distributions. However, when they had to give up part of their reward to shift to a more equal distribution, they chose not to do so.

Amiel et al. (1999) belongs to the second type of experiment in method (1), in which social inequality aversion is estimated via the *leaky-bucket* experiment. A sample of students were asked to indicate the amount of "lost money" that they were willing to accept for a transfer of money from a richer to a poorer individual, where this loss came about for example due to administrative costs. The median value of inequality aversion was estimated to be between 0.1 and 0.22, which is much lower than the existing estimates from the alternative approach, such as in Johansson-Stenman et al. (2002). However, the circumstances of the two experiments are very different, making a clear comparison of the results rather difficult.

That these large differences in the value of inequality aversion result from the different measurement techniques is confirmed by Pirttilä and Uusitalo (2010). The authors estimated inequality aversion using a questionnaire approach in a representative survey of Finns. The advantage of this questionnaire is that the same individual was asked questions based on two different measurement techniques: the leaky bucket and the preferred wage distribution under the veil of ignorance. The median value of the inequality aversion parameter from the leaky-bucket questions lay below 0.5. However, the results from the preferred distribution question gave a much higher value for inequality aversion, with the parameter being over 3. There are thus a considerable number of respondents who are willing to sacrifice the mean wage to bring about a more equal distribution of wages, but who at the same time are not willing to carry out costly transfers from richer to poorer.

Pirttilä and Uusitalo proposed a number of explanations for this rather radical difference in the results. One possibility is that people simply have different attitudes toward the implied efficiency–equity trade-off in different situations. The leaky-bucket question is specifically focused on redistribution, whereas the change in the wage distribution is a bargaining result. The two questions may also be measuring the same phenomenon but at a different scale. In addition, the leakage, that is the efficiency loss, is explicitly visible in the leaky-bucket question, whereas the respondent would have to calculate it in the wage-distribution question. Respondents may have had efficiency concerns in mind in the leaky-bucket question, and their preferences over efficiency could explain part of their unwillingness to support the transfer.

Pirttilä and Uusitalo also confirm the results in Beckman et al. (2004): the actual position of the respondent in the income distribution affects the answer given in the leaky-bucket experiment. As expected, support for this transfer is higher among the individuals who would benefit from it.

In the income-distribution literature the indices that are deemed appropriate to measure inequality are those that conform to the Lorenz dominance criterion. These indices fulfill four basic axioms: scale invariance, symmetry, the population principle, and the Pigou-Dalton transfer principle. For a recent survey of these properties and the dominance criteria see, among others, the excellent chapter in Chakravarty (2009). The first three properties are commonly assumed in the majority of indices of well-being; only the transfer principle, as we mentioned in the introduction, is at the heart of inequality measurement.

Attitudes toward inequality have been interpreted by some authors as being revealed by the reaction of (some relatively informed part of) the general public to these four basic properties. This is the contribution of the authors in group (2), where some general social welfare function is assumed but without any a priori functional form. The main question that is addressed in this part of the literature is what inequality seems to represent for the general public, and in particular whether these four basic axioms are reflected in individuals' views. The seminal book is this area is Amiel and Cowell (1999). Given that the defining concept for inequality measurement is the Pigou–Dalton transfer principle, we will discuss only those experimental results that cover this aspect of inequality.

In Amiel and Cowell (1992), the transfer principle is presented to respondents both as a numerical problem and verbally. In the former, they are asked to say which of two distributions of income are more unequal: $A=(1, 4, 7, 10, 13)$ versus $B=(1, 5, 6, 10, 13)$.

Verbally, they are asked to say what happens to inequality in the following scenario: "Suppose we transfer income from a person who has more income to a person who has less, without changing anyone else's income. After the transfer the person who formerly has more still has more."

Nearly two-thirds of the student sample in Amiel and Cowell (1992) did not think that inequality was lower in B than in A, whereas 40% did not agree that inequality would fall following the verbal scenario. The difference in these figures likely comes from individuals thinking of some kind of Robin Hood redistribution in the verbal case, whereas the actual numerical problem involves redistribution from the fairly poor to the even poorer. Amiel et al. (2012) examined many "flavors" or interpretations of the transfer problem. Only 21.6% of the sample are found to be in line with the researcher's standard view. A critique of the way in which some of these kinds of questions are asked is provided by Jancewicz (2012).[15]

Similar to Kroll and Davidovitz (2003) and Carlsson et al. (2005), Amiel and Cowell (2002), Gaertner and Namazie (2003), and Cowell and Cruces (2004), using method (2), examined the degree to which the principle of transfers is followed by people who evaluate inequality and risk. About 60% of respondents in the latter contribution viewed an equalizing transfer as inequality/risk reducing, and consistency in the risk version of the questionnaire was higher than consistency with the principle of transfers in the inequality version. This finding is confirmed by Gaertner and Namazie and Amiel and Cowell (2002), where the proportions of acceptance in the sample are 23% in the risk questionnaire and 17% for inequality.

Overall, individuals do have normative preferences over the distribution of income. It is, however, hard to argue that these are isolated in happiness regressions, as the latter are not able to separate out the comparative and normative components of attitudes to inequality. The experimental literature has been more successful in this respect, but even there the variety of different methods have produced quite a large range for the estimated value of inequality-aversion. Part of the problem here seems to be that the different methods make salient different preferences (such as risk aversion or preferences over efficiency). Another is that there are almost an infinite number of ways in which we can change the inequality of the income distribution, and preferences over taking money from the rich to give to the poor, and taking money from the middle or

[15] For example, the lack of a "Don't Know" response category, and there being no natural unit of account given for the figures in the numerical problem.

lower-middle class to give the poor may reasonably differ, even if the final impact on the Gini coefficient is the same.

13.4. OUTSTANDING ISSUES

This section discusses a number of issues that extend the existing literature on income gaps and income inequality described earlier.

13.4.1 Inequality and Other Outcome Variables

The discussion to date has considered individuals' relationship to others' incomes purely in the sense of "do they like it or not," whether that be revealed by survey information on subjective well-being or behavior in experiments. At the risk of opening a Pandora's box of other possible dependent variables, this is far from being the only outcome of interest. A number of other possible outcomes have been investigated across the social sciences. The following is a brief sample of some recent areas of research in this respect.

de Vries et al. (2011) tested the hypothesis that income inequality may produce individuals who are more competitive and less friendly toward others. These latter attitudes are captured by the Big Five personality factor of Agreeableness, which now appears in a number of surveys.[16] The regression analysis in de Vries et al. (2011) is based on almost 700,000 observations between 2001 and 2009 from an American web-based survey aimed at measuring personality. Agreeableness scores are significantly negatively correlated with state-level income inequality (as measured by the Gini coefficient on pretax household income matched in from the 2000 Census). This individual-level personality finding can be argued to be consistent with the considerable amount of existing evidence on aggregate inequality and measures of violent behavior. See Daly et al. (2001) for evidence on Canadian provincial-level murder rates and Macours (2011) for the role of district-level income inequality (over a period of income growth) in fueling civil conflict (as measured by mass abductions by Maoist rebels) in Nepal.

Loughnan et al. (2011) analyzed self-enhancement, which is the propensity to see yourself as being better than the average. They considered the relationship between self-enhancement and income inequality, with the argument that the gain from being better than others will be larger in more unequal societies. They administered a self-enhancement questionnaire to (mainly student) samples across 15 countries. In these questionnaires, respondents were asked about 20 different desirable characteristics. For each characteristic, they said whether they have more, the same, or less of it than the average student (or average person, in the nonstudent samples). They first showed that respondents on average think they have more of the characteristic than the average in

[16] As measured by the answers to questions on being interested in people, taking time out for others, and not being interested in other people's problems (this latter being reverse-coded).

14 out of 15 countries (the exception is Japan). They further demonstrated that self-enhancement is greater in countries with a higher Gini coefficient. This relationship is resistant to the introduction of a range of individual-level psychological variables.

In DeBruine et al. (2011), data from almost 5000 women aged 16–40 across 30 developed countries shows that women's preferences for facial masculinity are negatively correlated with a composite measure of country health: The value of masculinity as a proxy for developmental health is greater in countries where health is on average worse. Brooks et al. (2011) built on this work by noting that facial masculinity may also matter via the spread of the benefits that it confers. In the same way that a greater dollar return to higher rank in a golf tournament seems to lead to greater effort by players (Ehrenberg and Bognanno, 1990), any signal predicting competitive success is more valuable when rewards are more spread out. They hence match in data on the national Gini coefficient (from the United Nations Statistics Division) to DeBruine et al.'s original preference data. Their subsequent empirical analysis suggests that national income inequality is a better predictor of female preferences for facial masculinity than is national health.

Van de Werfhorst and Salverda (2012), in their introduction to a special issue of *Research in Social Stratification and Mobility*, suggested that income inequality at the national level is associated with a number of observable and attitudinal outcome variables. A number of the papers contained in this special issue go on to examine in detail the negative relationships between income inequality, on the one hand, and all of solidarity toward others, expressed support for democracy, and actual political participation.

Rothstein and Uslaner (2005) simultaneously estimated a measure of generalized trust and income inequality (the Gini coefficient). They concluded that inequality does indeed significantly diminish trust, whereas the estimated coefficient on trust in the income inequality equation is negative but insignificant. These findings have recently been critically reevaluated by Steijn and Lancee (2011), who specifically underlined the potential importance of non-Western countries with particularly high levels of income inequality and a confounding role of national wealth. Their regressions on Western country data (from the International Social Survey Programme, ISSP, and European Social Survey, ESS) show that the bivariate correlation between income inequality and trust is negative and significant, but that this relationship becomes insignificant in multivariate analysis once wealth is controlled for.

We are not necessarily arguing here that these additional potential attitudinal[17] correlates of income inequality are to be considered separately and in isolation. Rather, we think that they indeed represent some of the channels via which income inequality leads

[17] Moving beyond the individual level, we can also consider the attitudes expressed by other societal actors. Burgoon (2013) analyzes party position-taking in almost fifty years of annual data across 22 different countries. Net income inequality is positively and significantly associated with antiglobalization position taking.

through to overall well-being outcomes (and to those regarding individual health, on which there is a substantial literature that we have not covered here; see Chapter 17).

13.4.2 Other Measures of Different Aspects of the Distribution of Income

All our discussion of attitudes toward the distribution of income has been in terms of gaps to others in the reference group, in Section 13.2, and a normalized sum of all the gaps in society, as the Gini coefficient in Section 13.3. We have presumed that these are indeed the salient measures of others' income. But we do not know that for sure.[18]

Consider two log-normal distributions of income, where one is a horizontal displacement of the other, as in Figure 13.1. Which is the most unequal? If we are not in the income distribution then our (normative) evaluation of the dispersion in these two curves depends on which distribution measure we choose. Some measures of various aspects of the distribution of income are identical across the two; this is the case for the absolute Gini coefficient, the variance, the interquartile range, and the percentage of the population in relative poverty (as defined as income below 60% of the median, say). Other measures are

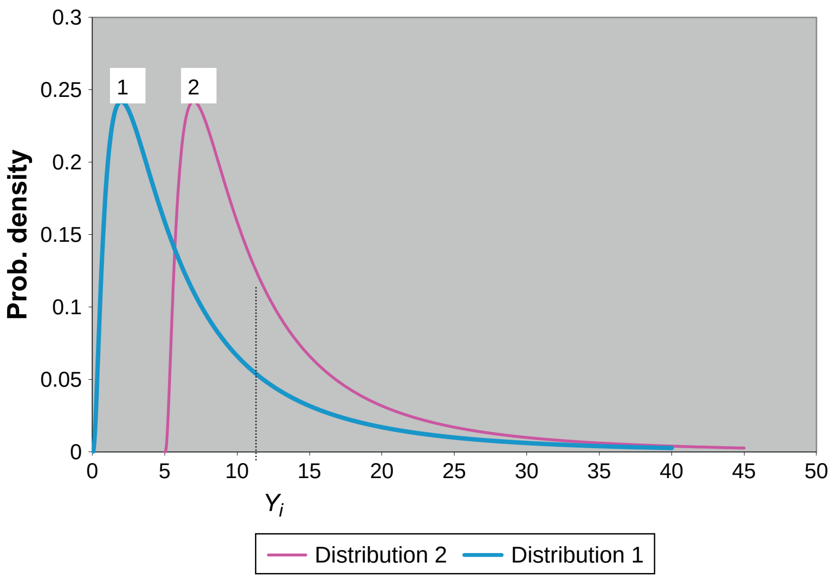

Figure 13.1 Two log-normal income distributions, with the same variance.

[18] A question that we do not address here is whether it is the pretax or post-tax income distribution that is correlated with subjective well-being. One reading is that it is the distribution of pretax income, which determines both well-being and preferences for redistribution, and this latter influences the actual tax system, which in turn determines the posttax distribution of income. At the practical level, not all empirical papers make clear whether their income measures are net or gross.

not the same in distributions 1 and 2: the percentage in absolute poverty, the relative Gini coefficient, and the D9/D1 or D5/D1 ratios.

If the individual making the evaluation is in the income distribution, then their evaluation will also depend on their own income position; this is the comparative evaluation. At an income of Y_i, an individual will feel more deprived in distribution 2 than in distribution 1; their relative deprivation will be higher (more people above them), and their satisfaction will be lower (fewer people beneath them).

We have considered the relationship between objective measures of inequality, such as the Gini, and subjective well-being. But do people actually know what the value of the regional or national Gini coefficient is? Individuals' perceptions of the degree of inequality around them may not be well reflected in the Gini coefficient, and equally they may believe the distribution of income to be different from what is actually measured in statistics.

Macunovich (2011) is an intriguing contribution using the fourth (2005) wave of the WVS. She analyzed not only the Gini coefficient, but also two measures of crowding at the bottom of the distribution: the ratio of the number of people who say that they are in the lowest income decile in the country to the number who say that they are in the highest, and the same ratio with respect to self-reported social class. Although the Gini coefficient continues to exhibit a positive correlation with both happiness and life satisfaction, the estimated coefficients on these two ratios are negative and often significant. This might be thought of as consistent with some of those at the bottom providing a negative signal (as in D'Ambrosio and Frick, 2012), or more generally with some negative externalities in society associated with poverty.

O'Connell (2004) used information on (the log of) the income received by the top quintile in a country to that received by the bottom quintile. This is shown to be negatively associated with life satisfaction in an aggregate-level analysis of 15 EU countries in Eurobarometer data over the 1995–1998 period.

Some of the work appearing in Table 13.1 uses a variety of measures of income distributions. Both Tomes (1986) and Brodeur and Flèche (2013) considered the bottom end of the distribution, with the former including the share of income earned by the bottom 40%, and the latter the county-level percentage in poverty according to three separate definitions.

In general, however, very few contributions here have tested different measures against each other in a beauty contest to see which one is the most salient correlate of subjective well-being. Ebert and Welsch (2009) is relatively unusual in this literature in that they did consider a wide class of inequality indices comprising the Atkinson and Gini family as special subclasses (see Ebert, 1988) and evaluated their effects on individual reported life satisfaction in 20 years of Eurobarometer data. As the self-reported income data in the Eurobarometer is not sufficiently good to allow detailed measures to be computed from within the data set, these latter are matched in from the

Luxembourg Income Study (LIS), which somewhat reduces the number of countries that can be used in the empirical analysis.[19]

Ebert and Welsch started by considering the Gini, Atkinson 0.5, and Atkinson 1.0 indices. All three of these are shown to be significantly correlated with life satisfaction in ordered probit regressions. They then considered generalizations of these indices. Their analysis of life satisfaction leads them to conclude that both rank and level inequality aversion matter, and that the overall degree of inequality aversion is larger than that implied by the standard measures applied in empirical analysis.[20]

A last point with respect to the question of "which measure of others' income" is that existing work has very much concentrated on cardinal measures of comparisons, as picked up by income gaps and Gini coefficients. Although there is likely some role for such comparisons, it also seems probable that individuals are rank-sensitive. Some previous work has considered the role of income rank in determining well-being. In Brown et al. (2008), income rank is shown to outperform average reference group income in three satisfaction equations (influence over the job, achievement, and supervisor's respect): see also Clark et al. (2009a) for economic satisfaction and Boyce et al. (2010) for life satisfaction. In the field experiment in Card et al. (2012), information on the individual's revealed rank in the income distribution was more important in determining their satisfaction than was the relative wage level. Clark et al. (2010) appeal to both survey and experimental evidence on the role of relative income in determining the level of effort that workers supply. In both types of data, the individual's rank in the income distribution is a more powerful determinant of their effort decision (as measured by the log-likelihood) than is the relation of the individual's own income to mean income in the reference group. Mujcic and Frijters (2013) came to the same conclusion in the analysis of hypothetical choice data from a sample of just over 1000 Australian students. Finally, Clark and Senik (2014) appealed to Chinese panel data from Guizhou province, in which all households in the village were interviewed. This complete data allows household rank in the village income distribution to be determined. Being at the top (top decile) or bottom (lowest 25%) of the income distribution seems to matter disproportionately for satisfaction with income.

It may also be the case that not all ranks are of equal importance, so that the correlation between income rank and subjective well-being is nonlinear. The experimental and survey results in Kuziemko et al. (2014) underline the importance of the aversion to being last in the distribution. Experimental subjects accept gambles, which may move them out

[19] Although not in the context of subjective well-being, Jancewicz (2014) provides an extremely interesting analysis of the criteria that individuals use to sort different income distributions into groups that have similar perceived levels of inequality.

[20] It would also be of great interest to evaluate the relationship between income polarization and individuals' reports of subjective well-being. We are not aware of any contributions in this respect.

of last place that they reject if anywhere else in the distribution. Equally, subjects randomly placed in second-to-last place in modified-dictator games are the most likely to give money to the person one rank above them instead of the person one rank below. One implication is that the relatively poor may oppose redistribution if it is especially targeted at those who are just beneath them in the income distribution. Survey data does indeed show that respondents who earn just above the minimum wage are those who are the most likely to oppose any rise in the minimum wage.

These kinds of rank comparisons are of great interest. They do imply a role for inequality in the determination of individual well-being in that, given own income, a mean-preserving spread of income in the reference group implies lower individual rank. However, at the societal level this will not matter. By construction, rank is zero-sum: My loss must be offset by others' gains. Unless we have heterogeneity in the taste for rank (as in Frank, 1985), the degree of inequality will here not affect the way in which income comparisons affect overall well-being.

13.4.3 Fairness and Preferences for Redistribution

The measures of income distribution used in the preceding literature have been objective: They measure what others in the society actually earn. This is of course not necessarily what individuals *believe* that others earn, and it may well be this latter, and its relation to what it is believed that others *should* earn, that is the most important for determining individual attitudes toward inequality.

Almost no one in our societies thinks that everyone should receive the same income. Incomes differ often for very good reasons, such as number of hours of work for example. In general, we can think of the causes of income distribution as being partitioned into factors for which the individual is responsible and those for which she is not (see Fleurbaey, 1995). These are respectively referred to as effort and circumstances in the literature on the equality of opportunity (see Chapter 4 of this volume for a survey in great detail).[21] Almås et al. (2011) proposed the measurement of a "responsibility-sensitive" fair income distribution. This is applied to 1986–2005 Norwegian data. They show that although the Gini index fell over this period, unfair income inequality actually rose. Further, the pretax unfair income Gini rose less than the posttax unfair income Gini, so that the tax system has become less profair.

An alternative approach to fairness, which does not require the explicit distinction of responsibility and nonresponsibility factors, is to explicitly ask individuals about how much they think others should earn. For example, the cross-country ISSP surveys have asked direct questions a number of times about perceived and fair distributions of

[21] We might expect inequality to be less acceptable when it occurs by chance, rather than from individual effort. In this context, it is noticeable that there is no particular push to redistribute from lottery winners. This may reflect that they on average already pay a tax by spending more on the lottery than they receive. In the UK National Lottery, for example, less than half of the money spent on tickets is won in prizes.

incomes. Each year the ISSP survey administers a number of core questions, as well as rotating modules on specific topics. These modules in 1987, 1992, 1999, and 2009 were on Social Inequality. Individuals were asked directly how much they thought that individuals in certain job types earned. For example, in the 1987 wave, variable v26 refers to the answer to the following question:

> *We would like to know what you think people in these jobs actually earn. Please write in how much you think they usually earn each year, before taxes. (Many people are not exactly sure about this, but your best guess will be close enough. This may be difficult, but it is important, so please try.). First, about how much do you think a bricklayer earns?*

Variable v27 refers to the answer to the same question, but now with respect to a doctor in general practice. The following nine questions then cover the income of a bank clerk, an owner of a small shop, the chairman of a large national company, a skilled worker in a factory, a farm worker, a secretary, a city bus driver, an unskilled factory worker, and a cabinet minister in a national government.

Last, individuals are asked a series of 11 questions covering the same occupations, but this time are asked to indicate what they think that these individuals *should* earn each year before taxes, regardless of what they do actually receive.

The same types of questions are repeated across the different Social Inequality modules, although by 2009 the questions only covered the five occupations of a doctor in general practice, the chairman of a large national company, a shop assistant, an unskilled factory worker, and a cabinet minister in a national government.

Similar kinds of questions have appeared in a number of other surveys, including the 2005 wave of the SOEP. It is also possible to ask these questions about actual and just rewards with respect to the individual herself, or regarding a hypothetical third person with a given set of demographic characteristics (see Jasso, 2007).

One application of the answers to these questions is to consider the responses that are given for occupations at the top and bottom end of the income distribution; for example, in the preceding ISSP questions, the incomes of the chairman of a large national company and an unskilled factory worker. The ratio of these two gives an indication of the income inequality that the respondent perceives. Along the same lines, a fairness index can be calculated as the ratio of the incomes that the individual believes that these two occupations should earn. The comparison of these two ratios gives an indication of how much of the gap in earnings that the individual perceives is considered to be fair.

An empirical application of this kind of approach can be found in Schneider (2012), who used German data from the 2006 wave of International Social Justice Project to consider the relationship between subjective well-being and income inequality. Instead of calculating a Gini coefficient from within the data set, or matching it in at some level from an external data source, she calculated a direct measure of the individual's perception of the fairness of the income distribution.

Using the responses to the questions about the perceived incomes (PI) and just incomes (JI) of a managing director (MD) and an unskilled worker, she calculated a measure of the overall legitimacy of income inequality as follows:

$$\text{legitimate inequality} = \ln\left[(PI_{MD}/PI_{unskilled})/(JI_{MD}/JI_{unskilled})\right].$$

Someone who believes that the current income distribution is just has a value of legitimate inequality of zero. Those who believe that the income gaps should be wider will have a negative value, whereas those who perceive some inequality of reward will have a positive value. This measure of legitimate inequality varies at the individual level, therefore providing far more potential explanatory power than the aggregate-level measures of income inequality that have been discussed so far.[22]

In her 2006 data, Schneider reported an average value of the first term in the square brackets, $PI_{MD}/PI_{unskilled}$ of around 644, with the average value of $JI_{MD}/JI_{unskilled}$ being slightly over 300. This yields a value of legitimate inequality of around 0.75. The individual level of the perception of inequality is shown to be negatively correlated with life satisfaction. This correlation is stronger for the higher than for the lower income groups.

Osberg and Smeeding (2006) appealed to these questions in the 1999 ISSP survey. However, instead of looking at the gaps with respect to the top and bottom occupations in the list, they considered the entire set of responses regarding perceived and just incomes. By assuming that there are equal numbers of individuals in each of the nine occupations, they could calculate Gini coefficients, both with respect to the income that the individual actually believes is earned and a "just" Gini coefficient for the income that she believed should pertain. They then calculated the ratio of these two Gini coefficients: a value of less than one implies that the individual believes that there should be less inequality than that which she believes exists.[23]

Most people are in favor of some leveling of incomes, whereas very few believe that all incomes should be the same. The average value of the ratio of the Gini coefficients is less than one in all of the 27 countries that appear in the 1999 ISSP. The average figure across all countries is 0.75. In some countries, such as the United States and Japan, this figure is around 0.8; in others such as Spain and Sweden, it is under 0.7. As well as cross-country differences in this measure of the desire to redistribute, there are systematic

[22] Legitimate inequality does differ across individuals, which is good. However, it is also potentially endogenous, with unhappy people thinking that people at the top of the income distribution earn more (or should earn less), for example.

[23] Blanchflower and Freeman (1997) are along the same lines. They used the 1987 and 1992 ISSP surveys and considered the standard deviation of the log response given across the different occupations. They did this both for the perceived and fair distributions (which they call the perceived and appropriate differentials). Their main result is that ex-Communist countries both perceive and consider appropriate tighter income distributions compared to Western countries, but that this gap fell sharply over the transition process (here between 1987 and 1992).

differences by individual characteristics. In particular, Osberg and Smeeding underlined the importance of age, education, and family income in this respect.

A more direct approach to perceived income inequality, and its relation to subjective well-being, was taken by Smyth and Qian (2008), who used Chinese data from a 2002 survey of 31 cities. In this data, individuals were asked directly about their perceptions of inequality of the income distribution, on a 1–5 ordered scale. These perceptions are shown to be correlated with individual happiness scores.[24] The sign of this correlation depends on the individual's own position in the income distribution. In particular, perceived inequality is negatively correlated with happiness for individuals who are in the bottom quintile of the income distribution, whereas this correlation is positive for those who are in the top quintile.

The importance of inputs and income inequality has also appeared in the experimental literature: It matters where income comes from. Abeler et al. (2010) found, in a gift-exchange game, that equal wages lead to systematically lower levels of effort being furnished by workers than when the firm can decide to pay workers differently. Their explanation is that workers do not want their wage–effort ratio to be lower than that of their coworkers, and they consequently work less hard. Clark et al. (2010) also found that the wages offered to other experimental participants in a gift-exchange game are negatively correlated with the effort furnished by the worker. Krawczyk (2010) found in experimental work that the equality of opportunity moderates the desire to redistribute.

Perhaps the most direct evidence of attitudes toward inequality comes from asking individuals whether they want to see less of it, by redistributing from the richer to the poorer. There is a considerable literature on the desire to redistribute (see Förster and Tóth, 2014). One of the first contributions is Persson and Tabellini (1994), who both proposed a theoretical model and presented some empirical results with respect to the median-voter theorem. The individuals here are purely concerned with their own self-interest and have no social preferences as such. The median here refers to the distribution of some variable, for example, income or skills (as measured by education). The individual's voting preferences will then depend on their own position in that distribution.

A second well-known contribution is Piketty (1995), who developed a theoretical model to explain why, in the long run, left-wing dynasties in the lower class are more supportive of redistributive policies, whereas right-wing dynasties in the upper-middle classes are less so. As in Persson and Tabellini (1994), individual income is here related to

[24] This correlation is arguably large in size. Happiness in their survey is on a 1–5 scale, as is the individual's perception of inequality. The overall partial correlation between happiness and fairness in their Table 2 is –0.09. As such, the effect of moving from the bottom to the top of the perceived income inequality scale has an effect of 0.36, which is 9% of the scale range. We cannot directly compare this figure to the correlation between subjective well-being and the Gini coefficient in Section 13.3.1, as we cannot map the seriousness of inequality to a particular Gini figure.

political opinion: those with higher incomes are more right-wing and less favorable to redistributive policies, whereas those with lower incomes are more likely to vote for left-wing parties and to be in favor of redistribution.[25]

It is not only the individual's situation today that counts, but also where she thinks she might end up tomorrow. The "prospect of upward mobility" (POUM) literature explicitly appeals to individuals' future prospects of social mobility. As such, own current income is not a sufficient statistic to know the individual's current preferences over redistribution. The currently poor may oppose redistribution if they expect their own income to improve in the future (Benabou and Ok, 2001, provide theoretical and empirical evidence that the POUM hypothesis works to limit the extent of redistribution in democracies). There is an obvious parallel between the POUM hypothesis and what we referred to as the signal effect of others' incomes in Section 13.2.1.

A number of pieces of empirical work have correspondingly underlined the importance of both current and future income. Along these lines, Ravallion and Lokshin (2000), using Russian microdata, were the first to show that self-assessed expected own social mobility, or the belief of being on a rising income trajectory, leads to lower demand for redistribution. Alesina and La Ferrara (2005) showed that preferences for redistribution are sensitive to the objectively measured future gains and losses that would result from it (again, this is consistent with pure self-interest). They also stressed the importance of mobility as an objective measure of the future expected gains and losses resulting from redistribution. In particular, there is a negative relationship between upward mobility (defined as the individual's own job prestige being higher than that of their father) and preferences for redistribution.[26] A subjective measure of whether the respondent says that he and his family "have a good chance of improving their standard of living" is very strongly negatively correlated with support for redistribution. Cojocaru (2014b) analyzed data from the second wave of the LiTS survey (the data are from 2010), and showed that preferences for redistribution are indeed linked to future upward mobility. The demand for redistribution is lower among those who are poor today but expect to be rich[27] in 4 years' time than for those who expect to be poor at both points in time. In line with the original POUM hypothesis, this finding only holds for those with lower levels of risk aversion (from a question on whether the individual would sell their car to buy insurance against a catastrophic drought).

[25] There is also a lively literature that emphasizes not necessarily whether I myself will benefit from redistribution, but also whether "people like me" are likely to do so. A recent survey of ethnic diversity and preferences for redistribution is provided by Stichnoth and Van der Straeten (2013).

[26] The survey in Alesina and Giuliano (2010) emphasizes the role of the past in general, both the individual's own past and the country's history.

[27] Poor and rich (now and future) are derived from the individual's response to a question about which decile of the income distribution they are at now and expect to be in four years' time. The poor (rich) are those who give an answer that is under (over) the average answer for the population.

Guillaud (2013) used 2006 ISSP data covering 33 countries to show that income and occupation are both important predictors of redistributive preferences. Equally, downward social mobility (having a lower position on the social scale now relative to 10 years ago) increases the demand for redistribution, whereas upward social mobility reduces it. There is some evidence that the downward mobility coefficient is larger in size than that on upward mobility, as if individuals were loss-averse with respect to status.

Clark and D'Angelo (2013) analyzed 18 waves of BHPS data. They showed that higher social status is associated with less favorable attitudes to redistribution and the public sector, as is commonly found. However, they also found that upward mobility (relative to one's parents) is associated with more left-wing attitudes, which are shown to be translated into actual reported voting behavior.

As noted in Section 13.3.1, Alesina et al. (2004) showed that the effect of inequality on happiness is larger in value in Europe than in the United States. The explanation proposed in Alesina et al. is in terms of greater perceived social mobility in the United States than in Europe.

Measures of the demand for redistribution have also been shown to be correlated with the individual's view of the fairness of the income distribution (Corneo and Grüner, 2002; Luttens and Valfort, 2012). The former test the importance of fairness in determining preferences for redistribution via the answer to the ISSP question "How important is hard work for getting ahead in life?" with responses "essential," "very important," "fairly important," "not very important," and "not important at all." They show that there is a self-interested component, in that those who state that they would personally benefit from lower inequality are indeed in favor of redistribution, whereas those with higher incomes are against distribution. The estimated coefficient on their fairness variable, "hard work is key" (defined as providing one of the first three responses given earlier), is shown to be negative and significant in a preferences for redistribution regression.

Luttens and Valfort (2012) appealed to data from the WVS and the ESS. They showed that both own income and the individual's perception of fairness determine redistribution preferences. It is of interest to note that individuals in the United States seem to more sensitive to fairness considerations in determining redistribution than are European respondents.

Tóth and Keller (2011) considered data from the 2009 Poverty and Social Exclusion module of the Eurobarometer. They calculated a Redistributive Preferences Index (RPI) using Principal Component Analysis of five questions on redistribution. The values of this index were then correlated with both individual and country-level variables. The latter include estimates of the distribution of income matched in from LIS data. They showed that the RPI is higher for those with lower material status, those who expect the situation to deteriorate over the next 12 months, and those who do not think that the poor are lazy. They also considered a number of percentile distribution measures (P95/P5, P95/P50, and P50/P5), as well as the Gini coefficient. All of the three percentile ratio measures attract positive significant estimated coefficients, so that the desire to redistribute rises with inequality. Inequality at the top and bottom of the distribution seems to play an equal role here. Yamamura (2012) also showed that the prefecture-level Gini coefficient is positively associated with redistributive preferences in 7 years of Japanese GSS data, although with a significant effect only for the richer.

One perhaps salient point here is that the questions used to establish preferences for redistribution are very different from one survey to another, which hampers the comparability of the existing results. Attitudes to income inequality are measured as follows in the BHPS: "People have different views about the way governments work. The government should place an upper limit on the amount of money that any one person can make." Answers to this question are on a 1–5 scale, where 1 represents complete disagreement and 5 complete agreement. This is not a question about redistribution in general, but about pulling the top of the distribution down. In the ISSP, respondents are asked "On the whole, do you think it should or should not be the government's responsibility to reduce income differences between the rich and the poor?" with answers on a 1–4 scale. The relevant question in the WVS asks individuals to indicate, on a 1–10 scale, which of the two extremes they most agree with: "People should take more responsibility to provide for themselves" versus "The government should take more responsibility to ensure that everyone is provided for." As Luttens and Valfort (2012) noted, this does mix up concerns for the income distribution with perceptions of government efficiency. Last, the question in the ESS is similar to that in the WVS, asking individuals to choose between "Government should decrease taxes a lot and spend much less on social benefits and services" and "Government should increase taxes a lot and spend much more on social benefits and services."

As well as individuals' stated preferences for redistribution, a recent paper has provided intriguing evidence that the actual observed progressivity of the tax system is positively correlated with average national well-being. Oishi et al. (2012) used data from 54 countries in the 2007 Gallup World Poll. Respondents here reported three different kinds of well-being measures: Cantril's ladder of the worst to best possible life, and positive and negative daily experiences. The country averages of these scores were correlated with the progressivity of the national tax system from Worldwide-Tax.com (calculated as the highest minus the lowest marginal tax rates, or the difference in the tax rates of those earning 67% and 167% of the country mean income). Tax progression is positively correlated with subjective well-being (see their Figure 1). This is not a simple revenue effect, as both the overall tax rate and government spending are significant in the well-being regressions.

13.4.4 Only Self-Interest?

The view of others in the comparative view of the reference group is arguably rather a depressing one. Other people are a negative externality in that $Y_i > Y_j$ brings relative satisfaction and $Y_i < Y_j$ relative deprivation for individual i. However certain others may be relevant for the individual, but not viewed in this comparative way. Rather, as intimated in the Introduction, there may well be a sentiment of extended sympathy toward some groups. In a parallel to the comparative reference group, the individuals toward whom one behaves altruistically will be chosen by the individual and may well exclude certain groups in society.

This leads us to the discussion of altruistic behavior, whereby transferring one's own money to others not only increases the recipient's well-being but also that of the donor. Although it is commonplace that generous people record higher well-being scores, showing causality from the former to the latter is more difficult.[28] Luckily there are a number of pieces of research that have suggested such a causal link.

One way of establishing causality is to use experiments. There has been something of a cottage industry in using randomized allocations or natural experiments to look at the relationship between own income and subjective well-being. Dunn et al. (2008) built on the observed positive correlation between prosocial spending and subjective well-being by considering a randomized experiment in which some individuals are forced to be generous. In particular, experimental participants first reported their happiness. They are then given an envelope with either \$5 or \$20 to spend that day. Half are told to spend the money on themselves, and the other half on someone else. Happiness recorded later that same evening showed a significant subjective well-being margin in favor of those who spent on others. Importantly, when surveyed regarding what they thought would make them happy, a separate sample of respondents thought that spending on themselves would make them happier than spending on others; as such, individuals are not necessarily aware of the happiness benefits of altruism *ex ante*.

Aknin et al. (2013) made the same point more broadly. They first reported a positive correlation between prosocial spending and happiness in 136 countries from the Gallup World Poll. They also appealed to experimental analysis. In Canada and Uganda, individuals asked to recall a past instance of prosocial spending reported higher happiness scores than did those who were asked to recall a past instance of personal spending; equally, in India individuals asked to recall a past instance of prosocial spending reported higher happiness scores than did those who were not asked to recall past spending. Last, along the same lines as Dunn et al. (2008), participants in Canada and South Africa who were randomly assigned to buy items for charity reported greater positive affect than those who were assigned to purchase the same items for personal use.

Boehm and Lyubomirsky (2009) showed that individuals in a treatment group who were told to perform three extra acts of kindness a day experienced a sustained rise in happiness compared to a control group.

[28] The experimental approach in Konow and Earley (2008) shows that those with (previously elicited) happiness scores are subsequently more generous in dictator games.

It is a small step from monetary donations to others to volunteering in general, and Carpenter and Myers (2010) showed that the two are indeed correlated. Meier and Stutzer (2008) analyzed survey data around the time of German reunification, which led to a sharp reduction in volunteering opportunities in East Germany. Meier and Stutzer showed that the drop in subjective well-being was larger for those who had previously volunteered than for those who had not: A natural conclusion is then that volunteering caused well-being.

A vibrant research area of interest in this respect covers charitable giving. Individuals may give to charity either because they care about the recipients of their largesse or because they derive some process utility from the act of giving that is independent of the use to which their gift is put (which is what Andreoni, 1989, calls "impure altruism").[29] Konow (2010) appeals to a series of carefully designed experiments to show that giving to others cannot be only explained by the "warm glow" of the process utility, and that the student subjects are systematically more generous toward charities than toward fellow students. This latter holds even when the charities are not known to the subjects, avoiding any role for familiarity. Konow suggested an overarching role for context-dependent norms in the determination of giving to others, which he identified as equity and need in his experiments. Useful relevant symposia on charitable donations can be found in the June 2011 special issue of the *Journal of Public Economics* on Charitable Giving and Fundraising and the forthcoming book edited by Fack and Landais (2014).

As noted by Clotfelter (2014), charitable giving is a more important phenomenon in the United States than in other G7 countries. However, it does remain unclear whether such giving is always redistributional, in the sense of being aimed at the less well-off. A first point is that some charitable donations, especially among the richer, go to the arts or education. Perhaps even more saliently, charitable donations in the United States are regressive in terms of the percentage of income donated (see http://philanthropy.com/article/Interactive-How-America-Gives/133709/).

Section 13.2.1 described a number of pieces of research in the vein of the comparative reference group, whereby higher incomes among relevant others were associated with lower levels of subjective well-being. This correlation is not always found to be negative, however. A variety of contributions have found that satisfaction and the income of close neighbors are actually positively correlated. This is the case in survey data in Canada (Barrington-Leigh and Helliwell, 2008), China (Kingdon and Knight, 2007), and Denmark (Clark et al., 2009a). Although the nonexperimental protocol here makes interpretation more difficult (there are any number of reasons why people might be happier with richer neighbors, including tunnel effects or the provision of local public goods), these findings are consistent with empathy with respect to close neighbors.

[29] Alternatively, charitable giving may be seen as a good that endows status on the benefactor, as in Frank (2004).

Kranton et al. (2013) also underlined that individuals can be altruistic toward some individuals, but comparative with respect to others. Individuals in their experiment make a series of choices regarding income allocations between two subjects. These subjects can be the individual, a member of her own group, or a member of another group. These groups are determined either by political persuasion, or as "minimal groups" depending on a preference over two nearly identical lines of poetry, landscape images, and abstract paintings. The authors found considerable heterogeneity in social preferences and showed that individuals are less generous (or even downright destructive, as in Zizzo and Oswald, 2001), toward individuals outside their group, even when groups are essentially randomly formed.

The theoretical implications of altruism in terms of redistribution are analyzed in Hochman and Rogers (1969). In this case, some redistribution can make everyone better off. Hochman and Rogers considered transfers only from richer to poorer and that do not change the income ranking. Transfers are costless; there is no leaky bucket. One of the central aims of their analysis is to establish how the amount transferred depends on the income gap between the rich and the poor. They distinguished two salient cases, which depend on the "transfer elasticity." When this elasticity is zero, the same fixed sum is always transferred; when it equals one, then the amount transferred is proportional to the income gap between the rich and the poor. A calibration suggests that actual U.S. income tax rates are more consistent with the elasticity being one than zero.

13.5. CONCLUSION

As so often in economics, asking about the relationship between income inequality and individual attitudes looked to be a pretty simple question, but turned out to be remarkably more delicate to answer.

The broad question addressed here is why individuals should care about the distribution of income in a society. The first useful distinction is whether they figure in the society in question or not. In the former case, income inequality will have implications for both their own income and their income relative to others; this is the comparative view of the income distribution. In the latter case, individuals can evaluate a distribution of income dispassionately, as it were, as this distribution will have no implications for either their own absolute income or their relative income; this is the normative view of the income distribution.

As a broad conclusion, there is now a variety of types of evidence that are consistent with individuals caring about their income position relative to others. To that extent, individuals do indeed have social preferences. It is worth underlining the unanimity that individuals dislike earning less than others. The "comparative" response to earning more than others remains open to debate. There may well be something of an asymmetry here, with the well-being advantage of earning more than others being smaller in absolute value than the well-being loss of earning less than others (a type of comparative loss aversion). However, the more extreme version of this aversion, with individuals actually disliking earning more than others remains unsettled. In general, the well-being effect of a rise in inequality under the comparative lens is ambiguous: Some people will become richer than those in their reference group, others will become poorer.

In contrast to these comparative findings, the happiness literature on the normative view of the income distribution has provided a wide scattershot of findings. One obvious difficulty in any approach based on survey subjective well-being data is effectively controlling for relative income when estimating the correlation between happiness and the income distribution. Very few analyses do so and therefore provide some kind of compound correlation, which includes both comparative and normative elements. The experimental approach here has a notable advantage in being able to distinguish the two.

Our reading of the many empirical analyses is that others' income most certainly does affect individual well-being, certainly in a comparative sense and very likely normatively too. At the same time, there are many qualifications to any broad-brush conclusion. First, the source of the income under consideration is key, with a consistent finding that individuals are less accepting of income gaps between individuals that are seen to be undeserving. Second, individuals can have separate views of different income distributions: It is quite possible to be altruistic with respect to one group, but comparative with respect to another. In this sense, it is not clear that there is only one "attitude" to inequality. Nor is it clear that such attitudes are fixed over time. For example, preferences for redistribution depend (in a self-interested way) on the individual's perceived position in the income distribution and on the degree of empathy toward others. Research in psychology has suggested that younger cohorts are more likely to rate themselves as above average (Konrath et al., 2011) and are less empathic (Twenge et al., 2012). What may have been unacceptable in the past in terms of the distribution of income may become anodyne in the future.

Research in this area has appealed to contributions from a variety of fields of research, both within economics and across the social sciences. It is striking how little these various fields communicate with each other. Any attempt to integrate at least some of the revealed preference, experiment, and happiness approaches would surely be welcome.

Individuals do have attitudes toward income inequality, whether these be stated, revealed, or measured physiologically or neurologically. To this extent, at least, man is a social animal. There is unlikely to be agreement any time soon about the "right" degree of inequality. This will be tied up with the societal extent of jealousy, altruism, fairness, and values. That many of these concepts are of such interest across the social sciences bodes well for Volume 3 of this Handbook.

Abstract

We revise some of the main ways in which the study of aggregate performance of an economy overlaps with the study of inequality.

Keywords

Macromodels of inequality, Inequality dynamics, Inequality and financial markets, Political economy of inequality

In a handbook devoted to income distribution, a chapter devoted to macroeconomics should start by clarifying the role of macroeconomics. Two of the main concerns about macroeconomics are aggregation and general equilibrium. The first ensures that the various sections of the economy aggregate, that is, by adding the incomes, wealth, and other variables of all households, we obtain the economywide value of these variables. The second macroeconomic concern is general equilibrium, that is, how changes in any section of the economy propagate to other sections of the economy via implied adjustments in prices and tax rates that are necessary to clear markets and balance the government's budget constraint. Although a large body of macroeconomic research abstracts from distributional considerations among individuals and households, a significant strand of studies are also concerned about the interaction between distribution and aggregate outcomes. In this chapter we will explore the possible interactions between distribution and the aggregate dynamics of the economy.

Since Bertola (2000) (the macroeconomics chapter in Volume 1 of this handbook series), many changes have taken place in the way macroeconomists deal with income inequality. One important change is that interest has shifted away from the study of the relation between inequality and long-term growth and has focused more on other aspects of macroeconomic performance. Perhaps the main reason for this change is that, in general, there is less concern about long-term growth. Now, the more popular view is that all advanced economies grow by about 2% annually. The main question is, what does it take for less-developed countries to accelerate the process of development and join the group of rich countries? As a result of these changes, macroeconomists have two main concerns with regard to inequality. One is what determines the joint distribution of earnings (or labor income) and wealth, and the other is how the explicit account of empirically sound inequality shapes the answers to the standard questions in macroeconomics. The models typically used feature a large number of agents that differ in earnings, wealth, and, in some cases, other characteristics. Consequently, we find it convenient to separate the two main branches of macroeconomic studies in this vein: the branch primarily interested in understanding the sources or causes of inequality and the branch concerned with the consequences of inequality for the aggregate performance of the economy. Such a distinction is not always applicable, yet it provides a natural organization of the literature. We will also find it occasionally convenient to separate studies that are primarily interested in economic growth from those focusing on business cycles.

The outline of the chapter is as follows. We start in Section 14.1 with some facts on the U.S. income and wealth distribution that are relevant from a macroeconomic point of view. We look at both cross-sectional evidence and the changes observed in the last few decades. Although some of these facts are analyzed in more detail in other chapters of this handbook (for example, Chapters 7–9), it will be useful to summarize them here as they are the reference for some of the theories we will review in this chapter.

After summarizing the main empirical facts about the income and wealth distribution, we take a look in Section 14.2 at how macroeconomists make sense of these facts. First, we show how the distribution of wealth is determined given an exogenous process for earnings. After reviewing the models used by macroeconomists to examine this question and their success in replicating the wealth distribution observed in the data, we turn to models of endogenous determination of earnings. We look at models of human capital investment to determine why some people are more successful than others, in the sense of earning higher labor incomes. Thus, we will look at earnings inequality not as a purely stochastic process (luck) but as an outcome of different mechanisms such as investment in human capital (for example, education) or the higher relative demand of certain skills (affecting the relative prices of certain skills compared with other skills). The section concludes with a look at how occupational choices can also determine labor earnings. This section is concerned with inequality as a permanent or steady-state phenomenon, and the occupational choice part is informed by the bad employment performance of the Great Recession, which includes business-cycle aspects.

Next we turn to the dynamics of inequality. Section 14.3 studies how inequality may change both over the business cycle and over a longer horizon. Here we consider a simple model in which factor shares—of capital and labor—can change.

Section 14.4 deals with what is possibly one of the most exciting ways in which macroeconomics and inequality interact: the role of financial markets or, more specifically, financial frictions. We start by looking at how the ability to borrow shapes the income and wealth distribution (and the allocation efficiency) by reallocating investment funds to entrepreneurs that are efficient and reliable, but not always both. We then turn to how wealth inequality is shaped by borrowing ability even when the rate of return of savings is equated across households. First, we look at how the sheer ability to borrow shapes inequality, and then we consider endogenous theories of borrowing where financial frictions arise from the institutional environment. We also look at various extensions of these ideas where the frictions are endogenous. In addition to exploring the effects of financial frictions on inequality, we look at the long-term effects on the performance of the economy, including some issues that have become of concern to macroeconomists, such as implications for global imbalances.

In Section 14.5 we analyze how the political system interacts with inequality to yield different policies that have an impact on the aggregate performance of the economy. People have different views about the desirability of alternative economic policies that depend on the position of individuals in the economywide distribution of income. The aggregation of individual preferences leads to the choice of particular policies. As the distribution of income changes, so does the choice of policies, which in turn affect the aggregate performance of the economy.

Section 14.6 concludes the chapter with a global assessment of what may be behind some of the changes observed in the last few decades.

Finally, a note of caution and a disclaimer. Throughout the chapter, we make use of various theoretical models that, for expositional purposes, are kept simple. Although this makes the intuitions of the basic mechanisms easy to understand, it also implies that these models may not be completely suited to address quantitative questions. Therefore, even if we often illustrate the properties of the model quantitatively, we should be careful in interpreting the simulation numbers as they are often intended to provide a qualitative, rather than quantitative, assessment of the model. The disclaimer is about the necessary incompleteness of this chapter. As much as we have tried to provide a general presentation of the studies that deal with inequality in macroeconomics, covering all possible subjects is impossible. There are many topics that we do not review. For example, we exclude studies that introduce behavioral elements in macroeconomic analysis. In part, this is motivated by our limited expertise in these subjects. We have also avoided for the most part the study of inequality in developing countries. We have marginally touched on issues such as the impact of the rise in inequality on the U.S. economy, the macroeconomic causes for the rising inequality, and globalization and inequality among others. Perhaps, more importantly, we have only scratched the surface of how income inequality translates into consumption inequality, which is what most economists think is what really matters. The topic of income inequality is quite vast, and different authors would write it quite differently; in fact, Thomas Piketty's chapter in this volume includes some macro modeling of the wealth distribution with a very different flavor than this chapter.

14.1. SOME FACTS ON THE INCOME AND WEALTH DISTRIBUTION

Here we outline some general features of the Lorenz curves for earnings and wealth and their correlation and persistence over a medium span of 5–10 years for both individuals and across generations. We draw data from Díaz-Giménez et al. (2011), Kuhn (2014), and Budría et al. (2001) for the United States.[1] The data come from the Survey of Consumer Finances (SCF). Although the facts are for the U.S. economy, they may apply in varying degrees to other countries. In general, the United States is a more extreme version of the other developed countries in the sense that it is characterized by higher inequality.

Table 14.1 shows the shares of earnings (the part of the income that can be attributed to labor), income (earnings plus capital income plus government transfers before taxes), and wealth (both financial and real assets, but not defined benefits pensions). See Díaz-Giménez et al. (2011) for details about the definition of these variables. As we can see, a large number of households have zero or negative earnings, almost two-thirds of all earnings come from the top quintile, and the top 1% receive almost 20% of all earnings. Our definition of earnings includes part of self-employment income that is imputed as labor income.[2] Because self-employment income can be negative, several households have zero or even negative earnings in our sample. Negative earnings contribute to a much higher Gini index compared to other measures provided in the literature, such as those that result from using earnings data from the Current Population Survey (CPS). However, correcting the CPS data by tax information could lead to Gini indexes that exceed 0.6 (see Alvaredo, 2011 and the discussion in Chapter 9). Wealth is more concentrated than income, and the poorest quintile holds negative wealth. Furthermore, more than 85% of the wealth is held by the richest quintile and more than one-third of all wealth by the richest 1%. Table 14.2 shows a few measures of dispersion that are useful to keep in mind.

The properties of the distribution of earnings, income, and wealth (total (Wea) and excluding housing (N–H–W)) have changed in the last few years. Tables 14.3–14.5 show the values of a few measures of concentration for 1998, 2007, and 2010. For earnings, the Ginis, the coefficient of variations, the various ratios involving the median and the shares of top groups have all increased, most of them monotonically. For income, the picture presented by the SCF is muddier. The Gini seems unchanged, with some measures indicating an increase in inequality and others a decrease. The same seems to have happened for wealth. While the Gini, the ratio of the 90th percentile to the median and of the

[1] In Krueger et al. (2010) various macroeconomists study inequality in a variety of other countries with a similar way of looking at the data as we do in this chapter.

[2] In fact, owing to the recession, the overall fraction of business income attributed to labor is larger in 2010 (93.4%) and in earlier waves of the SCF when it was around 85%. See Díaz-Giménez et al. (2011) for details on how to calculate such fraction.

Table 14.1 Distribution of earnings and net worth in the U.S. economy

	Bottom (%)			Quintiles					Top (%)			All
	0–1	1–5	5–10	1st	2nd	3rd	4th	5th	90–95	95–99	99–100	0–100

Earnings	−0.1	0	0	−0.1	3.5	11	20.6	65.0	12.1	18.3	18.0	100
Income	0.8	0.4	0.9	6.5	8.5	10.5	17.8	56.7	10.3	16.5	15.9	100
Net worth	4.5	0.5	0.7	11.6	13	6.3	9.9	59.1	8.6	21.2	20.2	100
Shares of total sample sorted by net worth (%)												
Earnings	0.9	2.8	2.3	8.4	10.7	14.6	17.5	48.8	10.3	15.7	10.8	100.0
Income	0.8	2.6	2.2	8.4	10.0	13.9	17.6	50.1	10.2	15.3	12.2	100.0
Net worth	−0.3	−0.3	−0.1	−0.7	0.7	3.3	10.0	86.7	13.5	26.8	34.1	100.0

Data are from the 2010 Survey of Consumer Finances. Income includes all transfers including food stamps. Earnings are defined as the part of income earned by labor. Farm and business incomes are assigned split between labor (93.4%) and capital (6.6%) (a much lower capital share than in other years).

mean to the median have all gone up, the shares of the top 10%, 1% and 0.1%, have either remained stable or have gone down.

The modest evidence for an increase in inequality in income and wealth contrasts drastically with the picture reported by Piketty and Saez (2003), Piketty (2014), and Saez and Zucman (2014), who have used tax data. They have documented a big increase in inequality in the last few years in both income and wealth. Their evidence for income is direct as it comes straight from tax returns. The evidence for the evolution of wealth concentration in Saez and Zucman (2014) is indirect; it imputes the value of the assets that generate the reported capital income using the capitalization method with the rates of return for each class of assets that are obtained in the Flow of Funds. Yet it is quite persuasive. They suggest that the discrepancies that result between using the SCF and using tax data is due mostly to the top 0.1% of the top wealth holders. The SCF excludes the richest 400 households (the Forbes 400), and it is quite possible that even within income strata, response rates to the SCF voluntary questionnaire vary by income. The two sets of data are complementary, and the SCF is working hard to improve how it represents the very richest. There is likely to be a major update of the SCF that tries hard to improve in these dimensions. Hopefully, such improvements in the SCF will be available in the next few months, and we will get a much better picture of the characteristics of the very rich.

Turning to consumption inequality, there are some doubts about whether it has also increased. Using data from the Consumer Expenditure Survey, Krueger and Perri (2006) have documented that consumption inequality has increased only slightly. However, Attanasio et al. (2004) and Aguiar and Bils (2011) claim that the increase in consumption inequality has been more significant. One of the reasons these studies reach different conclusions is because they use different survey data. Krueger and Perri (2006) use data in which consumption comes from survey collecting interviews, and Attanasio et al. (2004) use diary data. In addition, Aguiar and Bils (2011) have argued that the observed reduction in the quality of the consumption data in terms of how much of aggregate consumption is recovered in the interviews is concentrated among goods that are mostly purchased by rich people and among the high income groups, and both features point to a larger increase in the underlying consumption inequality than what is obtained by using the data without special adjustments.

To summarize, over the last 10–20 years, the evidence points to a sizable increase in inequality.

14.2. MODELING THE SOURCES OF MACRO INEQUALITY

In this section we show what macroeconomics has to say about inequality. We start by exploring in Section 14.2.1 the implications of existing macro models for the distribution of wealth. Most of the models reviewed in this section start from the assumption that the process for earnings is exogenous: it can be stochastic, but it cannot be affected by individual decisions. In Section 14.2.1.3 we describe some of the theories in which the process for earnings is endogenous in the sense of being affected by individual choices. Because individual choices respond to policies, these models have interesting predictions about the impact of economic policies on the distribution of earnings.

14.2.1 Theories of Wealth Inequality Given the Process for Earnings

We start this section by emphasizing the limits of the neoclassical growth model with infinitely lived agents and complete markets in predicting wealth inequality. After reviewing the prediction of the overlapping generations model, we analyze models with incomplete markets. As we will see, the consideration of market incompleteness allows for more precise predictions about the distribution of wealth for given processes of individual earnings.

14.2.1.1 The Irrelevance of Income and Wealth Inequality in the Neoclassical Model

The deterministic neoclassical growth model says very little about income and wealth inequality. Note that we mean the neoclassical growth model in its modern meaning of incorporating fully optimizing saving behavior.[3] In an important article by Chatterjee (1994), reiterated later by Caselli and Ventura (2000), it is shown that any initial distribution of wealth is essentially self-perpetuating. To see this, consider the typical problem of a household $i \in \{1, \ldots, I\}$. Using recursive notation with primes denoting next period variables, the household's problem can be written as

$$v^i(a) = \max_{c,\, a'} u^i(c) + \beta_i v^i(a'), \tag{14.1}$$

$$\text{subject to} \quad c + a' = a(1+r) + \varepsilon_i w. \tag{14.2}$$

Here, $u^i(c)$ is a standard utility function (differentiable, strictly concave), $\beta_i \in [0, 1]$ is the discount factor, and ε_i is the household's endowment of efficient units of labor, which we assume constant for now. The necessary condition for optimality is

$$u_c^i(c_i) = \beta_i \ (1+r') \ u_c^i(c_i'), \tag{14.3}$$

where $u_c^i(c_i)$ is the marginal utility of consumption. In steady state, the allocation is constant over time, $c_i = c_i'$, and $r = r'$, which requires that the rate of return on savings is equal to the rate of time preference in every period, that is, $\beta_i = (1+r)^{-1}$. One implication is that, if households have interior first order conditions so that Equation (14.3) is satisfied with equality, then $\beta_i = \beta$ for all i. Otherwise, some households would reduce their assets as much as they can until they reach some lower bound that depends on the borrowing ability.

Because the rate of return in the neoclassical growth model is given by the marginal productivity of capital, we have that

[3] As such, the standard analysis of Stiglitz (1969) does not apply, since there saving behavior is postulated and not derived from first principles.

$$\beta^{-1} = 1 + r = F_K(K, N) - \delta, \tag{14.4}$$

where K is aggregate capital, $N = \sum_i \varepsilon_i$ is the aggregate effective labor (hours worked weighted by their efficiency), F is the production function, and δ is the constant rate of capital depreciation. In the neoclassical growth model, physical capital is the only form of wealth, so the following has to hold:

$$K = \sum_i a_i \tag{14.5}$$

where a_i are the assets held by household i. Note that these last three equations are the only ones imposed by the theory. It turns out that any distribution of wealth $\{a_i\}_{i=1}^{I}$ that satisfies Equations (14.4) and (14.5) is a steady state of this economy in which each individual household i consumes its income, $c_i = ar + \varepsilon_i w$. This is the sense in which the theory poses no constraints whatsoever on the distribution of a. Note that this is true no matter how efficiency units of labor (and hence earnings) are distributed across households. Nonseparability between consumption and leisure does not change this finding.

Small details qualify the behavior of the system outside a steady state. Under constant relative risk-aversion (CRRA) preferences, Equation (14.3) can be written as $\left(\frac{c_i'}{c_i}\right)^{\sigma} = \beta_i(1 + r')$, where $1/\sigma$ is the intertemporal elasticity of substitution. Depending on the joint distribution of earnings and wealth, the evolution of the wealth distribution is dictated by this equation and the budget constraint.

What other possibilities does the neoclassical growth model or its variants offer? Not many. Consider heterogeneity in the per period utility function. We have already noted that this does not change any steady-state consideration. Outside the steady state, the model just takes the initial wealth distribution and uses the first order conditions and the budget constraints to propagate the wealth distribution into the future, essentially dispersing or concentrating the wealth distribution without much endogenous action on the part of the model.

What about stochastic versions of these economies? With complete markets, all idiosyncratic uncertainty disappears (it is insured away), whereas the aggregate uncertainty is borne by those who are more willing to bear it. If such ability to bear the risk is increasing in wealth, then the model could generate some redistribution in response to aggregate shocks. But abstracting from aggregate uncertainty, we will see that the irrelevance result no longer applies when markets are incomplete (and agents continue to face idiosyncratic shocks). Before exploring the implications of incomplete markets, however, we briefly review the overlapping generations model.

14.2.1.2 Overlapping Generations Models and Wealth Inequality

In overlapping generations models, new households are born every period and live up to a certain number of periods J (they may also die earlier with some probability).[4] In what follows, we abstract from differences among households in any given age cohort and assume that the heterogeneity is only between cohorts. Households in age cohort j have earnings ε_j, which we take as exogenous. This specification can accommodate retirement and, with some extra work, government-provided Social Security (see Section 14.2.2 for theories of the determination of age-specific earnings). In a steady state, households solve the following problem:

$$\max_{\{c_j,\, a_{j+1}\}_{j=1}^{J}} \sum_{j=1}^{J} \beta_j u(c_j), \tag{14.6}$$

$$\text{subject to} \quad c_j + a_{j+1} = a_j(1+r) + w\varepsilon_j, \tag{14.7}$$

$$a_1 = 0, \tag{14.8}$$

$$a_{J+1} \geq 0. \tag{14.9}$$

Here, β_j is the specific weight that households place in the age-j utility. Note that households are born with no assets and cannot die with debts. Steady-state factor prices are r and w. The solution of the problem includes age-specific consumptions, c_j, and asset holdings, a_j, that satisfy the Euler equation

$$u_c(c_j) = \frac{\beta_{j+1}}{\beta_j}(1+r)u_c(c_{j+1}). \tag{14.10}$$

Steady-state factor prices are equal to the marginal productivities of a neoclassical production function with respect to aggregate capital, $K = \sum_{j=1}^{J} A_j$, and labor, $N = \sum_{j=1}^{J} \varepsilon_j$. We are using capital A_j to denote the assets of households of age j of which there are many, making it an aggregate variable which explains the use of capital letters.

When mapping these models to the data, we calibrate the earnings profile to have an inverse U shape as in the data (even after including Social Security payments). If we pose a constant discount rate, that is, we substitute β_j with β^j in Equation (14.6), as most researchers do, the model generates wealth holdings with an inverse U shape that typically peaks a little beyond 60 years of age. From that point on, the model predicts a slow but certain depletion of assets until death. Because in equilibrium household wealth has to add up to capital, households have to save during their finite lifetime to accumulate the whole capital stock. Although the prediction of the overlapping generations model in terms of lifetime wealth is broadly consistent with the data, the prediction for lifetime consumption is not. The strong incentive to save, together with the Euler equation,

[4] Sometimes the literature uses the term "overlapping generations model" for environments in which new agents are born every period and die with some probability at any point in the future. We refer to this particular environment as the Blanchard–Yaari model (Blanchard, 1985; Yaari, 1965), which is very similar mathematically to the infinitely lived model.

implies that $c_{j+1} > c_j$ for all j. In the data, however, consumption is also hump shaped. Various approaches are proposed in the literature to get around this shortcoming. They include demographic shifters, nonseparable leisure in the utility function (Auerbach and Kotlikoff, 1987; Ríos-Rull, 1996), existence of both durable goods and incomplete financial markets (Fernandez-Villaverde and Krueger, 2011), borrowing constraints and low rates of return (Gourinchas and Parker, 2002), and others.

With stochastic mortality, the model produces identical predictions as long as there is a market for annuities (which are available even if scarcely used). To see why, consider the probability of surviving between ages j and $j+1$, which we denote by φ_j. The survival probability multiplies the discount factor $\frac{\beta_{j+1}}{\beta_j}$, capturing the fact that the household gets utility only if alive.[5] Fairly priced (i.e., issued at zero expected cost) annuities imply that households save by purchasing them, and one unit of savings today yields $\frac{1}{\varphi_j}(1+r)$ units of the good tomorrow if the household survives and zero otherwise. Clearly, this asset dominates noncontingent investment of savings and the budget constraint (14.7) becomes

$$c_j + \frac{a_{j+1}}{\varphi_j} = a_j(1+r) + w. \tag{14.11}$$

It can be verified that with these modifications to discounting and the budget constraint, we obtain the same first order conditions as in Equation (14.10).

If we assume that there are no annuities, as in Hansen and Imrohoroglu (2008), we have to make some assumption about the allocation of the assets left by the deceased households. There are various options. One possibility is to assume that any household is like a pharaoh and assets are buried with their owners. The predictions of the model change a little relative to the basic model because there is now a smaller amount of total wealth due to the lower rate of return tilting the allocation toward young ages. Other options include the assumption that there is a 100% estate tax (with implications identical to that of the pharaoh model except for the use of public revenues) or that the assets of the deceased go to those in a certain age group. If the assets are distributed equally among the households of certain age groups, the wealth distribution will present a hike at the age at which households inherit, which is not a feature of the data. A more attractive alternative that has not been directly explored is to build direct links between a dead household and a randomly chosen younger household that inherits the assets. In this case, there will be limited within-cohort inequality that results from differences in the timing of the death and the wealth of the ancestors.

What about versions of overlapping generations economies with aggregate shocks? With aggregate shocks, even if there are markets for one-period-ahead state-contingent

[5] In this model, there is nothing that the household can do to affect survival, so the relative value of being alive or dead is irrelevant. With a CRRA utility function with more curvature than log, the utility is negative and, implicitly, our formulation seems to indicate that the household would rather be dead than alive.

assets, there could be incomplete insurance because households that are not alive cannot insure each other. The answers depend first on the size of the shocks. For (small) business-cycle type shocks, there are no great differences between the allocations implied by complete or incomplete markets. Ríos-Rull (1996) and Ríos-Rull (1994) find that the allocations are almost identical with and without typical business-cycle shocks. Larger and persistent shocks are a different matter. For example, Krueger and Kubler (2006) study the role of Social Security in reducing market incompleteness across generations and do not find large effects. Glover et al. (2011) study the redistributional implications of the (most recent) recession and find that the loss of output and consequent drop in the price of assets affect the old generations more than the young ones. The intuition for this result is that the recent crisis has been associated with large drops in asset prices, including housing, and old generations own more assets than the young.

If markets for the insurance of idiosyncratic risks are not present and households can save only by holding noncontingent assets, the situation changes dramatically and the model has very tight predictions. We will see this in the next section.

14.2.1.3 Stationary Theories of Earnings and Wealth Inequality

When households do not have access to insurance against shocks, the accumulation of riskless assets acts as a mechanism that allows households to smooth consumption—saving in good times when earnings are above the mean and dissaving in bad times. This means that in environments in which households are subject to uninsurable risks, those that have been lucky and have enjoyed good realizations of the shocks are wealthier than those that faced adverse realizations. This type of ex post inequality has been widely studied in models in which the risk was on endowments or earnings and agents could save only in the form of non-state-contingent assets. The basic theory was first developed in Bewley (1977), and the general equilibrium and quantitative properties were studied later by İmrohoroğlu (1989), Huggett (1993), and Aiyagari (1994). These ideas have important applications such as those in Carroll (1997) and Gourinchas and Parker (2002).

Successive studies have extended these models to improve the ability to generate greater wealth inequality. Among these approaches are the addition of special earning risks (Castañeda et al., 2003), entrepreneurial risks (Angeletos, 2007; Buera, 2009; Cagetti and De Nardi, 2006; Quadrini, 2000), endogenous accumulation of human capital (Terajima, 2006), and stochastic discounting (Krusell and Smith, 1998). Because in these models inequality is endogenous, the degree of wealth concentration can be affected by policies. This opened the way to studies that investigate the importance of taxation policies for wealth inequality. Examples are Díaz-Giménez and Pijoan-Mas (2011), Cagetti and De Nardi (2009), and Benhabib et al. (2011).

We start by reviewing how to pose the process for earnings (Section 14.2.1.3.1), and then we describe the main features of the Aiyagari model (Section 14.2.1.3.2).

14.2.1.3.1 Stochastic Representation of Earnings

A large body of literature tries to provide a parsimonious representation of the stochastic processes for wages or earnings. This literature uses panel data to estimate a univariate process for labor income or earnings, sometimes at the level of individual earners and sometimes at the household level (which is more in line with the data used in Tables 14.1 and 14.2).[6] (See, for example, Guvenen, 2009 or Guvenen and Kuruşçu, 2010; Guvenen and Kuruşçu, 2012.)

One important feature to take into account, as we will see below, is that the most common data sets do not include the very rich. The SCF is designed to provide a better picture of the rich but, unfortunately, it has no panel dimension and therefore cannot be used to separate individual effects from shocks and other interesting property that affects the most appropriate representation of earnings as a stochastic process. A comparison between the properties of the cross section in both data sets gives an idea of the differences in the sample. Recent work using either tax data (Atkinson et al., 2011; DeBacker et al., 2011) or Social Security data (Guvenen et al., 2012) looks very promising in terms of including both the very top earners and information about the persistence of their earnings.

14.2.1.3.2 The Aiyagari (1994) Model

Consider an economy populated by many, in fact a continuum, of infinitely lived agents that can be of finitely many types $i \in I$. They are subject to shocks that cannot be insured. Without loss of generality, we pose that there are finitely many possible realizations of the shock $m \in M$ and that it follows a Markov chain with (possibly type-specific) transition matrix $\Gamma^i_{m,m'}$. For compactness, we write Γ to denote a block diagonal matrix in which each block is $\Gamma^i_{m,m'}$. For the most part, the shock refers to the agents' endowment of efficiency units of labor, so we denote the shock by $s \in S = \{s^1, s^2, \ldots, s^M\}$.

Households do not care for leisure and assess consumption streams through a per period utility function $u^i(c)$ with intertemporal discount factor β_i. The utility function and the discounting may be type specific.

We start by considering the most primitive financial structure in which households have access to saving only in one-period noncontingent assets, and they cannot borrow. To map the model to a real economy and to consider its empirical implications, we build the model economy on top of a neoclassical growth model with exogenous labor supply. With a Cobb–Douglas production function, the prices of capital (rental rate of capital) and labor (wage) depend only on the capital-labor ratio. Because the aggregate labor supply is constant, prices depend only on aggregate capital K, and we can express them as $r(K)$ and $w(K)$.

[6] The process could also be for wages, but given the low variability of individual variance of hours worked for primary earners, wages and earnings have similar properties.

We consider only steady-state equilibria in which households face a constant interest rate r and a constant wage w per efficiency unit of labor. This approach is common in these types of studies because it greatly simplifies the computational burden. In fact, by focusing on steady states, when we solve the individual problem we can ignore the evolution of the aggregate states and we only need to keep track of the individual states (household's type i, asset position a, and realization of the idiosyncratic shock m). Of course, by doing so we have to exclude from the analysis changes that affect the whole economy, such as aggregate productivity shocks or structural changes. The consideration of aggregate and recurrent shocks represents a major computational complication (see, for example, Krusell and Smith, 1998). However, if we restrict ourselves to explore the implications of a one-time completely unexpected shock (a somewhat oxymoronic term) or structural change, then the computation remains tractable. For simplicity of exposition, we limit the analysis here to steady-state comparisons with the caveat that in the real economy, the distribution will take a long time to converge to a new steady state.

The household's problem can be written as

$$v^i(m, a; K) = \max_{c, a'} u^i(c) + \beta_i \sum_{m'} \Gamma^i_{m,m'} v^i(m', a'; K), \tag{14.12}$$

$$\text{s.t.} \quad c + a' = ws^m + a(1+r), \tag{14.13}$$

$$a' \geq 0, \tag{14.14}$$

where the superscript i denotes the household's type. Because this does not vary over time, we wrote it outside the arguments of the value function. The first order condition is given by

$$u^i_c(c) \geq \beta_i(1+r) \sum_{m'} \Gamma_{m,m'} u^i_c(c'), \quad \text{with equality if } a'_i > 0. \tag{14.15}$$

Standard results show that this problem is well behaved and the solution is given by a function $a_i'(m, a; K)$. Moreover, when $\beta_i^{-1} < (1+r)$, it is easy to show that for all i and m, there is a level of wealth $\overline{a}$ such that $a_i'(m, \overline{a}) < \overline{a}$. This means that there is a maximum level of wealth accumulated by an individual household. Thus, the set of possible asset holdings is the compact set $A = [0, \overline{a}]$.

To describe the economy, we could use a list of households with their types, shocks, and assets along with their names, but it is easier to use a measure x. This measure tells us how agents have certain characteristics in the space (i, m, a). Then, aggregate capital, which is just the sum of the assets of all households, can be written as

$$K = \int a \, dx. \tag{14.16}$$

The measure x gives us all the information that we need. For example, the total amount of efficiency units of labor or aggregate labor input is equal to

$$N = \int s^m dx, \tag{14.17}$$

and the variances of both wealth and earnings are

$$\sigma_k^2 = \int (a - K)^2 dx, \tag{14.18}$$

$$\sigma_N^2 = \int (s^m - N)^2 dx. \tag{14.19}$$

To calculate the Gini index for wealth, we need to compute the Lorenz curve and then calculate its integral. Note that any point of the Lorenez curve, for example, its value at 0.99 denoted by $\ell_{0.99}$, is one minus the share of wealth held by the richest 1%. To compute $\ell_{0.99}$, we start by finding the threshold of wealth that separates the richest 1% from the rest of households. Once we have found the threshold, we compute the wealth held by those households with wealth above the threshold relative to total wealth. The Gini index is simply twice the area between the Lorenz curve and the triangle below the diagonal between 0 and 1. (See Figure 14.6, for instance.) Other inequality statistics are also readily obtained from x, including those pertaining to the joint distribution of earnings and wealth and their intertemporal persistence.

The Aiyagari model has unique predictions about wealth and income inequality for any specification of the process of earnings. Therefore, the determination of the properties of the earning process becomes the central issue in the application of this model to the data. Should we think of people as being all ex ante equal in the sense that there is only one i type and they differ only in the realization of the shock? Or should we think of people consisting of different ex ante types? In either case, how do we determine which process to use? We now turn to this issue.

As we have seen in Section 14.1, the distribution of wealth in the United States is highly skewed, with about one-third of all the wealth in the hands of a mere 1% of households. How did those households become so wealthy? In order to become rich, households need both motive and opportunity. The reason for the opportunity is clear: at some point, the households had to have high enough earnings to be able to save and accumulate high levels of wealth. Motive is also important: why should households save rather than consume if they are impatient? If high earnings are not going to be around forever, then prudent households would want to save for the bad times that are likely to lie ahead. The issue is whether motives and opportunities are big enough to generate the wealth concentration observed in the United States.

To choose the actual parameterization of the earnings process for the model, we first need a Markovian process for earnings. If the focus is on the U.S. economy, one possibility is to specify a process estimated using the Panel Study of Income Dynamics (PSID). This is what Aiyagari (1994) did in his seminal paper, which relied on existing empirical studies such as Abowd and Card (1987) and Heaton and Lucas (1996).

The results are disappointing. The first row of Table 14.6 shows the shares of wealth of key groups in the U.S. data, and the second row displays those same shares as predicted by a model in which the earning process is calibrated using PSID data. The red line in Figure 14.4 shows the associated Lorenz curve. There is very little inequality compared with the inequality observed in the U.S. economy. The shares of wealth of the top 1% and the top quintile generated by the model are 4% and 27%, respectively, whereas in the United States these shares are 34% and 87%. The use of alternative estimates of the earning process, such as those provided by Storesletten et al. (2001), improves the performance of the model but only marginally.

The model fails to replicate the high concentration of wealth observed in the data for many possible reasons. One obvious explanation is that the model misses important pieces; for example, the model ignores life-cycle heterogeneity with all the demographic complications of actual lives. Or it ignores the permanent characteristics of people as well as education and human capital acquisition. It also ignores the fact that lives are affected by many other types of shocks such as health or unforeseen expenditures.

Castañeda et al. (2003) take a different approach and argue that the reason for the failure is the misrepresentation of the process of earnings. The PSID sample does not include very rich households. A comparison of its data with that of the SCF in which the emphasis is on wealthy people shows a large mismatch. The PSID does a better job at including people outside the top 10% of income earners and asset holders, but it is not appropriate to capture the dynamic properties of the incomes earned by the top of the distribution. Based on this observation, Castañeda et al. (2003) propose to ignore the PSID and focus instead on the specification of a process for earnings where the cross-sectional dispersion is similar to the SCF but its persistence is engineered so that it replicates the main features of the wealth inequality.

The third row of Table 14.6 displays the wealth distribution of an economy where the earning process has been calibrated following the above criteria. As we can see from the table, the model replicates quite well (by construction) the empirical data. Comparing the two processes for earnings (at least in the parsimonious representation used in Díaz et al., 2003) is very useful. The version of their economy designed to replicate the properties of the original Aiyagari economy has three values for earnings that are essentially symmetric, as are the persistence properties of the process: the earnings of agents in the middle and top thirds are $1.28\times$ and $1.63\times$, respectively, the earnings of those of the bottom third. Households in both, the top and the bottom thirds, have a one-third probability of moving out of their current situation by the next period. This society is very equal. Moreover, encountering bad luck, that is, being sent to the bottom third, is not really that bad. Clearly, because there are few motives to save money in this society, households soon stop doing so and consume all of their income.

The process that replicates the U.S. wealth distribution is extremely different from the process just described. The bottom of the society is now almost *half* of all households. Moreover, once at the bottom, less than 1% of these households move up each year.

Table 14.6 Concentration of wealth of various economies

Economy	1st	2nd	3rd	4th	5th	Top 10%	Top 5%	Top 1%	Gini
2010 U.S. Data	−0.7	0.7	3.3	10.0	86.7	74.4	60.9	34.1	0.85
PSID Ear–Pers	3.7	10.1	17.0	25.1	44.1	26.7	15.5	4.0	0.41
SCF Ear–Wea	0.0	0.0	0.3	4.5	95.2	78.3	53.2	14.7	0.87
Emp–Unemp	10.4	16.2	19.6	23.4	30.4	16.8	9.1	2.3	0.19
Stochastic β	1.7	6.5	12.5	21.1	59.3	40.3	25.3	6.7	0.56

Aiyagari (1994) used the PSID Ear–Pers calibration, Castañeda et al. (2003) used the SCF Ear–Wea calibration, and Krusell and Smith (1998) used both the Emp–Unemp and the Stochastic β calibrations.
U.S. data source Kuhn (2014).

Households that make up the middle class, almost one-half of the population, earn 5 × more than those at the bottom and have an equal chance (1%) of moving up or down. Only 6% of the households are in the top earnings group, and their earnings are huge: 47 × those of the poor and 9 × those of the middle class. More than 8% of these households will move down in a given year. Although these particular values are somewhat arbitrary, they give an accurate sense of how extreme both motives and opportunities have to be in order to induce the U.S. wealth disparities in a model in which agents differ only in the realization of a common earnings process.

Krusell and Smith (1998) pursue a very different approach to get a suitable wealth distribution. Instead of tracking the behavior of earnings, they pose a simple employment/unemployment process to generate earnings inequality, and they assume that the discount rate of individual agents is also stochastic. Therefore, in addition to the idiosyncratic shock to earnings, they consider a second idiosyncratic shock to the discount rate. The earnings process alone generates almost no inequality because the only way to get rich is through remaining employed but without earning more than other employed workers. In the extension with stochastic discounting, they assume that β can take three values, $\{0.9858, 0.9894, 0.9930\}$, with a symmetric distribution that satisfies the following properties: (i) the average duration of the extremes is 50 years (so it lasts the length of the adult life of a person); (ii) the transition from extreme to extreme requires a spell in the middle; and (iii) the (stationary) size of the middle group is 80%. Interestingly, the model with stochastic discounting yields disarmingly similar inequality indexes as in the data (see the last row of Table 14.6).

Various papers used life-cycle models with idiosyncratic risk to study wealth inequality. An important early contribution is Huggett (1996). De Nardi (2004), Cagetti and De Nardi (2006), and Cagetti and De Nardi (2009) study the role of bequest, estate taxation, and entrepreneurship in shaping the wealth distribution.

14.2.2 Theories of Earnings Inequality

So far we have described how macroeconomists think of the distribution of wealth given the distribution of earnings. But what about the distribution of earnings itself? Where is it coming from? In general, we can think of the differences in earnings as resulting from a combination of heterogeneity in (i) innate abilities or ex ante luck that persists for the lifetime of the agent; (ii) ex post luck due to the realization of shocks that are not under the control of the agent; (iii) effort or occupational choice; and (iv) investment in human capital. In the model considered in the previous section, the heterogeneity in earnings was only a consequence of innate heterogeneity (captured by the agents' type) and ex post luck (captured by the Markov process for skills). In this section we make the earnings endogenous by allowing for the optimal choice of effort and investment in human capital. An important consequence of endogenizing the earning process is that the distribution of earnings can be affected by several factors including financial market development (which, for example, facilitates access to the financing of investment in human capital) and taxation policies (which, for example, affect the marginal decision of effort and investment in human capital).

Next we briefly describe three aspects of models with endogenous earnings: models in which earnings are the result of explicit choices of either learning by doing or learning by not doing, including education (Section 14.2.2.1); models in which not all types of labor are perfect substitutes (Section 14.2.2.3); and models with occupational choices in which agents decide which occupation to take (Section 14.2.2.5).

14.2.2.1 Human Capital Investments

A common approach to endogenizing the process for earnings is the assumption that human capital is endogenous and depends on the individual investment chosen by agents. If the return from the investment is stochastic, then agents will be characterized ex post by different levels of human capital and, therefore, unequal earnings. An interesting feature of this setup is that it generates a positive relation between the aggregate performance of the economy and the degree of inequality. More specifically, higher investment in human capital leads to higher income or growth or both, but also to higher inequality because investment amplifies the impact of idiosyncratic shocks.

We illustrate this point with a simple model without taking a stand on the issue of what type of investment yields higher human capital. The investment can be either the result of time and hence forgone output or leisure, or the result of effort that generates a disutility, or the result of investment in goods. In this sense and at this level of abstraction, it accommodates both learning by direct investment in schooling or more general human capital investment such as that pioneered by Ben-Porath (1967). It also captures the key mechanisms formalized in more recent studies such as Guvenen et al. (2009), Manuelli and Seshadri (2010), and Huggett et al. (2011). For an extensive discussion of the life-cycle human capital model, see von Weizsäcker (1993).

Consider an economy with a continuum of risk-neutral workers, each characterized by human capital h. Production, which in this simple model corresponds to earnings, is equal to the worker's human capital h. Individual human capital can be enhanced with investment captured by the variable y. Investment is costly in terms of either utility or output (given risk neutrality, they are essentially the same). We assume that the cost takes the form $\frac{\alpha y^2 h}{2}$ and human capital evolves according to

$$h' = h(1 + y\varepsilon'),$$

where ε' is an i.i.d. random variable with $\mathbb{E}\varepsilon' = \bar{\varepsilon}$. To simplify notation, we denote by $g(y, \varepsilon') = 1 + y\varepsilon'$ the gross growth rate of human capital.

Because the outcome of the investment is stochastic, the model generates a complex distribution of human capital among workers. In the long run, the distribution will be degenerate because at the individual level h follows a random walk. To make the distribution stationary and keep the model simple, we assume that workers die with probability λ in each period and are replaced by the same mass of newborn workers. To allow for ex ante heterogeneity or innate abilities, we also assume that newborn agents are heterogeneous in initial human capital. In particular, there are I types of newborn agents indexed by $i \in \{1, ..., I\}$, each of size x_0^i and with initial human capital h_0^i. The initial distribution of newborn agents satisfies $\sum_i x_0^i = \lambda$.

Because of the linearity assumption, it will be convenient to normalize by h the optimization problem solved by a worker. We can then write the problem recursively as

$$\omega = \max_y \left\{ 1 - \frac{\alpha y^2}{2} + \beta(1-\lambda)\mathbb{E}[g(y, \varepsilon')\omega'] \right\}, \tag{14.20}$$

where ω is the expected lifetime utility normalized by human capital h. The non-normalized lifetime utility is ωh. Of course, the linearity of the accumulation function is crucial here. If the new human capital was a Cobb–Douglas function of old human capital, as in the Ben-Porath (1967) model, the analysis would be more complex analytically.

The first order condition gives

$$\alpha y = \beta(1-\lambda)\bar{\varepsilon}\omega', \tag{14.21}$$

where $\bar{\varepsilon}$ is the average value of the stochastic variable ε.

Because the first order condition is independent of h, the investment variable y is constant over time, which in turn implies that the normalized lifetime utility for the worker, ω, is constant. Therefore, y and ω can be determined by the two equations that define the value for the worker and the optimal investment, that is,

$$\omega = 1 - \frac{\alpha y^2}{2} + \beta(1-\lambda)(1 + y\bar{\varepsilon})\omega, \tag{14.22}$$

$$\alpha y = \beta(1-\lambda)\omega\bar{\varepsilon}. \tag{14.23}$$

Given the distribution of human capital for newborn workers x_0 and the investment variable y, we can determine the economywide distribution of human capital (equal to the distribution of earnings) and compute a cross-sectional index of inequality. We focus on the square of the coefficient of variation, that is,

$$\text{Inequality index} \equiv \frac{\text{Var}(h)}{\text{Ave}(h)^2},$$

which can be calculated exactly in a steady-state equilibrium.

Before we do this, note that the mass or measure of agents of age $j+1$ is given by $\sum_i x_j^i = \sum_i x_0^i (1-\lambda)^j$ and the average human capital is equal to

$$\text{Ave}(h) = \sum_i x_0^i \sum_{j=0}^{\infty} (1-\lambda)^j \mathbb{E}_j h_j^i. \tag{14.24}$$

The index j denotes the age of the worker and i the cohort of newly born agents with human capital h_0^i. The population size of newborn agents of type i is x_0^i, and the total mass of newborn agents is $\sum_i x_0^i = \lambda$. Because workers survive with probability $1-\lambda$, the fraction who is still alive after j periods is $(1-\lambda)^j$.

The cross-sectional variance of h is calculated using the formula

$$\text{Var}(h) = \sum_i x_0^i \sum_{j=0}^{\infty} (1-\lambda)^j \mathbb{E}_j \left[h_j^i - \text{Ave}(h) \right]^2, \tag{14.25}$$

which has an interpretation similar to the formula used to compute the average h. Of course, for the variance to be finite, we have to impose some parameter restrictions. In particular, we need to impose that the death probability λ is sufficiently large and the return on human capital accumulation $\mathbb{E}[\varepsilon']$ is not too big.

Using Equations (14.24) and (14.25), Appendix A shows that the average human capital and the inequality index take the forms

$$\text{Ave}(h) = \frac{\lambda \bar{h}_0}{1-(1-\lambda)\mathbb{E}[g(\gamma,\varepsilon)]}, \tag{14.26}$$

$$\text{Inequality index} = \left[\frac{\sum_i x_0^i \left(h_0^i\right)^2}{\bar{h}_0^2} \right] \frac{[1-(1-\lambda)\mathbb{E}g(\gamma,\varepsilon)]^2}{1-(1-\lambda)\mathbb{E}g(\gamma,\varepsilon)^2} - 1, \tag{14.27}$$

where $\bar{h}_0$ is the aggregate human capital of newborn agents.

We can see from Equation (14.26) that the average human capital and, therefore, aggregate output are strictly increasing in the investment variable γ. This is intuitive given the structure of the model.

As far as the inequality index is concerned, Equation (14.27) shows that this results from the product of two terms. The first term in parentheses captures the ex ante inequality, that is, the distribution of human capital at birth. If all agents are born with the same human capital, this term is 1. However, if the initial endowment is heterogeneous (heterogeneity in innate abilities), then this term is bigger than 1. The second term in parentheses captures the inequality generated by investment. It is easy to show that this term, and therefore, the inequality index, are strictly increasing in γ. Because the average value of h is also strictly increasing in γ, we have established that there is a positive relation between macroeconomic performance and inequality. The intuition for this dependence is simple. If $\gamma = 0$, human capital for all workers will be equal to h_0^i and the inequality index is fully determined by the ex ante heterogeneity. As γ becomes positive, inequality increases for two reasons. First, because the growth rate $g(\gamma, \varepsilon)$ is stochastic, human capital will differ *within* the same age-cohort of workers. Second, because each age-cohort experiences growth, the average human capital will differ *between* different age-cohorts.[7] Both mechanisms are amplified by the growth rate of human capital, which increases in the investment γ.

Using this model, we can analyze how changes that have an impact on the incentives to invest in human capital affect macroeconomic performance and inequality simultaneously. An example is a change in income taxes.

Suppose that the government taxes income at rate τ. The equilibrium conditions (14.22) and (14.23) become

$$\omega = 1 - \tau - \frac{\alpha\gamma^2}{2} + \beta(1-\lambda)(1+\gamma\bar{\varepsilon})\omega, \tag{14.28}$$

$$\alpha\gamma = \beta(1-\lambda)\omega\bar{\varepsilon}. \tag{14.29}$$

A bit of algebra shows that γ is strictly decreasing in τ. Effectively, the tax reduces the value of human capital, ω, which in turn must be associated with a reduction in γ (see Equation 14.29). Then, we can see from Equations (14.26) and (14.27) that higher taxes reduce inequality but also reduce the average human capital. This mechanism captures, in stylized form, the idea of Guvenen et al. (2009) used to explain cross-country wage inequality. They argue that higher taxation of labor accounts for the wage compression and lower productivity in Europe relative to the United States. Note also that the effects of higher labor taxation in the short run would differ from those in the long run in environments like this. In this particular model, taxation has no short-run disincentive effects (they would exist, however, if leisure were valued). Taxation does have long-run effects because agents would invest less in human capital. Empirical studies based only on short-run data would miss these effects.

14.2.2.2 Human Capital Investment Versus Learning by Doing

The stylized model considered in the previous section can easily be extended to include learning by doing. To do so, we can simply interpret the variable γ as the fraction of time spent investing (in human capital) and $1-\gamma$ the fraction of time spent producing. Output is produced according to the function $h(1-\alpha\gamma^2/2)$, which is strictly decreasing and

[7] This is in addition to the differences in initial human capital among the I types of newborn agents.

concave in the time spent investing. The equation determining the evolution of human capital becomes

$$h' = h(1 + \gamma\varepsilon') + \chi(1 - \gamma).$$

The first term captures the time spent investing, whereas the second results from learning by producing. The analysis conducted so far extends trivially to this case. In particular, the two Equations (14.22) and (14.23) become

$$\omega = 1 - \frac{\alpha\gamma^2}{2} + \beta(1 - \lambda)[(1 + \gamma\bar{\varepsilon}) + \chi(1 - \gamma)]\omega, \tag{14.30}$$

$$\alpha\gamma = \beta(1 - \lambda)\omega(\bar{\varepsilon} - \chi). \tag{14.31}$$

A further extension is to assume that the return from learning by doing is stochastic, that is, χ is a stochastic variable. Also, we could consider the special case in which the evolution of human capital is determined only by learning by doing. This case is obtained by setting $\varepsilon = 0$. These extensions do not change the basic properties of the model illustrated in the previous subsection, including the analysis of the short- and long-run effects of labor income taxation.

14.2.2.3 Prices of Skills

So far we have presented a model in which there is only one type of human capital or skills. Individuals have different levels of human capital and, therefore, earn different incomes. In reality, different types of skills are combined together with physical capital to produce goods and services. If those skills are not additive, they have a relative price that may be changing, implying that the distribution of income also depends on those relative prices, which in turn depend on the relative supplies and demands of the various skills.

To fix these ideas, suppose that there are three types of agents according to their skill types, H_1, H_2, and H_3. Production takes place through the technology

$$(H_1 + AH_2)^{\theta} H_3^{1-\theta}.$$

Assuming that markets are competitive, the prices of the three types of skills are equal to their marginal productivities, that is,

$$\begin{aligned} W_1 &= \theta(H_1 + AH_2)^{\theta-1} H_3^{1-\theta}, \\ W_2 &= \theta A(H_1 + AH_2)^{\theta-1} H_3^{1-\theta}, \\ W_3 &= (1 - \theta)(H_1 + AH_2)^{\theta} H_3^{-\theta}. \end{aligned}$$

In this example, the relative prices for the three types of skills depend on three factors: (i) the relative supplies of the skill types; (ii) the parameter A determining the productivity of H_2 relative to H_1; (iii) the parameter θ determining the relative productivity between the aggregation of H_1 and H_2 on one side and H_3 on the other. For example, an increase in the parameter A, keeping constant the relative supplies of the three skills, increases the productivity of H_2 and H_3 but reduces the marginal productivity of H_1. This changes the distribution of income between the three groups. The change in A could be the result of particular technological progress. As we will see in Section 14.3, a similar idea has been used by Krusell et al. (2000) to explain the increase in the skill premium observed in the United States since 1980.

14.2.2.4 Search and Inequality

Where does workers' luck come from? Some economists think it is from the arbitrariness of the process that matches workers to jobs. The idea is that some firms are better than others, and these firms end up paying more for essentially identical workers. The argument relies on two considerations. The first is that certain frictions make it difficult for firms to get a worker. The second is that wages depend on the characteristics of both workers and firms.

We can discuss these ideas with the help of the basic labor market model (see Pissarides, 1990) in which firms are created through the random matching of job vacancies and unemployed workers. Workers have linear utility $\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t c_t$. Risk neutrality implies that the interest rate is constant and equal to $r = 1/\beta - 1$.

A firm is created by paying a cost κ_0 that entails a draw of a productivity level z from the distribution $F(z)$. After the initial draw, z stays constant over time. Then the firm has to post a vacancy at cost κ_1. If matched with an unemployed worker, the firm produces output z starting in the next period until the match is separated, which happens exogenously with probability λ. The firm can use only one worker. The number of newly formed matches is determined by the function $M(v, u)$, where v is the number of vacancies and u is the number of unemployed workers. The probability that a vacancy is filled is $q = M(v, u)/v$, and the probability that an unemployed worker finds occupation is $p = M(v, u)/u$. The second ingredient of this model is that wages are determined through Nash bargaining, where we denote by η the bargaining power of workers. A worker attached to a firm with productivity z is paid the wage $w(z)$ and the firm earns $z - w(z)$.

The value of a firm that has a worker can be written recursively as

$$J^1(z) = \left\{ z - w(z) + \beta(1-\lambda) J^1(z) \right\}, \tag{14.32}$$

which implies that the value is $J^1(z) = \frac{z - w(z)}{1 - \beta(1-\lambda)}$. A newly created firm has value

$$J^0(z) = \left\{ -\kappa_1 + \beta(1-\lambda)\left[q J^1(z) + (1-q) J^0(z) \right] \right\}, \tag{14.33}$$

which can also be expressed as $J^0(z) = \dfrac{-\kappa_1 + \beta(1-\lambda)\dfrac{(z - w(z))q}{1 - \beta(1-\lambda)}}{1 - \beta(1-\lambda)(1-q)}$.

The value of a worker employed by a firm with productivity z is

$$W(z) = w(z) + \beta[(1-\lambda)W(z) + \lambda U], \tag{14.34}$$

where U is the value if the worker does not have a job. Such value is given by

$$U = \overline{u} + \beta\left\{p\int W(z)F(\mathrm{d}z) + (1-p)U\right\}, \tag{14.35}$$

where $\overline{u}$ is the flow utility for the unemployed worker.

To derive the bargaining problem, let's define the following functions:

$$\hat{J}(z,w) = z - w + \beta(1-\lambda)J^1(z), \tag{14.36}$$

$$\hat{W}(z,w) = w + \beta[(1-\lambda)W(z) + \lambda U]. \tag{14.37}$$

These functions are, respectively, the value of a firm and the value of an employed worker, given an arbitrary wage w paid in the current period and future wages determined by the function $w(z)$. The actual wage function $w(z)$ is the solution to the problem

$$\max_w \left[\hat{J}(z,w) - J^0(z)\right]^{1-\eta}\left[\hat{W}(z) - U\right]^{\eta}. \tag{14.38}$$

Notice that the terms inside the brackets describe, respectively, what the firm and the worker would lose if they do not reach an agreement and break the match. Parameter η captures the bargaining power of workers. To reach an equilibrium, a couple of additional conditions are needed. One is free entry of firms, that is, the expected value of creating a firm, $\int J^0(z)F(dz)$, equals its cost, κ_0. To get a steady-state equilibrium, total firm creation has to be sufficient to create enough vacancies to replace the jobs of workers that join unemployment from job separation.

It is easy to see that the wage is an increasing function of z. In this fashion, a theory of wage inequality can arise from the sheer luck of matching with a very productive firm, even though there is nothing inherently different between two workers in different firms. Hornstein et al. (2011) proposed a new method to assess the quantitative importance of the wage dispersion induced by search frictions and found that it is very small. In fact, the actual dispersion is $20\times$ larger than the dispersion generated by the type of search frictions described here. To understand this finding, think of an intermediate step between a worker being matched with a firm and before the actual bargaining process takes place. In this step, the worker could forecast what the wage will be and could potentially choose whether to take the job or keep searching. The minimum wage makes the worker indifferent between accepting the job and continuing searching. Such a wage can be compared with the average wage that workers get. Hornstein et al. (2011) found that for empirically sound values of the parameters, the difference between the minimum and the average wages generated by search frictions was tiny.

14.2.2.5 Occupational Choice and Earnings Inequality

Workers' choice of occupation has recently come to the fore as a source of income inequality. Income inequality may occur not only because workers accumulate different levels of human capital, but also because they work in different occupations. As evidenced by Kambourov and Manovskii (2009b), among others, human capital is largely occupation specific. We will discuss how occupation choices can directly affect the return to human capital and wage growth. In another vein, some workers' occupations may make them more sensitive to cyclical dynamics and unemployment. As in Wiczer (2013), the occupation specificity of human capital makes workers less flexible in response to specific shocks during the business cycle, and this generates inequality across occupations in terms of unemployment rates, unemployment duration, and earnings.

To see the pathways through which occupation choices may affect earnings inequality, consider a simple model with occupations indexed by $j=\{1,\ldots,J\}$. Human capital is only imperfectly transferable between occupations. Therefore, the human capital of a worker with current human capital h in occupation j that switches to occupation ℓ becomes $h'=\omega(h,j,\ell)$.

This is the basic framework with which Kambourov and Manovskii (2009a) connected occupational mobility to wage inequality. Workers who remain in the same occupation experience the same wage growth. Workers who switch occupations lose human capital, that is, experience negative growth in earnings. Let's normalize $h=1$ for experienced workers. When a new employee arrives, the human capital is $\omega_{j,\ell}=\omega(1,j,\ell)$, and it takes one period to become experienced. Let $g(j,\ell)$ be the probability that a worker switches from j to ℓ, and x_j is the measure of workers in occupation j. The variance of wages is

$$\mathrm{var}(w)=\sum_j x_j \sum_\ell g(j,\ell)\left(\omega_{j,\ell}-\mathbb{E}w\right)^2.$$

Clearly, without switching occupations, the variance would be zero. But, occupational switching is not infrequent and has, in fact, been rising concurrently with the recent rise in earnings inequality—the probability of switching occupations rose by 19% from the 1970s to the 1990s.[8] Kambourov and Manovskii (2009a) connect the former to the latter, posing a common cause for both. If occupation-specific shocks are on the rise, they will affect wage inequality through two channels. Directly, they will increase the dispersion in wages of those attached to an occupation, but shocks will also increase switching and create more wage inequality. Because these shocks are difficult to observe directly, Kambourov and Manovskii (2009a) use the occupational switching behavior of workers to inform the underlying process that would generate such behavior; as switching rose,

[8] This probability uses the 1970 Census occupations definitions at the three-digit level and PSID data.

the shocks must have also amplified. With this identification logic, occupational switching accounts for 30% of the overall rise in earnings inequality.

Unobserved, occupation-specific shocks are certainly not the only hypothesis for why workers move to different occupations. Several authors, e.g., Papageorgiou (2009) and Yamaguchi (2012), propose that workers' wages depend on occupation-specific match quality that is learned only through the course of the match. In these papers, earnings inequality is exacerbated by occupational mismatch, which slows the wage growth for some workers. On the other hand, aggregate factors such as business-cycle pressures and unemployment may also increase occupational switching. Indeed, unemployed workers are $3\times$ more likely than employed workers to switch occupations. In this vein, we introduce a simple model with unemployment and search as motives to switch occupations.

The critical object to be determined in this environment is the stochastic finding rate, $\{p_{j,\ell}\}$, at which workers with occupation j find a job in occupation ℓ. Denote by $P=\{p_{j,\ell}\}_{j,\ell\in\{1,\ldots,J\}}$ the collection of all such finding rates. Denote by $g(j,\ell)$ the fraction of time spent searching for occupation ℓ by a worker with previous occupation j. We assume that looking for jobs in a particular area has decreasing returns at rate $\varphi<1$, so that not all workers from occupation j shift to the same type of new occupation ℓ. This simplification could be a stand-in for any number of more realistic elements of a model such as heterogeneous preferences. Clearly, the allocation of searching time determines the realized finding rate.

The characteristics of the equilibrium are going to depend on the type of wage-setting rule we use, but here we consider the simplest case in which workers earn their marginal product. Hence, the wage of a worker who has just switched occupations is $\omega_{j,\ell}$ and 1 for an experienced worker.

Let W be the value function for an employed worker and U for an unemployed worker. These functions are defined recursively as

$$\begin{aligned} W(\ell,P) &= \omega_{\ell,\ell}+\beta(1-\lambda)\mathbb{E}\,W(\ell,P')+\beta\lambda\mathbb{E}\,U(\ell,P'),\\ U(j,P) &= \max_{g(j,\ell)}\sum_{\ell=1,\ldots,J} g(j,\ell)^{\varphi}p_{j,\ell}\big(\omega_{j,\ell}+\beta\mathbb{E}W(\ell,P')\big)+\left(1-\sum_{\ell=1,\ldots,J} g(j,\ell)^{\varphi}p_{j,\ell}\right)\\ &\quad\times(\overline{u}+\beta\mathbb{E}U(j,P')). \end{aligned}$$

In this case, $g(j,\ell)$ is chosen so that, given wages and finding rates, the marginal return to search time satisfies

$$\begin{aligned} &g(j,j)^{\varphi-1}p_{j,j}\{1-\overline{u}+\beta\mathbb{E}[W(j,P')-U(j,P')]\}\\ &\quad=g(j,\ell)^{\varphi-1}p_{j,\ell}\big\{\omega_{j,\ell}-\overline{u}+\beta\mathbb{E}[W(\ell,P')-U(j,P')]\big\},\quad\forall\ell. \end{aligned}$$

To get a taste of the dynamics, suppose that $p_{j,j}$ falls. The indifference condition holds that search time toward this occupation falls so that $g(j,j)^{\varphi-1}$ will rise. This increases earnings inequality through two channels: (1) the increase in the unemployment rate among type j workers and (2) more of the new matches go to different occupations, where they produce only $\omega_{j,\ell} < 1$.

The model we have presented has the essential elements of that explored in Wiczer (2013) and, in tying it to data, he shows that recessions often bring a correlated change in P that hurts some occupations much more than others. In such a case, workers from the affected occupations can be unemployed for very long durations and keep the level of unemployment high for a long time. To allow for this result, Wiczer (2013) builds upon Kambourov and Manovskii (2009a) by introducing search frictions, so that the job finding rate is endogenous and affected by business-cycle conditions. As in the case of a typical matching function, the finding rate is reduced by *congestion*.

To extend our framework to endogenous matching frictions, following Wiczer (2013) let $p_{j,\ell} = p(z_\ell, g(j,\ell))$, where z_ℓ is a shock affecting hiring in occupation ℓ and the more workers looking for the same types of job lowers the finding rate, $\frac{\partial p}{\partial g} < 0$. Then, when $p_{j,j}$ falls, the probability of successfully switching occupations also falls. Whereas Kambourov and Manovskii (2009a) find their shocks to reconcile switching behavior, Wiczer (2013) maps his shocks to measured value added by occupation. Looking directly at productivity allows Wiczer (2013) to address business cycles in which unemployment and earnings dispersion across occupations increases even though search frictions prevent workers from mass switches into new jobs.

How to identify "occupations" in the data is still an open question. Whereas Wiczer (2013) uses two-digit occupation codes, Carrillo-Tudela and Visschers (2013) take a similar model but with a finer definition of occupation that highlights the interaction between occupation-specific skills and other job characteristics such as location. Hence, the position of a machinist in Detroit may be even more volatile than machinists in general. Both papers generate significant volatility in unemployment and earnings over the business cycle beyond search models that abstract from occupational heterogeneity.

14.3. THE DYNAMICS OF INEQUALITY

So far we have looked at how to build theories of inequality in earnings and wealth that aggregate into a macro model. Now we turn to the analysis of factors that affect the dynamics of inequality. We first consider in Section 14.3.1 changes in inequality that take place over the business cycle, and in Section 14.3.2 we analyze the dynamics over a longer horizon.

14.3.1 Inequality and the Business Cycle

A well-established feature of the business cycle is that the labor share of income is highly countercyclical. As shown in Figure 14.1, the labor share in the U.S. economy tends to increase during recessions. The figure also shows a declining trend in the labor share since

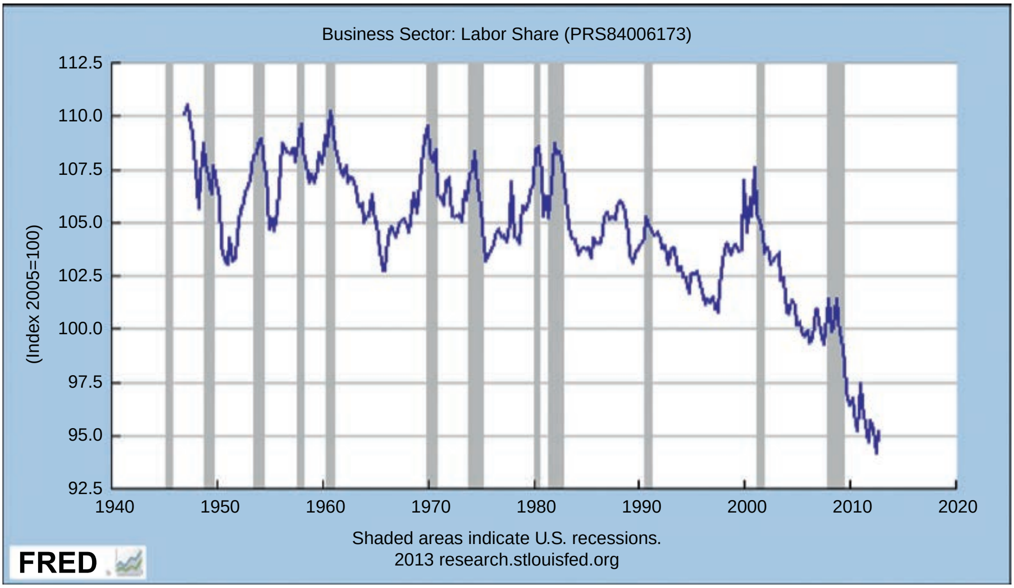

Figure 14.1 Labor share in the U.S. business sector as defined by the Bureau of Labor Statistics. *Source: U.S. Department of Labor: Bureau of Labor Statistics.*

the early 1980s. To the extent that agents are heterogeneous in the sources of their income—that is, some agents earn primarily capital incomes whereas others earn primarily labor income—there is significant redistribution over the business cycle.

To capture the cyclical properties of the labor share, we have to deviate from the standard neoclassical model with a Cobb–Douglas production function, because in this model the labor share is constant. In this section, we review some models in which the compensation of workers is determined through bargaining between employers and workers. Because the bargaining strength of workers depends on macroeconomic conditions, this mechanism has the potential to generate a labor income share that changes over the business cycle.

We start in Section 14.3.1.1 by using the search and matching model developed in Section 14.2.2.4 modified to allow for the study of the determination of the labor share. The modification associates the creation of firms with actual investors, which gives an explicit separation of labor and capital income. We look at two versions of this model: a simple one and another in which investors use both debt and external financing with bonds. An important property of this model is that shocks that affect the bargaining position of workers also affect the distribution of income as well as the macroeconomic impact of these shocks. We will consider two types of shocks: standard productivity shocks and shocks that affect access to credit. Then in Section 14.3.1.2, we will review the financial accelerator model in which the distribution is also interconnected with the business cycle. We will conclude this section by discussing the ability of these models to replicate the empirical properties of the data beyond the contemporaneous correlation.

14.3.1.1 The Determination of Factor Shares: Productivity Shocks, Bargaining Power Shocks, and Financial Shocks

Consider a version of the search and matching model described in Section 14.2.2.4 (Pissarides, 1987) in which the owners of firms—investors—are distinct from workers, but in which productivity is stochastic and common to all firms. Therefore, z is the same across firms and changes stochastically over time. We will focus on the distribution of income between investors and workers. Both types of agents have the same utility $\mathbb{E}_0\sum_{t=0}^{\infty}\beta^t c_t$.

As before, a firm is created when a posted vacancy is filled by an unemployed worker. A new firm produces output until the match is destroyed exogenously, which happens with probability λ, but now the level of output varies over time. The number of matches is determined by the matching function $M(v,u)$, where v is vacancies and u is unemployed workers. The probability that a vacancy is filled is $q=M(v,u)/v$, and the probability that an unemployed worker finds a job is $p=M(v,u)/u$. Wages are determined through Nash bargaining, where we denote by η the bargaining power of workers. We also consider the possibility that the bargaining power η may be stochastic. With these stochastic terms we rewrite the value functions for investors as

$$J^1(z,\eta)=z-w(z,\eta)+\beta(1-\lambda)\mathbb{E}J^1(z',\eta'|z,\eta), \tag{14.39}$$

$$J^0(z,\eta)=-\kappa_1+\beta(1-\lambda)\left[q\mathbb{E}J^1(z',\eta'|z,\eta)+(1-q)\mathbb{E}J^0(z',\eta'|z,\eta)\right], \tag{14.40}$$

and for workers

$$W(z,\eta)=w(z,\eta)+\beta\mathbb{E}[(1-\lambda)W(z',\eta')+\lambda U(z',\eta')], \tag{14.41}$$

$$U(z,\eta)=\overline{u}+\beta\mathbb{E}[pW(z',\eta')+(1-p)U(z',\eta')]. \tag{14.42}$$

After some rearrangement, the values for the firm and the worker can be written as

$$J^1(z,\eta)-J^0(z,\eta)=(1-\eta)S(z,\eta), \tag{14.43}$$

$$W(z,\eta)-U(z,\eta)=\eta S(z,\eta), \tag{14.44}$$

where $S(z,\eta)=J^1(z,\eta)-J^0(z,\eta)+W(z,\eta)-U(z,\eta)$ is the bargaining surplus that is split between the contractual parties, proportional to their relative bargaining power. The surplus function can be written recursively as

$$S(z,\eta)=z-\overline{u}+(1-\lambda)\beta\mathbb{E}S(z',\eta')-\eta\beta p\mathbb{E}S(z'\eta'). \tag{14.45}$$

Using the free-entry condition $\kappa_1=q\beta\mathbb{E}S(z',\eta')$, the sharing rules (14.43) and (14.44), and the functions (14.39), (14.41), and (14.42), we can derive the following expression for the wage:

$$w(z,\eta) = (1-\eta)\overline{u} + \eta z + \frac{\eta p \kappa_1}{q}.$$

14.3.1.1.1 Shocks to Productivity

Figure 14.2 plots the impulse responses of employment and the investor's share of income to a positive productivity shock under the heading baseline model. An economic boom is characterized by a larger share of income going to investors. However, the quantitative effects in terms of income distribution and employment are not large. The weak employment response is a well-known property of the matching model (see Costain and Reiter, 2008 or Shimer, 2005). What is interesting is that the inability of the model to generate large employment fluctuations is related to the inability of the model to generate large movements in the distribution of income. Because wages respond too quickly to

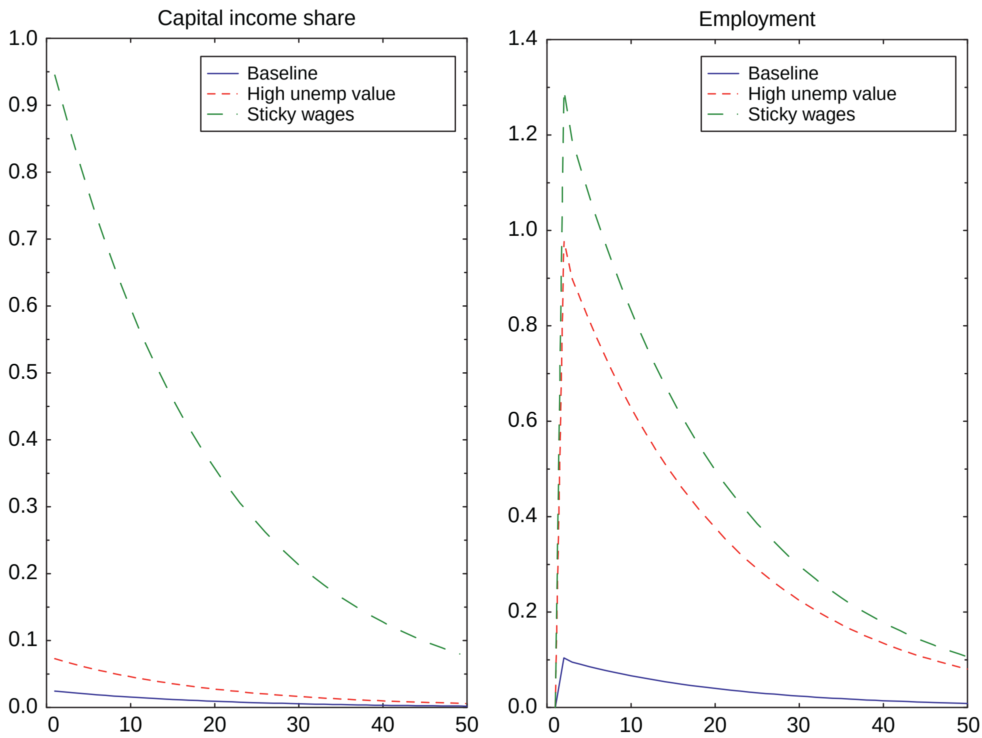

Figure 14.2 Impulse response to productivity shock. The common parameters to all versions of the model are $\beta = 0.985$, $\alpha = 0.5$, $\mathbb{E}z = 1$, $\rho_z = 0.95$, $\sigma_z = 0.01$. The remaining parameters $\overline{u}$, κ, λ, and A are chosen to achieve the following steady-state targets: a replacement rate of unemployment of 50% (95% in the model with high unemployment value), 10% unemployment rate, 93% probability of filling a vacancy, 70% probability of finding a job. The resulting values are $\overline{u} = 0.473$ (0.944 in the model with high unemployment value), $\kappa = 0.316$ (0.034 in the model with high unemployment value), $\lambda = 0.103$, and $A = 0.807$.

productivity, the share of income going to investors increases only slightly. As a result, the incentive to create new vacancies does not increase much. However, if wages would respond less, the increase in the share of income going to investors and the increase in employment would be bigger.

Recognizing the direct link between distribution and employment, several authors have proposed some mechanisms for generating smoother responses of wages and, therefore, larger fluctuations in income shares. Here we summarize three of these approaches. The first approach, proposed by Hagedorn and Manovskii (2008), is to assume that the flow utility received by workers when unemployed is not much smaller than the flow utility from working. In terms of the model, this is obtained by choosing a large value for the parameter $\overline{u}$, that is, the flow utility in the unemployment state. Although many consider this assumption implausible, the paper illustrates how this feature could bring the model closer to the data. The second approach proposed by Gertler and Trigari (2009) is to assume that wages are sticky. To illustrate these two cases, we first assign a higher value for the parameter $\overline{u}$ so that the replacement rate from unemployment is 95%. The impulse responses for this case, plotted in Figure 14.2, are labeled "High unemp. value." The figure also plots the impulse responses when the wage is exogenously fixed at the steady state with flexible wages (an extreme case of wage rigidity). As can be seen, both assumptions generate much higher volatility of employment and income distribution between investors and workers. This shows that inequality and macroeconomic volatility are closely interconnected: more volatile income distribution over the business cycle is associated with greater macroeconomic volatility. A third approach is explored in Duras (2013). The idea is that in periods with high productivity or output, the cost for workers to break the match is higher than in normal times. This weakens workers' bargaining position, alleviating the upward pressure on wages when productivity rises.

14.3.1.1.2 Shocks to Bargaining Power

Although it has been customary to assume that macroeconomic fluctuations are driven by productivity shocks, economic disturbances have many other possible sources. Here we summarize the effects of shocks that have a direct impact on the distribution of income, in particular, shocks that directly affect the bargaining power of workers, that is, the bargaining share η. When η decreases, a larger share of income will go to investors, increasing income inequality. At the same time, as investors appropriate a larger share of the surplus, they have a higher incentive to hire workers, thereby inducing a macroeconomic expansion. A similar approach has been studied by Ríos-Rull and Santaeulàlia-Llopis (2010) in the context of a neoclassical model.

14.3.1.1.3 Financial Shocks

The next step is to show that similar effects to those generated by shocks to bargaining power can be generated by the expansion and contraction of financial markets. The presentation of this case follows Monacelli et al. (2011).

Consider another slight modification of the search and matching model presented earlier, where we allow firms to borrow at the gross rate r. Borrowing, however, is subject to the constraint $b' \leq \varphi \mathbb{E} J'(b')$, where φ is stochastic. This variable captures the possible changes to the tightness of credit markets.

The firm enters the period with debt b. Given the new debt b' and the wage w, the dividends paid to investors are $d = z - w + b'/R - b$, where $R = (1+r)/(1-\lambda)$ is the gross interest rate paid by the firm conditional on survival. We assume that, in the event of exit, the firm defaults on the outstanding debt. Anticipating this, the lender charges the gross interest rate $R = (1+r)/(1-\lambda)$ so that the expected return from the loan is r. Notice that investors are shareholders and bondholders at the same time. We write the value functions exclusively as functions of debt, ignoring the potential variability of both productivity and bargaining power (that is, we now assume that z and η are constant).

The equity value of the firm can be written recursively as

$$J(b) = \max_{b'} \left\{ z - g(b) - b + \frac{b'}{R} + \beta(1-\lambda)\mathbb{E}J'(b') \right\} \tag{14.46}$$

$$\text{subject to} \quad b' \leq \varphi \mathbb{E} J'(b'),$$

where $w = g(b)$ denotes the (to be determined) wage paid to the worker. As we will see, the wage will depend on the debt. Notice that we have also used a prime to denote the next period value of equity, because this also depends on the next period aggregate states, specifically, the unemployment rate and credit market conditions. To avoid cumbersome notation, we do not include the aggregate states as explicit arguments of the functions defined here. Instead we use the prime to distinguish current versus future functions.

The value of an employed worker is

$$W(b) = g(b) + \beta \mathbb{E}[(1-\lambda)W'(b') + \lambda U'], \tag{14.47}$$

which is defined once we know the wage $g(b)$. The function U' is the value of being unemployed and is defined recursively as

$$U = \overline{u} + \beta \mathbb{E}[pW'(b') + (1-p)U'],$$

where p is the probability that an unemployed worker finds a job and $\overline{u}$ is the flow utility for an unemployed worker. Although the value of an employed worker depends on the aggregate states and the individual debt b, the value of being unemployed depends only on the aggregate states, because all firms choose the same level of debt in equilibrium. Thus, if an unemployed worker finds a job in the next period, the value of being employed is $W'(b')$.

The determination of the current wage solves the same problem as in Equation (14.38). We should take into account, however, that this solution also depends on b and on the function that determines future wages. Therefore, we write the solution of the bargaining problem as $w = \psi(g; b)$, where g is the function determining future wages. The equilibrium solution to the bargaining problem is the fixed point to the functional equation $g(b) = \psi(g; b)$.

Also in this case, the values for the firm and the worker satisfy

$$J(b) = (1-\eta)S(b), \tag{14.48}$$

$$W(b) - U = \eta S(b), \tag{14.49}$$

where the surplus is defined as $S(b) = J(b) + W(b) - U$. This can be written recursively as

$$S(b) = z - a - b + \frac{b'}{R} + (1-\lambda)\beta \mathbb{E}S'(b') - \eta\beta p \mathbb{E}S'(B'). \tag{14.50}$$

When a vacancy is filled, the newly created firm starts producing and pays wages in the next period. The only decision made in the current period is the debt b'. Therefore, the value of a vacancy just filled with a worker is

$$Q = \max_{b'} \left\{ \frac{b'}{1+r} + \beta(1-\eta)ES'(b') \right\} \tag{14.51}$$

$$\text{subject to} \quad b' \leq \varphi(1-\eta)\mathbb{E}S'(b').$$

Because the new firm becomes an incumbent starting in the next period, $S'(b')$ is the surplus of an incumbent firm defined in Equation (14.50). Notice that in the choice of b', a new firm faces a problem similar to that of incumbent firms (see problem 14.46). Even if the new firm has no initial debt and it does not pay wages, it will choose the same stock of debt b' as incumbent firms. We can then focus on a "representative" firm and in equilibrium $B = b$.

The value of posting a vacancy is equal to $V = qQ - \kappa$. Because in this version of the model there are no firm-specific productivity draws, $\kappa = \kappa_0 + \kappa_1$. As long as the value of a vacancy is positive, more vacancies will be posted. Free entry implies that $V = 0$ and in equilibrium we have

$$qQ = \kappa. \tag{14.52}$$

We now characterize the optimal choice of debt, that is, problem (14.46). Denoting by μ the Lagrange multiplier associated with the enforcement constraint, the first order condition is

$$\eta - R[1 + (1-\eta)\varphi]\mu = 0. \tag{14.53}$$

In deriving this expression, we have used the property of the model for which the choice of b' does not depend on the existing debt b and, therefore, $\frac{\partial S(b)}{\partial b} = -1$. We have also used the equilibrium condition $\beta R(1-\lambda) = \beta(1+r) = 1$.

Looking at the first order condition, we can see that the enforcement constraint is binding (that is, $\mu > 0$) if $\eta \in (0,1)$. Thus, provided that workers have some bargaining power, the firm always chooses the maximum debt and the borrowing limit binds. In this way, bargaining introduces a mechanism through which the financial structure is determined (Modigliani and Miller, 1958 does not apply). The reason is clear: by using outside finance, the firm is able to reduce the surplus that is bargained with the worker, increasing the possible rewards to equity.

To gather some intuition about the economic interpretation of the multiplier μ, it will be convenient to rearrange the first order condition as

$$\mu = \underbrace{\left(\frac{1}{1+(1-\eta)\varphi}\right)}_{\substack{\text{Total change}\\ \text{in debt}}} \times \underbrace{\left(\frac{1}{R} - \frac{1-\eta}{R}\right)}_{\substack{\text{Marginal gain}\\ \text{from borrowing}}} .$$

The multiplier results from the product of two terms. The first term is the change in next period liabilities b' allowed by a marginal relaxation of the enforcement constraint, that is, $b' = \varphi(1-\eta)\mathbb{E}S(b') + \bar{a}$, where $\bar{a} = 0$ is a constant. This is obtained by marginally changing $\bar{a}$. In fact, using the implicit function theorem, we obtain $\frac{\partial b'}{\partial \bar{a}} = \frac{1}{1+(1-\eta)\varphi}$, which is the first term.

The second term is the actualized net gain from increasing the next period liabilities b' by one unit (marginal change). If the firm increases b' by one unit, it receives $1/R$ units of consumption today in the form of additional dividends. In the next period, the firm has to repay one unit. However, the effective cost for the firm is lower than 1, because the higher debt allows the firm to reduce the next period wage by η, that is, the part of the surplus going to the worker. Thus, the effective repayment incurred by the firm is $1-\eta$. This cost is discounted by $R = (1+r)/(1-\lambda)$ because the debt is repaid only if the match is not separated, which happens with probability $1-\lambda$. Thus, the multiplier μ is equal to the total change in debt (first term) multiplied by the gain from a marginal increase in borrowing (second term).

Using the property for which the enforcement constraint is binding, that is, $\varphi EJ(b') = b'$, Appendix B shows that the wage can be written as

$$w = (1-\eta)\bar{u} + \eta(z - B) + \frac{\eta[p + (1-\lambda)\varphi]\kappa}{q(1+\varphi)}. \tag{14.54}$$

This equation makes clear that the initial debt B acts like a reduction in output in the determination of wages. Instead of getting a fraction η of output, the worker gets a fraction η of output "net" of debt. Thus, for a given bargaining power η, the larger the debt the lower the wage received by the worker. This motivates the firm to maximize the debt, as we have already seen from the first order condition.

Figure 14.3 plots the impulse responses to a credit shock, that is, a shock that raises φ and increases the credit available to firms. The credit expansion generates an increase in the capital income share and an increase in employment. Thus, changes in financial markets could alter the distribution of income and, with it, affect the incentives to create jobs. This is another example of how the distribution of income and macroeconomic performance are directly interconnected.

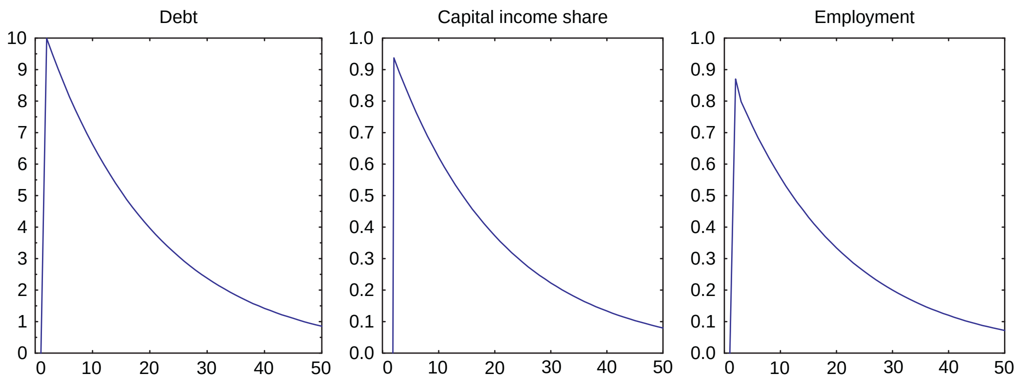

Figure 14.3 Impulse response to credit shock. The parameters are $\beta = 0.985$, $\alpha = 0.5$, $\mathbb{E}z = 1$, $\rho_z = 0.95$, $\sigma_z = 0.01$, $\bar{u} = 0.473$, $\kappa = 0.316$, $\lambda = 0.103$, and $A = 0.807$, $\overline{\varphi} = 0.0022$, $\rho_\varphi = 0.95$, $\sigma_\varphi = 100$.

14.3.1.2 Financial Accelerator and Inequality

A well-established tradition in macroeconomics introduces financial market frictions in business-cycle models. The key ingredients are based on two assumptions: market incompleteness and heterogeneity. Although not often emphasized, inequality plays a central role in these models. For example, in the seminal work of Bernanke and Gertler (1989) and (Kiyotaki and Moore (1997), entrepreneurial net worth is central to the amplification of aggregate shocks. When more resources are in the hands of constrained producers (i.e., these agents are richer), they can expand production and enhance macroeconomic activities. This can happen because they earn higher incomes or because their assets are worth more following asset price appreciations. Thus, these models posit a close connection between profit shares and the business cycle.

These models share some similarities with the matching models reviewed above: when a larger share of output goes to investors/entrepreneurs, the economy expands. At the same time, as the economy expands, a larger share of output or wealth (or both) is allocated to entrepreneurs. The mechanism of transmission, however, is different. In the matching model, the mechanism is the higher profitability of employment or investment. In the financial accelerator model, instead, it is the relaxation of the borrowing constraints. For a detailed review of the most common models used in the literature to explore the importance of financial frictions for macroeconomic fluctuations, see Quadrini (2011).[9]

[9] In addition to cyclical movements in the shares of income that go to labor and capital, there are cyclical movements in the shares of income earned by different groups of households. Castañeda et al. (1998) find that movements in unemployment rates by skill groups as well as movements in factor shares account for the bulk of the cyclical share of income earned by the various quintiles of households.

14.3.2 Low Frequency Movements in Inequality

We discuss here some theoretical ideas that have been proposed in the literature to explain some of the trends in the distribution of income that have occurred since the early 1980s. In Section 14.3.2.1 we look at the reduction in labor share, and in the following two sections we look at the increased inequality in wages and earnings. In Section 14.3.2.2 we examine the potential role of increased competition for human capital and in Section 14.3.2.3 the changes in the prices of skills due to skills-biased technical changes.

14.3.2.1 Labor Share's Reduction Since the Early 1980s

In a recent paper, Karabarbounis and Neiman (2014) document that labor share has significantly declined since the early 1980s for a majority of countries and industries. They pose a constant elasticity of substitution (CES) production function with nonunitary elasticity of substitution between labor and capital and argue that the well-documented decline in the relative price of investment goods (see Cummins and Violante, 2002; Gordon, 1990; Krusell et al., 2000) induced firms to substitute away from labor and toward capital. The consequence was the reduction in the price of labor. They conclude that roughly half of the observed decline in the labor share can be attributed to this mechanism.

To see how this mechanism works, consider the following aggregate production function:

$$Yt = F(K_t, N_t) = \left[\alpha_k (A_{K_t} K_t)^{\frac{\sigma-1}{\sigma}} + (1-\alpha_k)(A_{N_t} N_t)^{\frac{\sigma-1}{\sigma}}\right]^{\frac{\sigma}{\sigma-1}}, \tag{14.55}$$

where σ denotes the elasticity of substitution between capital and labor in production, α_k is a distribution parameter, and A_{K_t} and A_{N_t} denote, respectively, capital-augmenting and labor-augmenting technology processes. As σ approaches 1, this becomes a Cobb–Douglas production function. Under perfect competition, marginal productivities yield factor prices and one can easily obtain expressions for labor share that crucially depend on the elasticity of substitution σ.

Karabarbounis and Neiman (2014) estimate σ by using only trends in the relative price of investment and the labor share in a cross section of countries. They find a value of 1.25. With this value, the decline in the (observable) relative price of investment accounts for 60% of the observed reduction in labor share. The remaining reduction can be imputed to larger increases in capital-augmenting technology relative to labor-augmenting technology, and to changes in noncompetitive factors (the most important, perhaps, are the permanent changes in the bargaining power of workers relative to firms along the lines of the models discussed earlier). Additional explanations arise from changes in the sectoral composition of output toward industries with higher capital share (which does not really seem to be the case), in part associated with globalization or the increase in the share of output that is traded with other countries, especially developing countries.

14.3.2.2 Increased Wage Inequality: The Role of Competition for Skills

There has been a big increase in earnings dispersion that is well documented in the literature. A glimpse of it can be seen in Tables 14.3 and 14.4. We now explore a possible explanation based on increased competition for skills in the context of human capital accumulation. We have already seen in Section 14.2.2.1 that human capital accumulation could be an important mechanism through which income becomes heterogeneous and that the higher the incentive to invest in human capital, the greater the degree of income inequality. We now look at one of the mechanisms that could affect the incentive to invest in human capital: competition for skills.

To study the importance of competition, we explore yet another version of the matching model described above by adding investment in human capital. We ignore here the possibility of firms to raise debt and limit the analysis to the version of the model without aggregate shocks. However, we now assume that output depends on the human capital of the worker, denoted by h. The production technology has a structure similar to the model presented in Section 14.2.2.1. The key feature of the model we look at now is that human capital investment requires both an output loss or pecuniary cost within the firm denoted by γ and a utility cost for the worker that we assume quadratic, $\frac{\alpha\gamma^2 h}{2}$. Given γ, human capital evolves stochastically according to

$$h' = h(1 + \gamma\varepsilon'),$$

where ε is an i.i.d. random variable. The gross growth rate of human capital is denoted by $g(\gamma, \varepsilon') = 1 + \gamma\varepsilon'$.

Because the outcome of the investment is stochastic, the model generates a complex distribution of human capital among workers. In the long run, the distribution will be degenerate because at the individual level, h follows a random walk. We assume that workers die with probability λ and that a match breaks down only when a worker dies. Thus, λ represents at the same time the death probability of a worker and the probability of separation of a match. In this way, the distribution becomes stationary and converges to a steady state.

There are contractual frictions that derive from the ability of the worker to control the investment γ after bargaining over the wage. The worker unilaterally chooses an investment γ that may be, and indeed is, different from the investment that maximizes the surplus of the match. This would be the investment that the worker would choose if he had been able to commit. Of course, when the firm bargains the wage, it anticipates the investment that the worker will choose in absence of commitment.

Let's define a few items. We can write the values of the investor and the worker in normalized form, that is, rescaled by human capital h. Then, the value for the investor can be written as

$$j = h - y - w + \beta(1-\lambda)\mathbb{E}g(y, \varepsilon')j', \tag{14.56}$$

where $j = J/h$ and w is the wage per unit of human capital. The total wage received by the worker is wh. The value for the worker is

$$\omega = w - \frac{\alpha y^2}{2} + \beta(1-\lambda)\mathbb{E}g(y, \varepsilon')\omega', \tag{14.57}$$

where $\omega = W/h$.

The value of being unemployed is

$$u = \overline{u} + \beta(1-\lambda)[p\omega' + (1-p)u'], \tag{14.58}$$

where $u = U/h$.

Even though in equilibrium, employed workers do not lose their occupation, u is important because it affects the threat value in bargaining. In a steady state we have $v = v'$, $\omega = \omega'$, $u = u'$.

The optimal investment y chosen by the worker maximizes the worker's value, that is,

$$\max_y \left\{ w - \frac{\alpha y^2}{2} + \beta(1-\lambda)\mathbb{E}g(y, \varepsilon')\omega' \right\},$$

with the first order condition given by

$$y = \beta(1-\lambda)\omega'\mathbb{E}\varepsilon'. \tag{14.59}$$

The important part to remember is that bargaining happens before the worker chooses her investment, which means that the surpluses that enter the problem take the investment y as determined by condition (14.59). From this condition we can see that y depends on ω' but not on the current value of ω, which implies that y is not affected by the outcome of the wage bargaining in the current period. Effectively, the current bargaining problem takes y as given and solves

$$\max_w \left\{ j^{1-\eta}(\omega - u)^{\eta} \right\}. \tag{14.60}$$

The first order condition implies that the parties split the net surplus, $s = j + \omega - u$, according to the bargaining weight η, that is,

$$j = (1-\eta)s,$$
$$\omega = \eta s + u.$$

As a comparison, we can also characterize the optimal investment when the worker commits to a particular y chosen to maximize the surplus of the match. In this case, the bargaining problem maximizes the objective (Equation 14.60) over both w and y. The first order condition with respect to w does not change, whereas the first order condition with respect to y becomes

$$1+\alpha\gamma=\beta(1-\lambda)(j'+\omega')\mathbb{E}\varepsilon'. \tag{14.61}$$

Compared with the optimality condition when the investment is controlled by the worker, Equation (14.59), we observe that the left-hand side and right-hand side terms in Equation (14.61) are both bigger. Therefore, the optimal choice of γ with commitment could be smaller or bigger. However, provided that α is sufficiently small, that is, the cost for the worker is not too large, the investment without commitment will be bigger.

14.3.2.2.1 General Equilibrium and the Impact of Competition

So far we have not worried about what happens outside the match, but there is a free entry condition that determines how many vacancies are posted. This is given by

$$q\beta j=\kappa, \tag{14.62}$$

where κ is the normalized cost of a vacancy.[10] One way of thinking about increased competition is that the entry cost κ is lower. We then have the following proposition.

Proposition 3.1 *The degree of competition κ affects the steady-state value of γ only in the environment without worker commitment.*

This result has a simple intuition: A lower κ is associated with a higher probability that an unemployed worker finds an occupation. As a result, the value of being unemployed increases. Inasmuch as this represents the threat value in bargaining, the worker can extract a higher wage w, which in turn increases the incentive to invest.

We can now show how an increase in competition (lower κ) affects inequality and aggregate outcomes simultaneously. In particular, we have that lower κ generates: (i) more risk taking and greater income inequality and (ii) higher aggregate income. The first effect can be seen from the first order condition (14.59). A lower entry cost increases the number of vacancies and, therefore, the value of finding another occupation if the worker quits. This allows the worker to bargain a higher wage, which in turn increases the employment value ω. We can then see from Equation (14.59) that a higher value of ω is associated with a higher γ. As we have seen in Section 14.2.2.1, a higher γ implies greater inequality. The second property—the increase in aggregate income—is obvious because a higher γ implies higher aggregate human capital. Thus, there is a trade-off between inequality and aggregate income.

Cooley et al. (2012) use a model with similar features but where the accumulation of human capital takes place in the financial sector. They show that greater competition for skills in the financial industry increased the incentive to invest in human capital and generated greater income inequality within and between sectors. This seems consistent with the recent increase in inequality, with income more concentrated at the very top of the

[10] For simplicity we are assuming that the cost of vacancies is proportional to the amount of human capital.

distribution and in certain professions, namely, managerial occupations in the financial sector. This pattern is also observed in the United Kingdom, as documented by Bell and Van Reenen (2010).

The idea that competition may increase inequality may go against the common wisdom that wealth is very concentrated because those who control wealth are able to protect it by limiting competition. From this the call is for increased enforcement of competition to reduce inequality. Of course, this does not mean that the theory described above is not valid. It depends on the particular environment we are studying: in certain sectors competition may lead to more inequality, in other sectors to lower inequality.

The degree of competition is just one way of affecting the equilibrium properties of aggregate income and inequality. Taxes are also important. In the context of this model, higher taxes discourage human capital investment (because the after-tax return from investing is lower), but this could be mitigated by the tax deductibility of the investment. Because the costs (curtailment of future earnings) and benefits (tax deductibility) occur at different stages of life when the individual has different incomes, the degree of progressivity becomes more important than the overall taxation. However, to the extent that taxes reduce investment, they also lower inequality (because lower investment reduces the volatility of individual incomes).

14.3.2.3 Skill-Biased Technical Change

In addition to increased competition for skills, which ends up rewarding those who are more skilled, a natural explanation for the increased earnings inequality is skill-biased technical change (Katz and Murphy, 1992). Although this term refers in general to changes in the distribution of earnings as a whole, it is often applied more specifically to the premium that college-educated people command compared with those without a college degree. This is motivated by the fact that the college wage premium, defined as the mean log wages of college graduates relative to high school graduates, has increased from 0.3 to 0.6 (see Goldin and Katz, 2009).

To illustrate how skill-biased technical change may have contributed to the increased earnings inequality, consider the following production function:

$$Y_t = F(A_{s,t}S_t, A_{u,t}U_t), \tag{14.63}$$

where S stands for the number of skilled workers (with a college education) and U stands for the number of uneducated workers (without a college education). $A_{s,t}$ and $A_{u,t}$ are exogenous technical coefficients that could change over time. Under perfect competition in the labor market, wages are marginal productivities, that is

$$w_{s,t} = A_{s,t}\frac{\partial F(A_{s,t}S_t, A_{u,t}U_t)}{\partial S_t}, \tag{14.64}$$

$$w_{u,t} = A_{u,t} \frac{\partial F(A_{s,t}S_t, A_{u,t}U_t)}{\partial U_t}. \tag{14.65}$$

The skill wage premium is defined as

$$\frac{w_{s,t}}{w_{u,t}} = \frac{A_{s,t}\dfrac{\partial F_t}{\partial S}}{A_{u,t}\dfrac{\partial F_t}{\partial U}}. \tag{14.66}$$

Absent large changes in the relative quantities of skilled and unskilled workers, we can assume that $\frac{\partial F_{t+1}}{\partial S} / \frac{\partial F_{t+1}}{\partial U}$ is very close to $\frac{\partial F_t}{\partial S} / \frac{\partial F_t}{\partial U}$, and the same goes for the marginal productivity of the unskilled. Consequently, we have that the change in the skill wage premium is given by

$$\frac{\dfrac{w_{s,t+1}}{w_{u,t+1}}}{\dfrac{w_{s,t}}{w_{u,t}}} \sim \frac{\dfrac{A_{s,t+1}}{A_{u,t+1}}}{\dfrac{A_{s,t}}{A_{u,t}}} = \frac{\dfrac{A_{s,t+1}}{A_{s,t}}}{\dfrac{A_{u,t+1}}{A_{u,t}}}. \tag{14.67}$$

This implies that the increase in the wage premium is owing to faster growth in the technology coefficient A_{s_t} relative to the growth of A_{u_t}, hence, the commonly used term "skill-biased technical change." But is there something more tangible than just an exogenous and largely unobserved technological change, or can we track it down to something observable?

Krusell et al. (2000) argued that we can relate these changes to something observable. Gordon (1990) and later Cummins and Violante (2002) have documented that the price of equipment (which is the main part of capital) in terms of consumption goods has gone down dramatically during the period of the rising skill premium. At the same time, the quantity of equipment has gone up significantly relative to output. This is a measurable form of technical change. Combine this with the notion that equipment or capital and skilled labor are complements, whereas unskilled labor is a substitute, and we have an actual channel through which technical progress is skill biased. The formulation in Krusell et al. (2000) does not have factor-specific technical change because all the effects of skill-biased technical change are in the increased quantity of equipment and can be written as

$$Y_t = K_t^{\alpha}\left[\mu U_t^{\sigma} + (1-\mu)\left(\lambda E_t^{\rho} + (1-\lambda)S_t^{\rho}\right)^{\frac{\sigma}{\rho}}\right]^{\frac{1-\alpha}{\sigma}}, \tag{14.68}$$

where K_t stands for structures (buildings) that play no role as they enter the production function in a Cobb–Douglas form, U_t and S_t are again unskilled and skilled labor, and E_t is equipment. Using observed measures of inputs, they estimated the elasticities of substitution ρ and σ and the share parameters α, λ, and μ, and found that unskilled labor is indeed a substitute for the aggregate of equipment and skilled labor, with both items being complementary to each other. They also found that this specification accounts very well for the observed wage premium under perfect competition for factor inputs.

Other forms of technical innovation indirectly generate skill-biased technical change. Suppose that technical change, regardless of its final effects on total productivity, is sometimes more dramatic than other change. The introduction of information technology could be one of these instances even if its impact on productivity is not as clear (Solow, 1987). Yet, the adaptation to this new technology may be easier for educated people. This is the approach taken by Greenwood and Yorukoglu (1974), Caselli (1999), and Galor and Moav (2000). Alternatively, suppose that information technology reduces information and monitoring costs within firms, allowing for reorganizations with fewer vertical layers and with workers performing a wider range of tasks. This gives educated workers an advantage. See, for example, Milgrom and Roberts (1990) and Garicano and Rossi-Hansberg (2004). Yet another form of skilled-biased technical change is an increase in competition for skills, as in the previous section, which could be the result of the technical change. In the context of the model studied earlier, the technical change can take the form of a lower vacancy cost κ. The lower κ increases the demand of skilled workers, which in turn increases the incentive to accumulate skills.

The technological innovations introduced in the 1970s seem to have affected the economy in other respects. Greenwood and Jovanovic (1999) and Hobijn and Jovanovic (2001) assume that new information technologies required a level of restructuring that incumbent firms could not face. As a result, their stock market value dropped. This is another form of redistribution in the sense that the owners of incumbent firms lost market value to the owners of new firms. Acemoglu (1998) has proposed a theory of the technical change itself being the result of a surge in college graduates.

The rise of superstars is another possible mechanism that increases the concentration of income. Rosen (1981) viewed the increase in earnings dispersion among people in some occupations as the result of an increase in their ability to reach more users of rare skills. Although this applies naturally to the case of artists and athletes, it also applies more generally to other types of skills. For example, Gabaix and Landier (2008) propose a theory of CEO pay where the value of managerial superstars is enhanced by the increase in the size of firms.

14.3.2.3.1 Skill-Biased Technical Change and Human Capital Accumulation

How does human capital investment interact with skill-biased technical change? Heckman et al. (1998) provide an answer that relies on the difference between observed wages and the price of skills that is due to the unpaid on the job investment of the Ben-Porath (1967) type models. They find no special role to capital in generating the increase in the skill wage premium. Instead, they find that the endogenous response of both more college attendance and the allocation of time to invest in further skills is sufficient to account for the patterns in the data. Guvenen and Kuruşçu (2010) also explore the interaction of skill-biased technical change and human capital accumulation emphasizing differences across people in the ability to acquire human capital. Guvenen and Kuruşçu (2010) argue that increased biased technical change immediately induces an increase in investment by talented individuals that first depresses the skill wage premium and then raises it and that is consistent with the observed bad performance of median wages and with the lack of increase in consumption inequality.

14.4. INEQUALITY AND FINANCIAL MARKETS

A large body of work links, theoretically, inequality and financial markets. The lack of complete markets helps to shape inequality through two channels. In Section 14.4.1 we study how the limited access to borrowing prevents poor households from undertaking valuable investments. This limited access keeps them and their descendants from climbing the social ladder. In Section 14.4.2 we study environments in which access to borrowing affects inequality, even when there are no household-specific investments.

In the environments studied in the first two sections, the borrowing limits are set exogenously. In Section 14.4.3 we start exploring endogenous theories of the borrowing limit by looking at environments in which the ability to borrow is limited by the incentive to default. In doing so, we follow the ideas suggested in Kehoe and Levine (1993). In Section 14.4.4 we review recent papers in which the limits to borrow come from the legal ability to default on debts allowed by the U.S. bankruptcy code. In Section 14.4.5 we explore various extensions of these models. Finally, in Section 14.4.6 we briefly discuss the literature that links the long-term performance of an aggregate economy with the ability of households to borrow.

14.4.1 Financial Markets and Investment Possibilities

Agents with available funds are not necessarily those with the best opportunities to use the funds. It is then socially desirable that the funds are channeled from the former to the latter, which is the primary role played by financial markets. Financial market imperfections, however, limit the volume of funds that can be transferred, and as a result the allocation is inefficient.

Financial market imperfections can take different forms. In a simple overlapping generations model in which the only decision that agents make is how much to invest in the education of their children, the lack of borrowing possibilities implies that investments with a rate of return higher than the risk-free rate will not be undertaken. A similar mechanism operates when there are borrowing possibilities but investments are risky and there are no insurance possibilities. This implies that investing agents may be left with very little consumption if they are unlucky. As a result, risk-averse agents may choose not to undertake investments.

To illustrate the importance of financial market frictions, consider an environment in which agents can save but cannot borrow, similar to that of Aiyagari (1994) developed in Section 14.2.1.3.2. The difference now is that the amount of efficiency units of labor is not random but is the result of investment. Consequently, two different investment strategies are available: households can save in the financial asset a (which in this model is backed by real capital), or they can invest in their own human capital so that $s' = \varphi(s, y)$, where y is the amount invested. The household's problem can be written as

$$v(s, a) = \max_{c, y, a'} u(c) + \beta v(s', a'; K), \tag{14.69}$$

$$\text{subject to} \tag{14.70}$$

$$c + a' + y = ws + a(1 + r), \tag{14.71}$$

$$s' = \varphi(s, y), \tag{14.72}$$

$$a' \geq 0. \tag{14.73}$$

If constraint (14.73) is not binding, the first order conditions of this problem imply

$$w\varphi_y(s, y) = 1 + r, \tag{14.74}$$

that is, the rate of return of the two types of investment is equalized. Moreover, imagine for simplicity that $\varphi(s, y) = \varphi(y)$; then in a steady state, all agents will have the same labor income. An interesting feature of this model is that convergence will arise immediately. That is, all households will have within a period the same labor income, because all agents will make the same investment in human capital. Differences in initial wealth perpetuate. For more general human capital production functions, we can get similar results, with the speed of convergence depending on the decreasing returns in s but not on y.

How would the analysis change when constraint (14.73) is binding? It all depends on the shape of function $\varphi(s, y)$. Let's start with the case $\varphi(s, y) = \varphi(y)$. Assuming that the function $\varphi(y)$ is strictly concave and $\varphi_y(y)$ approaches infinity as y approaches zero, all households will make some investment and the first order condition is

$$u_c(c) = \beta\varphi_y(y)u_c(c')w'. \tag{14.75}$$

This equation looks very similar to the Euler equation in the standard representative agent growth model, in which there is curvature in the production function. Consequently, no matter how poor they start out, all agents will slowly but steadily converge to a level of human capital that satisfies $\varphi_y(y)w = \beta^{-1}$. So the economy converges to equal labor income, even if the wealth distribution can be very unequal. Policies that subsidize investment in human capital could speed up the equalization process but will not change the eventual convergence outcome.

A lot of concern remains about *poverty traps*, that is, situations in which households that start with insufficient initial resources never abandon their poverty status. For this situation to happen, some special assumptions are needed. In particular, $\varphi(y)$ cannot be strictly concave. The typical assumption is to have a state of discontinuity such as a minimum expenditure that is needed to increase human capital. One example is the investment required for educational advancement. In this case, households compare the two options: whether to invest in education or not. If initial household wealth is very low, they may be unable to invest and still have positive consumption. But even households with slightly higher initial wealth may find that educational investment is feasible but not worth it, because it requires that initial consumption is way too low and the cost in utility terms too high. Clearly, in cases like these, government intervention can be fruitful because it is able to circumvent households' inability to borrow. The government can tax richer households today and transfer resources to the poorer households, or it can borrow, transfer resources to the poor households, and tax them later after they have acquired more education. A policy that makes education compulsory even at the cost of severe current disutility will not be optimal because poor households could have chosen to do it themselves if this choice were preferable.

Another possibility in which the structure of financial markets matters is to have a stochastic return to the investment technology. Consider a version of Equation (14.72) where higher investments in y yield a high expected value of s' but also a high variance. If the household had access to insurance markets, then it would happily undertake the investment, but if not, its risk aversion would prevent it from doing so. Again, in this case, certain government interventions that provide some form of insurance could be desirable.

14.4.2 Changes in the Borrowing Constraint

One way of assessing the role of financial constraints is to see what happens when they are relaxed. The Aiyagari (1994) model described in Section 14.2.1.3.1 assumes that financial markets are extremely underdeveloped: only one asset needs to be backed by physical capital, and there are no borrowing possibilities. What would happen if the financial constraints were to be relaxed, that is, what if we allowed for some noncontingent borrowing?

Table 14.7 shows the steady-state wealth distribution under various borrowing limits that go from a quarter of per-household yearly GDP to 1-year GDP. Figure 14.4 shows their associated Lorenz curves. We can see from the figure that, regardless of the calibration of the earnings process, inequality increases substantially with the relaxation of the borrowing constraint, in some cases to implausible levels (we cannot imagine an actual economy in which more than 60% of the population have negative financial assets). The Gini indices go up substantially, with one economy displaying a value above one, which is possible when we allow for negative values for the variable of interest. Looser borrowing constraints are associated with greater inequality because the poorest households want

Table 14.7 Distribution of wealth for various borrowing limits (in terms of per household yearly output)

Borrowing Constraint	Quintiles 1st	2nd	3rd	4th	5th	Top 10%	Top 5%	Top 1%	Gini

−0.50	−3.50	−3.50	−0.88	2.89	104.99	85.16	57.03	16.19	0.99
−1.0	−7.21	−7.10	−1.87	2.88	113.30	90.75	60.68	16.94	1.11

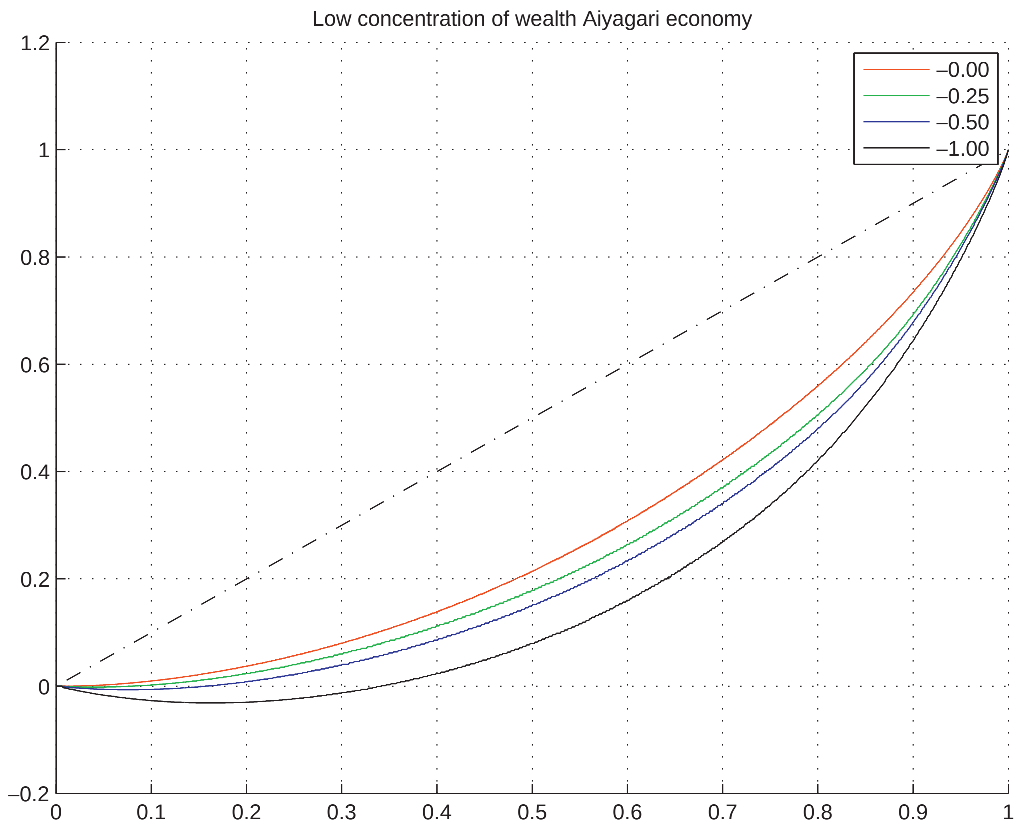
to borrow more. This result arises from the impatient nature of households in the general equilibrium. More specifically, households have a precautionary motive to save for the future when markets are incomplete, and on average they will never stop saving and will perpetually accumulate assets. But in a general equilibrium, the excess savings, which in aggregate takes the form of higher accumulation of capital, will drive down the marginal product of capital and, therefore, the return from savings. Consequently, in the steady-state equilibrium we have that $\beta^{-1} > 1 + r$, that is, households are more impatient than the return of their savings.[11] This result creates an incentive to anticipate consumption when the realization of earnings is low, which is made possible by the greater availability of credit (looser borrowing limit). This mechanism generates a greater concentration of wealth, as shown in Figure 14.4 and Table 14.7.

Another possibility is that improvements in the financial market allow agents not only to borrow more but also to buy insurance. In this case, agents could acquire assets or take liabilities with payments contingent on the realizations of idiosyncratic shocks. One

[11] To better understand why β^{-1} must be bigger than $1 + r$ in a steady-state general equilibrium, consider the following. Suppose that in a steady state $\beta^{-1} = 1 + r$. Given r, we can determine the stock of capital K from the equilibrium condition that equalizes the interest rate to the marginal product of capital. Lower interest rates must be associated with higher stocks of capital since the marginal product of capital is decreasing in K. Because agents face uninsurable risks, they save for precautionary reasons and, when $\beta^{-1} = 1 + r$, the average wealth accumulated by agents grows without bound (although individual wealth goes up and down stochastically, the average growth is positive). But in equilibrium the accumulated wealth is equal to K. Therefore, if wealth increases, K also increases, reducing the marginal product of capital and, with it, the interest rate r. As the interest rate declines, households save less until the average growth rate of wealth for the aggregate economy is zero. We therefore conclude that in a steady-state equilibrium, $1 + r$ must be lower than β^{-1}.

consequence is that households will no longer save for precautionary motives, because they can completely insure their individual consumption. Furthermore, there would not be too much aggregate savings, as in the economy without insurance. So the economy would slowly reduce savings until the interest rate became equal to the rate of time preference. Individual consumption could differ across households, as consumption depends on the initial distribution of physical and human wealth, as in Chatterjee (1994) (see Section 14.2.1.1).

Another important question is, how much borrowing can be sustained? In a model without leisure choice, the maximum sustainable debt is the one that can be paid in all states of nature. The worst state of the world is the lowest possible value of s, which we refer to as $\underline{s}$. A household that receives the lowest realization of earnings forever has the capability to pay a maximum amount of interest $\underline{s}w$. Thus, the maximum sustainable debt



(a)

(Continued)

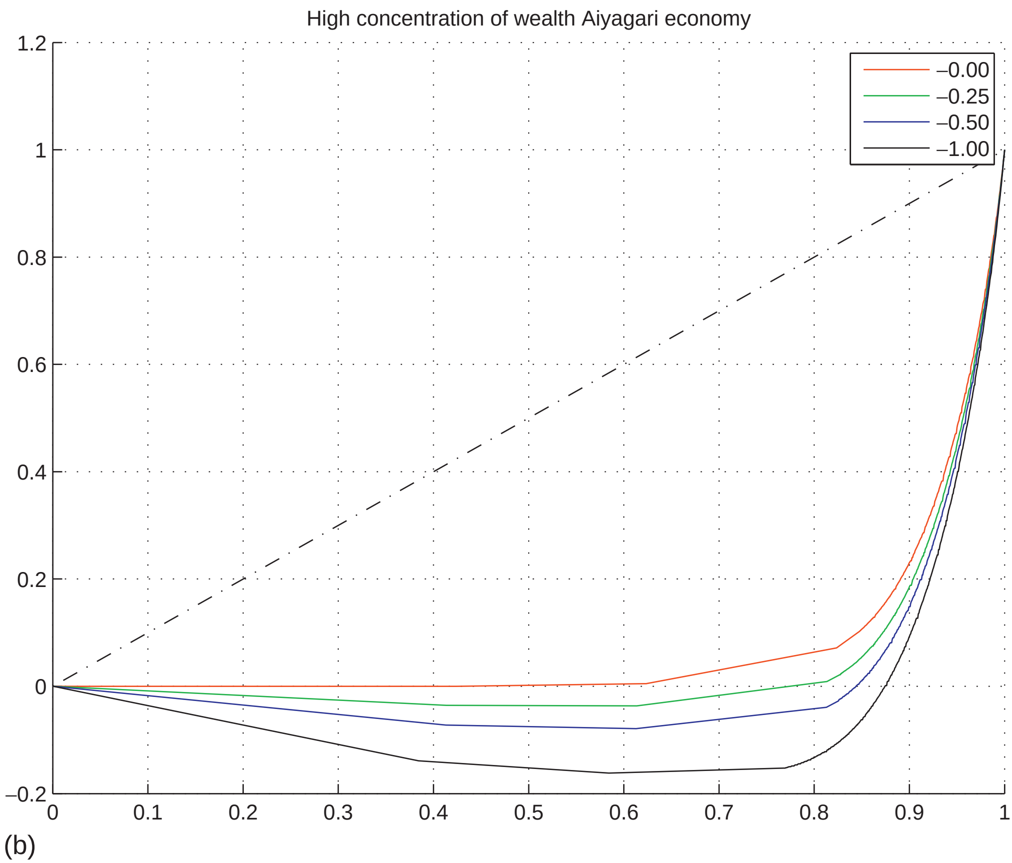

Figure 14.4—Cont'd (b) High concentration of wealth economy (SCF) calibrated as in Castañeda et al. (2003).

is $\frac{sw}{r}$, because the interest on this debt is exactly $\underline{s}$. Sometimes this is called the solvency constraint. Any debt larger than this value has a positive probability of not being paid.

14.4.3 Limits in the Ability to Borrow

So far, we have considered environments in which the access to credit markets is arbitrarily limited and there are no markets for contingencies. But why not? What limits the set of contracts that people can sign?

In a well-known and influential paper, Kehoe and Levine (1993) postulated that the ability of households to borrow is limited by their willingness to pay back when the alternative is to give up access to credit markets. In addition, a subset of the assets (physical or human or both) or endowments of the households can be seized, but not necessarily all of them. For example, future labor income may be outside of the reach of creditors.

Their approach does not preclude the existence of contingent markets. We would like to emphasize two features of this approach. The first feature is that it is the institutional environment that determines the set of contracts that are available. We think that this is an enormous advance compared with the literature that relies on exogenous borrowing limits. The second feature is that only the contracts that can be enforced ex post are available in the market. Therefore, once signed, there is complete compliance in the execution of these contracts. This feature is perhaps less appealing, as we see actual ex post reneging on formal contracts.

To show how this works, we could again slightly modify the Aiyagari economy. Let's first define the following object:

$$\overline{V}(s, a) = \max_{a' \geq 0} u(a(1+r) + sw - a') + \beta \sum_{s'} \Gamma_{s,s'} \overline{V}(s', a'), \tag{14.76}$$

which is the household's value without having access to borrowing. Moreover, with some abuse of notation, let's define $\overline{V}(s) = \overline{V}(s, 0)$ as the value attainable when the initial assets are zero. Clearly, this limit depends on the value of the shock s. Now consider the following problem:

$$v(s, a) = \max_{c, y, a'} u(c) + \beta_i v(s', a'; K), \tag{14.77}$$

$$\text{s.t.} \quad c + a' + y = ws + a(1+r), \tag{14.78}$$

$$a' \geq \underline{a}(s), \tag{14.79}$$

where $\underline{a}(s)$ is such that

$$v\left(s, \underline{a}(s)\right) = \overline{V}(s). \tag{14.80}$$

In words, households can borrow up to the level in which they would be better off in an autarkic state, that is, in a state in which they start from zero assets and never borrow again. Notice that it is quite possible that in this situation high-income people have more difficulties borrowing than low-income people, and this is because $\overline{V}(s^H) > \overline{V}\left(s^\ell\right)$ when $s^H > s^\ell$. Notice also that $\underline{a}(s)$ is an endogenous variable. We do not know its value before solving for the equilibrium of this economy.

We have written problem (14.77) under the implicit assumption that assets can never be confiscated. If the legal system were such that assets could be taken away in absence of compliance, we could substitute Equation (14.79) with

$$a' \geq \underline{\underline{a}}(s), \tag{14.81}$$

where $\underline{\underline{a}}(s)$ is such that $v\left(s, \underline{\underline{a}}(s)\right) = \overline{\overline{V}}(s)$ and $\overline{\overline{V}}(s) = u(sw) + \beta \sum_{s'} \Gamma_{s,s'} \overline{\overline{V}}(s')$. Essentially, the borrowing limit could be the amount that makes the agent indifferent between paying back the lender or defaulting and being forever unable to save or borrow.

In this model, all contracts are carried out, that is, loans and state-contingent contracts are always honored. In reality, however, many people file for bankruptcy. For example, in the 12 months between April 1, 2012, and March 31, 2013, 779,306 people filed for bankruptcy in the United States.[12] In some countries including the United States and Canada, debts are typically discharged after filing, whereas in other countries, such as Hungary, Romania, and Spain, there is no legal procedure to handle personal bankruptcy, and people are always liable for previous debts. The rest of the countries lie somewhere in between these extremes.

One possible strategy to deal with the pervasiveness of bankruptcy is to model it as a contingency fully negotiated ex ante by the parties. This strategy is hard to justify, however, because filing for bankruptcy is a legal procedure that can be completed unilaterally by the debtor. Hence, it is a right that cannot be forfeited. We need, then, to have explicit models that explicitly incorporate bankruptcy filings. One approach, followed within the optimal contracting tradition, is to assume that there are information asymmetries and costly state verification, as in Townsend (1979). The costly state verification model has been widely applied in macroeconomics, for example, in Bernanke and Gertler (1989), Bernanke et al. (1999), and Carlstrom and Fuerst (1995). In these models, default arises in equilibrium even if agents sign fully optimal contracts. In the next section, we will describe other approaches that are more in line with the literature that excludes the applicability of fully optimal contracts.

14.4.4 Endogenous Financial Markets Under Actual Bankruptcy Laws

During the last few years, considerable work has been done to bring together models with imperfect insurance and models with a legal system that allows agents to file for bankruptcy in a way that is similar to that of Chapter 7 in the U.S. bankruptcy code (Chatterjee et al., 2007; Livshits et al., 2007). We now present a version of these models and describe how their implications for the income and wealth distribution change compared with the basic Aiyagari model. These studies take advantage of a feature of the legal system that lists people who have filed for bankruptcy in public records for a certain number of years. The literature interprets the implications of the listing as limiting accessibility to borrowing for the duration of the public record.

Consider the following household problem, yet another variant of the basic Aiyagari problem:

$$v(s,a,1) = \max_{c,a'\geq 0} u(ws + a(1+r) - a') + \beta \sum_{s'} \Gamma_{s,s'} [(1-\delta)v(s',a',1) + \delta v(s',a',0)], \tag{14.82}$$

[12] See U.S. courts, http://www.uscourts.gov/.

$$v(s,a,0) = \max\left\{ u(sw) + \beta\sum_{s'}\Gamma_{s,s'}v(s',0,1), \quad \max_{c,a'} u(c) + \beta\sum_{s'}\Gamma_{s,s'}v(s',a',0), \right\} \tag{14.83}$$

$$\text{s.t.} \quad c + q(s,a')a' = ws + a. \tag{14.84}$$

The function $v(s, a, h)$ is the household's value function, with the last argument $h \in \{0,1\}$ denoting the household's credit history. When $h = 1$, the household's credit history is bad in the sense that the agent has defaulted in the near past and is prevented from having access to credit. Problem (14.82) depicts this case, showing that in the following period, its credit history may turn out to be good, $h = 0$, with parameter δ controlling the expected duration of market exclusion.

Problem (14.83) is of interest when the credit history is good, $h = 0$, and we have written it compactly, implicitly assuming that the household is in debt, $a < 0$. Here, the agent has two options: to file for bankruptcy or not. If the agent files, three things happen: household consumption equals current labor income, sw, credit history turns bad next period, $h' = 1$, and the household is prevented from saving. The latter property is a feature of the bankruptcy code, as the agent is not permitted to keep assets after filing for bankruptcy.[13] If the household does not file for bankruptcy, it can borrow or save as it wishes. Note, however, that we have written the budget constraint (14.84) differently from previous problems. The left-hand side, the uses of funds, has the asset position at the beginning of the following period multiplied by $q(s, a')$. This is the household-specific inverse of the interest rate. Lenders accurately forecast that the agent may file for bankruptcy and charge an extra premium so that in expected value they get the market return. The function $q(s, a')$ is an equilibrium object. If the household chooses to save, $a' \geq 0$, and the inverse of the interest rate is that of the safe asset: $q(s, a') = (1 + r)^{-1}$.

The optimal solution to the problem of a household with negative assets is to default for a range of its earnings. The set of earnings for which the household defaults increases with the stock of debt.

The solution to this problem has two interesting properties. First, inasmuch as default is costly (the household will not be able to borrow for a while), the household would not default if the debt is very small. Second, in some circumstances, the household may be too poor to default, opting instead to borrow even more for a sufficiently low realization of earnings. Consequently, the equilibrium of this model requires that the inverse of the interest rate $q(s, a')$ is such that lenders break even in expected value, which in turn implies that interest rates are increasing in the amount borrowed and in the likelihood of bad earnings realizations.

[13] In the United States, the agent can keep a maximum amount of assets, and this amount varies across states. Here, we have assumed zero retainable. In the discussion from which we are abstracting are other subtleties of the bankruptcy code, such as the requirement that labor income is below the state median's income.

This structure has proved useful in making sense simultaneously of the extent of unsecured borrowing in the United States as well as the frequency of bankruptcy filings, especially if the model is enhanced with a few bells and whistles such as expenditure shocks.

14.4.4.1 A Weakness of This Approach

Why are households refused credit when they have a bad credit history? Nothing in the law requires this. In fact, the opposite is true: in the United States, a bankruptcy filing under Chapter 7, the relevant case, precludes additional filings over a period of years, making a recent filer appear to be a better creditor than somebody with a clean slate.

This question has three possible answers, but none are completely satisfactory. First, a Nash equilibrium with a coordination problem can be constructed when lenders believe that agents with bad credit histories will not pay back and hence they will not lend, whereas prospective borrowers might as well choose to default, because they do not receive credit. Although this is indeed a Nash equilibrium, it is one that is always present in the event of lending, and there is no argument for why it happens only with a bad credit history. Another possibility is to construct a trigger strategy whereby lenders coordinate not to lend during a punishment period in the event of default. But like all triggers, this is not an equilibrium of the limit of finite economies. Hence, it is not a Markov equilibrium. Many economists are comfortable with trigger strategy equilibria, whereas others are not. The last rationale for exclusion of those with bad credit is to postulate the existence of a regulator that prevents lenders from lending to those with bad credit, something that is not actually done by any of the banking regulators.

14.4.5 Credit Scoring

Chatterjee et al. (2008) and Chatterjee et al. (2004) propose a solution to the weakness of models based on exogenous exclusion after bankruptcy filings. These papers note that in the United States, there is pervasive use of credit scores, which are assessments of reliability made by independent companies. The authors then pose a model in which two types of people differ in some fundamental attribute associated with reliability that is not directly observable by outsiders—for instance, patience or even good driving habits. The credit score is then used as the market assessment of being a good type, meaning the type that is more likely to pay back debts or be reliable. In this context, both types of agents fall under the model of borrowing in which there are multiple types. The key here is that both types of agents—both the patient and the impatient agents—want to repay their debts to signal that they are patient, which allows them to have access to better borrowing terms. In this context, filing for bankruptcy increases the market-assessed likelihood that an agent is of the bad type, which translates to a severe worsening of loan terms, if not an outright exclusion of future credit. Moreover, because the market is assessing traits that are relevant not only for the repayment of credit but also for other things (e.g., cheap property insurance, access to rental property, personal relationships), timely repayment of debts carries a strong incentive that allows for the possibility of many contracts to be carried out, even if the law lacks the necessary teeth to enforce these contracts.

14.4.6 Financial Development and Long-Run Dynamics

We now look at the extent to which access to financial markets can help us to understand the long-run dynamics of the economy. In Section 14.4.6.1 we briefly focus on long-term growth, and in Section 14.4.6.2 we discuss how the evolution of financial markets can also help us understand the issue of global imbalances, that is, the emergence of large and persistent balance of payments deficits.

14.4.6.1 Long-Run Growth and Financial Development

The Schumpeterian view places entrepreneurship at the center stage of economic development. Owing to financial constraints and the lack of insurance markets, however, entrepreneurial investment is suboptimal. Essentially, when financial markets are not well developed, resources cannot be redistributed from those who control the resources but do not have the best uses of these resources to those who have the best investment opportunities but lack the funds. This efficiency problem is especially severe when the distribution of resources is particularly concentrated. We may then end up with a situation in which the poor become (relatively) poorer because they cannot take advantage of investment opportunities and the economy as a whole grows less. Examples of studies that emphasize the importance of inequality for growth in the presence of financial constraints are Galor and Zeira (1993), Banerjee and Newman (1993), and Aghion and Bolton (1997). Because these studies were already reviewed by Bertola (2000) in a previous edition of the Handbook, we do not repeat their description in this chapter.

A more recent literature, however, also emphasizes that market incompleteness—that is, environments in which the trade of state-contingent claims is limited—could have both positive and negative effects on capital accumulation. In a world with only uninsurable and exogenous earning shocks as in Aiyagari (1994), market incompleteness generates more capital accumulation and, therefore, more growth. When risky income is endogenous, however, as in Angeletos (2007), market incompleteness may discourage investment. See also Meh and Quadrini (2006).

Another group of studies that investigates the relation between inequality and macroeconomic performance emphasizes the importance of social conflict and expropriation. Greater inequality often associated with underdeveloped financial markets means that a larger group of individuals are at the bottom of the distribution and face poor economic conditions compared with the rest of the population. Faced with poor economic conditions and the feeling that the prospects for economic improvement are impaired by the excessive concentration of wealth, the resentment toward the rich starts to rise, which creates incentives to expropriate either by stealing or through revolutions. The risk of expropriation has two negative effects. First, it acts as an investment tax that discourages investment. Second, agents devote more resources to protect property rights instead of using the resources for productive and growth-enhancing activities. Benhabib and Rustichini (1996) develop a model that formalizes this idea. Although not explicitly considered in this paper, financial underdevelopment could contribute to this because it makes it more difficult for poor people to escape from poverty.

Another theory of inequality affecting growth is developed in Murphy et al. (1989). This paper assumes that some technologies have increasing returns. These technologies become profitable only if the domestic market is sufficiently large, that is, enough demand exists for the goods produced with the new technologies. If wealth is highly concentrated, the domestic market remains small (because not enough consumers can afford these goods). As a result, growth-enhancing technologies will not be implemented. The paper does not explicitly explore the role of financial markets; however, to the extent that financial underdevelopment creates the conditions for greater concentration of wealth, the mechanism described in this paper becomes more relevant in economies in which the financial structure is relatively underdeveloped.

Kumhof and Rancière (2010) have proposed an explanation for the recent crisis based on the changes in income distribution pinpointing similarity with the Great Depression. The idea is that, because of an exogenous shock that affected the ability of the rich to grab earnings, income became more concentrated, and as a result, the poor started to borrow more, increasing the debt-to-income ratio in the economy. Eventually, the increase in borrowing triggered the crisis.

We conclude this section by citing the work of Greenwood and Jovanovic (1990). Although this paper does not deal directly with inequality, it shows that improvements in financial markets (in this particular case, through the information gathered by financial intermediaries) have important effects on economic growth. As we have seen in previous chapters, market incompleteness also creates inequality. Therefore, once complemented with the previous analysis, this paper could also be relevant for understanding the link between financial market development, inequality, and growth. Also important is the work of Greenwood et al. (2010).

14.4.6.2 Global Imbalances

We have not talked much about cross-country inequality because this topic is usually a concern for development-oriented economists. However, inequality may be shaped by the increase in trade that is properly known as globalization, which is due to the reduction in the trade barriers for both technological and policy reasons. We have already referred, if only obliquely, to a mechanism by which more trade across countries could affect inequality: opening to trade changes the relative price of skills and may be behind part of the recent increase in the wage-skill gap. But an increase in trade shapes inequality both within and between countries through other, more subtle mechanisms. In this section we illustrate some potential mechanisms through which inequality is linked to globalization. Further analysis of the role of globalization for inequality is conducted in Chapter 20.

The process of international globalization is commonly presented as taking the form of higher trade in goods and services (imports and exports) as a fraction of GDP. But there is another side to it. Several advanced countries, the United States in particular, have experienced over the last 30 years a persistent deficit in the balance of payments as a result of imports being higher than exports, with the consequent deterioration in their net foreign asset positions. On the other hand, oil-producing countries and several emerging countries, China in particular, have been accumulating positive net foreign asset positions. "Global imbalances" is the term often used to refer to the situation in which some countries accumulate large negative net foreign asset positions whereas others accumulate positive net foreign asset positions. This situation has affected inequality, but to understand the impact on inequality we first need a theory of why imbalances could emerge in the wave of globalization.

Mendoza et al. (2007) provide one such theory. They claim that sustained deficits cannot be explained solely with traditional trade forces (different factor prices, technological advantages, or lower transportation costs). We also need to understand the differential saving behavior of countries that in equilibrium lead to different rates of returns on savings (insofar as international financial markets are somewhat segmented). This is possible even if countries have identical preferences and production technologies, but agents in each country differ in the extent to which they are capable of insuring their individual risks. This can be illustrated with the now familiar Aiyagari economy.

Suppose that we compare two economies, both slightly modified versions of the Aiyagari environment described above, that differ only in the process for earnings, one being more volatile than the other. It is important to point out that the assumption that countries differ in the volatility of earnings is a shortcut to capture other, more micro-founded differences. For example, in Mendoza et al. (2007), countries do not differ in the underlying process for earnings but in the sophistication of financial markets. Agents (consumers and firms) in countries with more advanced financial markets have a better opportunity to insure their idiosyncratic risk. Because in terms of savings the implication of higher insurance is similar to lower variability of earnings, here we illustrate the mechanism by assuming lower earning volatility. In some applications the higher ability to insure could derive from government policies (for example, the provision of public-funded health insurance). In some cases, the differences could come from more uncertainty about the underlying process for earnings. For example, a country that is experiencing a process of transformation (such as China, during the last three decades) is also possibly characterized by greater uncertainty at the individual level. Independently of the actual sources (greater ability to insure or greater underlying uncertainty), it should be clear that the example provided here is just a shortcut to illustrate something more fundamental such as differences in the characteristics of the financial system.[14]

[14] See Mendoza et al. (2007) for more details on how differences in the financial system can lead to lower ability to insure.

Table 14.8 Two economies before and after being able to borrow from each other

	Before: autarky		After: mobility	
Economy	**Low var**	**High var**	**Low var**	**High var**
Capital to output ratio	3.34	3.88	3.67	3.67
Interest rate (%)	4.02	1.27	2.24	2.24
Wealth to output ratio	3.34	3.88	0.39	6.95
Gini index of wealth	0.41	0.59	0.50	0.39
Coeff. of var wealth	0.76	1.09	0.88	0.96
1st quantile	3.40	0.00	0.40	0.00
2nd quantile	10.21	0.69	6.06	3.35
3rd quantile	17.11	15.50	17.58	17.45
4th quantile	25.16	30.21	25.94	21.00
5th quantile	44.15	53.60	50.01	58.20
Top 10% (cumulative)	26.73	33.28	30.37	29.63
Top 5% (cumulative)	15.51	19.72	18.09	17.21
Top 1%	3.99	5.19	4.25	4.32

To this end, we use two different processes for earnings. The first process is what we used above for the version of the model that we called PSID economy or low-variability economy. The second process is what we used in the high-variability economy, a version of the SCF economy with a slightly less extreme good state. Besides the process for earnings, the two economies are alike in all other dimensions.

The first two columns of Table 14.8 display the steady states of these two economies under autarky. The first column, the low-variability economy, has a capital-to-output ratio of 3.34, implying an annual interest rate of 4.02%. Because in this economy wealth can only take the form of capital, total wealth is also 3.34 × output, and this is what households choose to hold to accommodate the shocks to earnings given the 4.02% interest rate. The second column of Table 14.8 refers to the economy with higher income variability also in the autarky regime. Households choose to hold more wealth (3.88 × output) to bear the high risk. Two things to note are that the interest rate is now much lower, 1.27%, and that output is slightly higher because of the higher capital.

The determination of the equilibrium is depicted in panel (a) of Figure 14.5. This figure plots the aggregate (steady-state) supply of savings as an increasing, concave function of the interest rate.[15] The demand for savings is downward sloping because of the diminishing marginal productivity of capital. Country 1 has a lower volatility of

[15] Aggregate savings converge to infinity as the interest rate approaches the rate of time preference from below, because agents need an infinite amount of precautionary savings to attain a nonstochastic consumption profile.

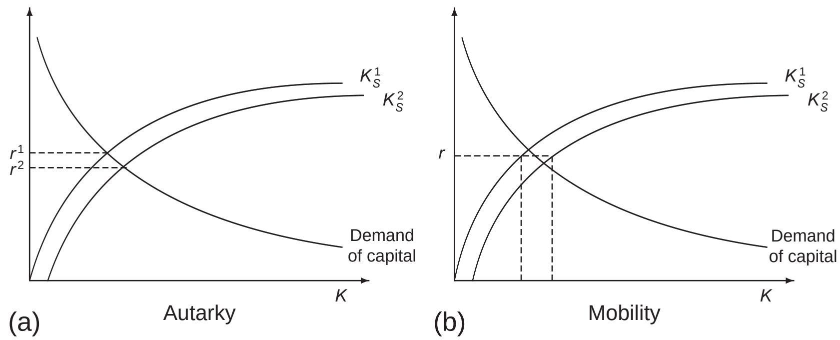

Figure 14.5 Steady-state equilibria with heterogeneous earning risks.

individual earnings and hence a lower supply of savings for each interest rate. As a result, the equilibrium in autarky implies a higher interest rate and a lower total capital.

Imagine now that households in these two economies can start owning capital in the other country, that is, the countries become financially integrated. After a brief period of transition that depends on the ease with which physical capital can flow or be reallocated, the interest rate in both countries will be equalized. This implies that the low-variability economy will experience a reduction in the interest rate and the high-variability economy will experience an increase in the interest rate. Then, in the country in which the interest rate decreases (low-variability economy), savings will fall, whereas in the country in which the interest rate increases (high-variability economy), savings will rise. The result is that households in the high-variability economy end up owning part of the capital installed in the low-variability economy. In this way, global imbalances may emerge as the low-variability economy dis-saves. Effectively, the low-variability economy consumes and invests more than it produces, with the difference covered by imports in excess of exports (trade deficit).

This process takes a long time until the aggregate savings of households in each country no longer change. This new steady state is depicted in panel (b) of Figure 14.5. The world interest rate is somewhere between the pre-liberalization interest rates in the two countries. Compared with autarky, the interest rate and the supply of savings fall in country 1 and rise in country 2, and hence the country with lower volatility of earnings ends up with a negative foreign asset position. Moreover, the capital stock rises relative to its autarky level in country 1 and falls in country 2. Thus, financial globalization leads capital to flow from economies with more risk to those with lower risk.

For analytical simplicity, we have modeled this process as the outcome of countries that differ in their earnings risk. However, as emphasized above, this is just a shortcut to capture other types of differences across countries that ultimately lead to different exposure to risk. It could very well be the case that the underlying risk is identical across countries but that the lower risk in one country is just the result of more-developed financial markets, which allow for higher insurability of risk. Formally, in the first country there are more markets for state-contingent claims. This is the approach taken in Mendoza et al. (2007), and the end result is similar to the case of differential processes for earnings: the country with a higher ability to insure saves less and has a higher interest rate than the country with less-developed financial markets. When the two countries integrate, it is the more financially developed country that accumulates negative foreign assets, whereas the less financially developed country accumulates positive foreign assets.

Therefore, financial market differences can affect the distribution of wealth across countries: in the long run, countries that are more financially sophisticated become poorer relative to countries that are less financially sophisticated (compared to the pre-liberalization era). This, however, does not mean that liberalization is welfare reducing for developed countries and welfare improving for less-developed countries. In Mendoza et al. (2007) we found, somewhat surprisingly, that liberalization was welfare improving for developed countries but slightly welfare reducing for less-developed countries (based on an equally weighted welfare function). In our example displayed in Table 14.8, the international redistribution of wealth is quite large, with the low-variability country ending up with barely 5% of total wealth. Yet, it started with almost half. The large international redistribution of wealth follows from the assumption that there are large differences in risk between the two countries. In reality, especially among integrated countries, the differences in risk may not be that big. Also, when a country accumulates too many foreign liabilities, there could be an incentive to default on these liabilities. This imposes a limit on the redistribution of wealth that can be generated across countries through this mechanism. Nevertheless, this example suggests that differences in savings could generate significant inequality in wealth across countries.

Cross-country financial market heterogeneity also plays a central role in Caballero et al. (2008) for explaining global imbalances. The mechanism proposed in this paper does not rely on risk but on the availability of saving instruments. The idea is that in certain countries, savers have difficulty storing their savings in high return assets. The implications for global imbalances, however, are similar to Mendoza et al. (2007). The two mechanisms are complementary ways of thinking about how the characteristics of financial systems can shape the distribution of wealth across countries in a globalized world. Interestingly, these contributions illustrate another mechanism through which financial globalization redistributes wealth. When productive inputs are not perfectly reproducible (as in the case of land), liberalization also leads to the equalization in the prices of these assets. Because under autarky these assets were cheaper in financially developed countries, these countries experience capital gains, whereas countries with less-developed financial markets experience capital losses.

The process of international redistribution of wealth also has consequences for the internal wealth distribution within each country. We see how wealth concentration increases in the low-variability country as measured by either the Gini index of the coefficient of variation of wealth or even by the shares held by the richest households (see Table 14.8). The opposite process happens in the less financially developed country, where the wealth distribution becomes more equal after international financial integration. Perhaps this process has contributed, at least in part, to the increased wealth concentration in the United States that we documented earlier.

14.5. THE POLITICAL ECONOMY CHANNEL

We have already seen in the previous sections some channels through which the distribution of income and wealth is interconnected with the aggregate performance of the economy. In this section, we discuss one particular channel through which inequality affects economic activities, that is, through the political and institutional system. Because many policies have redistributive consequences, the degree of inequality plays a central role in the choice of policies because societies with more unequal distributions of resources might demand greater redistribution. Because redistributive policies are often distortionary, the result is that more unequal societies tend to experience lower income or growth (or both).

Many contributions emphasize this mechanism, starting with Meltzer and Richard (1981). Examples are Persson and Tabellini (1994), Alesina and Rodrik (1994), Krusell and Ríos-Rull (1996), and Krusell et al. (1997). Many of these contributions, however, ignore individual uncertainty, which in a dynamic environment could play an important role in affecting the demand for redistribution as well as the distortions associated with redistributive policies. The goal of this section is to present a simple framework that illustrates the central idea of the early literature. It shows how the consideration of idiosyncratic uncertainty enriches the analysis and makes the relation between inequality and redistribution more complex than in these early studies.

14.5.1 A Simple Two-Period Model

Suppose that there is a continuum of agents who are alive for two periods. Agents value consumption, c_t, but dislike working, h_t, according to the utility function

$$u\left(c_t - \frac{h_t^2}{2}\right).$$

There are two sources of income: endowment, η_t, and labor, h_t. Individual endowments evolve according to

$$\ln(\eta_{t+1}) = \rho \cdot \ln(\eta_t) + \varepsilon_{t+1},$$

where $\varepsilon_{t+1} \sim N(0, (1-\rho^2)\cdot\sigma^2)$. This implies that the economywide distribution of log-endowments is normal with mean zero and variance σ^2, that is, $\ln(\eta_t) \sim N(0, \sigma^2)$. By changing ρ we change the persistence of endowments, but we keep the economywide distribution (inequality) constant. This parameter determines the degree of mobility: higher values of ρ imply lower mobility.

Before continuing, it will be helpful to derive some of the key moments of the cross-sectional distribution of endowments. Because endowments are log-normally distributed, that is, $\eta \sim LN(0, \sigma^2)$, the mean and the median are, respectively,

$$\mathrm{Mean}(\eta_t) = e^{\frac{\sigma^2}{2}}, \quad \mathrm{Median}(\eta_t) = 1.$$

These are unconditional moments. Also convenient is to derive the expected next-period endowment for an individual with current endowment η_t^i. The conditional mean is

$$\mathbb{E}\left[\eta_{t+1}^i | \eta_t^i\right] = e^{\rho \ln\left(\eta_t^i\right) + \frac{(1-\rho^2)\sigma^2}{2}}.$$

This conditional expectation will play an important role in the analysis of the model. Here we observe that if $\rho = 0$, the expected next-period endowment is the same for all agents. For an agent with median endowment, that is, $e_t^m = 1$, the conditional expectation becomes

$$\mathbb{E}\left[\eta_{t+1} | \eta_t^m\right] = e^{\frac{(1-\rho^2)\sigma^2}{2}}.$$

We can then compute the ratio of the next period economywide average endowment over the next period endowment expected by an agent whose current endowment is the median value. This is equal to

$$\frac{\mathrm{Mean}(\eta_{t+1})}{\mathbb{E}\left[\eta_{t+1} | \eta_t^m\right]} = e^{\frac{\rho^2\sigma^2}{2}}.$$

This expression makes it clear that the difference between the average endowment and the endowment expected by the agent with the median endowment in the current period depends on the persistent parameter ρ. The difference becomes zero if there is no persistence, that is, $\rho = 0$, and it is maximal when $\rho = 1$. Although the parameter ρ affects the ratio between the average endowment and the expected endowment by the median agent, ex post inequality does not depend on ρ. In fact, we have that

$$\frac{\mathrm{Mean}(\eta_{t+1})}{\eta_{t+1}^m} = e^{\frac{\sigma^2}{2}}.$$

We will use these moments below, after completing the description of the model.

The government taxes incomes, from endowment and labor, at rate τ_t and redistributes the revenues as lump-sum transfers. The budget constraint for the government is

$$T_t = \tau_t \int_i \left(\eta_t^i + h_t^i\right) di,$$

where i is the index for an individual agent.

Agents do not save and solve a static optimization problem. Given the tax rate and the transfer, an individual agent i maximizes the period utility by choosing the labor supply h_t^i, subject to the following budget constraint:

$$c_t^i = \left(\eta_t^i + h_t^i\right)(1-\tau_t) + T_t.$$

Taking first order conditions with respect to h_t for an individual worker with endowment η_t^i, we get the supply of labor $h_t = 1-\tau_t$. Substituting in the utility function and using the equation that defines the government transfers, we get the indirect utility for period t:

$$U^i(\tau_t) = u\left(\tau_t \int_\eta \eta dF_t + \tau_t(1-\tau_t) + \eta_t^i(1-\tau_t) + \frac{(1-\tau_t)^2}{2}\right).$$

Now suppose that agents vote for the next period tax rate τ_{t+1}. The tax rate preferred by an agent with current endowment η_t^i maximizes the expected next period indirect utility, that is,

$$\max_{\tau_{t+1}} \mathbb{E}_t\left[u\left(\tau_{t+1}\int_\eta \eta dF_{t+1} + \tau_{t+1}(1-\tau_{t+1}) + \eta_{t+1}^i(1-\tau_{t+1}) + \frac{(1-\tau_{t+1})^2}{2}\right)\eta_t^i\right],$$

where we have denoted by $F(\eta)$ the distribution of endowments. Because the log-endowments are normally distributed, $F(\eta)$ is a log-normal distribution.

Notice that the voter forms expectations about the future endowment conditional on the current endowment. Of course, the higher is the persistence, the higher the dependence of the expected value from the current value.

Taking the first order condition, we derive

$$\tau_{t+1}^i = \int_\eta \eta dF_{t+1} - \mathbb{E}\left[\eta_{t+1}^i|\eta_t^i\right] - \frac{\mathrm{Cov}\left(dU_{t+1}^i, \eta_{t+1}^i|\eta_t^i\right)}{\mathbb{E}\left[dU_{t+1}^i|\eta_t^i\right]}, \tag{14.85}$$

where dU_{t+1}^i denotes the derivative of the indirect utility for agent i with respect to the next-period tax rate. Notice that this term also depends on the tax rate. The above condition implicitly determines the tax rate.

The first term on the right-hand side of Equation (14.85) is the mean value of the economywide endowment, which is equal to $e^{\frac{\sigma^2}{2}}$. This term is the same for all agents. The second term is the expected endowment of agent i given the current endowment. This term is increasing in η_t^i, unless $\rho \leq 0$, which is excluded by assumption. Therefore, ignoring the third term, the preferred tax rate decreases with the current endowment.

The third term captures the role of risk aversion. Because the utility function is strictly concave and its derivative is strictly decreasing, $dU_{t+1}^i(.)$ decreases with the realization of next period endowment η_{t+1}^i, implying that the covariance term is negative. Therefore, preferences for taxes increase with the concavity of the utility function. This is the effect of risk aversion.

14.5.1.1 The Case of Risk Neutrality

Because the third term in the first order condition (14.85) is itself a function of τ^i_{t+1}, it is difficult to derive an analytical expression for the tax rate. Therefore, we first specialize to the case with risk-neutral agents so that $\text{Cov}(dU^i_{t+1}, \eta^i_{t+1} | \eta^i_t) = 0$ and the preferred tax rate reduces to the first two terms in Equation (14.85). We can then establish that the preferred tax rate is monotonically decreasing in the current endowment η^i_t and the equilibrium tax rate is the one preferred by the agent with the median endowment. Using the fact that endowments are log-normally distributed and the log-endowment of the median voter is zero, the conditional expectation of the median voter for the next period endowment is $\mathbb{E}\left[\eta_{t+1} | \eta^m_t\right] = e^{\frac{(1-\rho^2)\sigma^2}{2}}$, whereas the economywide average is $\int_\eta \eta dF_{t+1} = e^{\frac{\sigma^2}{2}}$. Substituting in the preferred tax rate, we obtain the equilibrium tax rate

$$\tau_{t+1}\left(e^m_t\right) = e^{\frac{\sigma^2}{2}} - e^{\frac{(1-\rho^2)\sigma^2}{2}}. \tag{14.86}$$

The first two terms capture the standard politico-economy theory: because the average endowment, $e^{\frac{\sigma^2}{2}}$, is bigger than the median endowment, $e^{\frac{(1-\rho^2)\sigma^2}{2}}$, there is demand for redistribution. If we increase inequality by raising σ, the demand for redistribution increases. Because the optimal effort chosen by all agents is $h = 1 - \tau$, higher taxes discourage effort with negative effects on aggregate production. In some of the models proposed in the literature, taxes distort the accumulation of capital instead of effort, but the idea is similar.

The mechanism described above links inequality to redistribution and macroeconomic activity and captures the key features of the model studied in Meltzer and Richard (1981). In addition to this mechanism, the model presented here emphasizes the role of mobility captured by the parameter ρ. If we reduce ρ so that the economy experiences higher mobility, the cross-sectional inequality does not change. In fact, the ratio of average endowment and median endowment remains $e^{\frac{\sigma^2}{2}}$. However, the tax rate preferred by the median voter declines, as we can see from Equation (14.86). Even if the median voter has low endowment in the current period, what matters for next period taxes is the future endowment. If mobility is high, the median voter does not expect to keep the low endowment in the future. Thus, it is not optimal to choose high tax rates. In the limiting case with $\rho = 0$, the expected future endowment for all agents will be the average endowment and, in expected terms, the future benefit of redistribution is zero for all agents.

The importance of mobility for political preferences has received less attention than cross-sectional inequality. But the simple model presented here shows that mobility is also an important factor in the determination of political preferences. More importantly, if inequality and mobility are not independent, either across countries or across times, by focusing only on inequality we may reach inaccurate conclusions. Suppose, for example, that an increase in cross-sectional inequality, σ, is associated with a decrease in ρ, that is, with an increase in mobility. Therefore, we have two contrasting effects: the increase in σ leads to higher taxes, whereas the decrease in ρ leads to lower taxes.

This example may help to explain why, in certain episodes of increasing inequality, such as in the United States before the recent crisis, we do not see a significant increase in demand for redistribution. Perhaps the reason is that voters perceive higher mobility as coincident with greater inequality. Then, thanks to the perceived mobility, voters do not demand higher taxes and the economy continues to perform well even if income becomes more concentrated. However, if the performance of the economy changes and voters start to perceive lower mobility, they will start demanding more redistribution, which will further deteriorate the performance of the economy. This idea has been developed in Quadrini (1999) in a model that features two equilibria. The first equilibrium is characterized by high growth, high inequality, and low redistribution. The second equilibrium is characterized by low growth, low inequality, and high redistribution.[16] The idea that the prospect of upward mobility reduces the demand for redistribution has also been studied in Benabou and Ok (2001).

14.5.1.2 The Case of Risk Aversion

We now assume that the utility function is concave and takes the following form:

$$u\left(c_t - \frac{h_t^2}{2}\right) = \frac{\left(c_t - \frac{h_t^2}{2}\right)^{1-\nu}}{1-\nu},$$

where the parameter ν captures the curvature of the utility function.

Figure 14.6 plots the preferred tax rate as a function of current endowment η_t^i for different values of ν. As can be seen from the figure, the preferred tax rate is monotonically decreasing in current endowment, and therefore, the median voter theorem also applies in the case of risk-averse agents. Furthermore, we see that, for each endowment level η_t^i, the preferred tax rate increases with risk aversion.

Figure 14.7 plots the preferred tax rate as a function of current endowment for different degrees of mobility and risk aversion. The first panel is for the case of risk neutrality. In this case, we see that lower mobility (ρ changes from 0.5 to 0.9) increases the equilibrium tax rate, that is, the tax rate preferred by the median voter, which in the figure is identified by the vertical line. These are the properties we have shown analytically in the previous subsection. However, when agents are risk averse, lower mobility reduces

[16] The increase in inequality in the United States is not a recent phenomenon. However, voters and politicians started to focus more on this issue after the recent crisis. During the good times in which financial markets were expanding, low-income households had access to credit, allowing them to own houses. For many this appeared as a new opportunity (mobility). However, with the crisis and the credit market and the freeze, these opportunities dried up and many households lost faith in the possibility of improving their current position (mobility). Not surprisingly, they turned to the government for help and asked for more populist policies.

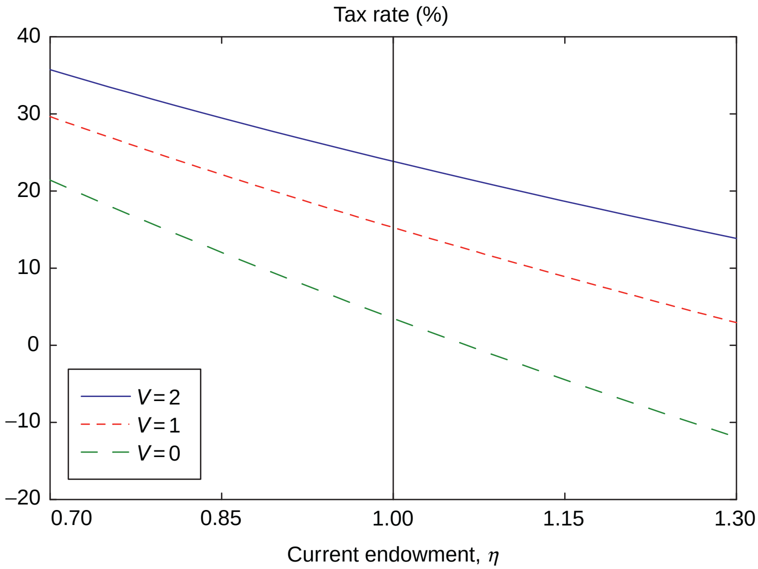

Figure 14.6 Preferred tax rates for different degrees of risk aversion. The inequality and mobility parameters are $\sigma = 0.5$ and $\rho = 0.5$. The vertical line denotes the median endowment.

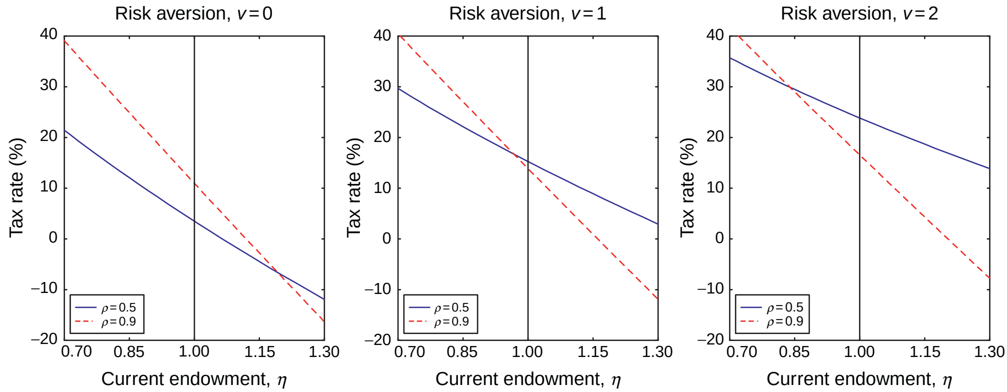

Figure 14.7 Preferred tax rates for different degrees of mobility, $\rho \in \{0.5, 0.9\}$, and risk aversion, $v \in \{0, 1, 2\}$. The inequality parameter is $\sigma = 0.5$. The vertical line denotes the median endowment.

the equilibrium tax rate. The reason is that, conditional on the current endowment, lower mobility means that agents face lower risk. In fact, with $\rho = 1$, next period endowment is equal to current endowment. Thus, there is less demand for insurance.

This example shows that mobility affects equilibrium policies through two mechanisms. The first mechanism works through the impact of mobility on the redistributive gains from next period taxes. When mobility is low, the expected redistributive gains are high. These gains vanish if mobility is perfect, that is, $\rho = 0$. The second mechanism works through the impact of mobility on individual risk. Given the current endowment, higher mobility (lower ρ) increases the conditional volatility of next period endowment and the median agent faces higher risk. Thus, greater redistribution is preferred if preferences are concave. This second mechanism is irrelevant when agents are risk neutral but becomes important when agents are risk averse. For a sufficiently high degree of risk aversion, the second mechanism dominates and the equilibrium tax rate declines with lower mobility.

Corbae et al. (2009) and Bachmann and Bai (2013) are two papers that study infinite horizon political economy models with income taxes and uninsurable idiosyncratic risks. Thus, these two papers are potentially capable of capturing the mechanisms described in this section.

14.5.2 More on the Political Economy Channel

Some theories formulate channels through which redistributive taxes have a beneficial effect on the macroeconomy in the presence of financial constraints. For example, in the Schumpeterian view where entrepreneurship is central to economic growth, financial constraints and the absence of insurance markets make entrepreneurial investment suboptimal. Under these conditions, redistribution may provide extra resources to constrained entrepreneurs and could facilitate more investments in growth-enhancing activities. At the same time, a redistributive system provides an implicit mechanism for consumption smoothing (a person pays high taxes when he or she earns high profits but receives payments in case of losses). Therefore, it provides insurance. Thus, if entrepreneurs are risk averse, redistribution could encourage investment.

A similar mechanism applies to the investment in education or human capital. If education is important for economic growth, and parents choose suboptimal levels of education because of financial constraints, then government transfers may allow for greater investment and growth. A more direct mechanism could work through the financing of public education, as in Glomm and Ravikumar (1992).

Political economy forces are also important for the choice of government borrowing. Azzimonti et al. (2014) propose a theory of public debt where greater income inequality could increase the incentive of the government to borrow more if the higher inequality is associated with greater individual risk. This is because higher risk increases the demand for safe assets, which are undersupplied when markets are incomplete. If financial markets are integrated, the increase in inequality (risk) in a few countries could induce a worldwide increase in public debt. In this way, the paper proposes one of the possible mechanisms for explaining the rising public debt observed in most of the industrialized countries since the early 1980s.

We close this section by mentioning that, although a large branch of the political economy literature has been developed on the assumption that voters are self-motivated and agree on their views of the world, so that their assessment of a policy is based on how much they benefit, some authors have proposed alternative frameworks. Especially interesting is Piketty (1995). This study develops a model in which agents prefer different policies not because they are selfish but because they have different beliefs. All voters care about social welfare, but some believe that luck is more important in generating income, whereas others believe that effort is more important. These beliefs evolve over time based on personal experience, but they never converge. Thus, at any point in time, preferences are heterogeneous. Although not explicitly explored in the original article, it is possible to introduce factors that could change the distribution of beliefs and with them the properties of the macro economy. This could be an interesting direction for future research.

14.6. CONCLUSION

In this chapter we have discussed a variety of topics that lie in the somewhat fuzzy intersection of income distribution and macroeconomics. The choice of topics and approaches has surely been idiosyncratic, reflecting our tastes, interests, and expertise, and we have left out many topics from behavioral and nonoptimizing models to issues in development, to the analysis of the impact of the rise of inequality on the U.S. economy. We have also touched other aspects only superficially, such as the role of globalization on the economy. In addition, we have only looked marginally at the implications of income inequality for consumption inequality or even for inequality in the duration of life,[17] which is in the end what really matters to determine the welfare costs of inequality.

We are very aware that a very different chapter covering the same could be written by other authors (in fact, the next chapter includes an example of this by providing some very different ideas of macro modeling of the wealth distribution). But we hope that this chapter has provided an idea of how macroeconomics is explicitly incorporating the analysis of inequality to improve our understanding of the dynamics of the aggregate economy, and also of how the discipline that macroeconomics brings to the table—that all pieces have to be mutually consistent and that dynamics is at the core of economics—shapes the way we think about income and wealth inequality.

ACKNOWLEDGMENTS

We are grateful for the comments from many people over the years. Many people contributed direct comments about and calculations for this paper. They include the editors for this handbook, but also Makoto Nakajima, Mariacristina De Nardi, Josep Pijoan-Mas, and Thomas Piketty. Others, such as David Wiczer and Moritz Kuhn, made even more direct contributions. We received research assistance from Kai Ding and Gero Dolfus, comments by Sergio Salgado and Annaliina Soikkanen, and editorial help from Joan Gieseke.

[17] Pijoan-Mas and Ríos-Rull (2014) argue that the welfare cost of inequality in life spans dwarfs that of inequality in consumption.

We thank all of them. Ríos-Rull thanks the National Science Foundation for grant SES-1156228. The views expressed herein are those of the authors and not necessarily those of the Federal Reserve Bank of Minneapolis or the Federal Reserve System.

APPENDIX A. DERIVATION OF THE INEQUALITY INDEX

In each period, there are different cohorts of workers who have been employed for j periods. They also differ in terms of initial human capital h_0^k at birth. Because workers die with probability λ, the fraction of workers in the j cohort (composed of workers who survive for j periods) is equal to $\sum_k x_0^k(1-\lambda)^j$. Denote by h_j^k the human capital of a worker born with initial human capital h_0^k of age $j+1$. Because human capital grows at the gross rate $g(y,\varepsilon)$, we have that $h_j^k = h_0^k \prod_{t=1}^{j} g(y,\varepsilon_t)$. Of course, this differs across workers of the same cohort because the growth rate is stochastic. The average human capital is then computed as

$$\overline{h} = \sum_k x_0^k \sum_{j=0}^{\infty} (1-\lambda)^j \mathbb{E} h_j^k, \tag{A1}$$

where $\mathbb{E}$ averages the human capital of all agents in the $j-k$ cohort. Because growth rates are serially independent, we have that $\mathbb{E}h_j^k = h_0^k \mathbb{E}g(y,\varepsilon)^j$. Substituting in the above expression and solving we get

$$\overline{h} = \frac{\overline{h}_0}{1-(1-\lambda)\mathbb{E}g(y,\varepsilon)},$$

where $\overline{h}_0 = \sum_k x_0^k h_0^k$ is the aggregate human capital of newborn agents.

We now turn to the variance, which is calculated as

$$\mathrm{Var}(h) = \sum_k x_0^k \sum_{j=0}^{\infty} (1-\lambda)^j \mathbb{E}\left(h_j^k - \overline{h}\right)^2.$$

This can be rewritten as

$$\mathrm{Var}(h) = \sum_k x_0^k \sum_{j=0}^{\infty} (1-\lambda)^j \left[\mathbb{E}\left(h_j^k\right)^2 - \overline{h}^2\right].$$

This can be further rewritten as

$$\mathrm{Var}(h) = \sum_k x_0^k \left(h_0^k\right)^2 \sum_{j=0}^{\infty} (1-\lambda)^j \mathbb{E}\left(\frac{h_j^k}{h_0^k}\right)^2 - \overline{h}^2.$$

The term h_j^k/h_0^k is independent of the initial human capital h_0^k. Taking into account the serial independence of the growth rates, we have that $\mathbb{E}\left(h_j^k/h_0^k\right)^2 = \left[\mathbb{E}g(\gamma,\varepsilon)^2\right]^j$. Substituting and solving, we have

$$\mathrm{Var}(h) = \left(\sum_k x_0^k \left(h_0^k\right)^2\right)\left(\frac{1}{1-(1-\lambda)\mathbb{E}g(\gamma,\varepsilon)^2}\right) - \overline{h}^2.$$

To compute the inequality index, we simply divide the variance by $\overline{h}^2$, where $\overline{h}$ is given by Equation (A1). This returns the inequality index (14.27).

APPENDIX B. WAGE EQUATION WITH ENDOGENOUS DEBT

Consider the value of a filled vacancy defined in Equation (14.51). Using the binding enforcement $B' = \varphi(1-\eta)\mathbb{E}S'(B')$ to eliminate B', this value becomes

$$Q = (1+\varphi)\beta(1-\eta)\mathbb{E}S'(B').$$

Notice that at this stage we are imposing $b = B$ and $b' = B'$, which hold in a symmetric equilibrium.

Next we use the free entry condition $V = qQ - \kappa = 0$. Eliminating Q using the above expression and solving for the expected value of the surplus, we obtain

$$\mathbb{E}S'(B') = \frac{\kappa}{q(1+\varphi)\beta(1-\eta)}. \tag{B1}$$

Substituting into the definition of the surplus—Equation (14.50)—and taking into account that $b' = \varphi(1-\eta)\mathbb{E}S'(B')$, we get

$$S(B) = z - \overline{u} - B + \frac{[1-\lambda-p\eta+\varphi(1-\lambda)(1-\eta)]\kappa}{q(1+\varphi)(1-\eta)}. \tag{B2}$$

Now consider the net value for a worker,

$$W(B) - U = w - \overline{u} + \eta(1-\lambda-p)\beta\mathbb{E}S'(B').$$

Substituting $W(B) - U = \eta S(B)$ in the left-hand side and eliminating $\mathbb{E}S'(B')$ in the right-hand side using Equation (B1), we obtain

$$\eta S(B) = w - \overline{u} + \frac{\eta(1-\lambda-p)\kappa}{q(1+\varphi)(1-\eta)}. \tag{B3}$$

Finally, combining Equations (B2) and (B3) and solving for the wage, we get

$$w = (1-\eta)\overline{u} + \eta(z-b) + \frac{\eta[p+(1-\lambda)\varphi]\kappa}{q(1+\varphi)},$$

which is the expression reported in (14.54).

Abstract

This chapter offers an overview of the empirical and theoretical research on the long-run evolution of wealth and inheritance. Wealth–income ratios, inherited wealth, and wealth inequalities were high in the eighteenth to nineteenth centuries up until World War I, then sharply dropped during the twentieth century following World War shocks, and have been rising again in the late twentieth and early twenty-first centuries. We discuss the models that can account for these facts. We show that over a wide range of models, the long-run magnitude and concentration of wealth and inheritance are an increasing function of $\bar{r} - g$ where $\bar{r}$ is the net-of-tax rate of return on wealth and g is the economy's growth rate. This suggests that current trends toward rising wealth–income ratios and wealth inequality might continue during the twenty-first century, both because of the slowdown of population and productivity growth, and because of rising international competition to attract capital.

15.1. INTRODUCTION

Economists have long recognized that the magnitude and distribution of wealth play an important role in the distribution of income—both across factors of production (labor and capital) and across individuals. In this chapter, we ask three simple questions: (1) What do we know about historical patterns in the magnitude of wealth and inheritance relative to income? (2) How does the distribution of wealth vary in the long run and across countries? (3) And what are the models that can account for these facts?

In surveying the literature on these issues, we will focus the analysis on three interrelated ratios. The first is the aggregate wealth-to-income ratio, that is the ratio between marketable—nonhuman—wealth and national income. The second is the share of aggregate wealth held by the richest individuals, say the top 10% or top 1%. The last is the ratio between the stock of inherited wealth and aggregate wealth (or between the annual flow of bequests and national income). As we shall see, to properly analyze the concentration of wealth and its implications, it is critical to study top wealth shares jointly with the macroeconomic wealth–income and inheritance–wealth ratios. In so doing, this chapter attempts to build bridges between income distribution and macroeconomics.

The wealth-to-income ratio, top wealth shares, and the share of inheritance in the economy have all been the subject of considerable interest and controversy—but usually on the basis of limited data. For a long time, economics textbooks have presented the wealth–income ratio as stable over time—one of the Kaldor facts.[1] There is, however, no strong theoretical reason why it should be so: With a flexible production function, any ratio can be a steady state. And until recently, we lacked comprehensive national balance sheets with harmonized definitions for wealth that could be used to vindicate the constant-ratio thesis. Recent research shows that wealth–income ratios, as well as the share of capital in national income, are actually much less stable in the long run than what is commonly assumed.

Following the Kuznets curve hypothesis, first formulated in the 1950s, another common view among economists has been that income inequality—and possibly wealth inequality as well—should first rise and then decline with economic development, as a growing fraction of the population joins high-productivity sectors and benefits from industrial growth.[2] However, following the rise in inequality that has occurred in most developed countries since the 1970s–1980s, this optimistic view has become less popular.[3] As a consequence, most economists are now fairly skeptical about universal laws regarding the long-run evolution of inequality.

Last, regarding the inheritance share in total wealth accumulation, there seems to exist a general presumption that it should tend to decline over time. Although this is rarely formulated explicitly, one possible mechanism could be the rise of human capital (leading maybe to a rise of the labor share in income and saving), or the rise in life-cycle wealth accumulation (itself possibly due to the rise of life expectancy). Until recently, however, there was limited empirical evidence on the share of inherited wealth available to test these hypotheses. The 1980s saw a famous controversy between Modigliani (a life-cycle advocate, who argued that the share of inherited wealth was as little as 20–30% of U.S. aggregate wealth) and Kotlikoff–Summers (who instead

[1] See, e.g., Kaldor (1961) and Jones and Romer (2010).

[2] See Kuznets (1953).

[3] See Atkinson et al. (2011). See also Chapter 7 in Handbook of Income Distribution, volume 2A by Roine and Waldenstrom (2015).

argued that the inheritance share was as large as 80%, if not larger). Particularly confusing was the fact that both sides claimed to look at the same data, namely U.S. data from the 1960s–1970s.[4]

Because many of the key predictions about wealth and inheritance were formulated a long time ago—often in the 1950s–1960s, or sometime in the 1970s–1980s—and usually on the basis of a relatively small amount of long-run evidence, it is high time to take a fresh look at them again on the basis of the more reliable evidence now available.

We begin by reviewing in Section 15.2 what we know about the historical evolution of the wealth–income ratio β. In most countries, this ratio has been following a U-shaped pattern over the 1910–2010 period, with a large decline between the 1910s and the 1950s, and a gradual recovery since the 1950s. The pattern is particularly spectacular in Europe, where the aggregate wealth–income ratio was as large as 600–700% during the eighteenth, nineteenth, and early twentieth centuries, then dropped to as little as 200–300% in the mid-twentieth century. It is now back to about 500–600% in the early twenty-first century. These same orders of magnitude also seem to apply to Japan, though the historical data is less complete than for Europe. The U-shaped pattern also exists—but is less marked—in the United States.

In Section 15.3, we turn to the long-run changes in wealth concentration. We also find a U-shaped pattern over the past century, but the dynamics have been quite different in Europe and in the United States. In Europe, the recent increase in wealth inequality appears to be more limited than the rise of the aggregate wealth–income ratio, so that European wealth seems to be significantly less concentrated in the early twenty-first century than a century ago. The top 10% wealth share used to be as large as 90%, whereas it is around 60–70% today (which is already quite large—and in particular a lot larger than the concentration of labor income). In the United States, by contrast, wealth concentration appears to have almost returned to its early twentieth century level. Although Europe was substantially more unequal than the United States until World War I, the situation has reversed over the course of the twentieth century. Whether the gap between both economies will keep widening in the twenty-first century is an open issue.

In Section 15.4, we describe the existing evidence regarding the evolution of the share φ of inherited wealth in aggregate wealth. This is an area in which available historical series are scarce and a lot of data has yet to be collected. However existing evidence—coming mostly from France, Germany, the United Kingdom, and Sweden—suggests that the inheritance share has also followed a U-shaped pattern over the past century. Modigliani's estimates—with a large majority of wealth coming from life-cycle savings—might have been right for the immediate postwar period (though somewhat exaggerated). But Kotlikoff–Summers' estimates—with inheritance

[4] See Kotlikoff and Summers (1981, 1988) and Modigliani (1986, 1988). Modigliani's theory of life-cycle saving was first formulated in the 1950s–1960s; see the references given in Modigliani (1986).

accounting for a significant majority of wealth—appear to be closer to what we generally observe in the long run, both in the nineteenth, twentieth, and early twenty-first centuries. Here again, there could be some interesting differences between Europe and the United States (possibly running in the opposite direction than for wealth concentration). Unfortunately the fragility of available U.S. data makes it difficult to conclude at this stage.

We then discuss in Section 15.5 the theoretical mechanisms that can be used to account for the historical evidence and to analyze future prospects. Some of the evolutions documented in Sections 15.2–15.4 are due to shocks. In particular, the large U-shaped pattern of wealth–income and inheritance-income ratios observed over the 1910–2010 period is largely due to the wars (which hit Europe and Japan much more than the United States). Here the main theoretical lesson is simply that capital accumulation takes time, and that the world wars of the twentieth century have had a long-lasting impact on basic economic ratios. This, in a way, is not too surprising and follows from simple arithmetic. With a 10% saving rate and a fixed income, it takes 50 years to accumulate the equivalent of 5 years of income in capital stock. With income growth, the recovery process takes even more time.

The more interesting and difficult part of the story is to understand the forces that determine the new steady-state levels toward which each economy tends to converge once it has recovered from shocks. In Section 15.5, we show that over a wide range of models, the long-run magnitude and concentration of wealth and inheritance are a decreasing function of g and an increasing function of $\bar{r}$, where g is the economy's growth rate and $\bar{r}$ is the net-of-tax rate of return to wealth. That is, under plausible assumptions, our three interrelated sets of ratios—the wealth–income ratio, the concentration of wealth, and the share of inherited wealth—all tend to take higher steady-state values when the long-run growth rate is lower or when the net-of-tax rate of return is higher. In particular, a higher $\bar{r}-g$ tends to magnify steady-state wealth inequalities. We argue that these theoretical predictions are broadly consistent with both the time-series and the cross-country evidence. This also suggests that the current trends toward rising wealth–income ratios and wealth inequality might continue during the twenty-first century, both because of population and productivity growth slowdown, and because of rising international competition to attract capital.

Owing to data availability constraints, the historical evolutions analyzed in this chapter relate for the most part to today's rich countries (Europe, North America, and Japan). However, to the extent that the theoretical mechanisms unveiled by the experience of rich countries also apply elsewhere, the findings presented here are also of interest for today's emerging economies. In Section 15.5, we discuss the prospects for the global evolution of wealth–income ratios, wealth concentration, and the share of inherited wealth in the coming decades. Finally, Section 15.6 offers concluding comments and stresses the need for more research in this area.

15.2. THE LONG-RUN EVOLUTION OF WEALTH–INCOME RATIOS

15.2.1 Concepts, Data Sources, and Methods

15.2.1.1 Country Balance Sheets

Prior to World War I, there was a vibrant tradition of national wealth accounting: economists, statisticians, and social arithmeticians were much more interested in computing the stock of national wealth than the flows of national income and output. The first national balance sheets were established in the late seventeenth and early eighteenth centuries by Petty (1664) and King (1696) in the United Kingdom, and Boisguillebert (1695) and Vauban (1707) in France. National wealth estimates then became plentiful in the nineteenth and early twentieth century, with the work of Colquhoun (1815), Giffen (1889), and Bowley (1920) in the United Kingdom, de Foville (1893) and Colson (1903) in France, Helfferich (1913) in Germany, King (1915) in the United States, and dozens of other economists.

The focus on wealth, however, largely disappeared in the interwar. The shock of World War I, the Great Depression, and the coming of Keynesian economics led to attention being switched from stocks to flows, with balance sheets being neglected. The first systematic attempt to collect historical balance sheets is due to Goldsmith (1985, 1991). Building upon recent progress made in the measurement of wealth, and pushing forward Goldsmith's pioneering attempt, Piketty and Zucman (2014) construct aggregate wealth and income series for the top eight rich economies. Other recent papers that look at specific countries include Atkinson (2013) for the United Kingdom and Ohlsson et al. (2013) for Sweden. In this section, we rely on the data collected by Piketty and Zucman (2014)—and closely follow the discussion therein—to present the long-run evolution of wealth–income ratios in the main developed economies.

In determining what is to be counted as wealth, we follow the U.N. System of National Accounts (SNA). For the 1970–2010 period, the data come from official national accounts that comply with the latest international guidelines (SNA, 1993, 2008). For the previous periods, Piketty and Zucman (2014) draw on the vast national wealth accounting tradition to construct homogenous income and wealth series that use the same concepts and definitions as in the most recent official accounts. The historical data themselves were established by a large number of scholars and statistical administrations using a wide variety of sources, including land, housing and wealth censuses, financial surveys, corporate book accounts, and the like. Although historical balance sheets are far from perfect, their methods are well documented and they are usually internally consistent. It was also somewhat easier to estimate national wealth around 1900–1910 than it is today: the structure of property was simpler, with less financial intermediation and cross-border positions.[5]

[5] A detailed analysis of conceptual and methodological issues regarding wealth measurement, as well as extensive country-specific references on historical balance sheets, are provided by Piketty and Zucman (2014).

15.2.1.2 Concepts and Definitions: Wealth Versus Capital

We define private wealth, W_t, as the net wealth (assets minus liabilities) of households.[6] Following SNA guidelines, assets include all the nonfinancial assets—land, buildings, machines, etc.—and financial assets—including life insurance and pensions funds—over which ownership rights can be enforced and that provide economic benefits to their owners. Pay-as-you-go Social Security pension wealth is excluded, just as all other claims on future government expenditures and transfers (such as education expenses for one's children or health benefits). Durable goods owned by households, such as cars and furniture, are excluded as well.[7] As a general rule, all assets and liabilities are valued at their prevailing market prices. Corporations are included in private wealth through the market value of equities and corporate bonds. Unquoted shares are typically valued on the basis of observed market prices for comparable, publicly traded companies.

Similarly, public (or government) wealth, W_{gt}, is the net wealth of public administrations and government agencies. In available balance sheets, public nonfinancial assets such as administrative buildings, schools, and hospitals are valued by cumulating past investment flows and upgrading them using observed real estate prices.

Market-value national wealth, W_{nt}, is the sum of private and public wealth:

$$W_{nt} = W_t + W_{gt}$$

and national wealth can also be decomposed into domestic capital and net foreign assets:

$$W_{nt} = K_t + NFA_t$$

In turn, domestic capital K_t can be written as the sum of agricultural land, housing, and other domestic capital (including the market value of corporations, and the value of other nonfinancial assets held by the private and public sectors, net of their liabilities).

Regarding income, the definitions and notations are standard. Note that we always use net-of-depreciation income and output concepts. National income Y_t is the sum of net domestic output and net foreign income: $Y_t = Y_{dt} + r_t \cdot NFA_t$.[8] Domestic output can be thought of as coming from some aggregate production function that uses domestic capital and labor as inputs: $Y_{dt} = F(K_t, L_t)$.

[6] Private wealth also includes the assets and liabilities held by nonprofit institutions serving households (NPISH). The main reason for doing so is that the frontier between individuals and private foundations is not always clear. In any case, the net wealth of NPISH is usually small, and always less than 10% of total net private wealth: currently it is about 1% in France, 3–4% in Japan, and 6–7% in the United States; see Piketty and Zucman (2014, Appendix Table A65). Note also that the household sector includes all unincorporated businesses.

[7] The value of durable goods appears to be relatively stable over time (about 30–50% of national income, i.e., 5–10% of net private wealth). See for instance Piketty and Zucman (2014, Appendix Table US.6f) for the long-run evolution of durable goods in the United States.

[8] National income also includes net foreign labor income and net foreign production taxes—both of which are usually negligible.

One might prefer to think about output as deriving from a two-sector production process (housing and nonhousing sectors), or more generally from n sectors. In the real world, the capital stock K_t comprises thousands of various assets valued at different prices (just like output Y_{dt} is defined as the sum of thousands of goods and services valued at different prices). We find it more natural, however, to start with a one-sector formulation. Since the same capital assets (i.e., buildings) are often used for housing and office space, it would be quite artificial to start by dividing capital and output into two parts. We will later on discuss the pros and cons of the one-sector model and the need to appeal to two-sector models and relative asset price movements to properly account for observed changes in the aggregate wealth–income ratio.

Another choice that needs to be discussed is the focus on market values for national wealth and capital. We see market values as a useful and well-defined starting point. But one might prefer to look at book values, for example, for short-run growth accounting exercises. Book values exceed market values when Tobin's Q is less than 1, and conversely when Tobin's Q is larger than 1. In the long run, however, the choice of book versus market value does not much affect the analysis (see Piketty and Zucman, 2014, for a detailed discussion).

We are interested in the evolution of the private wealth–national income ratio $\beta_t = W_t/Y_t$ and of the national wealth–national income ratio $\beta_{nt} = W_{nt}/Y_t$. In a closed economy, and more generally in an open economy with a zero net foreign position, the national wealth–national income ratio β_{nt} is the same as the domestic capital–output ratio $\beta_{kt} = K_t/Y_{dt}$.[9] If public wealth is equal to zero, then both ratios are also equal to the private wealth–national income ratio $\beta_t = \beta_{nt} = \beta_{kt}$. At the global level, the world wealth–income ratio is always equal to the world capital–output ratio.

15.2.2 The Very Long-Run: Britain and France, 1700–2010

Figures 15.1 and 15.2 present the very long-run evidence available for Britain and France regarding the national wealth–national income ratio β_{nt}. Net public wealth—either positive or negative—is usually a relatively small fraction of national wealth, so that the evolution of β_{nt} mostly reflects the evolution of the private wealth–national income ratio β_t (more on this below).[10]

[9] In principle, one can imagine a country with a zero net foreign asset position (so that $W_{nt} = K_t$) but nonzero net foreign income flows (so that $Y_t \neq Y_{dt}$). In this case the national wealth–national income ratio β_{nt} will slightly differ from the domestic capital–output ratio β_{kt}. In practice today, differences between Y_t and Y_{dt} are very small—national income Y_t is usually between 97% and 103% of domestic output Y_{dt} (see Piketty and Zucman, 2014, Appendix Figure A57). Net foreign asset positions are usually small as well, so that β_{kt} turns out to be usually close to β_{nt} in the 1970–2010 period (see Piketty and Zucman, 2014, Appendix Figure A67).

[10] For an historical account of the changing decomposition of national wealth into private and public wealth in Britain and France since the eighteenth century, see Piketty (2014, Chapter 3).

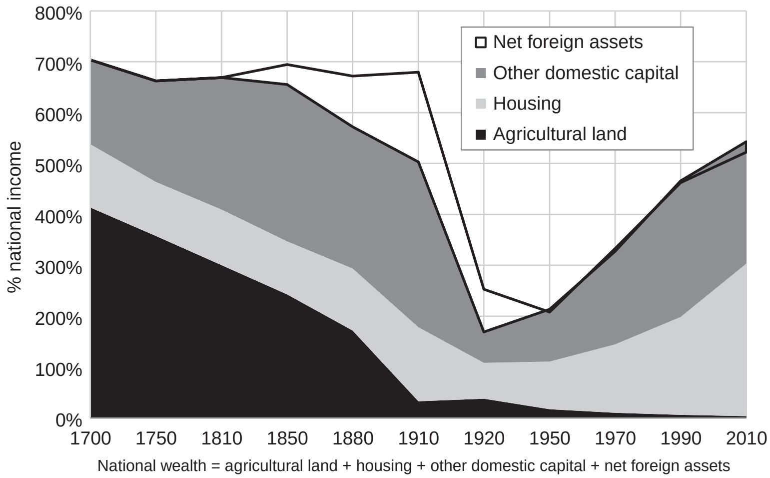

Figure 15.1 The changing level and nature of national wealth: United Kingdom 1700–2010.

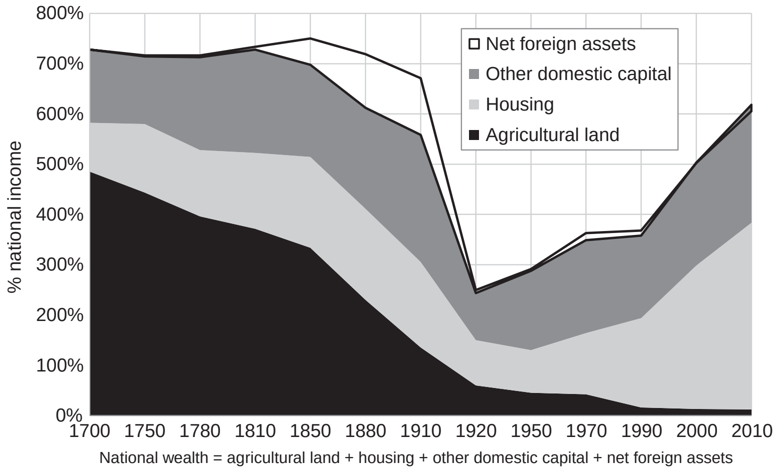

Figure 15.2 The changing level and nature of national wealth: France 1700–2010.

The evolutions are remarkably similar in the two countries. First, the wealth–income ratio has followed a spectacular U-shaped pattern. Aggregate wealth was worth about 6–7 years of national income during the eighteenth to nineteenth centuries on both sides of the channel, up until the eve of World War I. Raw data sources available for these two centuries are not sufficiently precise to make fine comparisons between the two countries or over time, but the orders of magnitude appear to be reliable and roughly stable (they come from a large number of independent estimates). Aggregate wealth then collapsed to as little as 2–3 years of national income in the aftermath of the two World Wars. Since the 1950s, there has been a gradual recovery in both countries. Aggregate wealth is back to about 5–6 years of national income in the 2000s to 2010s, just a bit below the pre-World War I level.

The other important finding that emerges from Figures 15.1 and 15.2 is that the composition of national wealth has changed in similar ways in both countries. Agricultural land, which made the majority of national capital in the eighteenth century, has been gradually replaced by real estate and other domestic capital, which is for the most part business capital (i.e., structures and equipment used by private firms). The nature of wealth has changed entirely reflecting a dramatic change in the structure of economic activity, and yet the total value of wealth is more or less the same as what it used to be before the Industrial Revolution.

Net foreign assets also made a large part of national capital in the late nineteenth century and on the eve of World War I: as much as 2 years of national capital in the case of Britain and over a year in the case of France. Net foreign-asset positions were brought back to zero in both countries following World War I and II shocks (including the loss of the colonial empires). In the late twentieth and early twenty-first centuries, net foreign positions are close to zero in both countries, just as in the eighteenth century. In the very long run, net foreign assets do not matter too much for the dynamics of the capital/income ratio in Britain or France. The main structural change is the replacement of agricultural land by housing and business capital.[11]

15.2.3 Old Europe Versus the New World

It is interesting to contrast the case of Old Europe—as illustrated by Britain and France—with that of the United States.

As Figure 15.3 shows, the aggregate value of wealth in the eighteenth to nineteenth centuries was markedly smaller in the New World than in Europe. At the time of the Declaration of Independence and in the early nineteenth century, national wealth in the United States was barely equal to 3–4 years of national income, about half that of Britain or France. Although available estimates are fragile, the order of magnitude again

[11] It is worth stressing that should we divide aggregate wealth by disposable household income (rather than national income), then today's ratios would be around 700–800% in Britain or France and would slightly surpass eighteenth to nineteenth century levels. This mechanically follows from the fact that disposable income was above 90% in the eighteenth to nineteenth centuries and is about 70–80% of disposable income in the late twentieth to early twenty-first century. The rising gap between disposable and household income reflects the rise of government-provided services, in particular in health and education. To the extent that these services are mostly useful (in their absence households would have to purchase them on the market), it is more justified for the purpose of historical and international comparisons to focus on ratios using national income as a denominator. For wealth–income ratios using disposable income as a denominator, see Piketty and Zucman (2014, Appendix, Figure A9).

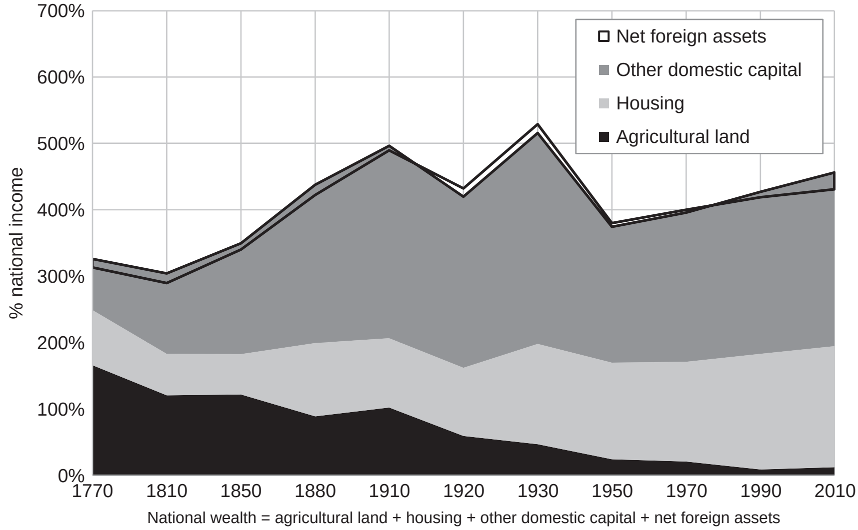

Figure 15.3 The changing level and nature of national wealth: United States 1770–2010.

appears to be robust. In Section 15.5, we will attempt to account for this interesting contrast. At this stage, we simply note that there are two obvious—and potentially complementary—factors that can play a role: first, there had been less time to save and accumulate wealth in the New World than in the Old World; second, there was so much land in the New World that it was almost worthless (its market value per acre was much less than in Europe).

The gap between the United States and Europe gradually reduces over the course of the nineteenth century, but still remains substantial. Around 1900–1910, national wealth is about 5 years of national income in the United States (see Figure 15.3) versus about 7 years in Britain and France. During the twentieth century, the U.S. wealth–income ratio also follows a U-shaped pattern, but less marked than in Europe. National wealth falls less sharply in the United States than in Europe following World War shocks, which seems rather intuitive. Interestingly, European wealth–income ratios have again surpassed U.S. ratios in the late twentieth and early twenty-first centuries.

This brief overview of wealth in the New World and Europe would be rather incomplete if we did not mention the issue of slavery. As one can see from Figure 15.4, the aggregate market value of slaves was fairly substantial in the United States until 1865: about 1–1.5 years of national income according to the best available historical sources. There were few slaves in Northern states, but in the South the value of the slave stock was so large that it approximately compensated—from the viewpoint of slave owners—the lower value of land as compared to the Old World (see Figure 15.5).

It is rather dubious, however, to include the market value of slaves into national capital. Slavery can be viewed as the most extreme form of debt: it should be counted as an

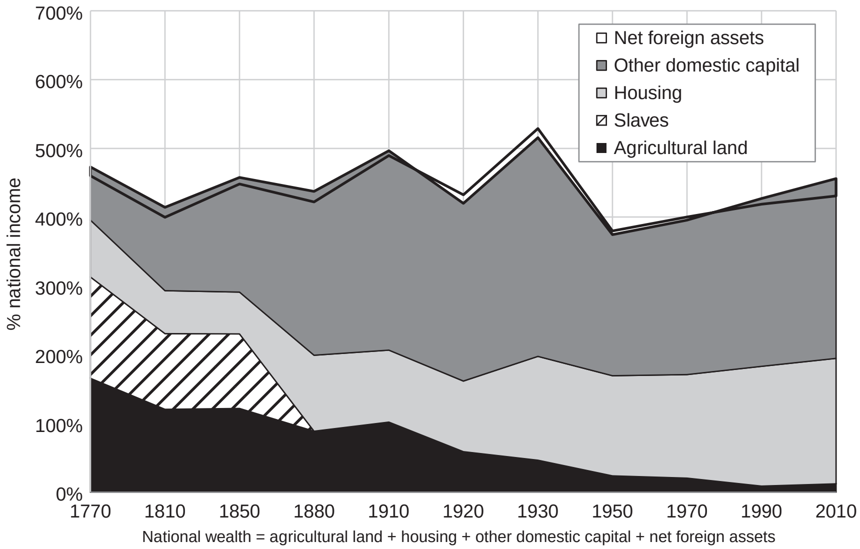

Figure 15.4 The changing level and nature of wealth: United States 1770–2010 (including slaves).

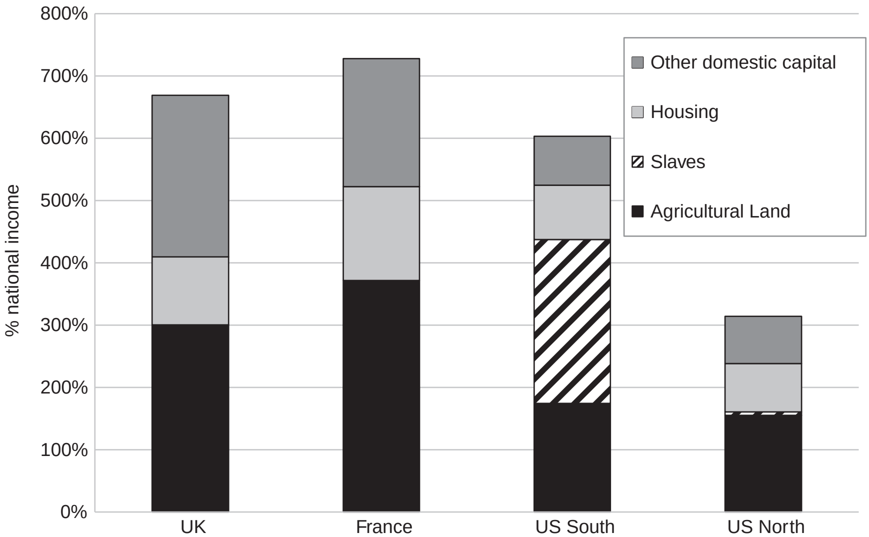

Figure 15.5 National wealth in 1770–1810: Old versus New World.

asset for the owners and a liability for the slaves, so that net national wealth should be unaffected. In the extreme case where a tiny elite owns the rest of the population, the total value of slaves—the total value of "human capital"—could be a lot larger than that of nonhuman capital (since the share of human labor in income is typically larger than

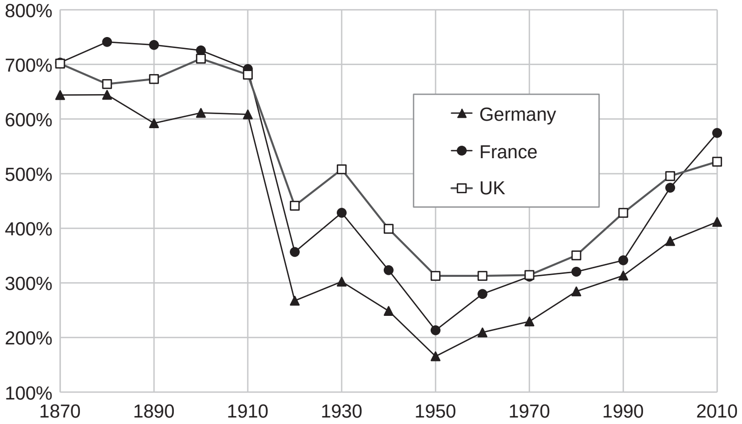
50%). If the rate of return r is equalized across all assets, then the aggregate value of human capital—expressed in proportion to national income—will be equal to $\beta_h = (1-\alpha)/r$, whereas the value of nonhuman capital will be given by $\beta_n = \alpha/r$, where α is the capital share and $1-\alpha$ the labor share implied by the production technology.[12] So for instance with $r=5\%$, $\alpha=30\%$, $1-\alpha=70\%$, the value of the human capital stock will be as large as $\beta_h=(1-\alpha)/r=1400\%$ (14 years of national income), and the value of the nonhuman capital stock will be $\beta_n=\alpha/r=600\%$ (6 years of national income). Outside of slave societies, however, it is unclear whether it makes much sense to compute the market value of human capital and to add it to nonhuman capital.

The computations reported on Figures 15.4 and 15.5 illustrate the ambiguous relationship of the New World with wealth, inequality, and property. To some extent, America is the land of opportunity, the place where wealth accumulated in the past does not matter too much. But it is also the place where a new form of wealth and class structure—arguably more extreme and violent than the class structure prevailing in Europe—flourished, whereby part of the population owned another part.

Available historical series suggest that the sharp U-shaped pattern for the wealth–income ratio in Britain and France is fairly representative of Europe as a whole. For Germany, the wealth–income ratio was approximately the same as for Britain and France in the late nineteenth and early twentieth centuries, then fell to a very low level in the aftermath of the World Wars, and finally has been rising regularly since the 1950s (see Figure 15.6). Although the German wealth–income ratio is still below that of the United Kingdom and France, the speed of the recovery over the past few decades has been similar.[13] On Figure 15.7, we compare the European wealth–income ratio (obtained as a simple average of Britain, France, Germany, and Italy, the latter being available only for the most recent decades) to the U.S. one. The European wealth–income ratio was substantially above that of the United States until World War I, then fell significantly below in the aftermath of World War II, and surpassed it again in the late twentieth and early twenty-first centuries (see Figure 15.7).

[12] That is, $1-\alpha$ is the marginal product of labor times the labor (slave) stock. The formula $\beta_h=(1-\alpha)/r$ implicitly assumes that the fraction of output that is needed to feed and maintain the slave stock is negligible (otherwise it would just need to be deducted from $1-\alpha$), and that labor productivity is unaffected by the slavery condition (this is a controversial issue).

[13] The factors that can explain the lower German wealth–income ratio are the following. Real estate prices have increased far less in Germany than in Britain or France, which could be due in part to the lasting impact of German reunification and to stronger rent regulations. This could also be temporary. Next, the lower market value of German firms could be due to a stakeholder effect. Finally, the return to the German foreign portfolio, where a large part of German savings were directed, was particularly low in the most recent period. See Piketty and Zucman (2014, Section V.C) and Piketty (2014, Chapter 3).



Private wealth = nonfinancial assets + financial assets–financial liabilities (household & nonprofit sectors).

15.2.4 The Return of High Wealth–Income Ratios in Rich Countries

Turning now to the 1970–2010 period, for which we have annual series covering most rich countries, the rise of wealth–income ratios, particularly private wealth–national income ratios, appears to be a general phenomenon. In the top eight developed economies, private wealth is between 2 and 3.5 years of national income around 1970, and between 4 and 7 years of national income around 2010 (see Figure 15.8). Although there are chaotic short-run fluctuations (reflecting the short-run volatility of asset prices),

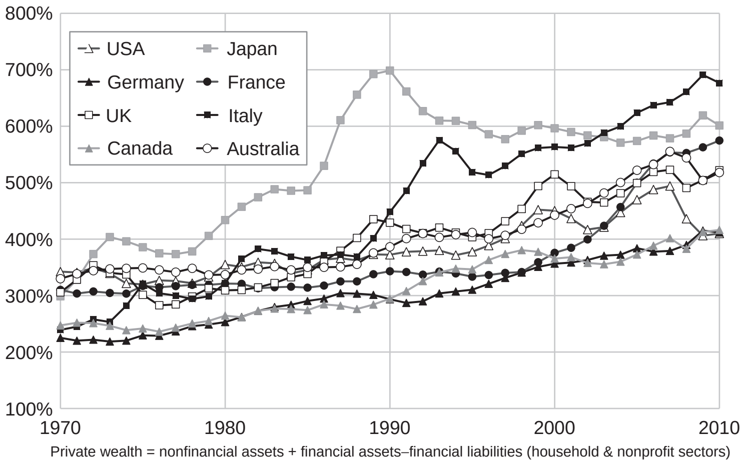

Figure 15.8 Private wealth/national income ratios, 1970–2010.

the long-run trend is clear. Take Japan. The huge asset price bubble of the late 1980s should not obscure the 1970–2010 rise of the wealth–income ratio, fairly comparable in magnitude to what we observe in Europe. (For instance, the Japanese and Italian patterns are relatively close: both countries go from about 2–3 years of national income in private wealth around 1970 to 6–7 years by 2010.)

Although we do not have national wealth estimates for Japan for the late nineteenth and early twentieth centuries, there are reasons to believe that the Japanese wealth–income ratio has also followed a U-shaped evolution in the long run, fairly similar to that observed in Europe over the twentieth century. That is, it seems likely that the wealth–income ratio was relatively high in the early twentieth century, fell to low levels in the aftermath of World War II, and then followed the recovery process that we see in Figure 15.8.[14]

To some extent, the rise of private wealth–national income ratios in rich countries since the 1970s is related to the decline of public wealth (see Figure 15.9). Public wealth has declined virtually everywhere owing both to the rise of public debt and the privatization of public assets. In some countries, such as Italy, public wealth has become strongly negative. The rise in private wealth, however, is quantitatively much larger than the decline in public wealth. As a result, national wealth—the sum of private and public wealth—has increased substantially, from 250–400% of national income in 1970 to 400–650% in 2010 (see Figure 15.10). In Italy, for instance, net government wealth fell by the equivalent of about 1 year of national income, but net private wealth rose by over

[14] The early twentieth century Japanese inheritance tax data reported by Morigushi and Saez (2008) are consistent with this interpretation.

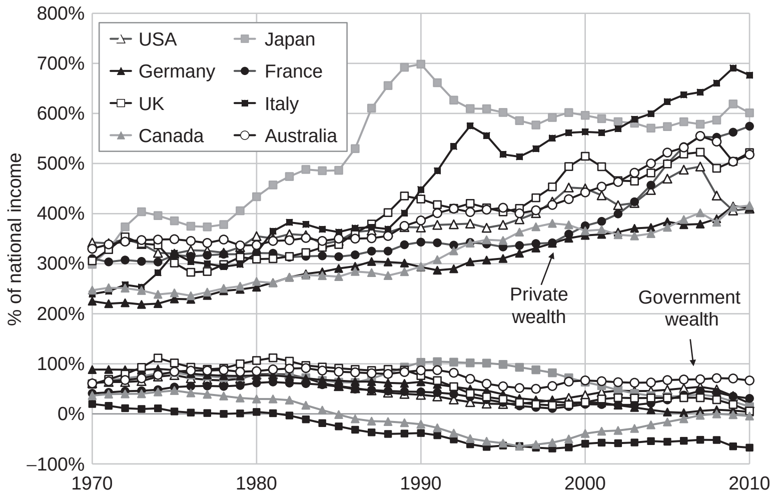

Figure 15.9 Private versus government wealth, 1970–2010.

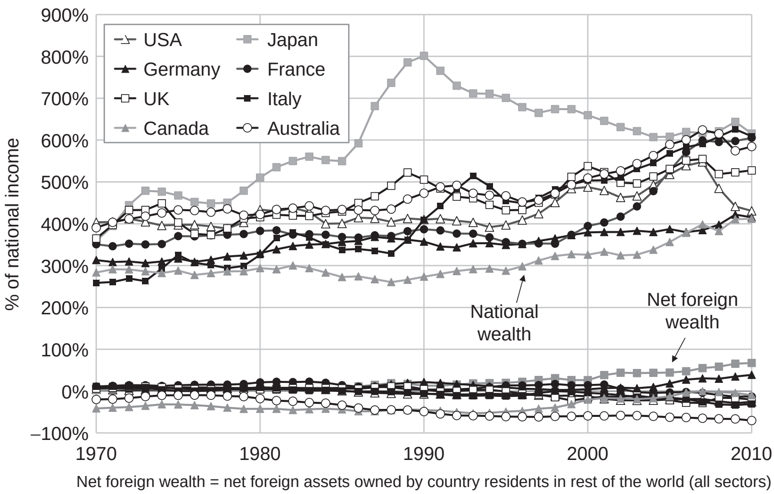

Figure 15.10 National versus foreign wealth, 1970–2010.

4 years of national income, so that national wealth increased by the equivalent of over 3 years of national income.

Figure 15.10 also depicts the evolution of net foreign wealth. Net foreign asset positions are generally small compared to national wealth. In other words, the evolution of national wealth–national income ratios mostly reflects the evolution of domestic capital–output ratios. There are two caveats, however. First, gross cross-border positions have risen a lot in recent decades, which can generate large portfolio valuation effects at the country level. Second, Japan and Germany have accumulated significant net foreign wealth (with net positions around 40% and 70% of national income, respectively, in 2010). Although these are still much smaller than the positions held by France and Britain on the eve of World War I (around 100% and 200% of national income, respectively), they are becoming relatively large (and were rising fast in the case of Germany in the first half of the 2010s, due to the large German trade surpluses).

15.3. THE LONG-RUN EVOLUTION OF WEALTH CONCENTRATION

15.3.1 Concepts, Data Sources, and Methods

We now turn to the evidence on the long-run evolution of wealth concentration. This question can be studied with different data sources (see Davies and Shorrocks, 1999, for a detailed discussion). Ideally, one would want to use annual wealth tax declarations for the entire population. Annual wealth taxes, however, often do to exist, and when they do, the data generally do not cover long periods of time.

The key source used to study the long-run evolution of wealth inequality has traditionally been inheritance and estate tax declarations.[15] By definition, estates and inheritance returns only provide information about wealth at death. The standard way to use inheritance tax data to study wealth concentration was invented over a century ago. Shortly before World War I, a number of British and French economists developed what is known as the mortality multiplier technique, whereby wealth-at-death is weighted by the inverse of the mortality rate of the given age and wealth group in order to generate estimates for the distribution of wealth among the living.[16] This approach was later followed in the United States by Lampman (1962) and Kopczuk and Saez (2004), who use estate tax data covering the 1916–1956 and 1916–2000 periods, respectively, and in the United Kingdom by Atkinson and Harrison (1978), who exploit inheritance tax data covering the 1922–1976 period.

To measure historical trends in the distribution of wealth, one can also use individual income tax returns and capitalize the dividends, interest, rents, and other forms of capital income declared on such returns. The capitalization technique was pioneered by King (1927), Stewart (1939), Atkinson and Harrison (1978), and Greenwood (1983), who used it to estimate the distribution of wealth in the United Kingdom and in the United States for some years in isolation. To obtain reliable results, it is critical to have detailed income data, preferably at the micro level, and to carefully reconcile the tax data with household balance sheets, so as to compute the correct capitalization factors. Drawing

[15] The difference between inheritance and estate taxes is that inheritance taxes are computed at the level of each inheritor, whereas estate taxes are computed at the level of the total estate (total wealth left by the decedent). The raw data coming from these two forms of taxes on wealth transfers are similar.

[16] See Mallet (1908), Séaillès (1910), Strutt (1910), Mallet and Strutt (1915), and Stamp (1919).

on the very detailed U.S. income tax data and Flow of Funds balance sheets, Saez and Zucman (2014) use the capitalization technique to estimate the distribution of U.S. wealth annually since 1913.

For the recent period, one can also use wealth surveys. Surveys, however, are never available on a long-run basis and raise serious difficulties regarding self-reporting biases, especially at the top of the distribution. Tax sources also raise difficulties at the top, especially for the recent period, given the large rise of offshore wealth (Zucman, 2013). Generally speaking, it is certainly more difficult for the recent period to accurately measure the concentration of wealth than the aggregate value of wealth, and one should be aware of this limitation. One needs to be pragmatic and combine the various available data sources (including the global wealth rankings published by magazines such as *Forbes*, which we will refer to in Section 15.5).

The historical series that we analyze in this chapter combines works by many different authors (more details below), who mostly relied on estate and inheritance tax data. They all relate to the inequality of wealth among the living.

We focus on simple concentration indicators, such as the share of aggregate wealth going to the top 10% individuals with the highest net wealth and the share going to the top 1%. In every country and historical period for which we have data, the share of aggregate wealth going to the bottom 50% is extremely small (usually less than 5%). So a decline in the top 10% wealth share can for the most part be interpreted as a rise in the share going to the middle 40%. Note also that wealth concentration is usually almost as large within each age group as for the population taken as a whole.[17]

15.3.2 The European Pattern: France, Britain, and Sweden, 1810–2010

15.3.2.1 France

We start with the case of France, the country for which the longest time series is available. French inheritance tax data is exceptionally good, for one simple reason. As early as 1791, shortly after the abolition of the tax privileges of the aristocracy, the French National Assembly introduced a universal inheritance tax, which has remained in force since then. This inheritance tax was universal because it applied both to bequests and to inter-vivos gifts, at any level of wealth, and for nearly all types of property (both tangible and financial assets). The key characteristic of the tax is that the successors of all decedents with positive wealth, as well as all donees receiving a positive gift, have always been required to file a return, no matter how small the estate was, and no matter whether any tax was ultimately owed.

In other countries, available data are less long run and/or less systematic. In the United Kingdom, one has to wait until 1894 for the unification of inheritance taxation (until this date the rules were different for personal and real estate taxes), and until the early 1920s

[17] See, e.g., Atkinson (1983) and Saez and Zucman (2014).

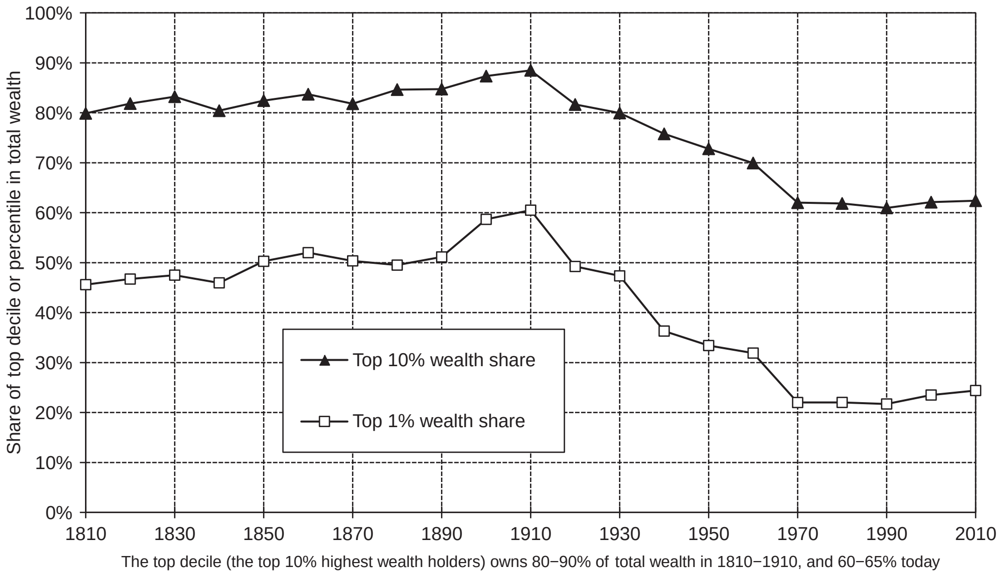

Figure 15.11 Wealth inequality in France, 1810–2010.

for unified statistics to be established by the U.K. tax administration. In the United States, one has to wait until 1916 for the creation of a federal estate tax and the publication of federal statistics on inheritance.

In addition, individual-level inheritance tax declarations have been well preserved in French national archives since the time of the revolution, so that one can use tax registers to collect large representative micro samples. Together with the tabulations by inheritance brackets published by the French tax administration, this allows for a consistent study of wealth inequality over a two-century-long period (see Piketty et al., 2006, 2013).

The main results are summarized on Figures 15.11 and 15.12.[18] First, wealth concentration was very high—and rising—in France during the nineteenth and early twentieth centuries. There was no decline in wealth concentration prior to World War I, quite the contrary: the trend toward rising wealth concentration did accelerate during the 1870–1913 period. The orders of magnitude are quite striking: in 1913, the top 10% wealth share is about 90%, and the top 1% share alone is around 60%. In Paris, which hosts about 5% of the population but as much as 25% of aggregate wealth, wealth is even more concentrated: more than two-thirds of the population has zero or negligible wealth, and 1% of the population owns 70% of the wealth.

[18] The updated series used for Figures 15.11 and 15.12 are based on the historical estimates presented by Piketty et al. (2006) and more recent fiscal data. See Piketty (2014, Chapter 10, Figures 10.1–10.2).

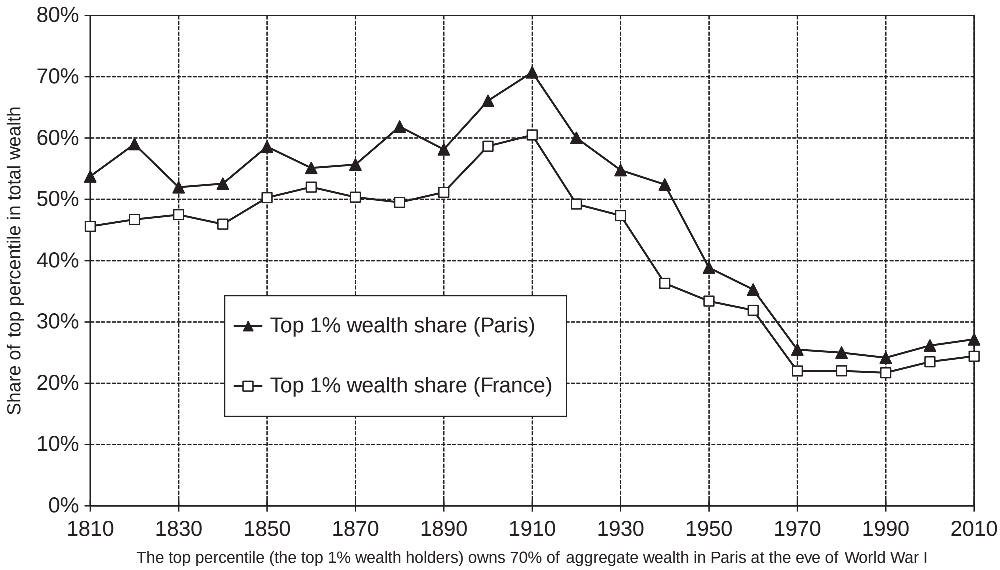

Figure 15.12 Wealth inequality: Paris versus France, 1810–2010.

Looking at Figures 15.11 and 15.12, one naturally wonders whether wealth concentration would have kept increasing without the 1914–1945 shocks. It might have stabilized at a very high level, but it could also have started to decline at some point. In any case, it is clear that the war shocks induced a violent regime change.

The other interesting fact is that wealth concentration has started to increase again in France since the 1970s–1980s—but it is still much lower than on the eve of World War I. According to the most recent data, the top 10% wealth share is slightly above 60%. Given the relatively low quality of today's wealth data, especially regarding top global wealth holders, one should be cautious about this estimate. It could well be that we somewhat underestimate the recent rise and the current level of wealth concentration.[19] In any case, a share of 60% for the top decile is already high, especially compared to the concentration of labor income: the top 10% of labor earners typically receive less than 30% of aggregate labor income.

15.3.2.2 Britain

Although the data sources for other countries are not as systematic and comprehensive as the French sources, existing evidence suggests that the French pattern extends to other European countries. For the United Kingdom, on Figure 15.13, we have combined historical estimates provided by various authors—particularly Atkinson and Harrison (1978)

[19] In contrast, the nineteenth and early twentieth centuries estimates are probably more precise (the tax rates were so low at that time that there was little incentive to hide wealth).

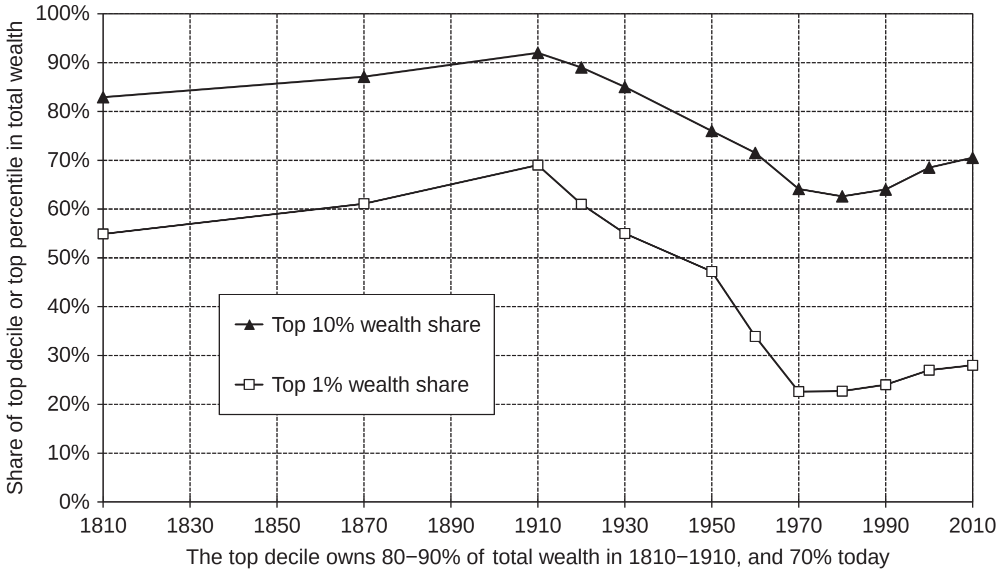

Figure 15.13 Wealth inequality in the United Kingdom, 1810–2010.

and Lindert (1986)—as well as more recent estimates using inheritance tax data. These series are not fully homogenous (in particular, the nineteenth century computations are based on samples of private probate records and are not entirely comparable to the twentieth-century inheritance tax data), but they deliver a consistent picture. Wealth concentration was high and rising during the nineteenth century up until World War I, then fell abruptly following the 1914–1945 shocks, and has been rising again since the 1980s.

According to these estimates, wealth concentration was also somewhat larger in the United Kingdom than in France in the nineteenth and early twentieth centuries. Yet the gap is much smaller than what French contemporary observers claimed. Around 1880–1910, it was very common among French republican elites to describe France as a "country of little property owners" (*un pays de petits propriétaires*), in contrast to aristocratic Britain. Therefore, the argument goes, there was no need to introduce progressive taxation in France (this should be left to Britain). The data show that on the eve of World War I the concentration of wealth was almost as extreme on both sides of the channel: the top 10% owns about 90% of wealth in both countries, and the top 1% owns 70% of wealth in Britain, versus 60% in France. It is true that aristocratic landed estates were more present in the United Kingdom (and to some extent still are today). But given that the share of agricultural land in national wealth dropped to low levels during the nineteenth century (see Figures 15.1 and 15.2), this does not matter much. At the end of the day, whether the country is a republic or a monarchy seems to have little impact on wealth concentration in the long run.

15.3.2.3 Sweden

Although widely regarded as an egalitarian haven today, Sweden was just as unequal as France and Britain in the nineteenth and early twentieth centuries. This is illustrated by Figure 15.13, where we plot some of the estimates constructed by Roine and Waldenstrom (2009) and Waldenstrom (2009).

The concentration of wealth is quite similar across European countries, both for the more ancient and the more recent estimates. Beyond national specificities, a European pattern emerges: the top 10% wealth share went from about 90% around 1900–1910 to about 60–70% in 2000–2010, with a recent rebound. In other words, about 20–30% of national wealth has been redistributed away from the top 10% to the bottom 90%. Since most of this redistribution benefited the middle 40% (the bottom 50% still hardly owns any wealth), this evolution can be described as the rise of a patrimonial middle class (Figure 15.14).

In the case of Sweden, Roine and Waldenstrom (2009) have also computed a corrected top 1% of wealth shares using estimates of offshore wealth held abroad by rich Swedes. They find that under plausible assumptions the top 1% share would shift from about 20% of aggregate wealth to over 30% (i.e., approximately the levels observed in the United Kingdom, and not too far away from the level observed in the United States). This illustrates the limitations of our ability to measure recent trends and levels, given the rising importance of tax havens.

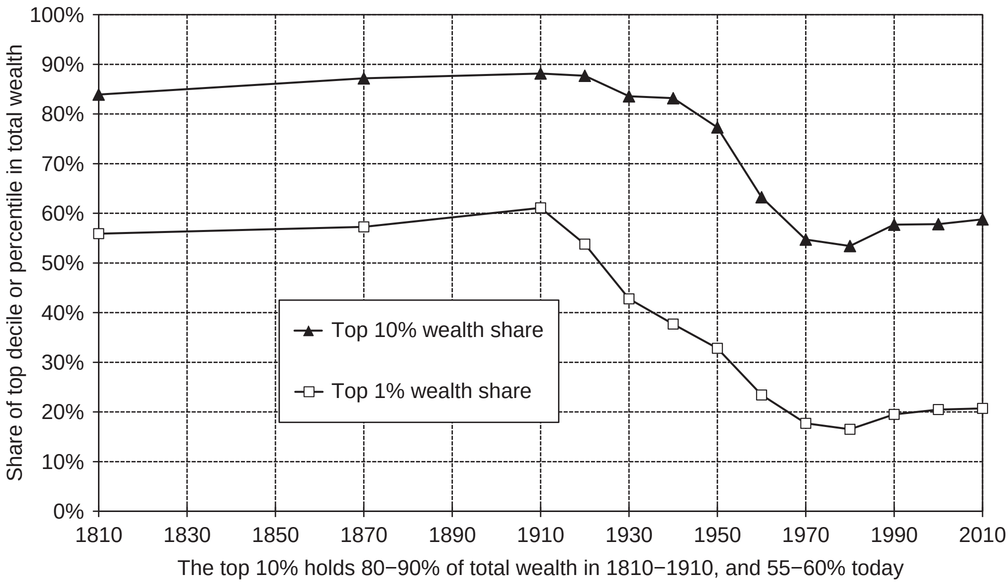

Figure 15.14 Wealth inequality in Sweden, 1810–2010.

15.3.3 The Great Inequality Reversal: Europe Versus the United States, 1810–2010

Comparing wealth concentration in Europe and the United States, the main finding is a fairly spectacular reversal. In the nineteenth century, the United States was to some extent the land of equality (at least for white men): the concentration of wealth was much less extreme than in Europe (except in the South). Over the course of the twentieth century, this ordering was reversed: wealth concentration has become significantly higher in the United States. This is illustrated by Figure 15.15, where we combine the estimates due to Lindert (2000) for the nineteenth century with those of Saez and Zucman (2014) for the twentieth and twenty-first centuries to form long-run U.S. series, and by Figure 15.16, where we compare the United States to Europe (defined as the arithmetic average of France, Britain, and Sweden).

The reversal comes from the fact that Europe has become significantly less unequal over the course of the twentieth century, whereas the United States has not. The United States has almost returned to its early twentieth-century wealth concentration level: at its peak in the late 1920s, the 10% wealth share was about 80%, in 2012 it is about 75%; similarly the top 1% share peaked at about 45% and is back to around 40% today. Note, however, that the United States never reached the extreme level of wealth concentration of nineteenth- and early twentieth-century Europe (with a top decile of 90% or more). The United States has always had a patrimonial middle class, although one of varying importance. The share of wealth held by the middle class appears to have been shrinking since the 1980s.

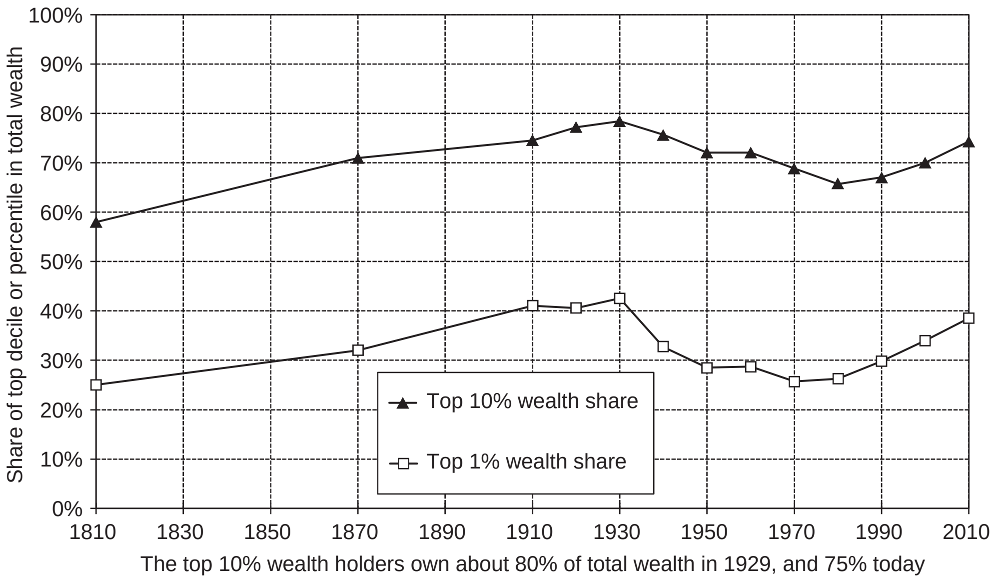

Figure 15.15 Wealth inequality in the United States, 1810–2010.

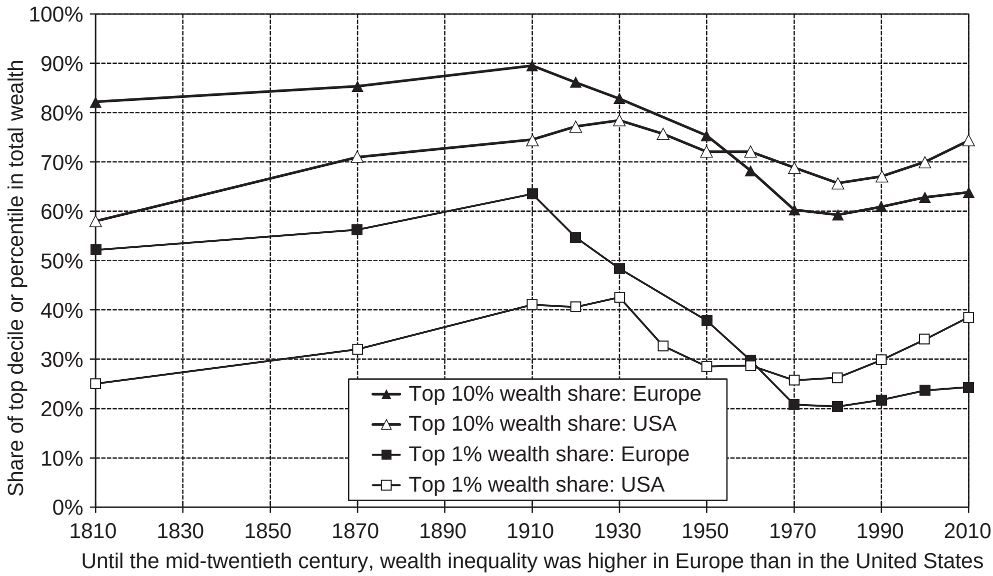

Figure 15.16 Wealth inequality: Europe and the United States, 1810–2010.

U.S. economists of the early twentieth century were very concerned about the possibility that their country becomes as unequal as Old Europe. Irving Fisher, then president of the American Economic Association, gave his presidential address in 1919 on this topic. He argued that the concentration of income and wealth was becoming as dangerously excessive in America as it had been for a long time in Europe. He called for steep tax progressivity to counteract this tendency. Fisher was particularly concerned about the fact that as much as half of U.S. wealth was owned by just 2% of U.S. population, a situation that he viewed as "undemocratic" (see Fisher, 1920). One can indeed interpret the spectacular rise of tax progressivity that occurred in the United States during the first half of the twentieth century as an attempt to preserve the egalitarian, democratic American ethos (celebrated a century before by Tocqueville and others). Attitudes toward inequality are dramatically different today. Many U.S. observers now view Europe as excessively egalitarian (and many European observers view the United States as excessively nonegalitarian).

15.4. THE LONG-RUN EVOLUTION OF THE SHARE OF INHERITED WEALTH

15.4.1 Concepts, Data Sources, and Methods

We now turn to our third ratio of interest, the share of inherited wealth in aggregate wealth. We should make clear at the outset that this is an area where available evidence is scarce and incomplete. Measuring the share of inherited wealth requires a lot more data than the measurement of aggregate wealth–income ratios or even wealth concentration. It is also an area where it is important to be particularly careful about concepts and definitions. Purely definitional conflicts have caused substantial confusion in the past. Therefore it is critical to start from there.

15.4.1.1 Basic Notions and Definitions

The most natural way to define the share of inherited wealth in aggregate wealth is to cumulate past inheritance flows. That is, assume that we observe the aggregate wealth stock W_t at time t in a given country, and that we would like to define and estimate the aggregate inherited wealth stock $W_{Bt} \leq W_t$ (and conversely aggregate self-made wealth, which we simply define as $W_{St} = W_t - W_{Bt}$). Assume that we observe the annual flow of inheritance B_s that occurred in any year $s \leq t$. At first sight, it might seem natural to define the stock of inherited wealth W_{Bt} as the sum of past inheritance flows:

$$W_{Bt} = \int_{s \leq t} B_s \cdot \mathrm{d}s$$

However, there are several practical and conceptual difficulties with this ambiguous definition, which need to be addressed before the formula can be applied to actual data. First, it is critical to include in this sum not only past bequest flows B_s (wealth transmissions at death) but also inter vivos gift flows V_s (wealth transmissions inter vivos). That is, one should define W_{Bt} as $W_{Bt} = \int_{s \leq t} B_s^{*} \cdot \mathrm{d}s$, with $B_s^{*} = B_s + V_s$.

Alternatively, if one cannot observe directly the gift flow V_s, one should replace the observed bequest flow B_s by some gross level $B_s^{*} = (1 + v_s) \cdot B_s$, where $v_s = V_s / B_s$ is an estimate of the gift/bequest flow ratio. In countries where adequate data is available, the gift–bequest ratio is at least 10–20%, and is often higher than 50%, especially in the recent period.[20] It is thus critical to include gifts in one way or another. In countries where fiscal data on gifts are insufficient, one should at least try to estimate $1 + v_s$ using surveys (which often suffers from severe downward biases) and harder administrative evidence from other countries.

Next, to properly apply this definition, one should only take into account the fraction of the aggregate inheritance flow $B_{st} \leq B_s$ that was received at time s by individuals who are still alive at time t. The problem is that doing so properly requires very detailed individual-level information. At any time t, there are always individuals who received inheritance a very long time ago (say, 60 years ago) but who are still alive (because they inherited at a very young age and/or are enjoying a very long life). Conversely, a fraction

[20] See below. Usually one only includes formal, monetary capital gifts, and one ignores informal presents and in-kind gifts. In particular in-kind gifts made to minors living with their parents (i.e., the fact that minor children are usually catered by their parents) are generally left aside.

of the inheritance flow received a short time ago (say, 10 years ago) should not be counted (because the relevant inheritors are already dead, e.g., they inherited at an old age or died young). In practice, however, such unusual events tend to balance each other, so that a standard simplifying assumption is to cumulate the full inheritance flows observed the previous H years, where H is the average generation length, that is, the average age at which parents have children (typically $H = 30$ years). Therefore we obtain the following simplified definition:

$$W_{Bt} = \int_{t-30 \leq s \leq t} (1 + v_s) \cdot B_s \cdot \mathrm{d}s$$

15.4.1.2 The Kotlikoff–Summers–Modigliani Controversy

Assume now that these two difficulties can be addressed (i.e., that we can properly estimate the factor $1 + v_s$ and the average generation length H). There are more substantial difficulties ahead. First, to properly compute W_{Bt}, one needs to be able to observe inheritance flows B_s^* over a relatively long time period (typically, the previous 30 years). In the famous Kotlikoff–Summers–Modigliani (KSM) controversy, both Kotlikoff and Summers (1981) and Modigliani (1986, 1988) used estimates of the U.S. inheritance flow for only 1 year (and a relatively ancient year: 1962), see also Kotlikoff (1988). They simply assumed that this estimate could be used for other years. Namely, they assumed that the inheritance flow–national income ratio (which we note $b_{ys} = B_s^*/Y_s$) is stable over time. One problem with this assumption is that it might not be verified. As we shall see below, extensive historical data on inheritances recently collected in France show that the b_{ys} ratio has changed tremendously over the past two centuries, from about 20–25% of national income in the nineteenth and early twentieth centuries, down to less than 5% at mid-twentieth century, back to about 15% in the early twenty-first century (Piketty, 2011). So one cannot simply use one year of data and assume that we are in a steady state: One needs a long-run time series on the inheritance flow in order to estimate the aggregate stock of inherited wealth.

Next, one needs to decide the extent to which past inheritance flows need to be upgraded or capitalized. This is the main source of disagreement and confusion in the KSM controversy.

Modigliani (1986, 1988) chooses zero capitalization. That is, he simply defines the stock of inherited wealth W_{Bt}^M as the raw sum of past inheritance flows with no adjustment whatsoever (except for the GDP price index):

$$W_{Bt}^M = \int_{t-30 \leq s \leq t} B_s^* \cdot \mathrm{d}s$$

Assume a fixed inheritance flow–national income ratio $b_y = B_s^*/Y_s$, growth rate g (so that $Y_t = Y_s \cdot e^{g(t-s)}$), generation length H, and aggregate private wealth–national income ratio

$\beta = W_t/Y_t$. Then, according to the Modigliani definition, the steady-state formulas for the stock of inherited wealth relative to national income W_{Bt}^M/Y_t and for the share of inherited wealth $\varphi_t^M = W_{Bt}^M/W_t$ are given by

$$W_{Bt}^M/Y_t = \frac{1}{Y_t}\int_{t-30\leq s\leq t} B_s^*\cdot \mathrm{d}s = \frac{1-\mathrm{e}^{-gH}}{g}\cdot b_y$$

$$\varphi_t^M = W_{Bt}^M/W_t = \frac{1-\mathrm{e}^{-gH}}{g}\cdot\frac{b_y}{\beta}$$

In contrast, Kotlikoff and Summers (1981, 1988) choose to capitalize past inheritance flows by using the economy's average rate of return to wealth (assuming it is constant and equal to r). Following the Kotlikoff–Summers definition, the steady-state formulas for the stock of inherited wealth relative to national income W_{Bt}^{KS}/Y_t and for the share of inherited wealth $\varphi_t^{KS} = W_{Bt}^{KS}/W_t$ are given by

$$W_{Bt}^{KS}/Y_t = \frac{1}{Y_t}\int_{t-30\leq s\leq t} \mathrm{e}^{r(t-s)}\cdot B_s^*\cdot \mathrm{d}s = \frac{\mathrm{e}^{(r-g)H}-1}{r-g}\cdot b_y$$

$$\varphi_t^{KS} = W_{Bt}^{KS}/W_t = \frac{\mathrm{e}^{(r-g)H}-1}{r-g}\cdot\frac{b_y}{\beta}$$

In the special case where growth rates and rates of return are negligible (i.e., infinitely close to zero), then both definitions coincide. That is, if $g=0$ and $r-g=0$, then $(1-\mathrm{e}^{-gH})/g = (\mathrm{e}^{(r-g)H}-1)/(r-g) = H$, so that $W_{Bt}^M/Y_t = W_{Bt}^{KS}/Y_t = Hb_y$ and $\varphi_t^M = \varphi_t^{KS} = Hb_y/\beta$.

Thus, in case growth and capitalization effects can be neglected, one simply needs to multiply the annual inheritance flow by generation length. If the annual inheritance flow is equal to $b_y = 10\%$ of national income, and generation length is equal to $H = 30$ years, then the stock of inherited wealth is equal to $W_{Bt}^M = W_{Bt}^{KS} = 300\%$ of national income according to both definitions. In case aggregate wealth amounts to $\beta = 400\%$ of national income, then the inheritance share is equal to $\varphi_t^M = \varphi_t^{KS} = 75\%$ of aggregate wealth.

However, in the general case where g and $r-g$ are significantly different from zero, the two definitions can lead to widely different conclusions. For instance, with $g = 2\%$, $r = 4\%$, and $H = 30$, we have the following capitalization factors: $(1-\mathrm{e}^{-gH})/(g\cdot H) = 0.75$ and $(\mathrm{e}^{(r-g)H}-1)/((r-g)\cdot H) = 1.37$. In this example, for a given inheritance flow $b_y = 10\%$ and aggregate wealth–income ratio $\beta = 400\%$, we obtain $\varphi_t^M = 56\%$ and $\varphi_t^{KS} = 103\%$. About half of wealth comes from inheritance according to the Modigliani definition, and all of it according to the Kotlikoff–Summers definition.

This is the main reason why Modigliani and Kotlikoff–Summers disagree so much about the inheritance share. They both use the same (relatively fragile) estimate for the United States b_y in 1962. But Modigliani does not capitalize past inheritance flows and concludes that the inheritance share is as low as 20–30%. Kotlikoff–Summers do capitalize the same flows and conclude that the inheritance share is as large as 80–90% (or even larger than 100%). Both sides also disagree somewhat about the measurement of b_y, but the main source of disagreement comes from this capitalization effect.[21]

15.4.1.3 The Limitations of KSM Definitions

Which of the two definitions is most justified? In our view, both are problematic. It is wholly inappropriate not to capitalize at all past inheritance flows. But full capitalization is also inadequate.

The key problem with the KSM representative-agent approach is that it fails to recognize that the wealth accumulation process always involves two different kinds of people and wealth trajectories. In every economy, there are inheritors (people who typically consume part of the return to their inherited wealth) and there are savers (people who do not inherit much but do accumulate wealth through labor income savings). This is an important feature of the real world that must be taken into account for a proper understanding of the aggregate wealth accumulation process.

The Modigliani definition is particularly problematic as it simply fails to recognize that inherited wealth produces flow returns. This mechanically leads to artificially low numbers for the inheritance share φ_t^M (as low as 20–40%), and to artificially high numbers for the life-cycle share in wealth accumulation, which Modigliani defines as $1-\varphi_t^M$ (up to 60–80%). As Blinder (1988) argues, "a Rockefeller with zero lifetime labor income and consuming only part of his inherited wealth income would appear to be a life-cycle saver in Modigliani's definition, which seems weird to me." One can easily construct illustrative examples of economies where all wealth comes from inheritance (with dynasties of the sort described by Blinder), but where Modigliani would still find an inheritance share well below 50%, simply because of his definition. This makes little sense.[22]

The Kotlikoff–Summers definition is conceptually more satisfactory than Modigliani's. But it suffers from the opposite drawback in the sense that it mechanically leads to artificially high numbers for the inheritance share φ_t^{KS}. In particular, φ_t^{KS} can easily be larger than 100%, even though there are life-cycle savers and self-made wealth accumulators in the economy, and a significant fraction of aggregate wealth accumulation comes from them. This will arise whenever the cumulated return to inherited wealth

[21] In effect, Modigliani favors a b_y ratio around 5–6%, whereas Kotlikoff–Summers find it more realistic to use a b_y ratio around 7–8%. Given the data sources they use, it is likely that both sides tend to somewhat underestimate the true ratio. See the discussion below for the case of France and other European countries.

[22] It is worth stressing that the return to inherited wealth (and the possibility to save and accumulate more wealth out of the return to inherited wealth) is a highly relevant economic issue not only for high-wealth dynasties of the sort referred to by Blinder, but also for middle-wealth dynasties. For instance, it is easier to save if one has inherited a house and has no rent to pay. An inheritor saving less than the rental value of his inherited home would be described as a life-cycle saver according to Modigliani's definition, which again seems odd.

consumed by inheritors exceeds the savers' wealth accumulation from their labor savings. In the real world, this condition seems to hold not only in prototype rentier societies such as Paris 1872–1937 (see Piketty et al., 2013), but also in countries and time periods when aggregate inheritance flow is relatively low. For instance, aggregate French series show that the capitalized bequest share φ_t^{KS} has been larger than 100% throughout the twentieth century, including in the 1950s–1970s, a period where a very significant amount of new self-made wealth was accumulated (Piketty, 2011).

In sum, the Modigliani definition leads to estimates of the inheritance share that are artificially close to 0%, whereas the Kotlikoff–Summers leads to inheritance shares that tend to be structurally above 100%. Neither of them offers an adequate way to look at the data.

15.4.1.4 The PPVR Definition

In an ideal world with perfect data, the conceptually consistent way to define the share of inherited wealth in aggregate wealth is the following. It has first been formalized and applied to Parisian wealth data by Piketty et al. (2013), so we refer to it as the PPVR definition.

The basic idea is to split the population into two groups. First, there are "inheritors" (or "rentiers"), whose assets are worth less than the capitalized value of the wealth they inherited (over time they consume more than their labor income). The second group is composed of "savers" (or "self-made individuals"), whose assets are worth more than the capitalized value of the wealth they inherited (they consume less than their labor income). Aggregate inherited wealth can then be defined as the sum of inheritors' wealth plus the inherited fraction of savers' wealth, and self-made wealth as the noninherited fraction of savers' wealth. By construction, inherited and self-made wealth are less than 100% and sum to aggregate wealth, which is certainly a desirable property. Although the definition is fairly straightforward, it differs considerably from the standard KSM definitions based on representative agent models. The PPVR definition is conceptually more consistent and provides a more meaningful way to look at the data and to analyze the structure of wealth accumulation processes. In effect, it amounts to defining inherited wealth at the individual level as the minimum between current wealth and capitalized inheritance.

More precisely, consider an economy with population N_t at time t. Take a given individual i with wealth w_{ti} at time t. Assume he or she received bequest b_{ti}^0 at time $t_i < t$. Note $b_{ti}^* = b_{ti}^0 \cdot e^{r(t-t_i)}$ the capitalized value of b_{ti}^0 at time t (where $e^{r(t-ti)}$ is the cumulated rate of return between time t_i and time t). Individual i is said to be an "inheritor" (or a "rentier") if $w_{ti} < b_{ti}^*$ and a "saver" (or a "self-made individual") if $w_{ti} \geq b_{ti}^*$. We define the set of inheritors as $N_t^r = \{i \,\mathrm{s.t.}\, w_{ti} < b_{ti}^*\}$ and the set of savers as $N_t^s = \{i \,\mathrm{s.t.}\, w_{ti} \geq b_{ti}^*\}$.

We note $\rho_t = N_t^r/N_t$ and $1-\rho_t = N_t^s/N_t$ as the corresponding population shares of inheritors and savers; $w_t^r = E(w_{ti}|w_{ti} < b_{ti}^*)$ and $w_t^s = E(w_{ti}|w_{ti} \geq b_{ti}^*)$ as the average wealth levels of both groups; $br_t^* = E(b_{ti}^*|w_{ti} < b_{ti}^*)$ and $bs_t^* = E(b_{ti}^*|w_{ti} \geq b_{ti}^*)$ as the levels of their average capitalized bequest; and $\pi_t = \rho_t \cdot w_t^r / w_t$ and $1-\pi_t = (1-\rho_t)\cdot w_t^s / w_t$ as the share of inheritors and savers in aggregate wealth.

We define the total share φ_t of inherited wealth in aggregate wealth as the sum of inheritors' wealth plus the inherited fraction of savers' wealth, and the share $1-\varphi_t$ of self-made wealth as the noninherited fraction of savers' wealth:

$$\varphi_t = \left[\rho_t \cdot w_t^r + (1-\rho_t)\cdot b_t^{s*}\right]/w_t = \pi_t + (1-\rho_t)\cdot b_t^{s*}/w_t$$

$$1-\varphi_t = (1-\rho_t)\cdot\left(w_t^s - b_t^{s*}\right)/w_t = 1-\pi_t-(1-\rho_t)\cdot b_t^{s*}/w_t$$

The downside of this definition is that it is more demanding in terms of data availability. Although Modigliani and Kotlikoff–Summers could compute inheritance shares in aggregate wealth by using aggregate data only, the PPVR definition requires micro data. Namely, we need data on the joint distribution $G_t(w_{ti}, b_{ti}^*)$ of current wealth w_{ti} and capitalized inherited wealth b_{ti}^* in order to compute ρ_t, π_t, and φ_t. This does require high-quality, individual-level data on wealth and inheritance over two generations, which is often difficult to obtain. It is worth stressing, however, that we do not need to know anything about the individual labor income or consumption paths (y_{Lsi}, c_{si}, $s<t$) followed by individual i up to the time of observation.[23]

For plausible joint distributions $G_t(w_{ti}, b_{ti}^*)$, the PPVR inheritance share φ_t will typically fall somewhere in the interval $[\varphi_t^M, \varphi_t^{KS}]$. There is, however, no theoretical reason why it should be so in general. Imagine, for instance, an economy where inheritors consume their bequests the very day they receive them, and never save afterward, so that wealth accumulation entirely comes from the savers, who never received any bequest (or negligible amounts) and who patiently accumulate savings from their labor income. Then with our definition $\varphi_t = 0\%$: in this economy, 100% of wealth accumulation comes from savings, and nothing at all comes from inheritance.

However, with the Modigliani and Kotlikoff–Summers definitions, the inheritance shares φ_t^M and φ_t^{KS} could be arbitrarily large.

[23] Of course, more data are better. If we also have (or estimate) labor income or consumption paths, then one can compute lifetime individual savings rate s_{Bti}, that is, the share of lifetime resources that was not consumed up to time t: $s_{Bti} = w_{ti}/(b_{ti}^* + y_{Lti}^*) = 1 - c_{ti}^*/(b_{ti}^* + y_{Lti}^*)$ with $y_{Lti}^* = \int_{s<t} y_{Lsi} e^{r(t-s)} ds$ = capitalized value at time t of past labor income flows, and $c_{ti}^* = \int_{s<t} c_{si} e^{r(t-s)} ds$ = capitalized value at time t of past consumption flows. By definition, inheritors are individuals who consumed more than their labor income (i.e., $w_{ti} < b_{ti}^* \leftrightarrow c_{ti}^* > y_{Lti}^*$), while savers are individuals who consumed less than their labor income (i.e., $w_{ti} \geq b_{ti}^* \leftrightarrow c_{ti}^* \leq y_{Lti}^*$). But the point is that we only need to observe an individual's wealth (w_{ti}) and capitalized inheritance (b_{ti}^*) to determine whether he or she is an inheritor or a saver, and in order to compute the share of inherited wealth.

15.4.1.5 A Simplified Definition: Inheritance Flows versus Saving Flows

When available micro data is not sufficient to apply the PPVR definition, one can also use a simplified, approximate definition based on the comparison between inheritance flows and saving flows.

Assume that all we have is macro data on inheritance flows $b_{yt} = B_t / Y_t$ and savings flows $s_t = S_t / Y_t$. Suppose for simplicity that both flows are constant over time: $b_{yt} = b_y$ and $s_t = s$. We want to estimate the share $\varphi = W_B / W$ of inherited wealth in aggregate wealth. The difficulty is that we typically do not know which part of the aggregate saving rate s comes from the return to inherited wealth, and which part comes from labor income (or from the return to past savings). Ideally, one would like to distinguish between the savings of inheritors and self-made individuals (defined along the lines explained above), but this requires micro data over two generations. In the absence of such data, a natural starting point would be to assume that the propensity to save is on average the same whatever the income sources. That is, a fraction $\varphi \cdot \alpha$ of the saving rate s should be attributed to the return to inherited wealth, and a fraction $1 - \alpha + (1 - \varphi) \cdot \alpha$ should be attributed to labor income (and to the return to past savings), where $\alpha = Y_K / Y$ is the capital share in national income and $1 - \alpha = Y_L / Y$ is the labor share. Assuming again that we are in steady state, we obtain the following simplified formula for the share of inherited wealth in aggregate wealth:

$$\varphi = \frac{b_y + \varphi \cdot \alpha \cdot s}{b_y + s},$$

$$\text{i.e.,} \varphi = \frac{b_y}{b_y + (1 - \alpha) \cdot s}.$$

Intuitively, this formula simply compares the size of the inheritance and saving flows. Because all wealth must originate from one of the two flows, it is the most natural way to estimate the share of inherited wealth in total wealth.[24]

There are a number of caveats with this simplified formula. First, real-world economies are generally out of steady state, so it is important to compute average values of b_y, s, and α over relatively long periods of time (typically over the past H years, with $H = 30$ years). If one has time-series estimates of the inheritance flow b_{ys}, capital share α_s, and saving rate s_s, then one can use the following full formula, which capitalizes past inheritance and savings flows at rate $r - g$:

[24] Similar formulas based on the comparison of inheritance and saving flows have been used by DeLong (2003) and Davies et al. (2012, pp. 123–124). One important difference is that these authors do not take into account the fact that the savings flow partly comes from the return to inherited wealth. We return to this point in Section **15.5.4**.

$$\varphi = \frac{\int_{t-H\le s\le t} e^{(r-g)(t-s)}\cdot b_{ys}\cdot ds}{\int_{t-H\le s\le t} e^{(r-g)(t-s)}\cdot\left(b_{ys}+(1-\alpha_s)\cdot s_s\right)\cdot ds}.$$

With constant flows, the full formula boils down to $\varphi = \frac{b_y}{b_y+(1-\alpha)\cdot s}$.

Second, one should bear in mind that the simplified formula $\varphi = b_y/(b_y+(1-\alpha)\cdot s)$ is an approximate formula. In general, as we show below, it tends to underestimate the true share of inheritance, as computed from micro data using the PPVR definition. The reason is that individuals who have only labor income tend to save less (in proportion to their total income) than those who have large inherited wealth and capital income, which. in turn, seems to be related to the fact that wealth (and particularly inherited wealth) is more concentrated than labor income.

On the positive side, simplified estimates of φ seem to follow micro-based estimates relatively closely (much more closely than KSM estimates, which are either far too small or far too large), and they are much less demanding in terms of data. One only needs to estimate macro flows. Another key advantage of the simplified definition over KSM definitions is that it does not depend upon the sensitive choice of the rate of return or the rate of capital gains or losses. Whatever these rates might be, they should apply equally to inherited and self-made wealth (at least as a first approximation), so one can simply compare inheritance and saving flows.

15.4.2 The Long-Run Evolution of Inheritance in France 1820–2010

15.4.2.1 The Inheritance Flow–National Income Ratio b_{yt}

What do we empirically know about the historical evolution of inheritance? We start by presenting the evidence on the dynamics of the inheritance to national income ratio b_{yt} in France, a country for which, as we have seen in Section 15.3, historical data sources are exceptionally good (Piketty, 2011). The main conclusion is that b_{yt} has followed a spectacular U-shaped pattern over the twentieth century. The inheritance flow was relatively stable, around 20–25% of national income throughout the 1820–1910 period (with a slight upward trend), before being divided by a factor of about 5–6 between 1910 and the 1950s, and then multiplied by a factor of about 3–4 between the 1950s and the 2000s (see Figure 15.17).

These are enormous historical variations, but they appear to be well-founded empirically. In particular, the patterns for b_{yt} are similar with two independent measures of the inheritance flow. The first, what we call the fiscal flow, uses bequest and gift tax data and makes allowances for tax-exempt assets such as life insurance. The second measure, what we call the economic flow, combines estimates of private wealth W_t, mortality tables, and observed age–wealth profile, using the following accounting equation:

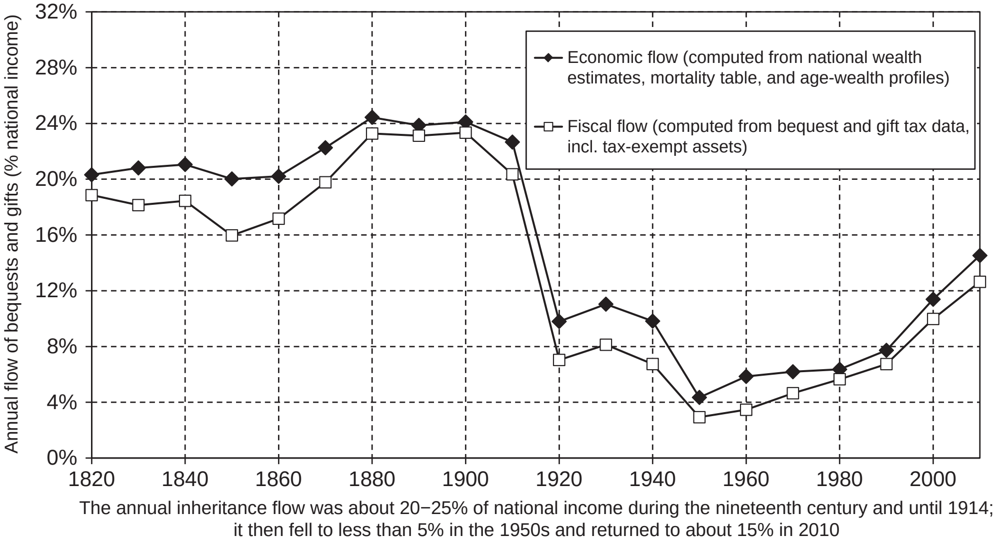

Figure 15.17 The annual inheritance flow as a fraction of national income, France 1820–2010.

$$B_t^* = (1 + v_t) \cdot \mu_t \cdot m_t \cdot W_t,$$

where m_t = mortality rate (number of adult decedents divided by total adult population), μ_t = ratio between average adult wealth at death and average adult wealth for the entire population, and $v_t = V_t / B_t$ = estimate of the gift/bequest flow ratio.

The gap between the fiscal and economic flows can be interpreted as capturing tax evasion and other measurement errors. It is approximately constant over time and relatively small, so that the two series deliver consistent long-run patterns (see Figure 15.17).

The economic flow series allow—by construction—for a straightforward decomposition of the various effects at play in the evolution of b_{yt}. In the above equation, dividing both terms by Y_t we get

$$b_{yt} = B_t^* / Y_t = (1 + v_t) \cdot \mu_t \cdot m_t \cdot \beta_t.$$

Similarly, dividing by W_t we can define the rate of wealth transmission b_{wt} as

$$\begin{aligned} b_{wt} &= B_t^* / W_t = (1 + v_t) \cdot \mu_t \cdot m_t = \mu_t^* \cdot m_t \\ \text{with} \, \mu_t^* &= (1 + v_t) \cdot \mu_t = \text{gift-corrected ratio} \end{aligned}$$

If $\mu_t = 1$ (i.e., decedents have the same average wealth as the living) and $v_t = 0$ (no gift), then the rate of wealth transmission is simply equal to the mortality rate: $b_{wt} = m_t$ (and $b_{yt} = m_t \cdot \beta_t$). If $\mu_t = 0$ (i.e., decedents die with zero wealth, such as in Modigliani's pure life-cycle theory of wealth accumulation) and $v_t = 0$ (no gift), then there is no inheritance at all: $b_{wt} = b_{yt} = 0$.

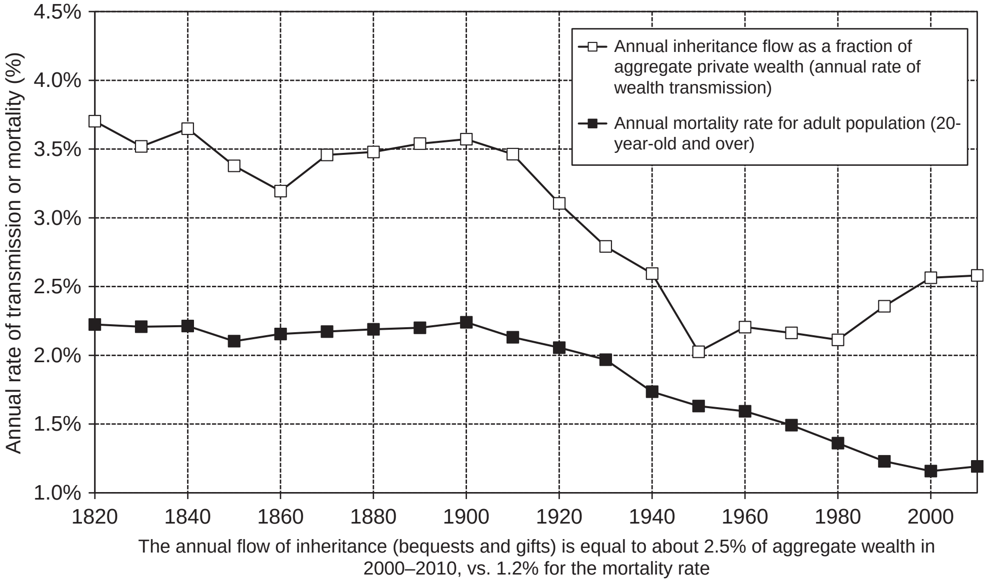

Figure 15.18 Inheritance flow versus mortality rate, France 1820–2010.

Using these accounting equations, we can see that the U-shaped pattern followed by the French inheritance-income ratio b_{yt} is the product of two U-shaped evolutions. First, it partly comes from the U-shaped evolution of the private wealth–income ratio β_t. The U-shaped evolution of b_{yt}, however, is almost twice as marked at that of β_t. The wealth–income ratio was divided by a factor of about 2–3 between 1910 and 1950 (from 600–700% to 200–300%, see Figure 15.2), whereas the inheritance flow was divided by a factor around 5–6 (from 20–25% to about 4%, see Figure 15.17). The explanation is that the rate of wealth transmission $b_{wt} = \mu_t^* \cdot m_t$ has also been following a U-shaped pattern: it was almost divided by 2 between 1910 and 1950 (from over 3.5% to just 2%), and it has been rising again to about 2.5% in 2010 (see Figure 15.18).

The U-shaped pattern followed by b_{wt}, in turn, entirely comes from μ_t^*. The relative wealth of decedents was at its lowest historical level in the aftermath of World War II (which, as we shall see below, is largely due to the fact that it was too late for older cohorts to recover from the shocks and reaccumulate wealth after the war). Given that aggregate wealth was also at its lowest historical level, the combination of these two factors explains the exceptionally low level of the inheritance flow in the 1950s–1960s. By contrast, the mortality rate m_t has been constantly diminishing: this long-run downward trend is the mechanical consequence of the rise in life expectancy (for a given cohort size).[25]

[25] The mortality rate, however, is about to rise somewhat in coming decades in France owing to the aging of the baby boomers (see Piketty, 2011). This effect will be even stronger in countries where cohort size has declined in recent decades (such as Germany or Japan) and will tend to push inheritance flows toward even higher levels.

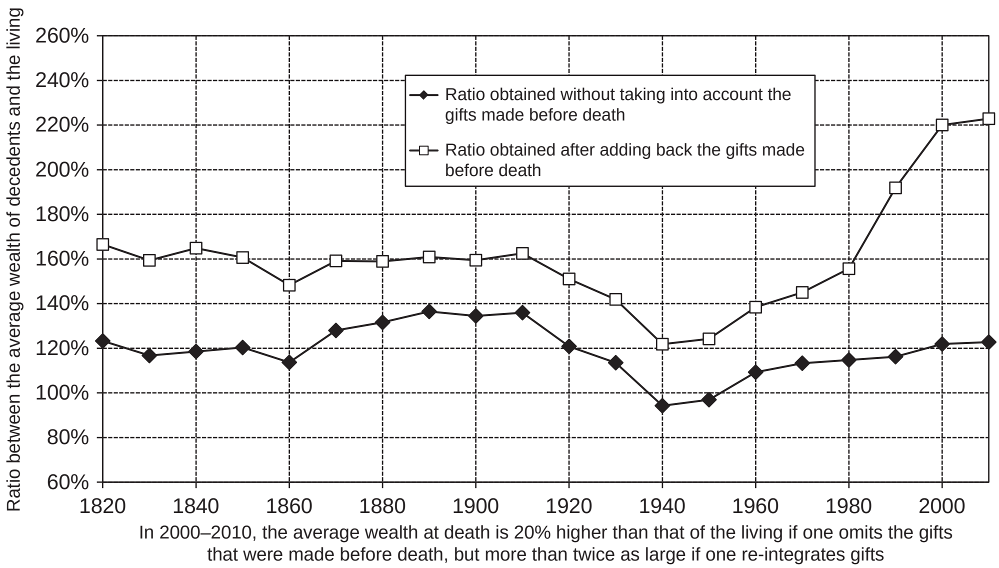

Figure 15.19 The ratio between average wealth at death and average wealth of the living, France 1820–2010.

In the recent decades, a very large part of the rise in $\mu_t^* = (1 + v_t) \cdot \mu_t$ comes from the rise in the gift–bequest ratio v_t, which used to be about 20% during most of the nineteenth to twentieth centuries, and has gradually risen to as much as 80% in recent decades (see Figure 15.19). That is, the gift flow is currently almost as large as the bequest flow.

Although there is still much uncertainty about the reasons behind the rise in gifts, the evidence suggests that it started before the introduction of new tax incentives for gifts in the 1990s–2000s, and has more to do with the growing awareness by wealthy parents that they will die old and that they ought to transmit part of their wealth inter-vivos if they want their children to fully benefit from it.

In any case, one should not underestimate the importance of gifts. In particular, one should not infer from a declining age–wealth profile at old ages or a relatively low relative wealth of decedents that inheritance is unimportant: this could simply reflect the fact that decedents have already given away a large part of their wealth.

15.4.2.2 The Inheritance Stock-Aggregate Wealth Ratio φ_t

How do the annual inheritance flows transmit into cumulated inheritance stocks? Given the data limitations we face, we show on Figure 15.20 two alternative estimates for the share φ_t of total inherited wealth in aggregate French wealth between 1850 and 2010. According to both measures, there is again a clear U-shaped pattern. The share of inherited wealth φ_t was as large as 80–90% of aggregate wealth in 1850–1910, down to as little as 35–45% around 1970, and back up to 65–75% by 2010.

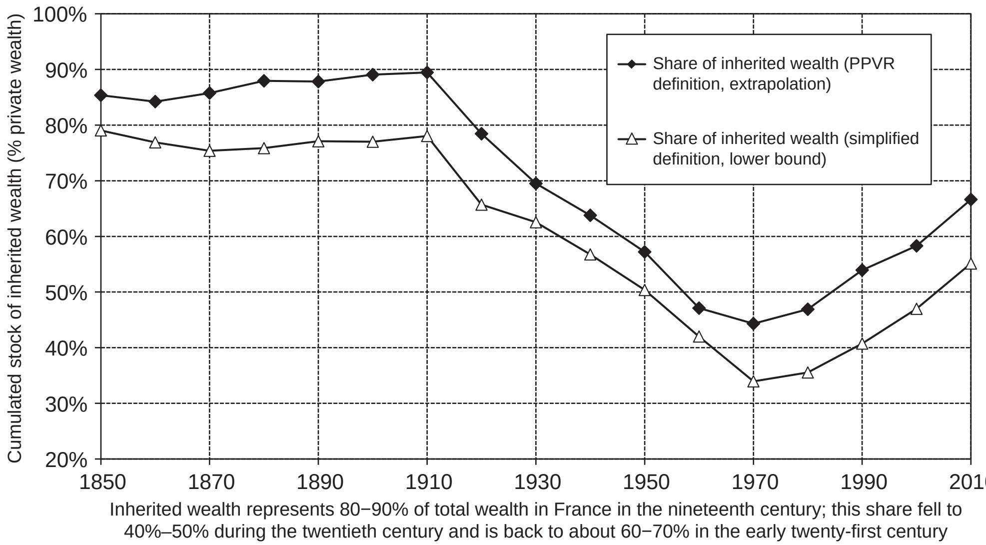

Figure 15.20 The cumulated stock of inherited wealth as a fraction of aggregate private wealth, France 1850–2010.

The higher series, which we see as the most reliable, was obtained by applying the micro-based PPVR definition (see Section 15.4.1.4). The limitation here is that the set of micro data on wealth over two generations that has been collected in French historical archives is more complete for Paris than for the rest of France (see Piketty et al., 2006, 2013). For years with missing data for the rest of France, the estimates reported on Figure 15.20 were extrapolated on the basis of the Parisian data. Ongoing data collection suggests that the final estimates will not be too different from the approximate estimates reported here.

The lower series, which we see as a lower bound, comes from the simplified definition based on the comparison of inheritance and saving flows (see Section 15.4.1.5).[26] The key advantage of this simplified definition is that it requires much less data: it can readily be computed from the inheritance flow series b_{yt} that were reported above. It delivers estimates of the inheritance share φ_t that are always somewhat below the micro-based estimates, with a gap that appears to be approximately constant. The gap seems to be due to the fact that the simplified definition attributes too much saving to pure labor earners with little inheritance.

In both series, the share φ_t of total inherited wealth in aggregate wealth reaches its lowest historical point in the 1970s, whereas the inheritance flow b_{yt} reaches its lowest point in the immediate aftermath of World War II. The reason is that the stock of

[26] The series was computed as $\varphi = b_y/(b_y + (1-\alpha)\cdot s)$ using 30-year averages for saving rates, capital shares, and inheritance flows.

inherited wealth comes from cumulating the inheritance flows of the previous decades—hence the time lag.

15.4.3 Evidence from Other Countries

What do we know about the importance of inheritance in countries other than France? A recent wave of research attempts to construct estimates of the inheritance flow–national income ratio b_{yt} in a number of European countries. The series constructed by Atkinson (2013) for Britain and Schinke (2013) for Germany show that b_{yt} has also followed a U-shaped pattern in these two countries over the past century (see Figure 15.21). Data limitations, however, make it difficult at this stage to make precise comparisons between countries.

For Britain, the inheritance flow b_{yt} of the late nineteenth to early twentieth centuries seems to be similar to that of France, namely about 20–25% of national income. The flow then falls following the 1914–1945 shocks, albeit less spectacularly than in France, and recovers in recent decades. Karagiannaki (2011), in a study of inheritance in the United Kingdom from 1984 to 2005, also finds a marked increase in that period. The rebound, however, seems to be less strong in Britain than in France, so that the inheritance flow appears smaller than in France today. We do not know yet whether this finding is robust. Available British series are pure "fiscal flow" series (as opposed to French series, for which we have both an "economic" and a "fiscal" estimate). As pointed out by Atkinson (2013), the main reason for the weaker British rebound in recent decades is that the gift–bequest ratio v_t has not increased at all according to fiscal data (v_t has remained relatively flat at a

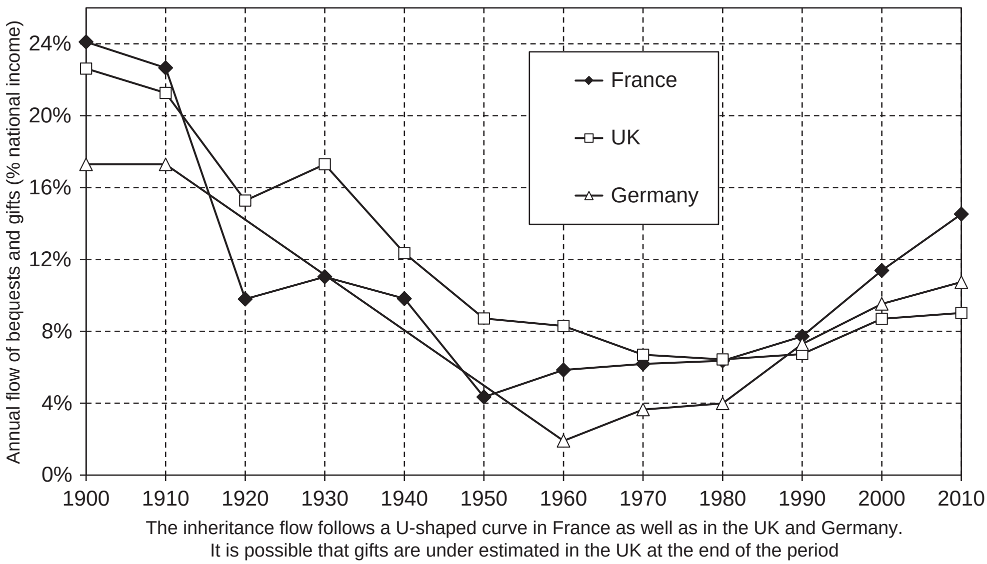

Figure 15.21 The inheritance flow in Europe, 1900–2010.

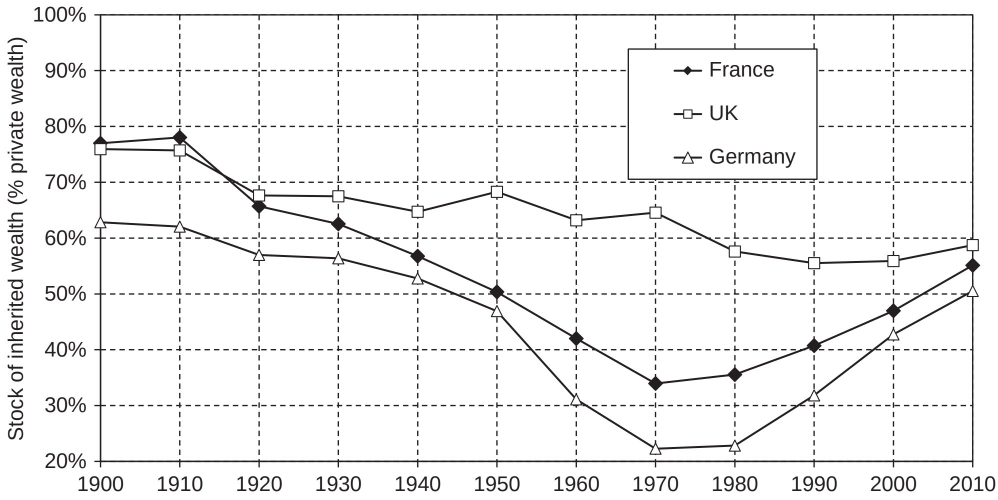


The inheritance share in aggregate wealth accumulation follows a U-shaped curve in France and Germany (and to a more limited extent in the UK and Germany). It is possible that gifts are underestimated in the UK at the end of the period

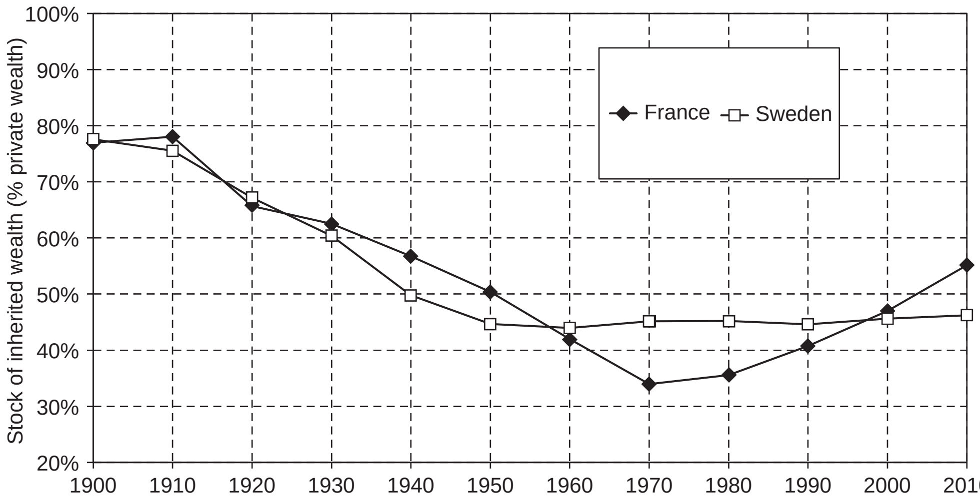
Figure 15.22 The inheritance stock in Europe, 1900–2010.

low level, around 10–20%). According to Atkinson, this could be due to substantial underreporting of gifts to tax authorities.

Germany also exhibits a U-shaped pattern of inheritance flow b_{yt} that seems to be broadly as sharp as in France. In particular, just as in France, the strong German rebound in recent decades comes with a large rise in the gift–bequest ratio v_t during the 1990s–2000s (v_t is above 50–60% in the 2000s). The overall levels of b_{yt} are generally lower in Germany than in France, which given the lower aggregate wealth–income ratio β_t is not surprising. Should we compare the rates of wealth transmission (i.e., $b_{wt} = b_{yt}/\beta_t$), then the levels would be roughly the same in both countries in 2000–2010.

We report on Figure 15.22 the corresponding estimates for the share φ_t of total inherited wealth in aggregate wealth, using the simplified definition $\varphi = b_y/(b_y + (1-\alpha)s)$. For Germany, the inheritance share φ_t appears to be generally smaller than in France. In particular, it reaches very low levels in the 1960s–1970s, owing to the extremely low inheritance flows in Germany in the immediate postwar period, and to large saving rates. In recent decades, the German φ_t has been rising fast and seems to catch up with France's. In the United Kingdom, the inheritance share φ_t apparently never fell to the low levels observed in France and Germany in the 1950s, and seems to be always higher than on the Continent. The reason, for the recent period, is that the United Kingdom has had relatively low saving rates since the 1970s.[27]

[27] In effect, British saving rates in recent decades are insufficient to explain the large rise in the aggregate wealth–income ratio, which can only be accounted for by large capital gain (Piketty and Zucman, 2014). The simplified definition of φ_t based on the comparison between inheritance and saving flows assumes the same capital gains for inherited and self-made wealth.



The inheritance share in aggregate wealth accumulation follows a broadly similar pattern in Sweden and France,although in recent decades the Swedish inheritance stock increased relatively little, as the private saving rate increased

Figure 15.23 The inheritance stock in France and Sweden, 1900–2010.

Recent historical research suggests that inheritance flows have also followed U-shaped patterns in Sweden (see Ohlsson et al., 2013). Here b_{yt} appears to be smaller than in France, but this again seems largely due to lower β_t ratios. When we look at the implied b_{wt} and φ_t ratios, which in a way are the most meaningful ratios to study, then both the levels and shape are relatively similar across European countries. As shown by Figure 15.23, the share of inherited wealth followed the same evolution in Sweden and France in the twentieth century (the main difference is that it seems to have increased a bit less in Sweden than in France in recent decades, because of a rise in the private saving rate). We stress again, however, that a lot more data needs to be collected—and to some extent is currently being collected—on the historical evolution of inheritance before we can make proper international comparisons.

Prior to the recent inheritance flow estimates surveyed above, a first wave of research, surveyed by Davies and Shorrocks (1999), mostly focused on the United States, with conflicting results—the famous Modigliani–Kotlikoff–Summers controversy. More recently, Kopczuk and Edlund (2009) observe that in estate tax data, the share of women among the very wealthy in the United States peaked in the late 1960s (at nearly one-half) and then declined to about one-third. They argue that this pattern reflects changes in the importance of inheritance, as women are less likely to be entrepreneurs. Wolff and Gittleman (2013) analyze Survey of Consumer Finances (SCF) data and find little evidence of a rise in inheritances since the late 1980s. Looking at *Forbes*' data, Kaplan and Rauh (2013) find that Americans in the Forbes 400 are less likely to have inherited their wealth today than in the 1980s. It is unclear, however, whether this result reflects a true economic phenomenon or illustrates the limits of *Forbes* and other wealth rankings.

Inherited wealth holdings are probably harder to spot than self-made wealth, first because inheritors' portfolios tend to be more diversified, and also because inheritors may not like to be in the press, while entrepreneurs usually enjoy it and do not attempt to dissimulate their wealth nearly as much. The conclusions about the relative importance of inherited versus self-made wealth obtained by analyzing *Forbe*s list data may thus be relatively fragile.

In the end, there remain important uncertainties about the historical evolution of inheritance in the United States. There are reasons to believe that inheritance has historically been less important in the United States than in Europe, because population growth has been much larger (more on this below). It is unclear whether this still applies today, however. Given the relatively low U.S. saving rates in recent decades, it is possible that even moderate inheritance flows imply a relatively large share φ_t of total inherited wealth in aggregate wealth (at least according to the simplified definition of φ based on the comparison between b_y and s).

One difficulty is that U.S. fiscal data on bequests and gifts are relatively low quality (in particular because the federal estate tax only covers few decedents; in 2012 only about 1 decedent out of 1000 pays the estate tax). One can use survey data (e.g., from the SCF) to estimate the relative wealth of decedents μ_t and compute the economic inheritance flow $b_{yt} = (1 + v_t) \cdot \mu_t \cdot \beta_t$. One key problem is that one needs to find ways to estimate the gift–bequest ratio v_t, which is not easy to do in the absence of high-quality fiscal data. Self-reported retrospective data on bequest and gift receipts usually suffer from large downward biases and should be treated with caution. In countries where there exists exhaustive administrative data on bequests and gifts (such as France, and to some extent Germany), survey-based self-reported flows appear to be less than 50% of fiscal flows. This may contribute to explain the low level of inheritance receipts found by Wolff and Gittleman (2013).[28]

15.5. ACCOUNTING FOR THE EVIDENCE: MODELS AND PREDICTIONS

15.5.1 Shocks Versus Steady States

How can we account for the historical evidence on the evolution of the aggregate wealth–income ratio, the concentration of wealth, and the share of inherited wealth? In this section, we describe the theoretical models that have been developed to address this question. While we still lack a comprehensive model able to rigorously and

[28] One additional challenge in this study is that inherited assets are generally valued using asset prices at the time the assets were transmitted: no capital gain is included—which probably contributes to a relatively low estimated inheritance share in total U.S. wealth (about 20%, just like in Modigiani's estimates). A comparison between inheritance flows and saving flows (using the simplified formula) would likely lead to more balanced results.

quantitatively assess the various effects at play, the literature makes it possible to highlight some of the key forces.

We are primarily concerned here about the determinants of long-run steady states. In practice, as should be clear from the historical series presented above, real-world economies often face major shocks and changes in fundamental parameters, so that we observe large deviations from steady states. In particular, the large decline in the aggregate wealth–income ratios β_t between 1910 and 1950 is due to the shocks induced by the two World Wars. By using detailed series on saving flows and war destructions, one can estimate the relative importance of the various factors at play (Piketty and Zucman, 2014). In the case of France and Germany, three factors of comparable magnitude each account for approximately one-third of the total 1910–1950 fall of β_t: insufficient national savings (a large part of private saving was absorbed by public deficits); war destructions; and the fall of relative assets prices (real estate and equity prices were historically low in 1950–1960, partly due to policies such as rent control and nationalization). In the case of Britain, war destructions were relatively minor, and the other two factors each account for about half of the fall in the ratio of wealth to income (war-induced public deficits were particularly large).[29]

In thinking about the future, is the concept of a steady state a relevant point of reference? Historical evidence suggests that it is. Whereas the dynamics of wealth and inequality has been chaotic in the twentieth century, eighteenth- and nineteenth-century United Kingdom and France can certainly be analyzed as being in a steady state characterized by low-growth, high wealth–income ratios, high levels of wealth concentration, and inheritance flows. This is true despite the fact that there were huge changes in the nature of wealth and of economic activity (from agriculture to industry).[30] The shocks of the twentieth century put an end to this steady state, and it seems justified to ask: if countries are to converge to a new steady state in the twenty-first century (that is, if the shocks of the twentieth century do not happen again), which long-term ratios will they reach?

We show that over a wide range of models, the long-run magnitude and concentration of wealth and inheritance are a decreasing function of g and an increasing function of $\bar{r}$, where g is the economy's growth rate and $\bar{r}$ is the net-of-tax rate of return to wealth. That is, under plausible assumptions, both the wealth–income ratio and the concentration of wealth tend to take higher steady-state values when the long-run growth rate is lower and when the net-of-tax rate of return is higher. In particular, a higher $\bar{r}-g$ tends to magnify steady-state wealth inequalities. Although there does not exist yet any

[29] For detailed decompositions of private and national wealth accumulation over the various subperiods, see Piketty and Zucman (2014).

[30] In particular, private wealth/income ratios and inheritance flows seemed quite stable in nineteenth-century France (with perhaps a slight upward trend at the end of the century), despite major structural economic changes. This suggests that although the importance of inheritance and wealth may rise and fall in response to the waves of innovation, a steady-state analysis is a fruitful perspective.

rigorous calibrations of these theoretical models, we argue that these predictions are broadly consistent with both the time-series and cross-country evidence. These findings also suggest that the current trends toward rising wealth–income ratios and wealth inequality might continue during the twenty-first century, both because of population and productivity-growth slowdown, and because of rising international competition to attract capital.

15.5.2 The Steady-State Wealth–Income Ratio: $\beta = s/g$

The most useful steady-state formula to analyze the long-run evolution of wealth–income and capital–output ratios is the Harrod–Domar–Solow steady-state formula:

$$\beta_t \to \beta = s/g.$$

With s = long-run (net-of-depreciation) saving rate, g = long-run growth rate.[31]

The steady-state formula $\beta = s/g$ is a pure accounting equation. By definition, it holds in the steady state of any micro-founded, one-good model of capital accumulation, independently of the exact nature of saving motives. It simply comes from the wealth-accumulation equation $W_{t+1} = W_t + S_t$, which can be rewritten in terms of wealth–income ratio $\beta_t = W_t/Y_t$:

$$\beta_{t+1} = \frac{\beta_t + s_t}{1 + g_t}$$

With $1 + g_t = Y_{t+1}/Y_t$ = growth rate of national income, $s_t = S_t/Y_t$ = net saving rate.

It follows immediately that if $s_t \to s$ and $g_t \to g$, then $\beta_t \to \beta = s/g$.

The Harrod–Domar–Solow says something trivial but important in a low-growth economy, the sum of capital accumulated in the past can become very large, as long as the saving rate remains sizable.

For instance, if the long-run saving rate is $s = 10\%$, and if the economy permanently grows at rate $g = 2\%$, then in the long run the wealth–income ratio has to be equal to $\beta = 500\%$, because it is the only ratio such that wealth rises at the same rate as income: $s/\beta = 2\% = g$. If the long-run growth rate declines to $g = 1\%$, and the economy keeps saving at rate $s = 10\%$, then the long-run wealth–income ratio will be equal to $\beta = 1000\%$.

In the long run, output growth g is the sum of productivity and population growth. In the standard one-good growth model, output is given by $Y_t = F(K_t, L_t)$, where K_t is non-human capital input and L_t is human labor input (i.e., efficient labor supply). L_t can be written as the product of raw-labor supply N_t and labor productivity parameter h_t. That is, $L_t = N_t \cdot h_t$, with $N_t = N_0 \cdot (1 + n)^t$ (n is the population growth rate) and $h_t = h_0 \cdot (1 + h)^t$ (h is

[31] When one uses gross-of-depreciation saving rates rather than net rates, the steady-state formula writes $\beta = s/(g + \delta)$ with s the gross saving rate, and δ the depreciation rate expressed as a proportion of the wealth stock.

the productivity growth rate). The economy's long-run growth rate g is given by the growth rate of L_t. Therefore it is equal to $1+g=(1+n)\cdot(1+h)$, i.e., $g\approx n+h$.[32] The long-run g depends both on demographic parameters (in particular, fertility rates) and on productivity-enhancing activities (in particular, the pace of innovation).

The long-run saving rate s also depends on many forces: s captures the strength of the various psychological and economic motives for saving and wealth accumulation (dynastic, life cycle, precautionary, prestige, taste for bequests, etc.). The motives and tastes for saving vary a lot across individuals and potentially across countries. Whether savings come primarily from a life cycle or a bequest motive, the $\beta=s/g$ formula will hold in steady state. In case saving is exogenous (as in the Solow model), the long-run wealth–income ratio will obviously be a decreasing function of the income growth rate g. This conclusion, however, is also true in a broad class of micro-founded, general equilibrium models of capital accumulation in which s can be endogenous and can depend on g. That is the case, in particular, in the infinite-horizon, dynastic model (in which s is determined by the rate of time preference and the concavity of the utility function), in "bequest-in-the-utility-function" models (in which the long-run saving rate s is determined by the strength of the bequest or wealth taste), and in most endogenous growth models (see box below). In all cases, for given preference parameters, the long-run $\beta=s/g$ tends to be higher when the growth rate is lower. A growth slowdown—coming from a decrease in population or productivity growth—tends to lead to higher capital–output and wealth–income ratios.

Box: The steady-state wealth–income ratio in macro models
Dynastic Model

Assume that output is given by $Y_t=F(K_t, L_t)$, where K_t is the capital stock and L_t is efficient labor and grows exogenously at rate g. Output is either consumed or added to the capital stock. We assume a closed economy, so the wealth–income ratio is the same as the capital–output ratio. In the infinite-horizon, dynastic model, each dynasty maximizes

$$V=\int_{t\geq s} e^{-\theta t}U(c_t)$$

where θ is the rate of time preference and $U(c_t)=c^{1-\gamma}(1-\gamma)$ is a standard utility function with a constant intertemporal elasticity of substitution equal to $1/\gamma$. This elasticity of substitution is often found to be small, typically between 0.2 and 0.5, and is in any case smaller than one. Therefore γ is typically bigger than one.

Continued

[32] To obtain the exact equality $g=n+h$, one needs to use instantaneous (continuous-time) growth rates rather than annual (discrete-time) growth rates. That is, with $N_t=N_0\cdot e^{nt}$ (with n=population growth rate) and $h_t=h_0\cdot e^{ht}$, we have $L_t=N_t\cdot h_t=L_0\cdot e^{gt}$, with $g=n+h$.

The first-order condition describing the optimal consumption path of each dynasty is: $\mathrm{d}c_t/\mathrm{d}t = (r - \theta) \cdot c_t/\gamma$, i.e., utility-maximizing agents want their consumption path to grow at rate $g_c = (r - \theta)/\gamma$. This is a steady state if and only if $g_c = g$, i.e., $r = \theta + \gamma g$, what is known as the modified Golden Rule of capital accumulation. The long-run rate of return $r = \theta + \gamma g$ is entirely determined by preference parameters and the growth rate and is larger than g.

The steady-state saving rate is equal to $s = \alpha \cdot g/r = \alpha \cdot g/(\theta + \gamma g)$, where $\alpha = r \cdot \beta$ is the capital share. Intuitively, a fraction g/r of capital income is saved in the long run, so that dynastic wealth grows at the same rate g as national income. The saving rate $s = s(g)$ is an increasing function of the growth rate, but rises less fast than g, so that the steady-state wealth–income ratio $\beta = s/g$ is a decreasing function of the growth rate.

For instance, with a Cobb–Douglas production function (in which case the capital share is entirely set by technology and is constantly equal to α), the wealth–income ratio is given by $\beta = \alpha/r = \alpha/(\theta + \gamma \cdot g)$ and takes its maximum value $\overline{\beta} = \alpha/\theta$ for $g = 0$.

One unrealistic feature of the dynastic model is that it assumes an infinite long-run elasticity of capital supply with respect to the net-of-tax rate of return, which mechanically entails extreme consequences for optimal capital tax policy (namely, zero tax). The "bequest-in-the-utility-function" model provides a less extreme and more flexible conceptual framework in order to analyze the wealth accumulation process.

Wealth-in-the-Utility-Function Model

Consider a dynamic economy with a discrete set of generations 0, 1, …, t, …, zero population growth, and exogenous labor productivity growth at rate $g > 0$. Each generation has measure $N_t = N$, lives one period, and is replaced by the next generation. Each individual living in generation t receives bequest $b_t = w_t \geq 0$ from generation $t-1$ at the beginning of period t, inelastically supplies one unit of labor during his lifetime (so that labor supply $L_t = N_t = N$), and earns labor income y_{Lt}. At the end of period, he then splits lifetime resources (the sum of labor income and capitalized bequests received) into consumption c_t and bequests left $b_{t+1} = w_{t+1} \geq 0$, according to the following budget constraint:

$$c_t + b_{t+1} \leq y_t = y_{Lt} + (1 + r_t) b_t$$

The simplest case is when the utility function is defined directly over consumption c_t and the increase in wealth $\Delta w_t = w_{t+1} - w_t$ and takes a simple Cobb–Douglas form: $V(c, \Delta w) = c^{1-s} \Delta w^s$. (Intuitively, this corresponds to a form of "moral" preferences where individuals feel that they cannot possibly leave less wealth to their children than what they have received from their parents, and derive utility from the increase in wealth, maybe because this is a signal of their ability or virtue.) Utility maximization then leads to a fixed saving rate: $w_{t+1} = w_t + s y_t$. By multiplying per capita values by population $N_t = N$ we have the same linear transition equation at the aggregate level: $W_{t+1} = W_t + s Y_t$. The long-run wealth–income ratio is given by $\beta_t \rightarrow \beta = s/g$. It depends on the strength of the bequest motive and on the rate of productivity growth.

With other functional forms for the utility function, e.g., with $V = V(c, w)$, or with heterogenous labor productivities or saving tastes across individuals, one simply needs to replace the parameter s by the properly defined average wealth or bequest taste parameter. For instance, with $V(c, w) = c^{1-s} w^s$, utility maximization leads to $w_{t+1} = s \cdot (w_t + y_t)$ and

Continued

$\beta_t \rightarrow \beta = s/(g+1-s) = \tilde{s}/g$, with $\tilde{s} = s(1+\beta) - \beta$ the conventional saving rate (i.e., defined relative to income). See Section 15.5.4.1 for a simple application of this model to the analysis of the steady-state distribution of wealth.

Endogenous Growth Models

In endogenous growth models with imperfect international capital flows, the growth rate might rise with the saving rate, but it will usually rise less than proportionally. It is only in what is known as the AK closed-economy model that the growth rate rises proportionally with the saving rate. To see this, assume zero population growth ($n=0$) and a Cobb–Douglas production function $Y = K^{\alpha} \cdot (A_L \cdot L)^{1-\alpha}$. Further assume that the productivity parameter is endogenously determined by an economy-wide capital accumulation externality, such that $A_L = A_0 \cdot K$. Then we have $Y = A \cdot K$, with $A = (A_0 \cdot L_0)^{1-\alpha}$. For a given saving rate $s > 0$, the growth rate is given by $g = g(s) = s \cdot A$. The growth rate rises proportionally with the saving rate, so that the wealth–income ratio is entirely set by technology: $\beta = s/g = 1/A$ is a constant.

In more general endogenous growth models, the rate of productivity growth depends not only on the pace of capital accumulation, but also—and probably more importantly—on the intensity of innovation activities, the importance of education spendings, the position on the international technological frontier, and a myriad of other policies and institutions, so that the resulting growth rate rises less than proportionally with the saving rate.

The slowdown of income growth is the central force explaining the rise of wealth–income ratios in rich countries over the 1970–2010 period, particularly in Europe and Japan, where population growth has slowed markedly (and where saving rates are still high relative to the United States). As Piketty and Zucman (2014) show, the cumulation of saving flows explains the 1970–2010 evolution of β in the main rich countries relatively well. An additional explanatory factor over this time period is the gradual recovery of relative asset prices. In the very long run, however, relative asset-price movements tend to compensate each other, and the one-good capital accumulation model seems to do a good job at explaining the evolution of wealth–income ratios.

It is worth stressing that the $\beta = s/g$ formula works both in closed-economy and open-economy settings. The only difference is that wealth–income and capital–output ratios are the same in closed-economy settings but can differ in open-economy environments.

In the closed-economy case, private wealth is equal to domestic capital: $W_t = K_t$.[33] National income Y_t is equal to domestic output $Y_{dt} = F(K_t, L_t)$. Saving is equal to domestic investment, and the private wealth–national income ratio $\beta_t = W_t/Y_t$ is the same as the domestic capital–output ratio $\beta_{kt} = K_t/Y_{dt}$.

In the open economy case, countries with higher saving rates $s_a > s_b$ accumulate higher wealth ratios $\beta_a = s_a/g > \beta_b = s_b/g$ and invest some their wealth in countries with

[33] For simplicity we assume away government wealth and saving.

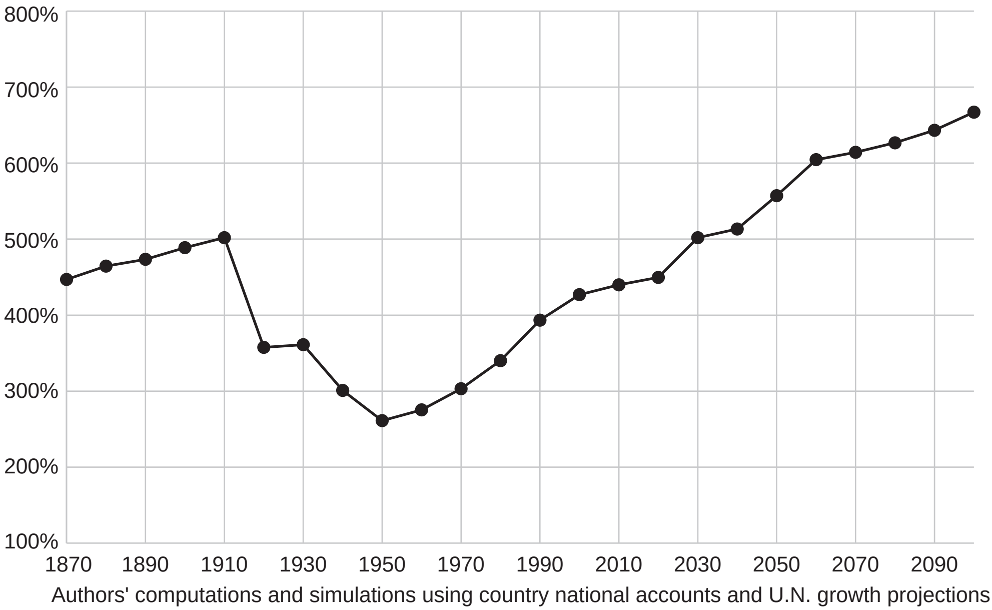


Figure 15.24 World wealth/national income ratio, 1870–2100.

lower saving rates, so that the capital–output ratio is the same everywhere (assuming perfect capital mobility). Noting N_a and N_b the population of countries a and b, $N=N_a+N_b$ the world population, $Y=Y_a+Y_b$ the world output, and $s=(s_a \cdot Y_a+s_b \cdot Y_b)/Y$ the world saving rate, and assuming that each country's effective labor supply is proportional to population and grows at rate g, then the long-run wealth–income and capital–output ratio at the world level will be equal to $\beta=s/g$. With perfect capital mobility, each country will operate with the same capital–output ratio $\beta=s/g$. Country a with wealth $\beta_a>\beta$ will invest its extra wealth $\beta_a-\beta$ in country b with wealth $\beta_b<\beta$. Both countries have the same per capita output $y=Y/N$, but country a has a permanently higher per capita national income $y_a=y+r\cdot(\beta_a-\beta)>y$, while country b has a permanently lower per capita national income $y_b=y-r\cdot(\beta-\beta_b)<y$. In the case of Britain and France at the eve of World War I, the net foreign wealth position $\beta_a-\beta$ was of the order of 100–200%, the return on net foreign assets was about $r=5\%$, so that national income was about 5–10% larger than domestic output.

At the world level, wealth–income and capital–output ratios always coincide (by definition). The long-run ratio is governed by the steady-state condition $\beta=s/g$. In the very long run, if the growth rate slows down at the global level (in particular due to the possible stabilization of world population), then the global β might rise. We report on Figure 15.24 one possible evolution of the world wealth–income ratio in the twenty-first century, assuming that the world-income growth rate stabilizes at about 1.5% and world saving rate at about 12%. Under these (arguably specific and uncertain) assumptions, the world β would rise to about 700–800% by the end of the twenty-first century.

15.5.3 The Steady-State Capital Share: $\alpha = r \cdot \beta = a \cdot \beta^{\frac{\sigma-1}{\sigma}}$

How does the evolution of the capital–income ratio β relate to the evolution of the capital share $\alpha_t = r_t \cdot \beta_t$ (where r_t is the average rate of return)? All depends on whether the capital–labor elasticity of substitution σ is larger or smaller than one.

Take a CES production function $Y = F(K, L) = \left(a \cdot K^{\frac{\sigma-1}{\sigma}} + (1-a) \cdot L^{\frac{\sigma-1}{\sigma}}\right)^{\frac{\sigma-1}{\sigma}}$. The rate of return is given by $r = F_K = a\beta^{-1/\sigma}$ (with $\beta = K/Y$), and the capital share is given by $\alpha = r \cdot \beta = a \cdot \beta^{\frac{\sigma-1}{\sigma}}$. If $\sigma > 1$, then as β_t rises, the fall of the marginal product of capital r_t is smaller than the rise of β_t, so that the capital share $\alpha_t = r_t \cdot \beta_t$ is an increasing function of β_t. Conversely, if $\sigma < 1$, the fall of r_t is bigger than the rise of β_t, so that the capital share is a decreasing function of β_t.[34]

As $\sigma \to \infty$, the production function becomes linear, that is, the return to capital is independent of the quantity of capital: this is like a robot economy where capital can produce output on its own. Conversely, as $\sigma \to 0$, the production function becomes putty clay, that is, the return to capital falls to zero if the quantity of capital is slightly above the fixed-proportion technology.

A special case is when the capital–labor elasticity of substitution σ is exactly equal to one: changes in r and in β exactly compensate each other so that the capital share is constant. This is the Cobb–Douglas case $F(K, L) = K^{\alpha} L^{1-\alpha}$. The capital share is entirely set by technology: $\alpha_t = r_t \cdot \beta_t = \alpha$. A higher capital–output ratio β_t is exactly compensated by a lower capital return $r_t = \alpha/\beta_t$, so that the product of the two is constant.

There is a large literature trying to estimate the elasticity of substitution between labor and capital, reviewed in Antras (2004) and Chirinko (2008); see also Karabarbounis and Neiman (2014). The range of estimates is wide. Historical evidence suggests that the elasticity of substitution σ may have risen over the development process. In the eighteenth to nineteenth centuries, it is likely that σ was less than one, particularly in the agricultural sector. An elasticity less than one would explain why countries with large quantities of land (e.g., the United States) had lower aggregate land values than countries with little land (the Old World). Indeed, when $\sigma < 1$, price effects dominate volume effects: when land is very abundant, the price of land is extremely low, and the product of the two is small. An elasticity less than 1 is exactly what one would accept in an economy in which

[34] Because we include all forms of capital assets into our aggregate capital concept K, the aggregate elasticity of substitution σ should be interpreted as resulting from both supply forces (producers shift between technologies with different capital intensities) and demand forces (consumers shift between goods and services with different capital intensities, including housing services versus other goods and services).

capital takes essentially one form only (land), as in the eighteenth and early nineteenth centuries. When there is too much of the single capital good, it becomes almost useless.

Conversely, in the twentieth century, capital shares α have tended to move in the same direction as capital–income ratios β. This fact suggests that the elasticity of substitution σ has been larger than one. Since the mid-1970s, in particular, we do observe a significant rise of capital shares α_t in rich countries (Figure 15.25). Admittedly, the rise in capital shares α_t was less marked than the rise of capital–income ratios β_t—in other words, the average return to wealth $r_t = \alpha_t/\beta_t$ has declined (Figure 15.26). But this decline is

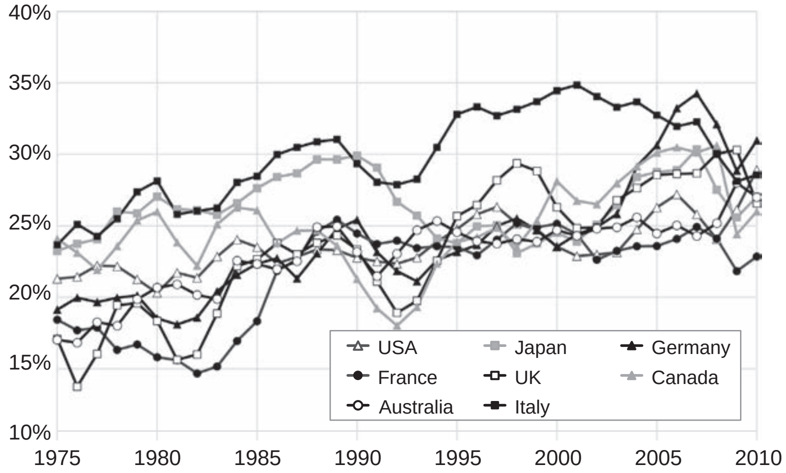

Figure 15.25 Capital shares in factor-price national income, 1975–2010.

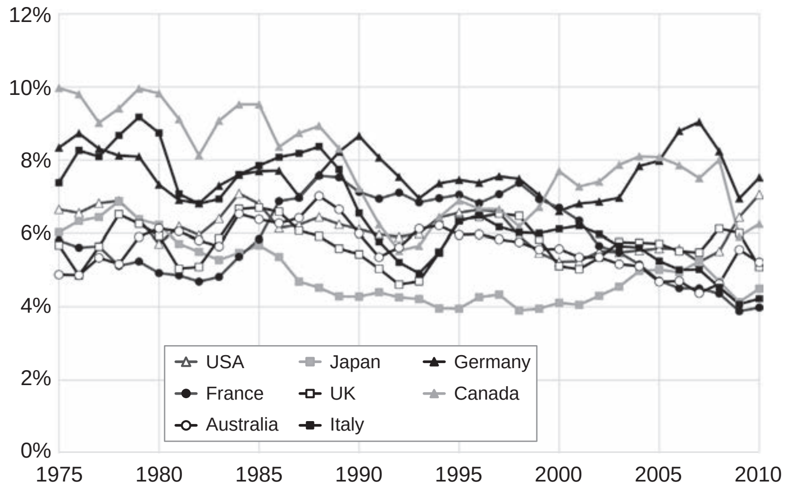

Figure 15.26 Average return on private wealth, 1975–2010.

exactly what one should expect in any economic model: when there is more capital, the rate of return to capital must go down. The interesting question is whether the average return r_t declines less or more than β_t increases. The data gathered by Piketty and Zucman (2014) suggest that r_t has declined less, i.e., that the capital share has increased, consistent with an elasticity $\sigma > 1$. This result is intuitive: an elasticity larger than one is what one would expect in a sophisticated economy with different uses for capital (not only land, but also robots, housing, intangible capital, etc.). The elasticity might even increase with globalization, as it becomes easier to move different forms of capital across borders.

Importantly, the elasticity does not need to be hugely superior to one in order to account for the observed trends. With an elasticity σ around 1.2–1.6, a doubling of capital–output ratio β can lead to a large rise in the capital share α. With large changes in β, one can obtain substantial movements in the capital share with a production function that is only moderately more flexible than the standard Cobb–Douglas function. For instance, with $\sigma = 1.5$, the capital share rises from $\alpha = 28\%$ to $\alpha = 36\%$ if the wealth–income ratio jumps from $\beta = 2.5$ to $\beta = 5$, which is roughly what has happened in rich countries since the 1970s. The capital share would reach $\alpha = 42\%$ in case further capital accumulation takes place and the wealth–income ratio attains $\beta = 8$. In case the production function becomes even more flexible over time (say, $\sigma = 1.8$), the capital share would then be as large as $\alpha = 53\%$.[35] The bottom line is that we certainly do not need to go all the way toward a robot economy ($\sigma = \infty$) in order to generate very large movements in the capital share.

15.5.4 The Steady-State Level of Wealth Concentration: $Ineq = Ineq\ (\bar{r} - g)$

The possibility that the capital–income ratio β—and maybe the capital share α—might rise to high levels entails very different welfare consequences depending on who owns capital. As we have seen in Section 15.3, wealth is always significantly more concentrated than income, but wealth has also become less concentrated since the nineteenth to early twentieth century, at least in Europe. The top 10% wealth holders used to own about 90% of aggregate wealth in Europe prior to World War I, whereas they currently own about 60–70% of aggregate wealth.

What model do we have to analyze the steady-state level of wealth concentration? There is a large literature devoted to this question. Early references include Champernowne (1953), Vaughan (1979), and Laitner (1979). Stiglitz (1969) is the first attempt to analyze the steady-state distribution of wealth in the neoclassical growth model. In his and similar models of wealth accumulation, there is at the same time both convergence of the macro-variables to their steady-state values and of the distribution of wealth to its steady-state form. Dynamic wealth-accumulation models with random

[35] With $a = 0.21$ and $\sigma = 1.5$, $\alpha = a \cdot \beta^{\frac{\sigma-1}{\sigma}}$ goes from 28% to 36% and 42% as β rises from 2.5 to 5 and 8. With $\sigma = 1.8$, α rises to 53% if $\beta = 8$.

idiosyncratic shocks have the additional property that a higher $\bar{r}-g$ differential (where $\bar{r}$ is the net-of-tax rate of return to wealth and g is the economy's growth rate) tends to magnify steady-state wealth inequalities. This is particularly easy to see in dynamic model with random multiplicative shocks, where the steady-state distribution of wealth has a Pareto shape, with a Pareto exponent that is directly determined by $\bar{r}-g$ (for a given structure of shocks).

15.5.4.1 An Illustrative Example with Closed-Form Formulas

To illustrate this point, consider the following model with discrete time $t=0, 1, 2, \ldots$. The model can be interpreted as an annual model (with each period lasting $H=1$ year), or a generational model (with each period lasting $H=30$ years), in which case saving tastes can be interpreted as bequest tastes. Suppose a stationary population $N_t=[0, 1]$ made of a continuum of agents of size one, so that aggregate and average variables are the same for wealth and national income: $W_t=w_t$ and $Y_t=y_t$. Effective labor input $L_t=N_t \cdot h_t=h_0 \cdot (1+g)^t$ grows at some exogenous, annual productivity rate g. Domestic output is given by some production function $Y_{dt}=F(K_t, L_t)$.

We suppose that each individual $i \in [0, 1]$ receives the same labor income $y_{Lti}=y_{Lt}$ and has the same annual rate of return $r_{ti}=r_t$. Each agent chooses c_{ti} and w_{t+1i} so as to maximize a utility function of the form $V(c_{ti}, w_{ti})=c_{ti}^{1-s_{ti}} w_{ti}^{s_{ti}}$, with wealth (or bequest) taste parameter s_{ti} and budget constraint $c_{ti}+w_{t+1i} \leq y_{Lt}+(1+r_t) \cdot w_{ti}$. Random shocks only come from idiosyncratic variations in the saving taste parameters s_{ti}, which are supposed to be drawn according to some i.i.d. random process with mean $s=E(s_{ti})<1$.[36]

With the simple Cobb–Douglas specification for the utility function, utility maximization implies that consumption c_{ti} is a fraction $1-s_{ti}$ of $y_{Lt}+(1+r_t) \cdot w_{ti}$, the total resources (income plus wealth) available at time t. Plugging this formula into the budget constraint, we have the following individual-level transition equation for wealth:

$$w_{t+1i}=s_{ti} \cdot [y_{Lt}+(1+r_t) \cdot w_{ti}] \quad (15.1)$$

At the aggregate level, since by definition national income is equal to $y_t=y_{Lt}+r_t \cdot w_t$, we have

$$w_{t+1}=s \cdot [y_{Lt}+(1+r_t) \cdot w_t]=s \cdot [y_t+w_t] \quad (15.2)$$

dividing by $y_{t+1} \approx (1+g) \cdot y_t$ and denoting $\alpha_t=r_t \cdot \beta_t$ the capital share and $(1-\alpha_t)=y_{Lt}/y_t$ the labor share, we have the following transition equation for the wealth–income ratio $\beta_t=w_t/y_t$:

[36] For a class of dynamic stochastic models with more general structures of preferences and shocks, see Piketty and Saez (2013).

$$\beta_{t+1} = s \cdot \frac{1-\alpha_t}{1+g} + s \cdot \frac{1+r_t}{1+g} \cdot \beta_t = \frac{s}{1+g} \cdot (1+\beta_t) \tag{15.3}$$

In the open-economy case, the world rate of return $r_t = r$ is given. From the above equation one can easily see that β_t converges toward a finite limit β if and only if

$$\omega = s \cdot \frac{1+r}{1+g} < 1$$

In case $\omega > 1$, then $\beta_t \to \infty$. In the long run, the economy is no longer a small open economy, and the world rate of return will have to fall so that $\omega < 1$.

In the closed-economy case, β_t always converges toward a finite limit, and the long-run rate of return r is equal to the marginal product of capital and depends negatively upon β. With a CES production function, for example, we have $r = F_K = \alpha \cdot \beta^{-1/\sigma}$ (see Section 15.5.3).

Setting $\beta_{t+1} = \beta_t$ in Equation (15.3), we obtain the steady-state wealth–income ratio:

$$\beta_t \to \beta = s/(g+1-s) = \tilde{s}/g$$

where $\tilde{s} = s(1+\beta) - \beta$ is the steady-state saving rate expressed as a fraction of national income.

Noting $z_{ti} = w_{ti}/w_t$ the normalized individual wealth, and dividing both sides of Equation (15.1) by $w_{t+1} \approx (1+g) \cdot w_t$, the individual-level transition equation for wealth can be rewritten as follows[37]:

$$z_{t+1i} = \frac{s_{ti}}{s} \cdot [(1-\omega) + \omega \cdot z_{ti}] \tag{15.4}$$

Standard convergence results (e.g., Hopehnayn and Prescott, 1992, Theorem 2, p. 1397) then imply that the distribution $\psi_t(z)$ of relative wealth will converge toward a unique steady-state distribution $\psi(z)$ with a Pareto shape and a Pareto exponent that depends on the variance of taste shocks s_{ti} and on the ω coefficient.

For instance, assume simple binomial taste shocks: $s_{ti} = s_0 = 0$ with probability $1-p$, and $s_{ti} = s_1 > 0$ with probability p (with $s = p \cdot s_1$ and $\omega < 1 < \omega/p$). The long-run distribution function $1 - \Psi_t(z) = \text{proba}(z_{ti} \geq z)$ will converge for high z toward

$$1 - \Phi(z) \approx \left(\frac{\lambda}{z}\right)^a,$$

with a constant term λ

[37] Note that $y_{Lt} = (1-\alpha) \cdot y_t$, where $\alpha = r \cdot \beta = r \cdot s/(1+g-s)$ is the long-run capital share. Note also that the individual-level transition equation given below holds only in the long run (i.e., when the aggregate wealth–income ratio has already converged).

$$\lambda = \frac{1-\omega}{\omega - p},$$

a Pareto coefficient a

$$a = \frac{\log(1/p)}{\log(\omega/p)} > 1, \tag{15.5}$$

and an inverted Pareto coefficient b

$$b = \frac{a}{a-1} = \frac{\log(1/p)}{\log(1/\omega)} > 1.$$

To see this, note that the long-run distribution with $\omega < 1 < \omega/p$ looks as follows: $z = 0$ with probability $1-p$, $z = \frac{1-\omega}{p}$ with probability $(1-p)\cdot p$, …, and $z = z_k = \frac{1-\omega}{\omega-p}\cdot\left[\left(\frac{\omega}{p}\right)^k - 1\right]$ with probability $(1-p)\cdot p^k$. As $k \to +\infty$, $z_k \approx \frac{1-\omega}{\omega-p}\cdot\left(\frac{\omega}{p}\right)^k$ The cumulated distribution is given by $1-\Phi(z_k) = \text{proba}(z \geq z_k) = \sum_{k' \geq k}(1-p)\cdot p^{k'} = p^k$. It follows that as $z \to +\infty$, $\log[1-\Phi(z)] \approx a\cdot[\log(\lambda) - \log(z)]$, i.e., $1-\Phi(z) \approx (\lambda/z)^a$. In case $\omega/p < 1$, then $z_k = \frac{1-\omega}{p-\omega}\cdot\left[1 - \left(\frac{\omega}{p}\right)^k\right]$ has a finite upper bound $z_1 = \frac{1-\omega}{p-\omega}$.[38]

As ω rises, a declines and b rises, which means that the steady-state distribution of wealth is more and more concentrated.[39] Intuitively, an increase in $\omega = s\cdot\frac{1+r}{1+g}$ means that the multiplicative wealth inequality effect becomes larger as compared to the equalizing labor income effect, so that steady-state wealth inequalities get amplified.

In the extreme case where $\omega \to 1^-$ (for given $p < \omega$), $a \to 1^+$ and $b \to +\infty$ (infinite inequality). That is, the multiplicative wealth inequality effect becomes infinite as compared to the equalizing labor-income effect. The same occurs as $p \to 0^+$ (for given $\omega > p$): an infinitely small group gets infinitely large random shocks.[40] Explosive wealth inequality paths can also occur in case the taste parameter s_{ti} is higher on average for individuals with high initial wealth.[41]

[38] See Piketty and Saez (2013, working paper version, pp. 51–52).

[39] A higher inverted Pareto coefficient b (or, equivalently, a lower Pareto coefficient a) implies a fatter upper tail of the distribution and higher inequality. On the historical evolution of Pareto coefficients, see Atkinson et al. (2011, pp. 13–14 and 50–58).

[40] In the binomial model, one can directly compute the "empirical" inverted Pareto coefficient $b' = \frac{E(z|z \geq z_k)}{z_k} \to \frac{1-p}{1-\omega}$ as $k \to +\infty$. Note that $b' \simeq b$ if $p, \omega \simeq 1$, but that the two coefficients generally differ because the true distribution is discrete, while the Pareto law approximation is continuous.

[41] Kuznets (1953) and Meade (1964) were particularly concerned about this potentially powerful unequalizing force.

15.5.4.2 Pareto Formulas in Multiplicative Random Shocks Models

More generally, one can show that all models with multiplicative random shocks in the wealth accumulation process give rise to distributions with Pareto upper tails, whether the shocks are binomial or multinomial, and whether they come from tastes or other factors. For instance, the shock can come from the rank of birth, such as in the primogeniture model of Stiglitz (1969),[42] or from the number of children (Cowell, 1998),[43] or from rates of return (Benhabib et al., 2011, 2013; Nirei, 2009). Whenever the transition equation for wealth can be rewritten so as take a multiplicative form

$$z_{t+1i} = \omega_{ti} \cdot z_{ti} + \varepsilon_{ti}$$

where ω_{ti} is an i.i.d. multiplicative shock with mean $\omega = E(\omega_{ti}) < 1$, and ε_{ti} an additive shock (possibly random), then the steady-state distribution has a Pareto upper tail with coefficient a, which must solve the following equation:

$$E\left(\omega_{ti}^{a}\right) = 1.$$

A special case is when $p \cdot (\omega/p)^a = 1$, that is $a = \log(1/p)/\log(\omega/p)$, the formula given in Equation (15.5) above. More generally, as long as $\omega_{ti} > 1$ with some positive probability, there exists a unique $a > 1$, so that $E(\omega_{ti}^{a}) = 1$. One can easily see that for a given average $\omega = E(\omega_{ti}) < 1$, $a \to 1$ (and thus wealth inequality tends to infinity) if the variance of shocks goes to infinity, and $a \to \infty$ if the variance goes to zero.

Which kind of shocks have mattered most in the historical dynamics of the distribution of wealth? Many different kinds of individual-level random shocks play an important role in practice, and it is difficult to estimate the relative importance of each of them. One robust conclusion, however, is that for a given variance of shocks, steady-state wealth concentration is always a rising function of $r - g$. That is, due to cumulative dynamic effects, relatively small changes in $r - g$ (say, from $r - g = 2\%$ per year to $r - g = 3\%$ per year) can make a huge difference in terms of long-run wealth inequality.

For instance, if we interpret each period of the discrete-time model described above as lasting H years (with $H = 30$ years = generation length), and if r and g denote instantaneous rates, then the multiplicative factor ω can be rewritten as

[42] With primogeniture (binomial shock), the formula is exactly the same as before. See, e.g., Atkinson and Harrison (1978, p. 213), who generalize the Stiglitz (1969) formula and get: $a = \log(1+n)/\log(1+sr)$, with s the saving rate out of capital income. This is the same formula as $a = \log(1/p)/\log(\omega/p)$: with population growth rate per generation $= 1+n$, the probability that a good shock occurs—namely, being the eldest son—is given by $p = 1/(1+n)$. Menchik (1980), however, provides evidence on estate division in the United States, showing that equal sharing is the rule.

[43] The Cowell result is more complicated because families with many children do not return to zero (unless infinite number of children), so there is no closed form formula for the Pareto coefficient a, which must solve the following equation: $\sum \frac{p_k \cdot k}{2}\left(\frac{2 \cdot \omega}{k}\right)^a = 1$, where p_k = fraction of parents who have k children, with $k = 1, 2, 3$, etc., and ω = average generational rate of wealth reproduction.

$$\omega = s \cdot \frac{1+R}{1+G} = s \cdot e^{(r-g)H}$$

with $1+R=e^{rH}$ the generational rate of return and $1+G=e^{gH}$ the generational growth rate. If $r-g$ rises from $r-g=2\%$ to $r-g=3\%$, then with $s=20\%$ and $H=30$ years, $\omega = s \cdot e^{(r-g)H}$ rises from $\omega=0.36$ to $\omega=0.49$. For a given binomial shock structure $p=10\%$, this implies that the resulting inverted Pareto coefficient $b=(\log(1/p))/(\log(1/\omega))$ shifts from $b=2.28$ to $b=3.25$. This corresponds to a shift from an economy with moderate wealth inequality (say, with a top 1% wealth share around 20–30%) to an economy with very high wealth inequality (say, with a top 1% wealth share around 50–60%).

Last, if we introduce taxation into the dynamic wealth accumulation model, then one naturally needs to replace r by the after-tax rate of return $\bar{r}=(1-\tau)\cdot r$, where τ is the equivalent comprehensive tax rate on capital income, including all taxes on both flows and stocks. That is, what matters for long-run wealth concentration is the differential $\bar{r}-g$ between the net-of-tax rate of return and the growth rate. This implies that differences in capital tax rates and tax progressivity over time and across countries can explain large differences in wealth concentration.[44]

15.5.4.3 On the Long-Run Evolution of $\bar{r}-g$

The fact that steady-state wealth inequality is a steeply increasing function of $\bar{r}-g$ can help explain some of the historical patterns analyzed in Section 15.3.

First, it is worth emphasizing that during most of history, the gap $\bar{r}-g$ was large, typically of the order of 4–5% per year. The reason is that growth rates were close to zero until the industrial revolution (typically less than 0.1–0.2% per year), while the rate of return to wealth was generally of the order of 4–5% per year, in particular for agricultural land, by far the most important asset.[45] We have plotted on Figure 15.27 the world GDP growth rates since Antiquity (computed from Maddison, 2010) and estimates of the average return to wealth (from Piketty, 2014). Tax rates were negligible prior to the twentieth century, so that after-tax rates of return were virtually identical to pretax rates of return, and the $\bar{r}-g$ gap was as large as the $r-g$ gap (Figure 15.28).

The very large $\bar{r}-g$ gap until the late nineteenth to early twentieth century is in our view the primary candidate explanation as to why the concentration of wealth has been so large during most of human history. Although the rise of growth rates from less than 0.5% per year before the eighteenth century to about 1–1.5% per year during the eighteenth to

[44] For instance, simulation results suggest that differences in top inheritance tax rates can potentially explain a large fraction of the gap in wealth concentration between countries such as Germany and France (see Dell, 2005).

[45] In traditional agrarian societies, e.g., in eighteenth-century Britain or France, the market value of agricultural land was typically around 20–25 years of annual land rent, which corresponds to a rate of return of about 4–5%. Returns on more risky assets such as financial loans were sometime much higher. See Piketty (2014).

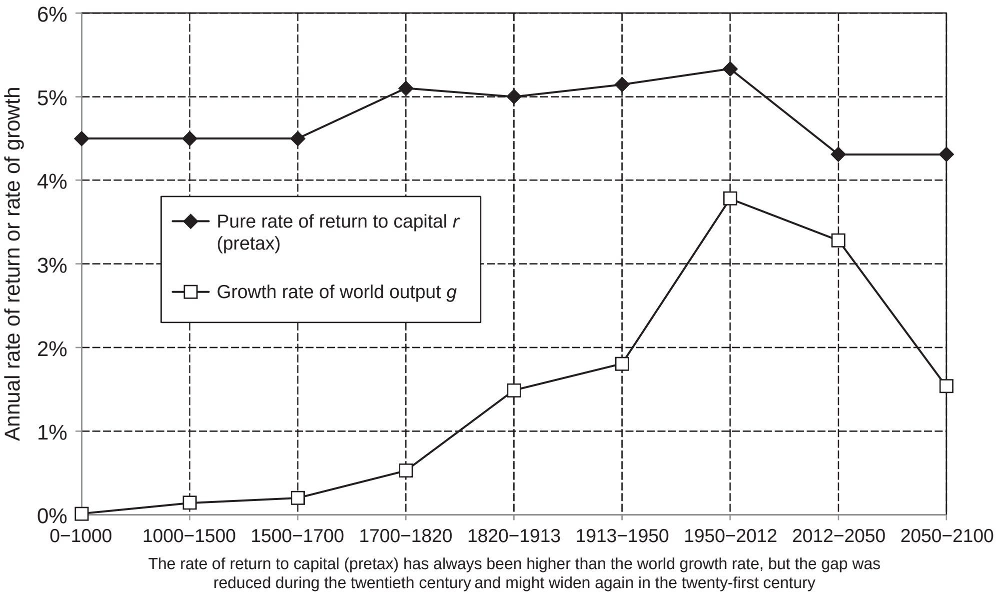

Figure 15.27 Rate of return versus growth rate at the world level, from antiquity until 2100.

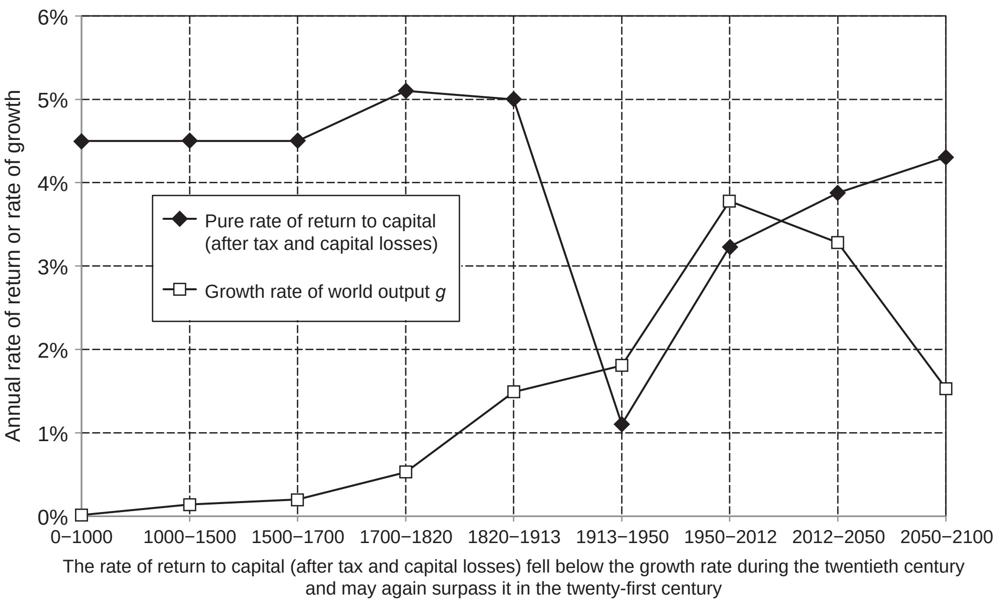

Figure 15.28 After tax rate of return versus growth rate at the world level, from antiquity until 2100.

nineteenth centuries was sufficient to make a huge difference in terms of population and living standards, it had a relatively limited impact on the $\bar{r}-g$ gap: $\bar{r}$ remained much bigger than g.[46]

The spectacular fall of the $\bar{r}-g$ gap in the course of the twentieth century can also help understand the structural decline of wealth concentration, and in particular why wealth concentration did not return to the extreme levels observed before the World Wars. The fall of the $\bar{r}-g$ gap during the twentieth century has two components: a large rise in g and a large decline in $\bar{r}$. Both, however, might well turn out to be temporary.

Start with the rise in g. The world GDP growth rate was almost 4% during the second half of the twentieth century. This is due partly to a general catch up process in per capita GDP levels (first in Europe and Japan between 1950 and 1980, and then in China and other emerging countries starting around 1980–1990), and partly to unprecedented population growth rates (which account for about half of world GDP growth rates over the past century). According to UN demographic projections, world population growth rates should sharply decline and converge to 0% during the second half of the twenty-first century. Long run per capita growth rates are notoriously difficult to predict: they might be around 1.5% per year (as posited on Figure 15.27 for the second half of the twenty-first century), but some authors—such as Gordon (2012)—believe that they could be less than 1%. In any case, it seems plausible that the exceptional growth rates of the twentieth century will not happen again—at least regarding the demographic component—and that g will indeed gradually decline during the twenty-first century.

Looking now at $\bar{r}$, we also see a spectacular decline during the twentieth century. If we take into account both the capital losses (fall in relative asset prices and physical destructions) and the rise in taxation, the net-of-tax, net-of-capital-losses rate of return $\bar{r}$ fell below the growth rate during the entire twentieth century after World War I.

Other forms of capital shocks could occur in the twenty-first century. But assuming no new shock occurs, and assuming that rising international tax competition to attract capital leads all forms of capital taxes to disappear in the course of the twenty-first century (arguably a plausible scenario, although obviously not the only possible one), the net-of-tax rate of return $\bar{r}$ will converge toward the pretax rate of return r, so that the $\bar{r}-g$ gap will again be very large in the future. Other things equal, this force could lead to rising wealth concentration during the twenty-first century.

The $\bar{r}-g$ gap was significantly larger in Europe than in the United States during the nineteenth century (due in particular to higher population growth in the New World). This fact can contribute to explain why wealth concentration was also higher in Europe. The $\bar{r}-g$ gap dramatically declined in Europe during the twentieth

[46] It is also possible that the rise of the return to capital during the eighteenth to nineteenth centuries was somewhat larger than the lower-bound estimates that we report on Figure 15.27, so that the $r-g$ gap perhaps did not decline at all. See Piketty (2014) for a more elaborate discussion.

century—substantially more than the United States, which can, in turn, explain why wealth has become structurally less concentrated than in the United States. The higher level of labor income inequality in the United States in recent decades, as well as the sharp drop in tax progressivity, also contribute to higher wealth concentration in the United States (see Saez and Zucman, 2014). Note, however, that the United States is still characterized by higher population growth (as compared to Europe and Japan), and that this tends to push in the opposite direction (i.e., less wealth concentration). So whether the wealth inequality gap with Europe will keep widening in coming decades is very much an open issue at this stage.

More generally, we should stress that although the general historical pattern of $\bar{r} - g$ (both over time and across countries) seems consistent with the evolution of wealth concentration, other factors do also certainly play an important role in wealth inequality.

One such factor is the magnitude of idiosyncratic shocks to rates of return r_{ti}, and the possibility that average rates of return $r(w) = E(r_{ti}|w_{ti} = w)$ vary with the initial wealth levels. Existing evidence on returns to university endowments suggests that larger endowments indeed tend to get substantially larger rates of returns, possibly due to scale economies in portfolio management (Piketty 2014, Chapter 12). The same pattern is found for the universe of U.S. foundations (Saez and Zucman, 2014). Evidence from *Forbes* global wealth rankings also suggests that higher wealth holders tend to get higher returns. Over the 1987–2013 period, the top fractiles (defined in proportion to world adult population) of the *Forbes* global billionaire list have been growing on average at about 6–7% per year in real terms, when average adult wealth at the global level was rising at slightly more than 2% per year (see Table 15.1).

Whatever the exact mechanism might be, this seems to indicate that the world distribution of wealth is becoming increasingly concentrated, at least at the top of the distribution. It should be stressed again, however, that available data is of relatively low quality. Little is known about how the global wealth rankings published by magazines

Table 15.1 The growth rate of top global wealth, 1987–2013

Average real growth rate per year (after deduction of inflation)	**1987–2013**
The top 1/(100 million) highest wealth holders (about 30 adults out of 3 billions in 1980s, and 45 adults out of 4.5 billions in 2010s)	6.8%
The top 1/(20 million) highest wealth holders (about 150 adults out of 3 billions in 1980s, and 225 adults out of 4.5 billions in 2010s)	6.4%
Average world wealth per adult	2.1%
Average world income per adult	1.4%
World adult population	1.9%
World GDP	3.3%

Between 1987 and 2013, the highest global wealth fractiles have grown at 6–7% per year, versus 2.1% for average world wealth and 1.4% for average world income. All growth rates are net of inflation (2.3% per year between 1987 and 2013).

are constructed, and it is likely that they suffer from various biases. They also focus on such a narrow fraction of the population that they are of limited utility for a comprehensive study of the global distribution of wealth. For instance, what happens above \$1 billion does not necessarily tell us much about what happens between \$10 and 100 million. This is a research area where a lot of progress needs to be made.

15.5.5 The Steady-State Level of the Inheritance Share: $\varphi = \varphi(g)$

15.5.5.1 The Impact of Saving Motives, Growth, and Life Expectancy

The return of high wealth–income ratios β does not necessarily imply the return of inheritance. From a purely logical standpoint, it is perfectly possible that the steady-state $\beta = s/g$ rises (say, because g goes down and s remains relatively high, as we have observed in Europe and Japan over the recent decades), but that all saving flows come from life-cycle wealth accumulation and pension funds, so that the inheritance share φ is equal to zero. Empirically, however, this does not seem to be the case. From the (imperfect) data that we have, it seems that the rise in the aggregate wealth–income ratio β has been accompanied by a rise in the inheritance share φ, at least in Europe.

This suggests that the taste for leaving bequests (and/or the other reasons for dying with positive wealth, such as precautionary motives and imperfect annuity markets) did not decline over time. Empirical evidence shows that the distribution of saving motives varies a lot across individuals. It could also be that the distribution of saving motives is partly determined by the inequality of wealth. Bequests might partly be a luxury good, in the sense that individuals with higher relative wealth also have higher bequest taste on average. Conversely, the magnitude of bequest motives has an impact on the steady-state level of wealth inequality. Take, for instance, the dynamic wealth accumulation model described above. In that model we implicitly assume that individuals leave wealth to the next generation. If they did not, the dynamic cumulative process would start at zero all over again at each generation, so that steady-state wealth inequality would tend to be smaller.

Now, assume that we take as given the distribution of bequest motives and saving parameters. Are there reasons to believe that changes in the long-run growth rate g or in the demographic parameters (such as life expectancy) can have an impact on the inheritance share φ in total wealth accumulation?

This question has been addressed by a number of authors, such as Laitner (2001) and DeLong (2003).[47] According to DeLong, the share of inheritance in total wealth accumulation should be higher in low-growth societies, because the annual volume of new savings is relatively small in such economics (so that in effect most wealth originates from inheritance). Using our notations, the inheritance share $\varphi = \varphi(g)$ is a decreasing function of the growth rate g.

[47] See also Davies et al. (2012, pp. 123–124).

This intuition is interesting (and partly correct) but incomplete. In low-growth societies, such as preindustrial societies, the annual volume of new savings—for a given aggregate β—is indeed low in steady state: $s = g \cdot \beta$. In contrast, the flow of inheritances is given by: $b_y = \mu \cdot m \cdot \beta$ (see Section 15.4). Therefore, for given μ and m, inheritance flows tend to dominate saving flows in low-growth economies, and conversely in high-growth economies.

For instance, if $\mu = 1$, $m = 2\%$, and $\beta = 600\%$, the inheritance flow is equal to $b_y = 12\%$. The inheritance flow b_y is four times bigger than the saving flow $s = 3\%$ if $g = 0.5\%$, it is equal to the saving flow $s = 12\%$ if $g = 2\%$, and it is 2.5 times smaller than the saving flow $s = 30\%$ if $g = 5\%$. Therefore—the argument goes—inherited wealth represents the bulk of aggregate wealth in low-growth, preindustrial societies; makes about half of aggregate wealth in medium-growth, mature economies; and a small fraction of aggregate wealth in high-growth, booming economies.

This intuition, however, is incomplete, for two reasons. First, as we already pointed out in Section 15.4, saving flows partly come from the return to inherited wealth, and this needs to be taken into account. Next, the μ parameter, i.e., the relative wealth of decedents, is endogenous and might well depend on the growth rate g, as well as on demographic parameters such as life expectancy and the mortality rate m. In the pure life-cycle model where agents die with zero wealth, μ is always equal to zero, and so is the inheritance share φ, independently of the growth rate g, no matter how small g is. For given (positive) bequest tastes and saving parameters, however, one can show that in steady state, $\mu = \mu(g, m)$ tends to be higher when growth rates g and mortality rates m are lower.

15.5.5.2 A Simple Benchmark Model of Aging Wealth and Endogenous μ

To see this point more clearly, it is necessary to put more demographic structure into the analysis. Here we follow a simplified version of the framework introduced by Piketty (2011).

Consider a continuous-time, overlapping-generations model with a stationary population $N_t = [0, 1]$ (zero population growth). Each individual i becomes adult at age $a = A$, has exactly one child at age $a = H$, and dies at age $a = D$. We assume away inter-vivos gifts, so that each individual inherits wealth solely when his or her parent dies, that is, at age $a = I = D - H$.

For example, if $A = 20$, $H = 30$, and $D = 60$, everybody inherits at age $I = D - H = 30$ years old. But if $D = 80$, then everybody inherits at age $I = D - H = 50$ years old.

Given that population N_t is assumed to be stationary, the (adult) mortality rate m_t is also stationary, and is simply equal to the inverse of (adult) life expectancy: $m_t = m = \frac{1}{D-A}$.[48]

[48] It is more natural to focus upon adults because minors usually have very little income or wealth (assuming that $I > A$, i.e., $D - A > H$, which is the case in modern societies).

For example, if $A=20$ and $D=60$, the mortality rate is $m=1/40=2.5\%$. If $D=80$, the mortality rate is $m=1/60=1.7\%$. That is, in a society where life expectancy rises from 60 to 80 years old, the steady-state mortality rate among adults is reduced by a third. In the extreme case where life expectancy rises indefinitely, the steady-state mortality rate becomes increasingly small: one almost never dies.

Does this imply that the inheritance flow $b_y=\mu\cdot m\cdot\beta$ will become increasingly small in aging societies? Not necessarily: even in aging societies, one ultimately dies. Most importantly, one tends to die with higher and higher relative wealth. That is, wealth also tends to get older in aging societies, so that the decline in the mortality rate m can be compensated by a rise in relative decedent wealth μ (which, as we have seen, has been the case in France).

Assume for simplicity that all agents have on average the same uniform saving rate s on all their incomes throughout their life (reflecting their taste for bequests and other saving motives such a precautionary wealth accumulation) and a flat age-income profile (including pay-as-you-go pensions). Then one can show that the steady-state $\mu=\mu(g)$ ratio is given by the following formula:

$$\mu(g)=\frac{1-\mathrm{e}^{-(g-s\cdot r)(D-A)}}{1-\mathrm{e}^{-(g-s\cdot r)H}}=\frac{1-\mathrm{e}^{-(1-\alpha)g(D-A)}}{1-\mathrm{e}^{-(1-\alpha)gH}}.$$

With $\alpha=r\cdot\beta=r\cdot s/g=$ capital share in national income.

In other words, the relative wealth of decedents $\mu(g)$ is a decreasing function of the growth rate g (and an increasing function of the rate of return r or of the capital share α).[49] If one introduces taxes into the model, one can easily show that μ is a decreasing function of the growth rate g and an increasing function of net-of-tax rate of return $\bar{r}$ (or the net-of-tax capital share $\overline{\alpha}$).[50]

The intuition for this formula, which can be extended to more general saving models, is the following. With high growth rates, today's incomes are large as compared to past incomes, so the young generations are able to accumulate almost as much wealth as the older cohorts, in spite of the fact that the latter have already started to accumulate in the past, and in some cases have already received their bequests. Generally speaking, high growth rates g are favorable to the young generations (who are just starting to accumulate wealth, and who therefore rely entirely on the new saving flows out of current incomes), and tend to push for lower relative decedent wealth μ. High rates of return $\bar{r}$, by contrast,

[49] This steady-state formula applies both to the closed-economy and open-economy cases. The only difference is that the rate of return r is endogenously determined by the marginal product of domestic capital accumulation in the closed economy case (e.g., $r=F_K=a\cdot\beta^{-1/\sigma}$ with a CES production function), while it is a free parameter in the open economy setup (in which case the formula can be viewed as $\mu=\mu(g, r)$).

[50] With taxes, $\bar{r}$ also becomes a free parameter in the closed-economy model, so the formula should always be viewed as $\mu=\mu(g,\bar{r})$.

are more favorable to older cohorts, because this makes the wealth holdings that they have accumulated or inherited in the past grow faster, and tend to pusher for higher μ.

In the extreme case where $g \to \infty$, then $\mu \to 1$ (this directly follows from flat saving rates and age-labor income profiles).

Conversely, in the other extreme case where $g \to 0$, then $\mu \to \overline{\mu} = \frac{D-A}{H} > 1$.

It is worth noting that this maximal value $\overline{\mu}$ rises in proportion to life expectancy $D-A$ (for given generation length H). Intuitively, with $g \approx 0$ and uniform saving, most of wealth originates from inheritance, so that young agents are relatively poor until inheritance age $I = D-H$, and most of the wealth concentrates between age $D-H$ and D, so that relative decedent wealth $\mu \approx \overline{\mu} = \frac{D-A}{H}$.[51]

That is, as life expectancy $D-A$ rises, wealth gets more and more concentrated at high ages. This is true for any growth rate, and all the more for low growth rates. In aging societies, one inherits later in life,[52] but one inherits bigger amounts. With $g \approx 0$, one can see that both effects exactly compensate each other, in the sense that the steady-state inheritance flow b_y is entirely independent of life expectancy. That is, with $m = \frac{1}{D-A}$ and $\overline{\mu} = \frac{D-A}{H}$, we have $b_y = \overline{\mu} \cdot m \cdot \beta = \frac{\beta}{H}$, independently from $D-A$. For a given wealth–income ratio $\beta = 600\%$ and generation length $H = 30$ years, the steady-state annual inheritance flow is equal to $b_y = 20\%$ of national income, whether life expectancy is equal to $D = 60$ years or $D = 80$ years.

Strictly speaking, this is true only for infinitely small growth $g \approx 0$. However, by using the above formula one can see that for low growth rates (say, $g \approx 1$–1.5%) then the steady-state inheritance flow is relatively close to $b_y = \frac{\beta}{H}$ and is almost independent of life expectancy. It is only for high growth rates—above 2–3% per year—that the steady-state inheritance flow is reduced substantially.

15.5.5.3 Simulating the Benchmark Model

Available historical evidence shows that the slowdown of growth is the central economic mechanism explaining why the inheritance flow seems to be returning in the early twenty-first century to approximately the same level $b_y \approx 20\%$ as that observed during the nineteenth and early twentieth centuries.

By simulating a simple uniform-saving model for the French economy over the 1820–2010 period (starting from the observed age–wealth pattern in 1820, and using observed aggregate saving rates, growth rates, mortality rates, capital shocks and age–labor

[51] In the extreme case where young agents have zero wealth and agents above age $I = D-H$ have average wealth $\overline{w}$, then average wealth among the living is equal to $w = \frac{(D-I) \cdot \overline{w}}{D-A}$ and, so that $\overline{\mu} = \frac{\overline{w}}{w} = \frac{D-A}{H}$. See Piketty (2011), Propositions 1–3.

[52] Although in practice, this is partly undone by the rise of inter vivos gifts, as we have seen above.

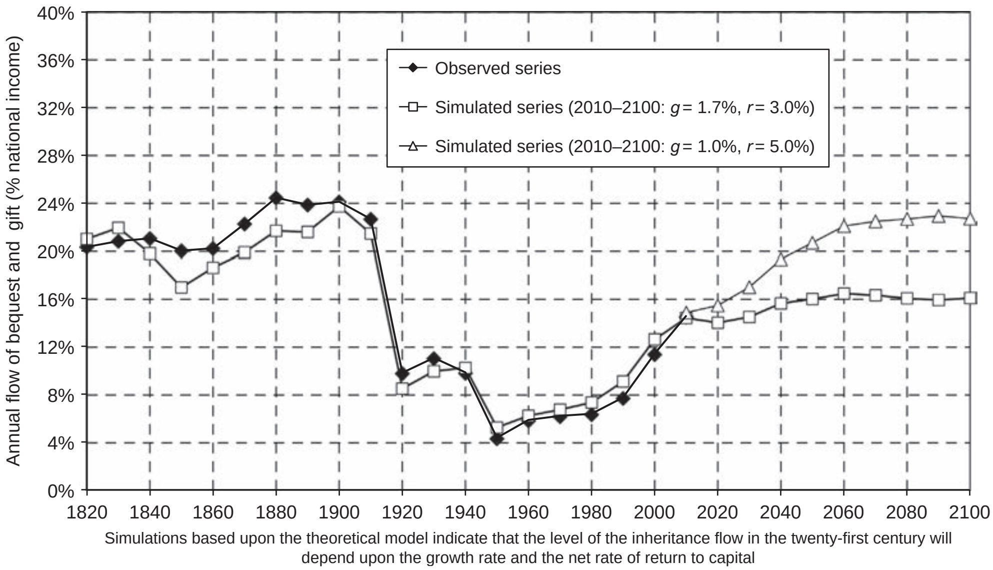

Figure 15.29 Observed and simulated inheritance flow, France 1820–2100.

income profiles over the entire period), one can reasonably well reproduce the dynamics of the age–wealth profile and hence of the μ ratio and the inheritance flow b_y over almost two centuries (see Figure 15.29).

We can then use this same model to simulate the future evolution of the inheritance flow in coming decades. As one can see on Figure 15.29, a lot depends on future values of the growth rate g and the net-of-tax rate of return $\bar{r}$ over the 2010–2100 period. Assuming $g = 1.7\%$ (which corresponds to the average growth rate observed in France between 1980 and 2010) and $\bar{r} = 3.0\%$ (which approximatively corresponds to net-of-tax average real rate of return observed in 2010), then b_y should stabilize around 16–17% in coming decades. If growth slows $g = 1.0\%$ and the net-of-tax rate of return rises to $\bar{r} = 5.0\%$ (e.g., because of a rise of the global capital share and rate of return, or because of a gradual repeal of capital taxes), b_y would keep increasing toward 22–23% over the course of the twenty-first century. The flow of inheritance would approximately return to its nineteenth and early twentieth centuries level.

In Figure 15.30, we use these projections to compute the corresponding share φ of cumulated inheritance in the aggregate wealth stock (using the PPVR definition and the same extrapolations as those described above). In the first scenario, φ stabilizes around 80%; in the second scenario, it stabilizes around 90% of aggregate wealth.

These simulations, however, are not fully satisfactory, first because a lot more data should be collected on inheritance flows in other countries, and next because one should ideally try to analyze and simulate both the flow of inheritance and the inequality of

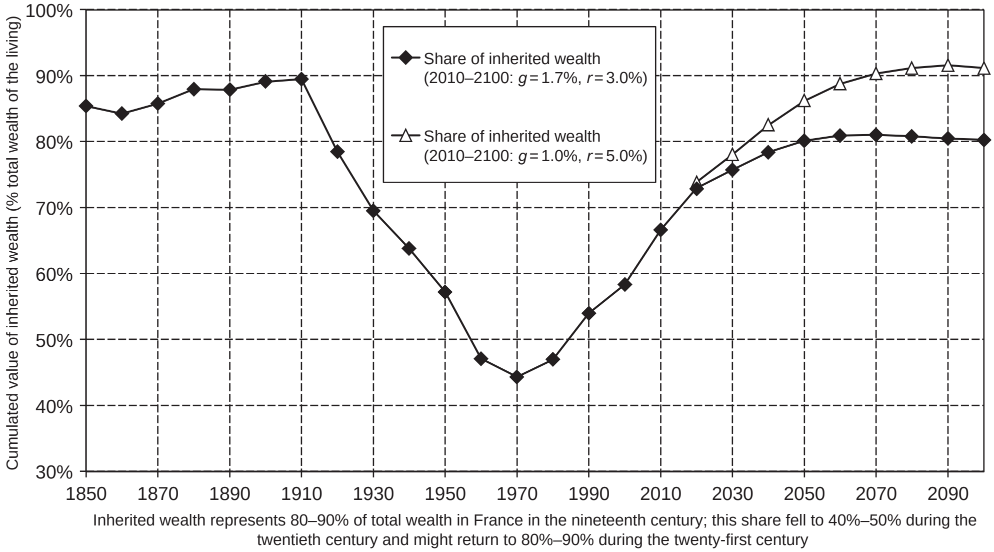

Figure 15.30 The share of inherited wealth in total wealth, France 1850–2100.

wealth. The computations presented here assume uniform saving and solely attempt to reproduce the age-average wealth profile, without taking into account within-cohort wealth inequality. This is a major limitation.

15.6. CONCLUDING COMMENTS AND RESEARCH PROSPECTS

In this chapter, we have surveyed the empirical and theoretical literature on the long-run evolution of wealth and inheritance in relation to output and income. The magnitude and concentration of wealth and inheritance (relative to national income) were very high in the eighteenth to nineteenth centuries up until World War I, then dropped precipitously during the twentieth century following World War shocks, and have been rising again in the late twentieth and early twenty-first centuries. We have showed that over a wide range of models, the long-run magnitude and concentration of wealth and inheritance are an increasing function of $\bar{r}-g$, where $\bar{r}$ is the net-of-tax rate of return to wealth and g is the economy's growth rate, and we have argued that these predictions are broadly consistent with historical patterns. These findings suggest that current trends toward rising wealth–income ratios and wealth inequality might continue during the twenty-first century, both because of the slowdown of population and productivity growth, and because of increasing international competition to attract capital.

We should stress, however, that this is an area where a lot of progress still needs to be made. Future research should particularly focus on the following issues. First, it becomes more and more important to study the dynamics of the wealth distribution from a global perspective.[53] In order to do so, it is critical to take into account existing macro data on aggregate wealth and foreign wealth holdings. Given the large movements in aggregate wealth–income ratios across countries, such macro-level variations are likely to have a strong impact on the global dynamics of the individual-level distribution of wealth. It is also critical to use existing estimates of offshore wealth and to analyze how much tax havens are likely to affect global distributional trends (see Zucman, 2014). Next, a lot more historical and international data needs to be collected on inheritance flows. Last, there is a strong need of a better articulation between empirical and theoretical research. A lot more work has yet to be done before we are able to develop rigorous and credible calibrations of dynamic theoretical models of wealth accumulation and distribution.

ACKNOWLEDGMENTS

We are grateful to the editors and to Daniel Waldenstrom for helpful comments. All series and figures presented in this chapter are available in an online data appendix.
