INTRODUCTION: INCOME DISTRIBUTION TODAY

Anthony B. Atkinson*, François Bourguignon†
*Nuffield College, Oxford, UK
†Paris School of Economics, Paris, France

1. SETTING THE SCENE

When the first volume of the *Handbook of Income Distribution* was published in 2000, the subject of income inequality was not in the mainstream of economic debate—despite the long history of engagement with this issue by earlier leading economists—see Chapter 1 by Agnar Sandmo. Fifteen years later, inequality has become very much centre stage. Rising income inequality has attracted the attention of the U.S. President, of international bodies such as the IMF and the OECD, and of participants in the Davos meeting.

This volume of the Handbook aims to cover the advances made in the past 15 years in our understanding of the extent, causes, and consequences of inequality. In this respect, the second volume should be seen as complementing, not supplanting, the first volume. We have encouraged authors to concentrate on the developments that have taken place since 2000, and the chapters should be read in conjunction with those in volume I. In this Introduction, we give a flavor of the issues discussed and some personal reflections on the state of the subject.

In our Introduction to volume I of the Handbook, we said that "income distribution may be considered the normative economic issue 'par excellence'" (Atkinson and Bourguignon, 2000, p. 41). People are concerned about economic inequality because they feel it to be socially unjust or unfair. It violates principles of social justice. The nature of these principles is of course much debated and there is disagreement about what constitutes an unacceptable level of inequality. People focus on different dimensions. But the concern is with inequality intrinsically. At the same time, there is a second set of—instrumental—concerns with the consequences of inequality. The societal consequences were highlighted by Joseph Stiglitz when he entitled his 2012 book, *The price of inequality*, where he says "the impact of inequality on societies is now increasingly well understood—higher crime, health problems, and mental illness, lower educational achievements, social cohesion and life expectancy" (inside cover). The social, political and cultural impacts of inequality have been the subject of the GINI (Growing

Inequalities' Impacts) research project (Salverda et al., 2014; Nolan et al., 2014). In the second volume of the Handbook, some of these consequences feature, notably those regarding health in Chapter 17 by Owen O'Donnell, Eddy Van Doorslaer, and Tom Van Ourti. But the wider societal impact of inequality is not the principal focus of the chapters that follow. This still leaves much to be discussed. Inequality is of instrumental importance within the field of economics itself. As we said in volume I, "income distribution assists our understanding of various fields of economics" (2000, p. 4). Now, as then, we believe that the study of economic inequality should be at the heart of economic analysis.

Upon reflecting the issues covered in this volume, this Introduction considers successively: (a) the concepts and approaches to economic inequality measurement, or the various facets of inequality (Section 2); (b) the care needed with data on inequality (Section 3); (c) the explanations of changes in various dimensions of economic inequality, most notably the distribution of income, earnings and wealth and the links with macroeconomics (Section 4); and (d) the policies available to influence those changes or to correct those distributions (Section 5).

We plunge straight into the subject matter with Figure 1, which depicts the evolution of economic inequality in the United States over the past century. The data are taken from the Chartbook of Economic Inequality (Atkinson and Morelli, 2014),[1] but are presented in four panels to highlight different dimensions of the distribution of income.[2] The pictures provide a good basis for describing what is covered in this Handbook and for identifying some of the issues that are missing. The fact that most of the lines in the different panels are rising to the right is the main reason why inequality is on the agenda. At the same time, the long run of historical data on inequality shows us that there have been periods in the past when inequality fell and when poverty was reduced. Indeed the past 100 years has seen a broadly U-shaped pattern. The series shown in Figure 1 also allow us to underline at the outset the crucial, and often overlooked, point that observed differences in income are not necessarily an indicator of the existence of inequality. Earnings at the top decile (shown in Panel C), for example, may have risen on account of increased costs of acquiring educational qualifications, and not represent any rise in inequality of lifetime incomes. For this reason, it is important to ask what we mean by "inequality."

[1] An alternative colored graph can be found here: http://www.chartbookofeconomicinequality.com/wp-content/uploads/StaticGraphs/USA_staticgraph_coloured.pdf.

[2] We are following here the advice of Schwabish (2014) to avoid "spaghetti" charts.

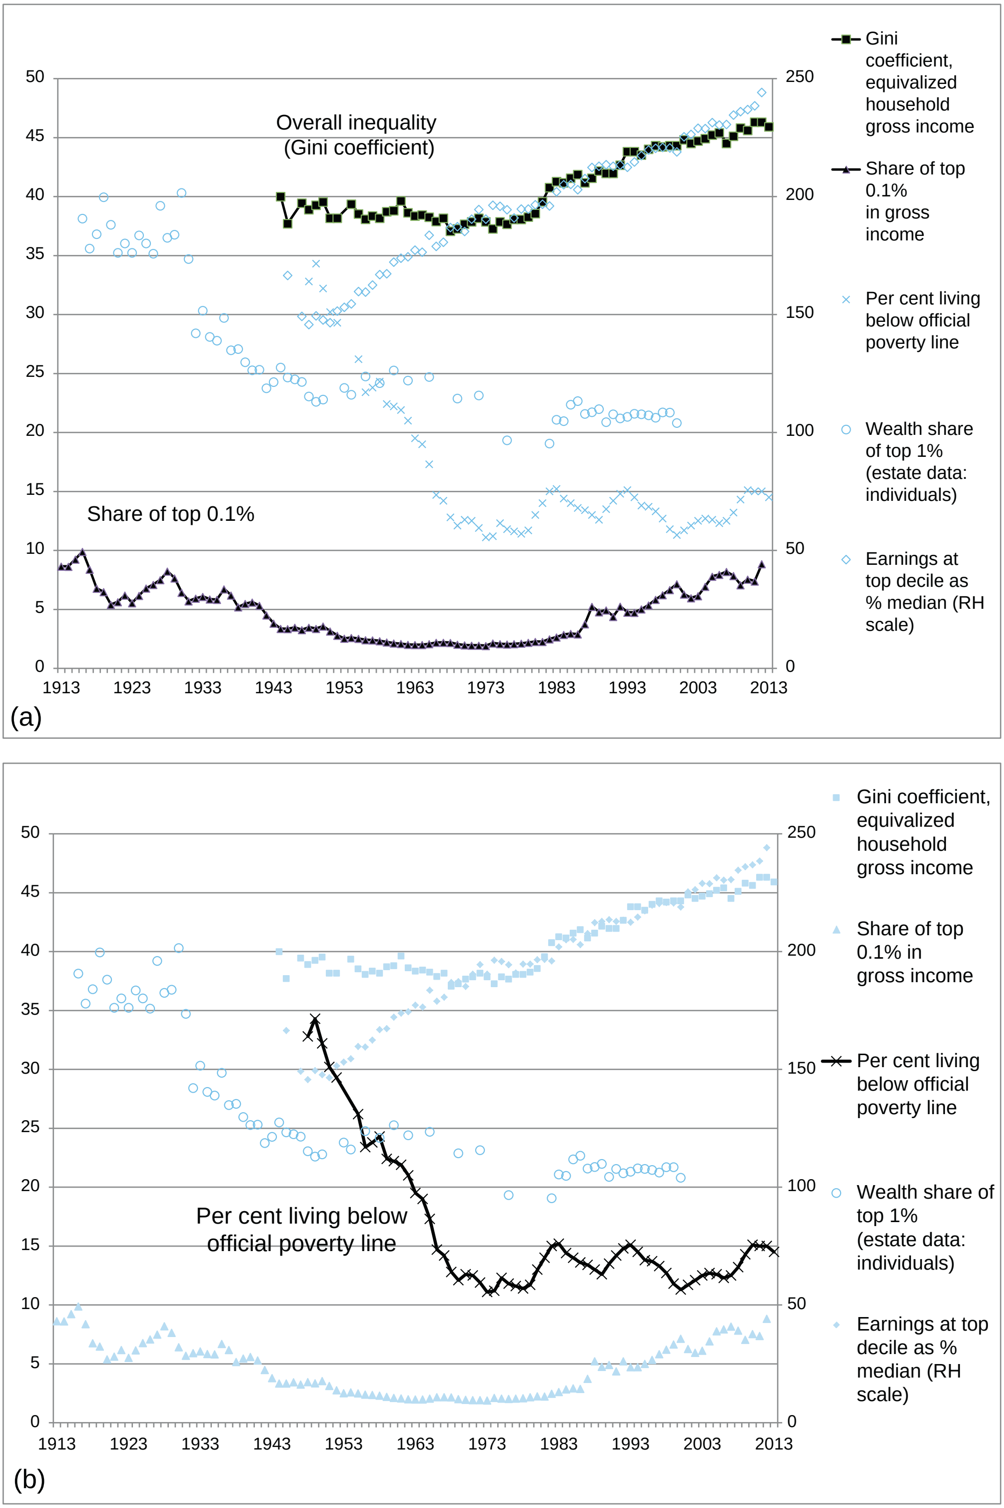

Figure 1 (See legend on next page.)

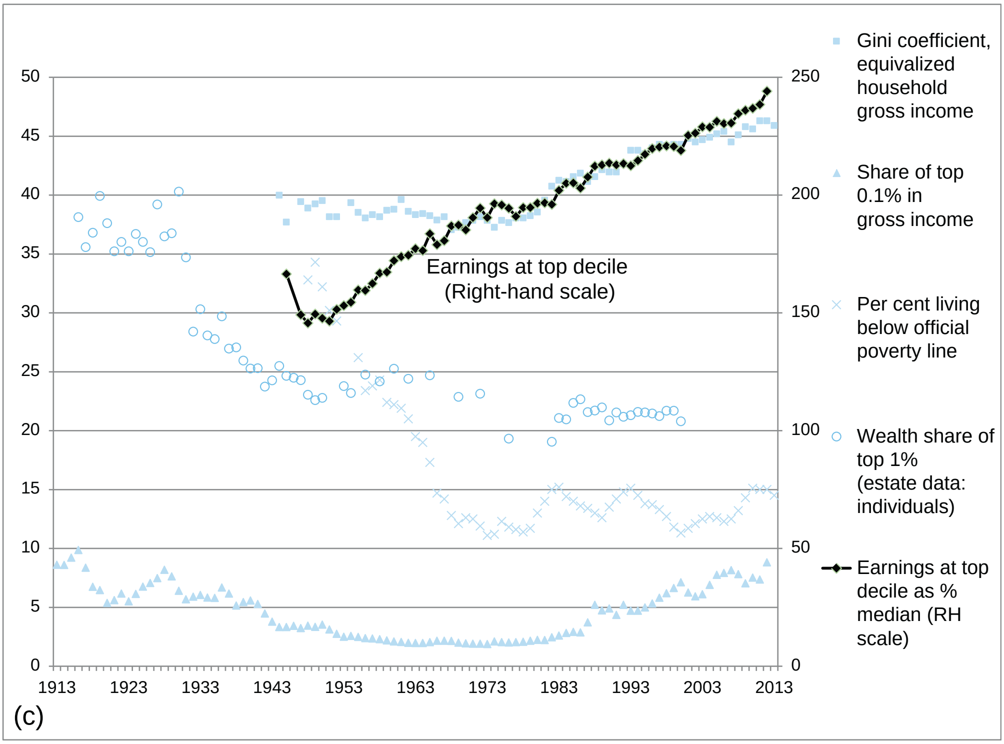

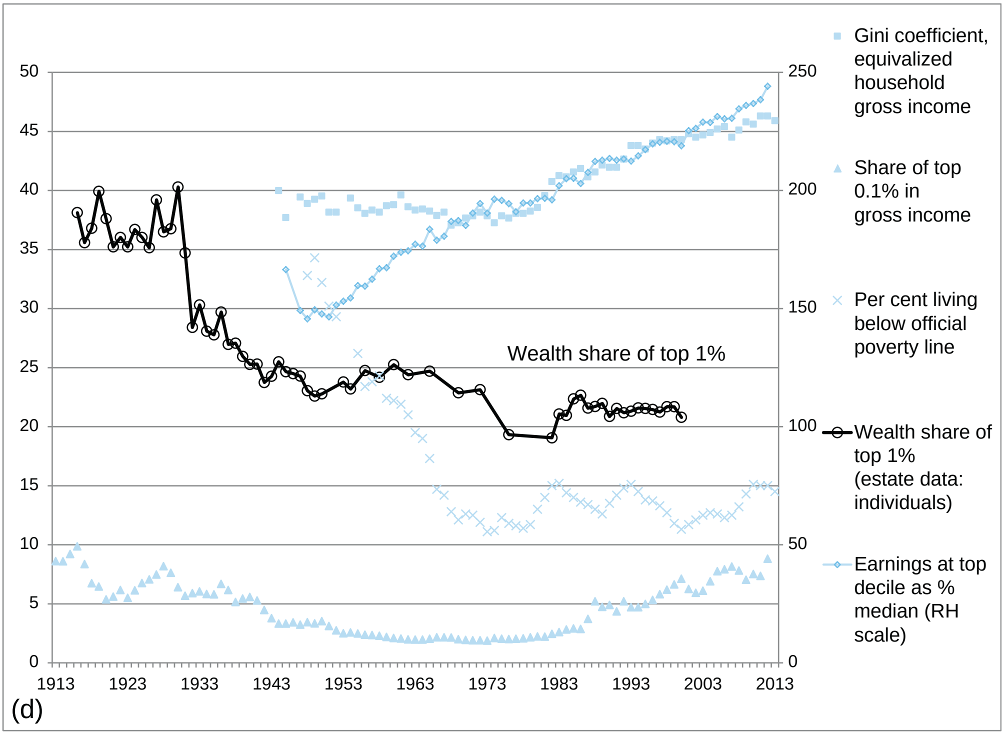

Figure 1 Inequality in the United States from 1913. (a) Overall inequality and top income shares. (b) Official poverty. (c) Earnings dispersion. (d) Top wealth shares. *Note: The right-hand scale relates to earnings at the top decile, and all other series are measured on the left-hand scale.* *Atkinson and Morelli (2014)*.

Box Sources of Data for Figure 1

Overall inequality: Gini coefficient of gross equalized household income from the U.S. Bureau of the Census, Income, Poverty, and Health Insurance Coverage in the United States: 2013 (table A-3, Selected measures of equivalence-adjusted income dispersion), where it has been assumed that half of the recorded change between 1992 and 1993 was due to the change in methods (and therefore 1.15 percentage points have been added to the values from 1992 back to 1967), this series is linked backward at 1967 to the series from 1944 given by Budd (1970, table 6).

Top income shares: The share in total gross income (excluding capital gains) of the top 0.1% is based on the work of Piketty and Saez (2003); updated figures are taken from the Web site of Emmanuel Saez:

http://eml.berkeley.edu/~saez/.

Poverty: The proportion of the population below the official poverty line before 1959 from Fisher (1986) and from 1959 from the U.S. Bureau of the Census Web site, Historical Poverty Tables, Table 2 and Table B1 from the U.S. Bureau of the Census, Income, Poverty, and Health Insurance Coverage in the United States: 2013.

Individual earnings: The series for the top decile of earnings, expressed as a percentage of the median, is based on the Current Population Survey (CPS) from the OECD iLibrary, linked at 1973 to the estimates of Karoly (1992, table 2B.2), and at 1963 to the estimates in Atkinson (2008, table T.10) from the CPS tabulations.

Wealth: The share in total personal wealth of the top 1% of adult individuals is based on estate data from Kopczuk and Saez (2004, table B1).

2. DIFFERENT FACETS OF INEQUALITY

There is much discussion of inequality but there is also much confusion, as the term means different things to different people. Inequality arises in many spheres of human activity. People have unequal political power. People may be unequal before the law. In these two volumes, we are concerned with one particular dimension: economic inequality.

Even limiting attention to economic inequality, there are many interpretations and careful distinctions have to be drawn. It is convenient to first make a distinction between monetary and nonmonetary inequality. The former, refers to standard dollar-valued magnitudes associated with the economic activity of an individual or a household (earnings, income, consumption expenditures, and wealth). Nonmonetary inequality, also referred to here as "beyond income" inequality, addresses broader dimensions of economic life such as well-being or capability.

2.1 Monetary Inequality

Restricting inequality to monetary magnitudes does not prevent confusion. In the media, one often hears statements like "the wealth of the richest *x* billionaires would feed all the poor in a particular country." But this confuses wealth, which is a stock, with income or consumption, which are flows. Flows have to be specified as occurring over a certain period, so that the figures for overall inequality in Figure 1a relate to annual income. Wealth, shown in Figure 1d, is in contrast measured at a point in time. If billionaires gave away all their wealth this year to feed poor families, then they would not appear in the Forbes list next year. If, on the other hand, they gave away the income from their wealth, then the gift would be smaller but they could go on doing it year after year.

There is often confusion between income and earnings. Articles in the academic literature may contain in their titles the words "distribution of income," but they are often actually about the distribution of earnings, and earnings are only part of income. Often too they look only at those in work, and tell nothing about the inequality of income among pensioners or the unemployed. The distinction between earnings and income is made clearly in Chapter 18 by Wiemer Salverda and Daniele Checchi. They observe that there appear to be two largely separate literatures, one concerned with earnings and one with income distribution; their chapter plays an important role in bridging this divide. As they note, it is a question not only of "inequality of what?" but also of "inequality among whom?" Earnings are typically considered on an individual basis. The earnings at the top decile (the person 10% from the top) shown in Figure 1c are those of individual workers, whereas the income measured by overall inequality is the total income of the household.

A person may have zero earnings, and no other income, but live in a household which is comfortably off. Such a situation does of course raise interesting questions—both for the analysis of inequality and in real life. What is the distribution within the household? The curve highlighted in the upper part of Figure 1a refers to the inequality of equivalized household income, which imputes to each member the total income of the household divided by the size of the household corrected by a factor that takes into account economies of scale as well as age-dependent needs. This assumes that all household members enjoy the same well-being. The topic of intrahousehold inequality is addressed in Chapter 16 by Pierre-André Chiappori and Costas Meghir. As they stress, both the level of inequality and the trend over time may be quite different. This issue is particularly relevant to gender inequality, which is the subject of Chapter 12 by Dominique Meurs and Sophie Ponthieux.

Overall inequality is summarized in Figure 1 in terms of the Gini coefficient, and this is the statistic most commonly published by statistical agencies. The typical explanation of the coefficient is geometric: the Gini coefficient is equal to the ratio of the area between the Lorenz curve and the diagonal to the area of the whole triangle under the diagonal. As illustrated in Figure 2, the Lorenz curve shows the proportion of income received by the bottom F percent as a function of F. Where the Lorenz curve is close to the diagonal (curve A in Figure 2), the Gini coefficient is small; where the Lorenz curve hugs the horizontal axis (curve B), the coefficient is closer to 1. If we are comparing two Lorenz

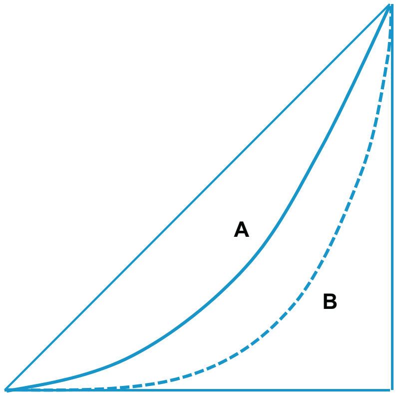

Figure 2 Lorenz curves. *Note: The Gini coefficient of the distribution A is equal to the ratio to the whole triangle of the area between the curve A and the diagonal.*

curves that do not cross, as with A and B, then one (in this case, A) definitely has a lower Gini coefficient. In this case we have Lorenz dominance, and A scores better than B on a wide variety of inequality measures (Atkinson, 1970). The converse is not true. The fact that the Gini coefficient is lower does not imply that the Lorenz curve is everywhere higher: the curves may intersect. The Gini coefficient can also be described in terms of the mean difference. A Gini coefficient of G percent means that, if we take any two households from the population at random, the expected difference is 2G percent times the mean. So that a rise in the Gini coefficient from 30% to 40% implies that the expected difference has gone up from 60% to 80% of the mean. Another useful way of thinking, suggested by Sen (1976), is in terms of "distributionally adjusted" national income, which with the Gini coefficient is (100G) percent of national income. So that a rise in the Gini coefficient from 30% to 40% is equivalent to reducing national income by 14% (i.e., $(100-40)/(100-30)=6/7$ of its previous value).

We may be interested, not just in overall inequality, but also in the top and bottom of the distribution. The top income shares, for which we have the longest run of data in Figure 1, stretching back in the United States to 1913, show the share of total gross income (i.e., before deducting the taxes paid) accruing to the top 0.1%. Figures like these, or the share of the top 1%, have appeared on the placards at demonstrations, such as those of the Occupy Movement. At the bottom of the scale, the poverty figures record the number of people living below the official line, which in the United States dates back to the War on Poverty launched by President Johnson in the 1960s. The evolution of top income shares receives particular attention in Chapter 7 by Jesper Roine and Daniel Waldenström on long-run trends. Chapter 8 by Salvatore Morelli, Timothy Smeeding, and Jeffrey Thompson discusses whether top shares are proxies for overall inequality. This chapter and Chapter 9 by Facundo Alvaredo and Leonardo Gasparini on the post-1970 trends provide evidence about both top and bottom of the scale. In a different sense, the concentration of people at the top and at the bottom of the distribution, or by complement the size of the "middle class," leads to the concept of "polarization," another concept, discussed in Chapter 5 by Jean-Yves Duclos and André-Marie Taptué. There are still many other ways to measure inequality than the Gini or percentage shares, whether it refers to income, earnings, consumption, or wealth. Likewise, there are many ways of expressing social welfare as a combination of some inequality measure and the mean income of a population. These were extensively reviewed in the first volume of this Handbook.

The panels in Figure 1 present therefore quite a rich picture of inequality in the United States over the past 100 years. But there is much that is missing. Figure 1 is a sequence of snapshots, rather than a movie. The top 0.1% in the United States in 1913 were those in the top group in that particular year; some of these people would have fallen out of the group by 1914. The statistics presented in Figure 1 tell us nothing about such mobility, which is the subject of Chapter 10 by Markus Jäntti and Stephen Jenkins. As they explain, there are two aspects. First, there is the subject of how an individual's income changes from one year to the next during their lifetime; on the other hand, there is the subject of income change between generations of parents and children. Such a distinction between intragenerational and intergenerational income mobility reflects the division in the existing literature, but one of the features of their chapter is that it draws out the elements of the measurement of income mobility that are common to both topics. They also raise the measurement issues associated with the inherently multidimensioned information about incomes over time; many of these issues are the counterpart of those that arise when one considers multidimensionality at a point in time (see in the next section).

Figure 1 shows evidence about the distribution of income within one country, but inequality is local and global as well as national. To begin with, money income has different purchasing power depending on local prices, and geographical variation can have a significant impact, as has been shown in the work of Moretti (2013) on the college wage premium in the United States. Spatial inequality is highlighted by Ravi Kanbur in Chapter 20. As he notes, "the spatial dimension of inequality is a key concern in the policy discourse, because it intersects with and interacts with disparities between subnational entities and jurisdictions. These entities sometimes have defined ethnic or linguistic characteristics, and in Federal structures have constitutional identities which naturally lead to a subnational perspective on national inequality." Inequality equally intersects with concerns about globalization, which is the main subject of Chapter 20. The world distribution of income is the subject of Chapter 11 by Sudhir Anand and Paul Segal—see also Bourguignon (2013).

We have referred above to the important topic of gender inequality. This is treated in Chapter 12, where the authors note that much of the literature is concerned with the gender gap in earnings. As they say, this is important, but only part of the story, since there is gender inequality in other forms of income and among those not in paid work, and all these inequalities interact with each other. See also Chapter 20 where Kanbur discusses globalization and gender inequality. Another important missing topic is that of inequality by race and ethnicity. It is a serious omission that we have not included a chapter on discrimination, although we should note that ethnic cleavages are one of the motivations for the theoretical analysis of polarization in Chapter 5.

In introducing considerations such as gender and ethnicity, we are, however, going beyond straight income inequality as pictured in Figure 1. We are abandoning the anonymity that lies behind a Gini coefficient or a top 1% income share. We are asking how unequal income is across various well-identified groups. This is adding a dimension to the inequality concept. Two populations A and B may have the same overall inequality of earnings but the distribution of earnings may be exactly the same for men and women in A, whereas it may be more favorable to men in B. Two countries may have the same share of the top 1%, but in one country they may be all men. World poverty may have fallen, but the number in a particular ethnic group below the poverty line may have risen.

2.2 "Beyond Income" Inequality

Much of the reflection about inequality over the past 15 years or so has been concerned with extending the concept to "beyond income" inequality. As Sen et al. (2010) proposed to incorporate nonmarket dimensions into the measure of social progress, thus going "Beyond GDP," the point here is also to take nonincome dimensions onboard when measuring inequality.

In addition to the quite remarkable perspective it offers on two centuries of economic thought on income distribution and redistribution, the chapter on the history of economic thought (Chapter 1) reminds us that there may be a historical bias in the way economists see and think about income distribution and inequality. This bias is likely to be as present today as it was in the past. Classical economists focused on functional income distribution among land, labor, and capital because they viewed the society they were living in as made up of classes deriving their income from different factors. This view does not fit well our own world, even though factor rewards and the functional income distribution still features today in macroeconomic distribution theories. Another interesting feature of Chapter 1 is the long-lasting reliance in normative economics on utilitarianism. It is only relatively recently, i.e., the 1970s, and very much under the influence of Rawls and Sen, which economists have begun to distance themselves from this approach and to consider alternatives.

It is noteworthy that this line of thought developed very much as a major extension of the previous literature on income inequality measurement, a literature that is comparatively young in a historical perspective. Several features of the income inequality measurement "paradigm" as it developed say between 1920 (Pigou, 1920; Dalton, 1920)[3] and the 1980s are worth stressing as it provides a point of reference for modern researchers who seek to extend this paradigm to a higher level of generality in terms of the definition of economic inequality. A first feature is that most properties of inequality indicators, their interpretation in terms of social welfare, and their analogy with risk analysis are now well understood. To be sure, work remains to be done on the income inequality measurement agenda. This volume of the Handbook gives two examples of it: polarization (Chapter 5) and the introduction of statistical methods in the measurement of income inequality (Chapter 8 by Frank Cowell and Emmanuel Flachaire). But considerable progress has been made. A second feature is that this was done rather quickly after the contributions by Kolm (1966, 1971), Atkinson (1970), and Sen (1973). A third feature is that, despite a possible analogy with utilitarianism, the paradigm was explicitly presented as nonutilitarian, even in the generalized sense of a social welfare function, thus breaking with an important and powerful school of economic thought on social issues. Finally, as the paradigm started to develop, its very relevance was questioned. "Equality of what?" asked Sen (1980), suggesting that the income focus was severely restrictive and even questioning the welfare basis for inequality measurement.

Four chapters in this volume of the Handbook deal in different ways with this extension of the income inequality measurement paradigm. The following simple framework is intended to help identify their main contribution, as well as the general issues in moving from income to other, more general, definitions of economic inequality. We first introduce the concept of "functionings," in the sense of Sen, of individual i, denoted by the vector a_i. Functionings include various aspects of life enjoyment: material consumption, health, job market status, housing and environment quality, etc. Among them, let us single out material consumption, as measured by money income, y_i, so that $a_i = (y_i, x_i)$ where x_i stands for nonmaterial consumption functionings. Let the preferences of individual i among those functionings be described by an ordinal utility $u_i(y_i, x_i)$ function, normalized to unity for some reference bundle $a°$. Let the "satisfaction" of individual i be an increasing function $S[u_i(y_i, x_i), b_i]$ where b_i stands for a set of individual characteristics that can influence the satisfaction that individual i derives from (y_i, x_i). Finally, assume that the economic environment, the technology and social habits are such that the vector of functionings must belong to an individual-specific set Q_i defined by y_i, x_i, and z_i, where z_i is a vector of attributes of individual i, which may differ from b_i. A person may, for example, be able to function at home but not in a formal labor market setting or may come from a social background that broadens her economic opportunities. The set Q_i thus describes the set of functionings individual i can reach, given her characteristics. This may include the standard budget constraint as well as the production function that permits the

[3] They gave their name to the Pigou–Dalton transfer principle, according to which a distribution is less unequal than another if it can be reached by a sequence of mean-preserving equalizing transfers of income.

transformation into functionings of the goods and services bought on the market. Let (y_i^*, x_i^*) be the bundle of functionings preferred by individual i in the set of possibilities, Q_i. Of course both y_i^* and x_i^* are individual-specific functions of z_i. It is also natural to assume that this preferred vector is also the observed vector of functionings. The corresponding satisfaction of individual i is $V_i = S[u_i(y_i^*, x_i^*), b_i]$, where the second argument allows for the fact that two individuals may get different levels of satisfaction from the same functioning bundles.

With the aid of this notation, it is then possible to describe the various approaches in the recent literature to extend the measurement of inequality beyond money income and to see their advantages and limitations.[4] They are discussed in Chapter 2 by Koen Decancq, Marc Fleurbaey, and Eric Schokkaert on inequality and well-being, Chapter 3 by Rolf Aaberge and Andrea Brandolini on multidimensional inequality, and Chapter 4 by John Roemer and Alain Trannoy on inequality of opportunity.

2.2.1 Defining Inequality on Functionings: Multidimensional Inequality Measurement

Inequality is to be defined on the collection of vectors (y_i^*, x_i^*) in the population. Various approaches can then be used with varying degrees of generality. The most obvious way to proceed is to aggregate the various dimensions into a single scalar and apply standard unidimensional inequality measurement to this scalar. The aggregator function, defined as $A(x,y)$, may be arbitrary, satisfying some basic properties, or it may be related to the framework set out in Section 2.2, in which case it is equivalent to assuming that all individuals have the same preferences, u, and the same characteristics b, so that they have the same satisfaction function, $S(u(x_i,y_i), b)$, of a functioning bundle (x_i,y_i). Alternatively, this function of (x_i,y_i) may be the preferences of the social evaluator. In any case, all individuals are assumed to apply the same trade-offs among the various functionings. Such a normative aggregation approach lies behind several specific multidimensional inequality measures based on some functional form for the aggregator function, as in Maasoumi (1986). The new inequality-extended Human Development Index used in the Development Program of the United Nations (UNDP) (Foster et al., 2005; Alkire and Foster, 2010), or the recent efforts by OECD to measure multidimensional living standards taking account of inequality, unemployment, and health (OECD, 2014) are examples of this approach. The recent poverty measurement literature based on the counting of deprivations follows the same logic. Deprivations are grouped by functioning, then the number of deprivations and the extent of deprivation in the various functionings are aggregated to

[4] It also allows us to distinguish the approach adopted in the inequality measurement literature of defining social welfare in terms of incomes y_i from an utilitarian approach where social welfare is defined over u_i (or $S[u_i,b_i]$).

generate an overall poverty indicator for individual i—see Alkire and Foster (2011) and Chapter 3.

Instead of using specific measures and specific aggregator functions, $A(x,y)$ or $S(u(x,y),b)$, it is possible to generalize social welfare dominance analysis in income inequality measurement—the counterpart to Lorenz dominance of income distributions (Kolm, 1977). Following Atkinson and Bourguignon (1982), a partial ordering of distributions of the bundles (y_i^*, x_i^*) in a population may be obtained by considering all the aggregator functions within some class of functions (see, for example, Duclos et al., 2011). As, however, is brought out in Chapter 3 by Aaberge and Brandolini, it is not straightforward to generalize the Pigou–Dalton principle of transfers to the multidimensional case. Moreover, we should not lose sight of the fact that nonmaterial functionings may require different treatment. The choice of aggregator function has to reflect the specific characteristics of, say, health as a variable. For example, health may be measured in ordinal rather than cardinal form, as is discussed by Allison and Foster (2004) and Duclos and Echevin (2011).

2.2.2 Individual Preferences and the Income Equivalent Approach

Interpreted in terms of individual preferences, the preceding approach imposes identical preferences on all individuals. If ordinal preferences are observed, then a particular individual-specific aggregator function can be used which has the dimension of income—see chapter 4 of Fleurbaey and Blanchet (2013). With a reference vector x° of nonincome functionings, the equivalent income corresponding to an observed bundle (y_i,x_i) is given by the solution $\mathring{y}_i$ of the equation: $u_i(\mathring{y}_i, x^\circ) = u_i(y_i, x_i)$. Such a solution does exist if $u_i(\ )$ is reasonably assumed to be continuous and monotonically increasing. The equivalent income is thus a function of the bundle (y_i,x_i) conditional on x°. It can be handled exactly in the same way as income is dealt with in income inequality measures. Of course, the issue is whether it is possible to estimate individual preferences $u_i(y,x)$. In Decancq et al. (2014), this is done using subjective satisfaction data and relating these data to income and observed functionings for individuals with common characteristics in some subset of (b_i). Another issue is the choice of the reference nonincome bundle, x°, since inequality measures will be conditional on that bundle—see Chapter 2.

2.2.3 Defining Inequality Using Subjective Satisfaction

Going further along the chain, another approach at measuring inequality is to focus directly on satisfaction levels, $V_i = S[u_i(y_i^*, x_i^*), b_i]$, as directly observed in satisfaction surveys. This is equivalent to using the individual-specific aggregator function, $u_i(y_i^*, x_i^*)$, as well as the satisfaction function $S(u,b_i)$. Several authors have followed this route, showing for instance that, unlike for observed income, inequality of "happiness" tended to go down over time in most developed countries and, as for income, to be smaller in richer than in poorer countries—see for instance Veenhoven

(2005), Stevenson and Wolfers (2008) on the United States, Ovaska and Takashima (2010), Becchetti et al. (2011), and Clark et al. (2012).

Since life satisfaction is generally recorded on an ordinal scale, there are evident problems in converting such measures to a cardinal scale and employing standard inequality indicators. For this reason, an alternative approach based on dominance criteria has been proposed by Dutta and Foster (2013). On the conceptual side, the issue arises as to the interpretation to be given to life satisfaction data. In particular, they may actually reveal the satisfaction of an individual relatively to his or her past experience and future expectations, and also possibly in relation to other individuals. If so they are improper for the measurement of "economic inequality." In terms of the notation introduced above, it is doubtful whether the individual characteristics b_i, which determine how ordinal preferences are cardinalized into satisfaction, should be taken into account in measuring economic inequality. The same bundle of functionings enjoyed by two individuals having the same preferences may yield different levels of satisfaction if one of them has a rather positive and the other a negative attitude toward life in general. A more detailed account of the interpretation to be given to subjective satisfaction data is offered in Chapter 13 by Andrew Clark and Conchita d'Ambrosio.

2.2.4 Inequality of Capabilities

Instead of defining inequality on the observed bundle of functionings (y_i^*, x_i^*), resulting from the choice of individual i in his/her choice set, Q_i, one could move upstream and consider the inequality of these choice sets, as in the capability approach. The first step is to identify these sets, as different from the particular point (y_i^*, x_i^*) actually achieved in the set. Presumably, this could be done by considering the set generated by all the functioning bundles observed for persons with the same vector as attributes, z. Assuming that such identification has been made, the second step would consist of defining an inequality measure on these sets rather than scalars, as with income, or vectors as with multidimensional inequality. In practice, the measurement of inequality based on capabilities has been reduced to emphasizing a few components of the vector of individual characteristics, z_i, that indirectly define the size of the set Q_i. Typically, these are variables like education, health, or the availability of material resources. These three variables are combined linearly at the aggregate national level to define the familiar Human Development Index used by the UNDP to measure the inequality of functionings between any pair of countries. Several attempts have been made to incorporate a larger set of variables at the individual level in specific countries (see, for instance, Anand et al. (2007).

2.2.5 Inequality of Opportunities

Inequality of opportunity is defined as that part of the inequality in optimal functionings, (y_i^*, x_i^*), that is, due to differences in individual characteristics, z_i, or possibly in a subset of these variables. Among these characteristics, a distinction is made between variables, on the one hand, that are outside the control of individuals, which are called the "circumstances" faced by the individual, and variables, on the other hand, which may be assumed under his/her control. Then the inequality of opportunity can be measured by the inequality that exists in the (y,x) space across groups of people facing the same circumstances. Those groups are called "types" by Roemer (1998). The simplest measure is obtained by considering the inequality of the mean vector (y, x) among the various types. More elaborate measures would compare the distributions (y,x), rather than means, across types. In Chapter 4, Roemer and Trannoy discuss methods for doing so when focusing on income distribution only. The implementation of this approach requires assumptions to be made about what may be considered as "circumstances" (gender, ethnicity, family background, . . .) and what may be assumed under the control of an individual (school achievement, for instance). Moreover, there are necessarily unobserved circumstances, so that one can at best measure the income inequality due to observed circumstances. A particular case frequently used is when one considers only one component of z_i, like ethnicity. In the space of earnings, the inequality of opportunity then corresponds to the familiar concept of wage discrimination, as is discussed for gender in Chapter 12.

Inequality in terms of opportunity or capability is both defined on an "*ex ante* basis," that is among groups of people with some common characteristics, and irrespective of differences in individual achievements in the space of functionings. (In contrast, inequality of outcomes, be they income, earnings, consumption spending or even "satisfaction," is an *ex post* inequality concept.) Practically, the main difference between the measurement of the inequality of capability and opportunity is that the former focuses on the inequality in the vectors of attributes, z_i, whereas the simplest approach to the latter considers the inequality between mean outcomes (y,x) across various "types" defined by identical "circumstances," z. A second difference may lie in the individual characteristics selected to differentiate people, determinants of the set of possible functionings on the side of capabilities, and exclusively circumstances outside the control of individuals on the side of opportunity. Recently, there have been a number of attempts at measuring the inequality of opportunity in several countries—for instance, Brunori et al. (2013) have put together estimates obtained for a set of 40 countries using earnings as outcome and family background as circumstances. A related literature, although with more antecedents, is concerned with intergenerational income and more generally social mobility—see Chapter 10. Here too, the issue is to measure the contribution of an observed circumstance, the parents' social status, the inequality of a particular functioning, and the children's social status.

Overall, "beyond income" inequality measurement touches upon the very fundamentals of economic inequality and a number of important conceptual advances have been made since the pathbreaking work by Rawls and Sen. Data limitations, the frequent difficulty of translating conceptual parameters into actual figures, and quite often the complexity of the analytical instruments being proposed have limited the empirical applications, but the area is promising for future research. A priority should be the search for simpler ways of making use of the conceptual advances in describing the multiple dimensions of economic inequality without reducing them to a single number.

3. DATA ON INEQUALITY

We began this chapter with the concrete example of Figure 1 in order to highlight the centrality of data. In all fields of economics, data play a key role, but in a field as politically charged as inequality, it is especially important to be careful with the quality of data. When faced with charts like those in Figure 1, showing the evolution of inequality, one should not take them simply on trust. One should ask: what data are there? Where do they come from? Are they fit for purpose? In what follows, we concentrate on data on monetary inequality, particularly income, but similar questions arise with data on non-monetary variables such as material deprivation or happiness.

3.1 Care with Data

There are two dangers. The first is the inappropriate use of data. All too often, people make claims that inequality is increasing, or decreasing, on the basis of comparing data at two different dates that are not comparable. Or country A is claimed to be performing better than country B on the basis of statistics derived from sources that cannot be compared. The share of the top 10% in total wealth may be obtained in one country from a household survey and in the other from the records of administering a wealth tax. The other danger is that of going to the other extreme and rejecting all evidence about inequality on the grounds and that it can only be measured imperfectly. That is a counsel of despair.

In our view, all forms of possible evidence should be brought to bear, but we need to take full account of their strengths and of their weaknesses. Here there have been remarkable advances. When one of us (ABA) started research on poverty in Britain in the late 1960s, the British government had decided not to allow access to the household records. The only materials were published tabulations. This changed in the 1970s. The first volume of the Handbook, published in 2000, could draw on the household survey data that had become much more widely available. Not only were there many more surveys being conducted, typically by statistical agencies, but also researchers more commonly had access to the microdata. Although this change is far from universal, it has allowed scholars to assemble internationally comparable datasets, notably the Luxembourg Income Study (LIS) founded by Tim Smeeding, Lee Rainwater, and Gaston Schaber in 1983, and the World Bank's PovcalNet covering some 850 household surveys from 127 countries.

In the decade and a half since the first volume, there have been at least four major departures. The first is the rapid growth of experimental research in economics, represented here by Chapter 13 by Andrew Clark and Conchita d'Ambrosio, where the authors show how data generated in experiments, together with survey evidence, can throw light on the subtleties of attitudes to inequality. The second is the much greater access to distributional data from administrative records. When the European Union Statistics on Income and Living Conditions (EU-SILC) replaced the European Community Household Panel from 2003, the regulations allowed flexibility as to the source of data and increasingly Member States have drawn information from administrative sources. The third is the renewed interest in historical data. Inspired by Piketty (2001), there has been a considerable investment in the construction of long-run time series, notably covering top income shares, as made available in the World Top Incomes Database administered by Facundo Alvaredo. Finally, the fourth improvement is the increasing standardization of the collection of data across countries, which permits more rigorous comparative work. EU-SILC is an example in Europe; the Program for the Improvement of Surveys and the Measurement of Living Conditions in Latin America and the Caribbean is another example. Even though more efforts are needed, cross-country comparisons today definitely make more sense than was the case one or two decades ago.

These developments mean that we now are much better informed about the extent of economic inequality and the trends over time, as is clear from reading the surveys of the evidence in Part II. The historical research is examined in Chapter 7 on long-run trends in the distributions of income and wealth, covering more than 25 countries and going back in some cases to the eighteenth century. The post-1970 evolution is the subject of Chapters 8 and 9. The former covers inequality and poverty in OECD and Middle Income countries, demonstrating that "data have come a long way" since the chapter by Gottschalk and Smeeding (2000) in volume I. The latter covers developing countries, where again there has been great progress in the measurement of inequality and poverty. Chapter 11 investigates the world distribution of income and global poverty.

The availability of data is, moreover, one key ingredient in the study of the causes of economic inequality, which is the focus of Part III. In many cases, these investigations are based on statistical analysis of country panel datasets on inequality (derived by pooling time series of observations for each of a number of countries). Differences over time and differences across countries are used to explore the multiple causes of inequality. This is the explicit concern of Chapter 19 by Michael Förster and István Tóth, and it underlies much of the analysis of Chapter 18 on the distribution of earnings by Wiemer Salverda and Daniele Checchi. In Chapter 21, the econometric analysis of the relationship among democracy, redistribution, and inequality by Daron Acemoglu, Suresh Naidu, Pascual Restrepo, and James Robinson uses international databases on inequality. It is on such international databases, now widely used, that we concentrate here, since they illustrate many of the issues.

3.2 International Databases on Income Inequality

In considering international income distribution databases, as listed and discussed in Chapter 19, a key distinction is between primary databases that rely directly on micro-data, standardized as much as possible to ensure comparability across countries and time periods, and secondary databases that compile estimates of income distribution indicators from available published sources. Examples of the former include LIS, the EU-SILC—which also coordinates the data collection in the countries covered—the OECD income distribution database, SEDLAC covering Latin America and the Caribbean and the World Bank's POVCAL/WYD. Secondary databases include the World Income Inequality Database (WIID) assembled by UNU-WIDER (an updated version of the dataset originally constructed by Deininger and Squire (1996) at the World Bank), and the "All the Ginis you ever wanted" database put together by Branko Milanovic (2013), also at the World Bank. The latter states clearly that "this dataset consists only of the Gini coefficients that have been calculated from actual household surveys," and a second important distinction is between databases, like "All the Ginis," that are restricted to actual observations and those databases that impute missing values of specific indicators for some countries and for some time periods. Aiming at "the widest possible coverage across countries and over time," the Standardized World Income Inequality Database (SWIID) "uses a custom missing-data algorithm to standardize the United Nations University's WIID and many, many additional observations" (SWIID Web site and documentation). The University of Texas Inequality Project (UTIP) Estimated Household Income Inequality Data Set is derived from the econometric relationship between the UTIP-UNIDO dataset on industrial pay, other conditioning variables, and the World Bank's Deininger-Squire dataset on income inequality.

The original World Bank Deininger and Squire (1996) database was scrutinized by Atkinson and Brandolini (2001), who showed the risks of reaching inconsistent conclusions using secondary databases, or, more generally, comparing income distribution indicators across countries or time periods that relied on different definitions of income or the statistical unit. While recognizing the value of such databases, they cautioned against their uncritical use and set out a number of principles which should guide the construction of secondary databases. Progress has been made since then. In a paper reviewing the WIID database for a special issue of the *Journal of Economic Inequality*, edited by Ferreira and Lustig (2015), on income inequality databases, Jenkins (2014) repeated the comparison made by Atkinson and Brandolini between the database and consistent estimates obtained from LIS for a sample of rich countries in the early 1990s, using WIID version 2c (2008) and found that differences had been reduced (and a new WIID version 3.0B was subsequently released in 2014). Yet, he reiterated that "one cannot simply use the WIID data 'as is'" (Jenkins, 2014, p. 15). As this kind of benchmarking has not been made for developing countries, it is not unlikely that inconsistencies are more frequent there. One should not use data from secondary databases without first making a careful inspection.

3.3 A Checklist of Questions

When using data on income inequality, what questions should one ask? Here, we give a checklist covering some of the most important. These issues, and many others, are discussed in the Canberra Group Handbook on Household Income Statistics (United Nations Economic Commission for Europe, 2011), which is the second edition of a handbook produced in 2001 by an International Expert Group on Household Income Statistics established in 1996 at the initiative of the Australian Bureau of Statistics. In describing it as a "checklist," we are not suggesting that there is a single right answer. The appropriate choice depends on the context and may differ between countries at different stages of development. The choice depends on the purpose of the analysis. But it is essential that the user be aware of what data they are employing.

3.3.1 Inequality of What?

In some countries statistical offices collect data on household income, whereas in others consumption expenditure data are collected. The Povcal database comprises both countries that report income inequality and others that report inequality in consumption expenditure. LIS avoids this heterogeneity by using income surveys for all countries. Income may be defined in a variety of ways: posttax (or disposable) income, pretax income allowing for deductions, such as interest paid (confusingly, this is often called "net income" in official statistics), or pretax income before deductions. As implemented, the income concept may follow more or less closely the definition adopted by the International Conference of Labour Statisticians (and the second edition of the Canberra Handbook), which covers all receipts whether in monetary form or in kind, apart from irregular or windfall receipts. Important issues here (as for the definition of consumption) are the inclusion or exclusion of imputed rent for owner-occupied housing, of home production, and of in-kind benefits.

Income and expenditure relate typically to a year, but may be measured over different time periods. This is particularly important in the case of earnings, as discussed in Chapter 18. The reference period may be the latest pay period or earnings that may relate to normal monthly earnings, excluding irregular bonuses, or they may be total annual earnings. They may be expressed per hour, and this may allow a decomposition into wage and leisure inequalities. The issue of timing also affects the population covered. People may be present for part of the year, and the inclusion or exclusion of such part-year incomes, or earnings, affects the measured degree of inequality. Another issue related to the comparability of earnings data across countries is the status of payroll charges and social security contributions. Earnings are net of all these charges in some cases and gross of contributions paid by employees in other cases, whereas payroll charges paid by employers are rarely recorded. From that point of view, progress in constructing international databases on income distribution has not been paralleled by the same effort for individual earnings.

An additional issue of importance with existing datasets on income inequality is the difference in the cost of living across geographical areas in the same country. Such data do not exist in all countries. Yet, these differences may be sizable and may have a major impact on the estimation of inequality. Uncertainty about the rural–urban cost of living differential has led the managers of the Povcal database in the World Bank to report separately on the distribution of income in rural and urban areas in both China and India and differences in reported estimates of income inequality in China are often due to different assumptions about the rural/urban cost of living ratio. Differences in the cost of living across cities—if only with respect to housing rents—in developed countries generate the same kind of imprecision (we have already cited the work of Moretti, 2013).

3.3.2 Among Whom?

Data on inequality may refer to differences between households, between inner families, between tax units, or between individuals. Much empirical evidence relates to households, and surveys are typically conducted on this basis. Such a measure however tells us nothing about the distribution within the household—the subject of Chapter 16. Where there are several generations of adults within the household, inequality may be concealed. The same applies to the inner family, in that the aggregation of the income (or consumption) of a couple conceals gender inequality—the subject of Chapter 12. In this context, it is interesting that a number of countries have moved to individual taxation under the personal income tax. From such administrative data, we can learn, for example, that women were seriously underrepresented among the top 1%. In Canada, in 2010, women accounted for only 21% of those with gross incomes in the top 1% (Statistics Canada, 2013); in the United Kingdom, in 2011, the corresponding figure was 17% (Atkinson et al., forthcoming).

Households and other units have differing size and composition, and adjustments have to be made using equivalence scales. Here, there is a variety of practice and some harmonization across primary databases would be welcome. For instance, the "equivalization" procedure differs between LIS ("Key Figures" webpage) and the OECD income distribution database, which use the square root of the total family size as an equivalence scale, and Povcal which uses the total family size, and imputes the total household per capita to each household member. In other words, the equivalence elasticity is set to 0.5 in the first case and to 1 in the second. These choices can make developing and emerging countries appear more unequal in comparison with developed countries, were the definition of income the same in both groups. To reestablish comparability, it would not be difficult for all the databases to provide estimates of income distribution indicators with both equivalence elasticities—something that is done in the SEDLAC database for Latin America. At the same time, it is not clear that economies of scale in consumption and therefore the equivalence scale should be the same across countries at different development levels.

Except where the reference unit is the individual, there is the further question of the weighting of observations—an issue that is often neglected, and not always documented. If we observe income at the household level, it does not follow that each household should be regarded as one unit regardless of size. Weighting is a separate issue from the choice of equivalence scale. The income of a household may be corrected by an equivalence scale that allows for economies of scale within the household but that does not mean that it should be weighted by the number of equivalent units. Weighting by the number of individuals may be judged more appropriate. This has, of course, the consequence that total income attributed to the multiperson households is greater.

3.3.3 Data Sources

Each source of data has strengths and weaknesses. Historically, evidence on income inequality, such as that used by Kuznets (1955), came from administrative records, of which the most important were the statistics derived from personal income taxation. The income tax data have serious limitations—the incomplete coverage of those below the tax threshold, the underreporting of income, and the impact of lawful tax avoidance and income shifting—which are discussed extensively in Chapters 7 to 9. They must therefore be used with caution. The same applies to the source that is now more widely used: household surveys.

In the case of household surveys, differences in survey questionnaires and in the methodology of correcting for nonresponse or missing observation reduce the comparability of inequality indicators. In his review of LIS, Ravallion (2014) emphasizes the issue of nonresponse and missing income data. Nonresponse by sampled households is in some cases handled by redrawing a comparable household in the same stratum, and in other cases by simply reweighting responding households. But there is a risk of a bias if nonresponse is relatively frequent and not random with regards to income. This bias is likely to be substantial if the very top of the distribution is simply not sampled, as it is often the case in developing countries—as shown by Korinek et al. (2006). The frequency of nonresponse might usefully be reported by statistical offices. The same applies to missing income values for responding households. In some cases, a value for total income or for an income component is imputed based on observed characteristics of households and household members. In others, no correction is made with the effect of the corresponding observation being taken out of the sample on which the income distribution is estimated. Again, in both cases, there is a clear problem if missing values are income-dependent.

3.3.4 Relation with National Accounts

Data from administrative records or from household surveys have to be viewed in relation to the national income accounts, which provide an important point of reference. Indeed, in the case of income tax data covering only part of the population, the national accounts are the standard source of the independent income control totals. In the case of household surveys, the issue may arise at the level of total household income, as has been extensively discussed in the literature on world income inequality—see Chapter 11. It may arise when some average income component in a survey appears to be relatively more underestimated in comparison with National Accounts than other components, provided that a full-fledged household account is available. In some cases, the statistical office scales up that income component so as to establish consistency with the National Accounts total. But where this is not distributed as total income, or where the discrepancy is due to underreporting as well as nonreporting, this may drastically modify most income distribution indicators. This kind of correction is now rarely done in advanced countries, but is still applied in some emerging countries, especially for property income, most often grossly underreported in household surveys. The database managed by the Economic Commission for Latin America and the Caribbean includes such an adjustment. In Chile, for instance, all income components in the CASEN survey (salaries, self-employment income, property income, transfers, and imputed rents) are scaled up (or down in the case of imputed rent) so as to match National Accounts. The only exception is for property income, for which the gap is imputed entirely to the top quintile of the distribution. As there are differences in the definition of income in surveys and in National Accounts, such a correction introduces additional noise in the distribution data that appear later in cross-country databases. Bourguignon (2014) indeed shows that the size of the adjustment may be substantial.

3.4 Implications of Data Heterogeneity

The consequences of the heterogeneity of income distributions indicators in cross-country databases for economic analysis and policy are important. In the first place, they make benchmarking across countries or time periods a fuzzy exercise. Not being able to check unambiguously that inequality has increased or decreased in a given country or to compare such an evolution to what has occurred in neighboring countries is a serious handicap for policy making and for the democratic debate in general. Relying on the most transparent and comparable measurement apparatus of income inequality is absolutely essential.

A second consequence of the imprecision and the lack of comparability of income distribution indicators is the weakening of standard econometric analyses of the consequences of income inequality. A noisy regressor introduces a bias in any regression. At the limit, if the noise is too big the estimated coefficient of that regressor goes to zero and income distribution is deemed unimportant in explaining, for instance, the pace of economic growth, political instability, or crime. Consider, for example, the widely cited study of Ostry et al. (2014), who test the influence of inequality and the extent of redistribution, as measured by the difference between the inequality of gross and net incomes, on growth. They find that “lower net inequality is robustly correlated with faster and more durable growth, for a given level of redistribution [and that] redistribution appears generally benign in terms of its impact on growth; only in extreme cases is there some evidence that it may have direct negative effects on growth. Thus, the combined direct and indirect effects of redistribution—including the growth effects of the resulting lower inequality—are on average pro-growth" (2014, p. 4). As the authors clearly recognize, these conclusions must be taken with care if one expects substantial measurement error in the difference between net and gross income inequality, and one should therefore look at the underlying source.[5] The study makes use of version 3.1 of the SWIID database created by Solt (2009). The SWIID data are indeed extensive, providing Gini coefficients for gross and net income for some 175 countries for years in the period 1960–2010. There are more than 4500 observations in the version 3.1 of the database. At the same time, many of these observations are imputed: many countries in the sample lack regular observation of both gross and net income inequality.[6] The author of the SWID database is to be commended for providing the standard deviations of imputed values, but a two standard deviation range for the Gini coefficient in Bhutan, for example, in 2012 of 24–45% (from SWIID version 4.0) means that there is limited information content, as does the range for Malaysia in 2012 of 32–61%. This means in turn that users need to take account of the underlying data quality and that studies that fail to do so are open to question, as is emphasized by Solt (2009). (Version 4.0 of the SWIID is set up to facilitate the application of the multiple imputation approach to parameter estimation, and we understand that version 5.0 goes further in that direction.)[7]

Another consequence of the inconsistency of the income distribution indicators found in cross-country databases is the likely inaccuracy of global income distribution indicators, which cumulate the measurement errors to be found in national income distribution indicators. Global income inequality estimates are certainly extremely noisy, as suggested by the discussion in Chapter 11, although the imprecision of national income distribution indicators is only one part of the problem. The inequality between countries represents a high share of total global inequality so that another major source of ambiguity lies in the estimates of the mean income of national populations relatively to each other. In both cases, moreover, it is clear that big countries play a major role, whereas the

[5] Chapter 21 by Acemoglu et al. in this volume uses the same database on income inequality with two important differences. On the one hand, they use only net income inequality rather than the difference between net and gross, necessarily more imprecise. On the other hand, the inequality appears on the left-hand side of their regression equation so that measurement errors do not create estimation biases.

[6] SWIID provides estimates of redistribution in countries where the source data include at least three observations of net inequality and at least three observations of market inequality (and excludes some countries that meet this criterion but the two are not contemporaneous). Ostry et al. (2014) also provide estimates of the relationship among growth, inequality, and redistribution restricted to that sample.

[7] Such improvements in datasets are much to be welcomed. At the same time, they mean that we should revisit the conclusions drawn in studies based on earlier versions. It also underlines the importance of recording the version of the dataset used and of maintaining archives.

imprecision on the degree of inequality or the mean income within small countries has very little impact on global inequality. This is well illustrated in Chapter 11 where the difference in the rate of growth of the mean individual standard of living in India as reported in the household surveys and in National Accounts is shown to have a significant impact on trends in global inequality. More work is needed to evaluate the degree of imprecision of global inequality estimates due to these different causes—imprecision of national income distribution data, of national means, and of course purchasing power parity estimates—so as to estimate confidence intervals and being able to check whether or not estimated changes are significant. The same applies to global poverty measurement, in particular when it is defined on the basis of a common absolute poverty line.

3.5 The Way Forward

What is the way forward? How can we improve our ability to make international comparisons of distribution and distribution trends, whether for benchmarking, econometric analysis, or global distribution estimates? In comparing income distribution across countries and over time, one would ideally like to access microdata and compute the appropriate summary measures controlling for the definition of the income unit (household or individual), income (gross, net, consumption expenditures, including or not in kind transfers, imputed rents, . . .). But, of course, this would be a herculean task. Hence, there is an obvious need for a first treatment of the data done once for all by the database managers rather than by every user of the database. This requires that data be standardized, as much as possible, in agreement with some consensual definition of income and income units. The "Key Figures" on the LIS Web site obey that logic, while access to the original microdata (and to the STATA or SPSS programs that generate the Key Figures) allows users to depart from this core definition.

Progress in this direction can best be made by following the route of national accounts, with the analogue of the UN System of National Accounts being developed, building on the work of the Canberra Group on Household Income Statistics and on regional initiatives such as the European Union social indicators (Atkinson and Marlier, 2010). Guidelines could then be agreed for the assembly and analysis of distributional data. But in the case of income distribution analysis, a further step is necessary, since a key element is that of access to the microdata. What is required is the possibility for outsiders to access the microdata themselves, under conditions that guarantee confidentiality as in LIS. The same kind of architecture could be developed in other regions or possibly within an international institution like the World Bank. Such guidelines and agreed access to income distribution microdata would not however solve the data problems inherent to the unavoidable incompleteness of the surveys. Moreover, these problems, notably those of securing adequate response rates, may in the future become more severe. From that point of view, complementing standard survey-based analysis with administrative sources has proved to be extremely promising in the recent years.

A number of European countries have moved in this direction, with their EU-SILC data being collected in this manner (although this does raise issues of comparability with the data from countries that rely solely on household surveys). The use being made of the top income database based on tax data in developed countries is a sign of the importance of complementary data—see the discussion in Chapter 8. Combining both sources is not an easy task. The reference unit is not always the same, household in one case, tax unit in the other. Income concepts may differ across the two types of source. Moreover, it is not clear whether top income individuals are absent from household surveys—the nonresponse issue alluded to above—or whether they are present but with underreported income. The correction to be made to inequality indicators is not the same in the two cases—see Alvaredo and Londoño Velez (2013). More generally, the required adjustments may differ across countries.

In line with the discussion in Section 2, one may also wonder whether cross-country inequality databases should not go "beyond income" and incorporate other dimensions relevant to economic inequality. Without getting into the difficulty of measuring the inequality of capabilities or opportunities, some components of a broader definition of inequality can easily be measured, and the dimensions extended. This is the case, in particular, of inequality across gender. Such a database, based on Labour Force Surveys, does exist for OECD countries at the OECD and also for some emerging countries in LIS' "Key Figures." It should not be a major effort for most other primary databases relying on household or labor force surveys covering a larger set of countries to report summary statistics on gender earnings ratios. More generally, primary databases could try to go "beyond income" by reporting summary statistics on the joint distribution of income variables and other individual or household attributes available in standard surveys. Education, gender, and ethnicity are the most obvious examples.

Going beyond the exploitation of standard income focused surveys is problematic because relevant attributes are typically covered in different surveys. For instance, the Demographic and Health Surveys (DHS) in developing countries cover self-reported health status, fertility, infant mortality at the individual or household level. Yet, they do not collect direct information on monetary resources, so that nonincome functionings cannot be considered jointly with income. Matching techniques with household income or consumption surveys could be used to impute an income to households in the DHS but then it is difficult to deal with the inherent imprecision. On the other hand, there are numerous international databases that combine income inequality data with other dimensions of functionings. In the field of health, this was achieved by the Globalization-Health Nexus database put together by Cornia et al. (2008). The problem with these databases, however, is that the nonincome indicators are essentially aggregate so that those databases generally give no information on the inequality of the corresponding nonincome attributes, and, of course, still less on their joint distribution with other attributes, including income or earnings. From that point of view, generalizing and standardizing poverty surveys that include questions on various types of deprivation may be the simplest way of monitoring one aspect of "beyond income" inequality.

4. TAKING ECONOMIC THEORY SERIOUSLY

Data are one important ingredient in studying economic inequality; the second important ingredient is provided by economic theory, which underpins the search for explanations of inequality in Part III. Here again, we make a plea for taking seriously the building blocks that are utilized. One cannot simply take an economic model off the shelf and apply it in an unthinking way to the problem at hand. Likewise, theorists must keep an attentive eye on basic empirical facts and make sure their representation of the way multiple economic mechanisms combine to generate specific properties of the degree of inequality in an economy fits these facts. In what follows, we illustrate and discuss this twofold requirement for identifying the mechanisms that perpetuate or modify inequality by focusing on the role of technical progress, human capital, and wealth accumulation within a largely macroeconomic framework. As can be seen from Chapters 15 and 16, models that incorporate these particular mechanisms are indeed central in the present theoretical reflections on economic inequality, including the accent recently put on the top of the income and wealth distribution. Much of the recent reflection on the possible causes of the observed rise in inequality actually bears upon macroeconomic factors.

In this section, we focus on the determinants of market incomes: wages and capital incomes. These subjects, particularly wages, are covered extensively in other Handbooks, such as the *Handbook of Labour Economics*, and in designing this volume we have sought to avoid overlap. For the same reason, we have devoted more space to this aspect in this Introduction, as a contribution to bridge-building across fields of economics. We should also underline that while wages and the return to capital are important elements in determining the distribution of household income, their impact depends on a variety of social and institutional mechanisms, such as household formation and demographics, and on the redistributive incidence of public policy (see Section 5).

4.1 The Race Between Technology/Globalization and Education

In the Introduction to volume I, we set out the application of supply and demand analysis—perhaps the simplest of economic theories—to the explanation of rising earnings dispersion. Jan Tinbergen (1975) famously described a "race" between increased demand for educated workers and the expansion of the educated population. Where demand—driven by new technology or by globalization—outstrips supply, then the premium for education rises. As typically portrayed, as in Figure 3, the supply and demand equilibrium is shifting up over time. The wage premium for higher-educated workers is rising because technological progress is biased in their favor—the skill-bias technical change (SBTC) hypothesis—or because increased global competition favors more

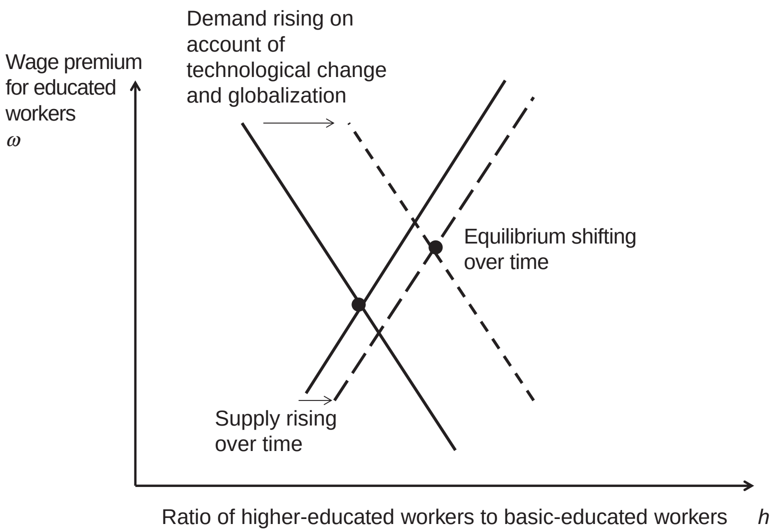

Figure 3 The "race" between technology/globalization and education.

educated workers. In what follows, we refer mainly to the SBTC hypothesis, but this does not mean that we discount the role of international trade.

First year economics appears to explain what is observed in the real world. However, second year economics teaches us that a race is a dynamic process and its outcome depends on how one specifies the underlying adjustments. Suppose, as seems reasonable, that at any moment, t, the ratio of higher-educated to basic-educated workers is fixed at $h(t)$ and that the relative wage, ω, clears the labor market. With aggregate output a function of the two kinds of labor, with a constant elasticity of substitution σ, the wage premium is determined by

$$\omega = A\,[\alpha_h/\alpha_b]^{(1-1/\sigma)}h^{-1/\sigma} \tag{1}$$

where A is a constant and α_i denotes the productivity of workers of type i (h for higher-educated and b for basic-educated). If over time skill-biased technical change (SBTC) raises the square bracket, and if (a condition that is often forgotten) the elasticity σ is greater than 1, then the wage premium rises for any given $h(t)$. In general, however, h will rise in response to the rising premium. If the growth rate of a variable x is denoted by $G(x)$, and the growth rate of the square bracket is a constant, g, then we can write

$$G(\omega) = (1-(1/\sigma))g - (1/\sigma)G(h) \tag{2}$$

Suppose that the growth rate of h responds to the difference between the wage premium and the cost of acquiring education with an elasticity β; moreover, suppose that the cost of education, in terms of the wage of basic-educated workers, is equal to a fee, F, plus the cost of postponing earnings by T years, given by e^{rT}, where r is the annual cost of borrowing, i.e.,

$$G(h) = \beta\{\omega - F - e^{rT}\} \tag{3}$$

So that, combining (2) and (3)

$$G(\omega) = (1 - 1/\sigma)g - (1/\sigma)\beta\{\omega - F - e^{rT}\} \tag{4}$$

and for positive ω the relative wage converges to a value

$$\omega^* = F + e^{rT} + g(\sigma - 1)/\beta \tag{5}$$

From this, we can see that SBTC (and $\sigma > 1$) does not lead to an ever-increasing wage premium. The move to a new, constant, rate of technological progress leads to an increase in wage dispersion but we should not expect this to continue, since supply adjusts.

We have set out this theory for two reasons. The first is that, when looking at the data, we need to distinguish between a continuing upward trend and an upward shift in the degree of wage dispersion. If, empirically, wage dispersion has ceased to increase, this does not mean that SBTC (or globalization) has come to an end.[8] Indeed, from (5), we can see that g falling to zero would imply that the wage premium fell back to its earlier value. The second reason for the explicit model of dynamics is that economic theory is valuable because it points to other mechanisms that may be important. From (5), we can see immediately that the same forces—SBTC or globalization—can have differing effects in different countries depending on the speed of adjustment of supply (via β). This is one response to the challenge to the SBTC explanation made by Lemieux: "if technological change is the explanation for growing inequality, how can it be that other advanced economies subject to the same technological change do not experience an increase in inequality?" (2008, p. 23). A country where the labor market is more responsive will see a smaller increase in wage dispersion. From (5), we can also see that wage dispersion may increase on account of increases in the cost of education. Raising student fees leads, with these market responses, to a higher wage premium. Such a rise in wage dispersion does not however imply a rise in inequality—when viewed over the life time as a whole.

4.2 Steady States and Transitional Dynamics

This condensed presentation of the supply and demand model of wage inequality shows the power of theory. At the same time, it raises questions as to whether the available models actually capture what is being observed and provide a reasonable basis for projecting the future development and drawing policy implications. On the one hand, there is the issue of the relative strength of the various mechanisms simultaneously at play—e.g., biased technical change, educational choices, supply of skills, capital accumulation

[8] The model has been discussed in terms of technological change, but similar considerations apply where demand is shifting on account of globalization.

and allocation, etc. On the other hand, there is the issue of the time scale, which is a key aspect that we would like to highlight—both here and, later, when we discuss the distribution of wealth.

To be tractable, the analysis generally focuses on the steady-state or long-run equilibrium properties of these models, without necessarily mentioning how long the long run is. In Chapter 14, Vincenzo Quadrini and Victor Rios-Rull thus warn the reader that: "for simplicity of exposition, we limit the analysis here to steady-state comparisons with the caveat that in the real economy, the distribution will take a long time to converge to a new steady state." However, to bring theory to bear on the observed evolution of the distribution of income and on policy, tackling transitional phases is essential. In distributional analysis, the fact that accumulation of human and physical capital, the factors the most likely to modify the distribution of income, takes time at both the individual and the aggregate level means that it may take a long time for the economy to adjust to an exogenous shock. After all, if a shock modifies the incentive to get tertiary education, it will take around 40 years—or the duration of active life—before the full effect is felt, or in other words all workers in the labor force have faced the new trade-off between education and work. In between, many other things may change.

To illustrate this point, consider the dynamics of the preceding model in adjusting to a steady state, where again we focus on SBTC. This requires modeling with a little more detail the behavior of h, the ratio of the skilled, L_h, to the unskilled, L_b, labor force. Assume the population is stationary so that a proportion n of the labor force is exiting every year and an equal proportion is entering. For a stationary population, n would be the inverse of the duration of active life, roughly 2.5%. The important point is that most of the change in the skill structure of the labor force goes through its progressive renewal and modifying educational choices made by the entrants. More precisely, assume that the dynamics of the skill structure of the labor force is given by:

$$\Delta L_h = n\left[1 + \beta\left(\omega - F - e^{rT}\right)\right] L_h - nL_h$$

$$\Delta L_b = nL - n\left[1 + \beta\left(\omega - F - e^{rT}\right)\right] L_h - nL_b$$

where L is the total labor force ($L_h + L_b$). In other words, the rate of growth of the skilled labor force depends on the net benefit from acquiring a skill from more schooling, whereas the growth of the unskilled labor force is driven by those entrants who have decided not to stay in school. Dividing these two equations respectively by L_h and L_b and subtracting the latter from the former yields:

$$G(h) = n(1 + h)\beta\left(\omega - F - e^{rT}\right) \tag{3'}$$

which is a slight modification of (3). Then the dynamics of the economy when skill-biased technical change (SBTC) takes place, and the productivity ratio (a_h/a_b) increases at the constant rate g, is given by (3′) and:

$$G(\omega) = (1-(1/\sigma))g - (1/\sigma)G(h) \tag{2}$$

Note that, with this modification of the labor supply dynamics, no steady state exists in the (2)–(3′) model as long as g is strictly positive. Simulating this dynamic system with $\sigma=1.2$, $h(0)=3$, $n=1/42$, $F=1.9$, $r=2.5\%$, $T=4$, $\beta=1$, and with no SBTC ($g=0\%$) yields an initial steady state. Then, in year 1, the rate of SBTC rises to $g=3\%$, and the economy evolves according to the trajectories shown in Figure 4 for the wage skill ratio or skill premium, ω, and for the size of the skilled labor force relatively to the number of unskilled workers, h. As before, the wage skill ratio rises, but—there being no steady state with positive g—it then falls back to the starting level.

Three features are of interest in Figure 4. The first is that, as expected, the wage skill ratio increases and then turns back down as the relative supply of skilled labor increases. Yet, this stabilization takes approximately 30 years to materialize. Even after 50 years, the curve has only just begun to turn down. The second feature is that the overall increase in the skill premium is rather modest, 3.1% in Figure 4. Such a limited increase is due of course to the labor supply response or the value of the elasticity β. Without such a response, the skill premium after 30 years of SBTC at the rate of 3% would have been 12% higher than initially. The third interesting feature in Figure 4 is the behavior of the skilled share of the labor force, which keeps increasing even when the wage skill premium has stabilized. In the presence of SBTC, such a persistent increase in the proportion of

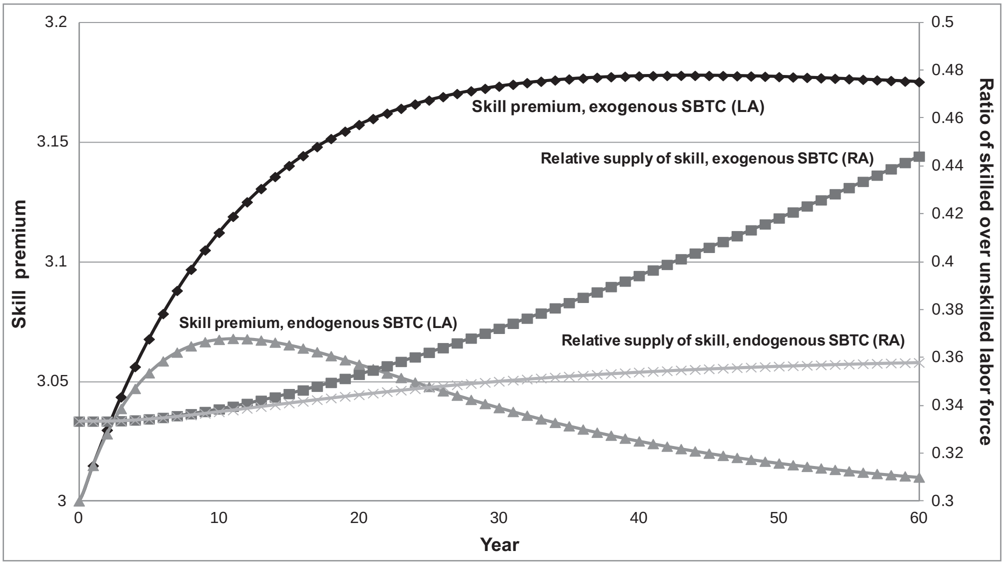

Figure 4 Skill-biased technical change: simulated trajectories of the skill premium and the relative supply of skilled labor with exogenous or endogenous rate of skill-biased technical progress. *Note: The skill premium is shown on the left-hand axis; the relative supply of skilled workers on the right-hand axis.*

skilled workers in the labor force is indeed needed to stabilize the wage skill premium and occurs because the long-run equilibrium premium is above the cost of acquiring a skill relatively to the unskilled wage level, unlike the case at the initial equilibrium.

Economic theory is thus important to understand switches from a long-run equilibrium to another but also the nonsteady-state behavior. In this respect, note that the transition modeled above depends on the way expectations are formed. Equation (3) and (3′) are implicitly based on static expectations about the skill premium. Rational expectations are somewhat irrelevant in the present framework as the cause of the increase in the skill premium is not necessarily known by economic agents. But adaptive expectations might yield another time path. Likewise, a stronger supply response, β, to a change in the skill premium makes the transition shorter, and the new long-run wage skill ratio smaller.

From the point of view of the inequality of earnings, Figure 4 shows that two forces are at play. On the one hand, the increase in the wage differential increases inequality in the sense that the Lorenz curve shifts outward. On the other hand, the fact that more people get skilled has an ambiguous effect on the distribution of earnings. As the average earnings increases, both low-skill and high-skill people lose relatively to the average—the bottom of the Lorenz curve shifts outward but the opposite occurs at the top. The relationship between these two ratios, ω and h, and the overall inequality as summarized by the Gini coefficient is discussed in Chapter 18. Note however, that this analysis refers to the distribution of earnings. Implications of the joint dynamics of technology and education for the inequality of income might be different because of various mechanisms including endogamy, joint labor force participation within couples or fertility differentials.

4.3 Endogenous Technological Change

To this point, technological change has been assumed to be exogenous, but the change in relative wages may induce a change in the degree of bias. In 1932, Sir John Hicks reasoned in his *The Theory of Wages* that "a change in the relative prices of the factors of production is itself a spur to invention, and to invention of a particular kind—directed to economizing the use of a factor that has become relatively expensive" (1932, pp. 124–125). This was later formalized in terms of the bias between capital- and labor-augmenting technological change by Kennedy (1964), Samuelson (1965), and Drandakis and Phelps (1965).[9] More recently, it has been taken up in the form of "directed technical change" by Acemoglu (for example, 2002).

[9] We may note that the induced technical progress literature identified the key role of the elasticity of substitution in determining the stability of the dynamic process governing the degree of bias: the condition for stability of the steady state in the model of Drandakis and Phelps (1965) is that the elasticity of substitution between capital and labor be less than 1. But the wage dispersion literature takes it for granted that the elasticity is greater than 1, which would be relevant if the same models were to be applied to the bias between skilled and unskilled workers.

Where technological progress is endogenous, this may substantially modify the trajectory of the economy. Following Acemoglu (2002), assume that the bias of technical progress is determined by the relative profitability of improving the productivity of the two factors of production. This profitability depends itself on two effects: a price effect, defined as the price of the technical bias—here the ratio $\omega/(a_h/a_b)$—and a market size effect according to which technical progress should favor the factor relatively the most abundant—i.e., the relative supply of skilled labor, h. Assuming that these two effects are multiplicative, and within the same CES framework as in (1), the relative profitability of investing in productivity gains of skilled labor thus depends on (Acemoglu, 2002, p. 790):

$$\frac{h\omega}{a_h/a_b} = A\left(\frac{a_h}{a_b}\right)^{-1/\sigma} h^{1-(1/\sigma)}$$

Then, the dynamics of the productivity differential can be specified as:

$$\Delta\left(\frac{a_h}{a_b}\right) = g.\left(\frac{a_h}{a_b}\right) = \gamma\left[A\left(\frac{a_h}{a_b}\right)^{-1/\sigma} h^{1-(1/\sigma)} - c\right] \tag{6}$$

where c stands for the relative cost of developing technical progress in one factor in comparison with the other and γ is the response rate of actual technical change to the economic incentive.

Adding Equation (6) to the preceding model (2)–(3′) modifies substantially the dynamics of the skill premium and relative labor supply. In the simulation shown in Figure 4, c is chosen so that (6) is initially stationary. Then an exogenous drop in the cost parameter, c, in year 1 triggers SBTC, initially at a rate identical to the exogenous rate, g, in the previous simulation (the response rate, γ, is taken to be 1). If the new trajectory is initially similar to the one obtained before, a divergence occurs after a few years. The rate of growth of the skill premium declines and a turning point is reached after 10 years. Then the skill premium starts falling as SBTC attenuates due to the negative price effect. If the relative supply of skilled labor keeps increasing—because the skill premium keeps being above its initial value—its rate of growth is much smaller than in the previous simulation. Interestingly enough, the new steady state to which the economy is very slowly converging displays the same wage skill premium as initially, but a larger relative supply of skill. In other words, in the very long run the fact that the cost of improving the relative productivity of skilled workers has fallen simply resulted in an increase in relatively more people being skilled. In the short run, however, the skill premium moved up.

This analysis demonstrates the value of theory in understanding the mechanisms behind the evolution of a simple aggregate inequality indicator like the wage skill premium. It shows the need to consider transitional paths between equilibria, not just steady states, as well as the multiplicity of mechanisms influencing specific economic magnitudes to interpret their observed evolution.

4.4 Beyond Supply and Demand

The supply and demand story assumes that all agents act as price-takers: that we have perfect competition. As was observed by Michael Kalecki, "perfect competition—when its real nature, that of a handy model, is forgotten—becomes a dangerous myth" (1971, p. 3). In the real world, there are firms that have market power, as do collective organizations such as trade unions, and market power affects the operation of the labor market. The relative bargaining power of different actors determines the way in which economic rents are shared and hence the distribution of income. Power in turn is affected by the legal rights of workers, their representatives, and of employers. Such considerations turn the spotlight on governments, where the trend of recent decades has been to scale back the rights of workers, but also on employers. Where employers have market power, they can make choices regarding their employment practices, such as, for example, adopting the policy of paying "a living wage" or of limiting the range between top and bottom pay in their enterprise.

Bargaining power is not limited to firms and unions, as is shown by search and matching models of the labor market that involve individual workers and employers. Frictions in the labor market mean that, while *ex ante* competition may drive down the expected value of filling a job vacancy to the cost of its creation, *ex post* the matching of a worker to a vacancy creates a positive surplus. Without a positive surplus, no jobs are created. The worker offered a job has a degree of bargaining power, since if he or she rejects the job offer, the employer has to return to the pool with the risk that no match can be secured. The magnitude of the risk, and hence the worker's leverage, depends on the tightness of the overall labor market; the worker's leverage also depends on the cost of remaining unemployed. The impact on the distribution of earnings depends on how bargaining power varies across jobs, but the important point is that market forces, even in a globalized world, impose only upper and lower limits on differentials. This becomes particularly important when there are multiple possible market outcomes. Atkinson (2008) suggests a behavioral model of changing pay norms, where there is more than one locally stable equilibrium consistent with profit-maximizing behavior by employers. What has been observed in recent decades may be a shift from one equilibrium to another with much wider pay dispersion, particularly at the top.

There is therefore considerable scope for social institutions and social norms to influence the degree of pay dispersion, as is discussed in Chapters 18 and 19. In the latter, Förster and Tóth note that "while it is widely recognized that institutions matter as an important factor for identifying the multiple causes of inequality . . . the weight attached to this factor in econometric studies has for a long time been limited" (p. 1801). As is stressed by Salverda and Checchi in Chapter 18, there is a pressing need to bring together the two rather separate literatures on supply/demand explanations and on institutions.

4.5 Bringing Back Capital

The SBTC explanation of rising wage dispersion focuses on the labor market, but—as the presence of the term e^{rT} in Equation (3) hints—we need to consider, not just the labor market, but also the capital market. Stated in terms of the aggregate production function, we have to consider not just $F(L_b,L_h)$, where L_b denotes basic-educated labor and L_h denotes higher-educated labor, but $F(K,L_b,L_h)$, where K is capital. We have to consider, not just the ratio of skilled to unskilled wages, but also the relative shares of wages and profits—the classical problem of distribution. Indeed, as in the classical analysis, we should extend the production function to include land and natural resources, N, giving output as $F(K,L_b,L_h,N)$.

The extension to three, or more, factors means that substitutability and complementarity becomes more complex, with richer potential outcomes for the distribution of income. The interesting possibilities include capital being a substitute for basic-educated workers but a complement to higher-educated workers. Such models, in the line of Krusell et al. (2000) are among those discussed in Chapter 14 by Quadrini and Rios-Rull. An alternative has been proposed by Summers in his Feldstein Lecture (2013). As Summers notes, capital can now be seen as playing two roles: not only directly via the first argument of the production function but also indirectly insofar as it supplants human labor through robotization. Denoting the first use of capital by K_1 and the second by K_2, the aggregate two-factor production function becomes $F(K_1, AL+BK_2)$, where A and B depend on the level of technology. The production function is such that capital is always employed in the first use, but may or may not be used to supplement labor. The condition under which robots, or other forms of automation, are used to replace human labor depends, as one would expect, on the relative costs of labor and capital. Where there is perfect competition, K_2 is zero where the ratio of the wage, w, to the rate of return, r, is less than A/B, and where K_2 is positive, then $w/r=A/B$. The ratio of the wage share to the capital share in the latter case is $(A/B)/(K/L)$ and falls with the capital–labor ratio.

We can therefore tell a story of macroeconomic development where initially the Solow model applies: the capital stock is below the level at which w/r exceeds A/B. In this context, a rising capital–labor ratio leads to rising wages and a falling rate of return. The capital share rises if and only if the elasticity of substitution between capital and labor is greater than 1 (about which there is debate—see Acemoglu and Robinson, 2014, footnote 12). Beyond a certain point, however, the wage/rate of return ratio reaches A/B, and K_2 begins to be positive. We then see further growth in the economy, as capital per head rises, but the wage/rate of return ratio remains unchanged. There is no longer any gain to wage-earners, since they are increasingly being replaced by robots/automation. What is more, the capital share rises, independently of the elasticity of substitution. It is as though the elasticity of substitution is increased discontinuously to infinity. In this way, the textbook Solow growth model can be modified in a simple way to highlight the central distributional dilemma: that the benefits from growth now increasingly accrue through rising profits. This outcome was indeed stressed some 50 years ago by James Meade in his *Efficiency, equality and the ownership of property* (1964), where he argued with considerable prescience that automation would lead to rising inequality.

4.6 The Distribution of Wealth

The distribution of wealth is the subject of the long-run studies in Chapter 7 by Roine and Waldenström and Chapter 15 by Piketty and Zucman. Both chapters show that the concentration of wealth was very high in the eighteenth to nineteenth centuries up until the First World War, dropped during the twentieth century, but has been rising again in the late twentieth and early twenty-first centuries. Chapter 15 shows that in France, the United Kingdom, and other countries, there has been a return of inheritance.

In Chapter 15, Piketty and Zucman begin by saying that

> *to properly analyze the concentration of wealth and its implications, it is critical to study top wealth shares jointly with the macroeconomic wealth/income and inheritance/wealth ratios. In so doing, this chapter attempts to build bridges between income distribution and macroeconomics.*

Building such a bridge is indeed one of our aims in this Introduction, and, with this in mind, we return to the question of the timescale for the macroeconomic magnitudes. Denoting aggregate capital by w_t, aggregate income by y_t, and their ratio by β_t, we have:

$$\beta_{t+1} = \frac{\beta_t + s_t}{1 + g_t} \tag{7}$$

where s_t and g_t are respectively the net saving rate and the growth rate of income at time t. Assuming that those two rates are constant, the steady-state equilibrium of the economy is given by $\beta^* = s/g$. With s equal to 10% and g equal to 3% per annum, the equilibrium capital–income ratio is 3.33. But, then, suppose that growth decelerates and the economy's constant growth rate falls to 2%. The economy will then converge toward a new equilibrium with a capital–income ratio equal now to 5. How long though will it take to get to this new equilibrium? As a matter of fact, the process described by (7) is quite slow. A simple simulation shows that, in going from 3.33 to 5, it will take almost 30 years for the capital–income ratio to reach 4, the double to reach 4.5 and more than a century to reach 4.8. As was shown many years ago by Ryuzo Sato (1963), the adjustment time in the neoclassical growth model can be extremely long.[10] With such a transitional phase, relying on the steady-state properties of a theoretical model may be misleading for economic or policy analysis, even with a horizon of a decade. The direction of changes expected at equilibrium

[10] As was pointed out by Sato (1966), the conclusions reached regarding convergence times are sensitive to the precise assumptions made concerning savings and technical change; the key issue is that transition path should be examined.

because of some exogenous modification or some policy changes is most likely to be felt along the whole transitional trajectory but their size might have to be substantially scaled down at the beginning of the transition. A tax on capital that reduces the saving rate by 1 percentage point, from 10% to 9%, for example, would lead to a drop in the steady-state capital–income ratio of 10%, but only 2.3% after 10 years and 4% after 20 years.

Let us now turn to the *distribution* of wealth. In that case, focusing on steady-states—or the golden rule—leads in some sense to the simple dismissal of distributional issues. Chapter 14 shows that any distribution of wealth combined with any distribution of work abilities is consistent with the steady-state equilibrium of the neoclassical model with dynastic agents, provided that aggregate wealth and aggregate effective labor satisfy some consistency relationship that involves the (common) rate of time preference of agents—the same kind of result holds trivially in endogenous growth models of the AK type, see Bertola et al. (2006, chapter 3). This is fine but possibly of limited practical relevance. Assume indeed that an economy initially at a steady state with a distribution D of wealth is then subject to some shock, for example, a technological shock or an income tax, that modifies its aggregate long-run equilibrium. Then, in moving toward this new equilibrium, the distribution D will change and, at the new equilibrium, there will be a new distribution D'. The fact that this new aggregate equilibrium may be supported by another distribution than D' is not the relevant point. What we are interested in is the change from D to D' and this is certainly not indeterminate. Likewise, the indeterminacy of distribution in a steady state does not mean that redistribution has no macroeconomic effect and no impact on the primary distribution of income. As long as redistribution cannot be lump sum, it will modify both the steady-state equilibrium and the distribution of primary and disposable income.

The models in Chapter 15 of the distribution of wealth are rather different and have different long-run properties. The treatment of time is again important. To be precise, let us take the unit of time as the lifetime (identical for all), with the present value of inherited wealth of individual i denoted by w_{it}. It is assumed that lifetime savings are a constant proportion of the aggregate of wealth and income:

$$w_{it+1} = S_{it}(w_{it} + y_{it}), \text{ with } y_{it} = y_{Lt} + Rw_{it} \tag{8}$$

where y_{Lt} is the lifetime labor income, assumed to be identical across individuals, R is the rate of return over the lifetime, and S_{it}, the individual saving rate defined on wealth plus lifetime income. S_{it} is assumed to be independently and identically randomly distributed around some mean value, S, across periods. Aggregating the accumulation equation over all individuals in a generation yields:

$$w_{t+1} = S(w_t + y_t), \text{ with } y_t = y_{Lt} + Rw_t \tag{9}$$

Combining (8) and (9) and assuming that the aggregate economy has converged to a steady state, it is shown in Chapter 15 that the dynamic behavior of the wealth of individual i, relatively to the mean wealth of the population, z_{it}, is given by the following multiplicative stochastic difference equation:

$$z_{it+1} = \frac{S_{it}}{S}[(1-\varphi+\varphi z_{it}], \text{ with } \varphi = S\frac{1+R}{1+G} \tag{10}$$

where G is the rate of growth over a lifetime.[11] Under the condition that $\varphi < 1$, the steady-state stochastic distribution of z_{it} has a Pareto upper tail, with a Pareto coefficient that decreases with φ, where a smaller coefficient corresponds to greater concentration of wealth. Denoting the annual rate of interest by r and the annual rate of growth by g, and assuming a lifetime of H years, φ can be expressed as $Se^{(r-g)H}$. It follows that long-run wealth concentration increases with $r-g$; it is also clear that concentration increases with the savings rate, S. Both elements have a role to play.

Suppose, instead, that one adopts an *intragenerational* perspective, with the time unit as the year rather than a lifetime, and assumes that people save a proportion of their current income, s_{it}, drawn randomly from some distribution with expected value s. Then (8) and (9) are transformed into:

$$w_{it+1} = w_{it} + s_{it}(y_t + rw_{it}); w_{t+1} = w_t + s(y_t + rw_t) \tag{11}$$

where y_t is now the common annual wage income. Assuming a steady state with growth rate, g, and using the same kind of derivation as above, the stochastic difference equation (10) becomes[12]

$$z_{it+1} = z_{it}\left[\frac{1}{1+g} + \frac{s_{it}}{s}\frac{rs}{1+g}\right] + \frac{s_{it}}{s}\frac{g-rs}{1+g} \tag{12}$$

Under the assumption that $E(rs/(1+g))(s_{it}/s) + (1/(1+g)) < 1$ or $rs < g$, the distribution of z_{it} converges toward a steady-state distribution with a Pareto upper tail, with a

[11] The derivation of that equation goes as follows. At a steady state: $w_{t+1} = (1+G)w_t$. From (8) and (9), it then follows that $z_{it+1} = (S_{it}/S)S((1+R)/(1+G))z_{it} + S_{it}(y_{Lt}/w_{t+1})$. But (9) implies at a steady state that: $w_{t+1} = S[y_{Lt} + (1+R)\cdot(w_{t+1}/1+G)]$. Then: $S(y_{Lt}/w_{t+1}) = 1 - S((1+R)/(1+G))$ and (10) follows.

[12] As before, at the steady state, $w_{t+1} = (1+g)w_t$. From (11), we obtain:

$$z_{it+1} = \frac{z_{it}}{1+g} + \frac{s_{it}}{s}\frac{rs}{1+g}z_{it} + \frac{s_{it}y_t}{w_{t+1}}. \tag{13}$$

Then, the second part of (11) becomes:

$$w_{t+1} = \frac{w_{t+1}}{1+g} + sr\frac{w_{t+1}}{1+g} + sy_t.$$

This implies:

$$\frac{y_t}{w_{t+1}} = \frac{g-rs}{s(1+g)}$$

and then plugging that expression back into (13) leads to (12).

Pareto coefficient that decreases, and a wealth concentration that increases, with $rs/(1+g)$. This refers to the distribution of current wealth, since there is a fresh drawing of s_{it} each period of life. (The independence assumption has therefore quite different implications.) In this model, it is the balance between rs and g that determines the long-run distribution, as in the early models of Meade (1964) and in the primogeniture version of Stiglitz (1969).[13]

Which model is the most appropriate? With the long horizon adopted to study the evolution of the distribution of income and wealth in Chapters 7 and 15, it would seem that the intergenerational framework is the most appropriate. It can also be argued that the assumption about randomness, with persistent lifetime good or bad luck, captures better our distributional concerns. Against this, it is the distribution of current wealth that is observed (as, for example, in Figure 1). It has, however, been shown by Benhabib, Bisin, and Zhu that when a model of lifetime wealth accumulation, with a realization fixed for any household during its lifetime, is embedded in a model of the current distribution of wealth, then "the power tail of the stationary distribution of wealth in the population is as thick as the thickest tail across the wealth distribution by age" (2011, p. 132). Put loosely, the upper tail of the current distribution tends to be dominated by the most unequal generation. But, it remains the case that the full effect of an increase in r–g from today onward is bound to be observed only some generations from now. As a matter of fact, the inegalitarian effect that will be observed in the second or even third generation might be very limited and r–g may change again in the distant future.

The conclusions that we draw are twofold. The first is that, as in the discussion of mobility in Chapter 10, it is necessary to consider both the intra- and the intergenerational dimensions, and that in both cases a better understanding of the transitional periods seems crucial. The second is that the evolution of the distribution of wealth depends on savings behavior, on the rate of return, and on the rate of growth. In this context, we should not forget that there were two arms to Kuznets (1955) Presidential Address, in which he sought to explain why inequality was at that time falling despite the existence of long-term forces leading to higher inequality. One arm was the theory of structural change that has come to characterize his approach, but the other was the concentration of savings in the upper income groups. This led him to conclude that "the basic factor militating against the rise in upper income shares that would be produced by the cumulative effects of concentration of savings, is the dynamism of a growing and free economic society" (1955, p. 11).

[13] It is rs–g that formed the basis for the time-series analysis of the share of the top 1% of wealth-holding in Great Britain over the period 1923–1972 carried out by Atkinson and Harrison (1978, chapter 9). They showed the significance of two variables likely to influence the rate of accumulation (rs): the share price index and the rate of estate taxation.

5. THE ROLE OF POLICY

The role of policy is considered in many of the chapters, but this is the explicit focus of the final part of the Handbook.

5.1 Policy Objectives

Here, we should begin by observing that the past 15 years has seen a major change in the extent to which there has been official adoption of distributional objectives. This development is the culmination of a series of shifts in attitudes toward policy, notably with regard to the abolition of poverty. In Chapter 22, Martin Ravallion traces, with a broad geographical and historical sweep, the evolution of thinking on poverty and antipoverty policy.

The most evident manifestation of this change has been the adoption at a world level of the Millennium Development Goals (MDGs). The goals were ratified by world leaders in 2000 at the U.N. Millennium Assembly, and the first on the list was the halving between 1990 and 2015 of the proportion of people whose income was less than \$1 a day (later \$1.25 a day). At a national level, countries have adopted their own goals, such as the national social target for poverty reduction in Ireland aiming to reduce consistent poverty. In the United Kingdom, the Child Poverty Act 2010 requires the government to produce a poverty strategy every 3 years setting out actions to end child poverty. At a regional level, the European Union adopted in 2010, as part of the Europe 2020 program, the objective of reducing by 20 million the number of people in or at risk of poverty and social exclusion. These have been translated to varying degrees into national targets (Social Protection Committee, 2014).

It is not clear whether the same kind of change is occurring in the field of inequality reducing policies. Due to the rise in inequality, and possibly to the recent crisis, it is certainly the case that the public spotlight is focused on inequality and some announcements have been made by politicians that important measures would be taken to fight inequality. Yet, few explicit targets have been set and no ambitious measure has been taken or is being seriously considered in advanced countries that would make a major dent in the existing income inequality.

5.2 Impact of Policy to Date

What grounds are there then for optimism if one is concerned with present levels of economic inequality? Can we point to past experience where inequality has been reduced? The first obvious, but important, point is that inequality is not increasing everywhere. Globally, the recent past has been more encouraging, as is well summarized in Chapter 9 by Alvaredo and Gasparini:

> *The available evidence suggests that on average the levels of national income inequality in the developing world increased in the 1980s and 1990s, and declined in the 2000s. There was a remarkable fall in income poverty since the early 1980s, driven by the exceptional performance*

> *of China over the whole period, and the generalized improvement in living standards in all the regions of the developing world in the 2000s.*

They caution that the decline in the 2000s was not universal: in 15% the fall was less than 2.5 percentage points, and in 20% of cases the Gini coefficient increased. The latter included two populous countries: China and Indonesia. The decline was most evident in Latin America, where they say

> *This remarkable decline appears to be driven by a large set of factors, including the improved macroeconomic conditions that fostered employment, the petering out of the unequalizing effects of the reforms in the 1990s, the expansion of coverage in basic education, stronger labour institutions, the recovery of some countries from severe unequalizing crises and a more progressive allocation of government spending, in particular monetary transfers.*

In other words, policy was relevant in influencing both market incomes and redistribution. In the case of Brazil, they conclude that the two major determinants were the decline in wage inequality, due to the expansion of the supply of educated workers and to the substantial increase in the minimum wage, and the expansion of cash transfers, notably the *Bolsa Família*. Despite this noticeable progress, however, it remains the case that Brazil, like most other countries in Latin America, is extremely unequal by world standards—with the exception of several countries in sub-Saharan Africa. The drop in inequality observed during the 2000s compensated for the increase that took place during the 1980s and part of the 1990s. Over the very long run, progress remains limited. Moreover, it must be kept in mind that top income earners are undersampled in the developing countries' household surveys so that it is not impossible that reported inequality figures miss the same increase at the top of the distribution as has been observed in many developed countries.[14]

Although lower than in Latin America, inequality is sizable in many emerging Asian countries and it is increasing. In discussing how far the policies pursued in several Latin American countries could be applied in an Asian context, Kanbur notes in Chapter 20 that

> *the additional expenditure on conditional cash transfers requires revenues, and the progressivity of the tax system is another major determinant of how globalization related increases in inequality can be mitigated. But progressivity is also important in addressing the rise in very high incomes the world over, especially in Asia. Asian tax systems do not generally score highly on progressivity. In fact, it is argued that raising progressivity of taxation would have a bigger impact on inequality than elsewhere in the world.*

[14] Alvaredo and Gasparini warn the reader in Chapter 9 that in the household surveys on which they are drawing there is substantial understatement of the top incomes. Cornia notes, in his analysis of recent distributive changes in Latin America, that "given the scarcity of information on capital incomes and the income of the 'working rich' in household surveys [it is not possible] to establish formally whether the distributive changes . . . concern also the top percentiles of the income distribution" (2014, p. 7).

What about the richer countries? In terms of reducing the inequality of market incomes, the standard policy response is educational expansion, as would be indicated by the supply and demand explanation for rising wage dispersion (as discussed in Section 4). The review of cross-country time series evidence by Förster and Tóth in Chapter 19 concludes that most evidence points to an equalizing impact of educational expansion:

> *none of the studies covering the set of OECD/EU countries suggest a dis-equalising role of the growth in average educational attainment over the past three decades, but to the contrary, in their majority rather an equalising one. Human capital can be seen as a complement to technology. Increases in human capital and in the supply of skills are necessary to decrease and eventually reverse the pressure to higher inequality that stems from technological change.*

The impact of labor market policy is reviewed in Chapter 18 by Salverda and Checchi who conclude that their empirical results

> *are consistent with the main findings in the literature. … They confirm that the presence and stringency of a minimum wage reduces earnings inequality, also setting an (implicit) control on the distribution of working hours, which seems to be the main channel of inequality reduction of the bargaining activity of unions. Less common in the literature is the finding of a negative impact of both active and passive labour market policies.*

The reason that the overall distributive effect of labor market regulations and institutions can be insignificant, as found by Förster and Tóth in their cross-country analysis, is that the employment and wage dispersion effects can operate in opposite directions.

When it comes to redistributive tax and transfer policy, Förster and Tóth conclude in Chapter 19 that:

- Policies are inequality reducing, but the effects vary across countries;
- Transfers are typically more effective than taxation;
- There has been a reduction in the redistributive effectiveness since the 1990s;
- Behavioral responses may offset but do not in general outweigh the first-round effects.

The last of these conclusions is particularly important. For understandable reasons, much of the analysis of public policy by economists in recent decades has focused on negative behavioral responses. Understandable, since the toolkit of economists is designed to illuminate these responses and the second-round effects are often missed in the public debate. At the same time, the analysis seems often to lose sight of the purpose for which transfers are paid. As put by Ive Marx, Brian Nolan and Javier Olivera in Chapter 23, "no advanced economy achieved a low level of inequality and/or relative income poverty with a low level of social spending, regardless of how well that country performed on other dimensions that matter for poverty, notably employment." The GINI project concluded that

> *The best performers among the rich countries in terms of employment and economic and social cohesion have one thing in common: a large welfare state that invests in people, stimulating them and supporting them to be active and adequately protecting them when everything else fails. This continues to offer the best prospect for rich countries pursuing growth with equity.*
>
> **Salverda et al. (2014, p. 349).**

But it is also clear, as these authors bring out, that it is not only the aggregate but also the design of spending that matters. It is for this reason that the construction of policy reforms has to be based on analysis of the contribution that they can make to distributive and efficiency objectives, and to this end an important development has been that of microsimulation modeling, as surveyed in Chapter 24 by Francesco Figari, Alari Paulus and Holly Sutherland. These models build on the improvements in data availability described in Section 1—their construction requires access to microdata. They also require in-depth knowledge of the institutional details of public policy and how it operates in reality. As is discussed in Chapter 24, there is a considerable challenge in modeling noncompliance and—the less commonly discussed—other side of the coin, which is the non-take-up of benefits to which people are entitled. In melding microdata and institutional detail, the microsimulation models provide an important bridge between the theoretical analysis of policy design and the implementation of policy in the form of legislation and administration.

5.3 Prospects for Future Policy

Given their high level of inequality and the limited development of redistribution in many developing countries, the scope for progress in redistributive policies and in pre-redistribution opportunity equalizing policies is considerable. This is especially true in middle income or emerging countries where state capacity is sufficient to manage effective redistribution instruments.

What should make things easier for emerging countries' governments wishing to strengthen their redistribution system is, on the one hand, that they can learn from the experience of developed countries and, on the other hand, that modern technology permits better monitoring and control of individual incomes. Beyond some level of income, it is difficult today to function without a bank account and a credit/debit card, so that individual transactions are recorded. Approaching 50% of all households in Latin America hold a bank account and this proportion is rising so that the tax authority's capacity of auditing taxpayers suspected of underreporting their income is necessarily increasing. Yet, the income tax is severely underdeveloped in most emerging countries, where it represents most often less than 2% of GDP. Brazil is an exception but with an income tax amounting to 6% of GDP, it is still lower than the 9% average rate observed in OECD countries. Modern technology also makes easier the transfer of income to people at the bottom of the distribution. Smart payment cards in particular assist in avoiding suspicious leakages. There is therefore scope for extending redistribution and making use of policies in the field of education, social protection, minimum pensions, or minimum wage that are currently seldom used or at a very low scale despite their huge equalizing potential in most countries. As a result, the extent of redistribution in emerging countries, evaluated with the same microsimulation tools as described in Chapter 24, appears much smaller than in developed countries. For instance, the fall in the Gini coefficient when moving from market income—including replacement income like public or private pensions—to disposable income averages 3 percentage points in Latin American countries where such simulation has been performed (Lustig, 2014), whereas it oscillates around 10 percentage points for rich countries (Immervoll et al., 2009).

Of course, having the capacity to redistribute will lead to a substantial redistribution only if there is the political willingness to do so, or if the political system permits a majority to impose some redistribution, as could be expected in a democracy. In the empirical work undertaken in Chapter 21, Acemoglu et al. find that a transition to democracy indeed tends to raise the average tax rate in a country. Yet, no significant effect is found on income inequality as such. This may suggest that the political system is more complex than the mere distinction between democracies and nondemocracies would imply; or, as the authors note, may reflect the poorer quality of the income inequality data, an aspect we discussed in Section 3.

In contrast, OECD countries may be closer to their frontier in terms of the trade-off between less inequality and a higher degree of aggregate economic efficiency. The distance depends however on the institutional features of taxes and transfers—aspects to which economists have devoted too little attention (Atkinson, 1999)—and there may be scope for new and innovative ideas, as discussed in the final part of this section. The frontier itself may have been affected itself by the globalization process, its requirement for more competitiveness and, through factor mobility, its weakening of redistributive instruments like the progressivity of income taxation, including capital or capital income. At the same time, the same forces of globalization may have increased the need for social protection, just as they did in the early days of the welfare state toward the end of the nineteenth century. Today, as then, the extent to which redistribution takes place depends on the political context. It may also be the case that the perception of inequality in the society today may not coincide with the evolution of inequality as measured by statisticians and economists. In the United States, for instance, the feeling that income mobility matters more than income inequality and the (unfounded) belief that income mobility is and remains high in comparison with other countries may make the public opinion insensitive to the mounting objective income and wealth inequality. Clearly, this cannot continue forever. At some stage, beliefs will change and it is not unlikely that this process is under way—as McCall (2013) seems to detect in the changing discourse on inequality in the U.S. media.

5.4 Thinking Outside the Box

At the beginning of this Introduction, we evoked the increasing attention being paid by policymakers to rising income inequality. To date, the response in terms of policy proposals has been along conventional lines, notably investment in education and reform of redistribution. In our view, these are important, but if progress is to be made, then we

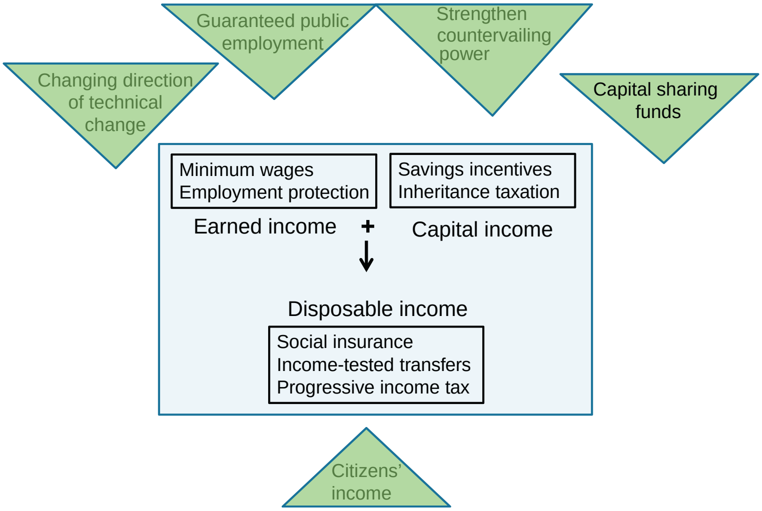

Figure 5 Thinking outside the box.

need to think outside of the box. We must consider ideas that—while far from new—are not on the current policy agenda.

The standard labor market policies—shown inside the box in Figure 5—clearly have a major role to play, and there have been moves to strengthen minimum wages, in order to reduce wage dispersion. As we have noted, however, central is the conjunction of wages and employment, and the latter has proved a hard nut to crack. In our view, one of the crucial elements is the direction of technical progress. Rather than concentrating on factor-augmentation, as in much of the literature, our discussion in Section 4.3 suggests that we should instead focus on the interaction between labor and capital, and specifically the supplantation of labor by capital. Given that much of the innovation is funded directly by public bodies, or subsidized through tax or other concessions, it would be possible to influence this trade-off. This is the first of the "out of the box" alternatives shown in Figure 5. The second concerns public employment. The fact that the present-day market economy does not deliver full employment suggests that we should learn from policy responses in other cases of market failure, notably in financial markets. Here, the government has intervened as a lender of last resort, and the obvious parallel is that the government should act as the employer of last resort. The state should guarantee to everyone seeking it employment at the minimum wage. Such a proposal may seem to some readers outlandish and infeasible on fiscal grounds, but to others it may appear no more outlandish or fiscally irresponsible than the policy that financial institutions are too big to fail. After all, such policies have already been pursued. It is an initiative of this type which was taken by the Indian government when it launched the Mahatma Gandhi National Rural Employment Guarantee Act in 2005. Public employment has formed part of active labor market programs in a number of countries. In the United States, it was authorized under the Humphrey–Hawkins Full Employment and Balanced Growth Act of 1978, which allowed the Federal Government to create a "reservoir of public employment," where these jobs were required to be in the lower ranges of skill and pay to minimize competition with the private sector.

The third proposal refers back to the discussion of bargaining power in Section 4.4. To the extent that rising inequality is the outcome of a shift in the balance of market power favoring profits and capital, its impact may be offset by strengthening the countervailing powers. This may take the form of a stronger role for the social partners, or it may involve more determined action to protect consumers against monopolistic pricing. Again such actions may be rejected as too radical, but again they are not so far removed from current policy. In the case of the European Union, both the promotion of competition and the encouragement of the social partners are already accepted objectives.

The fourth proposal draws attention to an aspect that has been missing from the policy arena—the capital market—but which has received increasing attention following the debate surrounding Piketty (2014). For macroeconomic reasons outlined in Section 4.6, and given the return of inherited capital in a number of richer countries, capital income is potentially of increasing significance, as it was in the past. The particular proposal is indeed far from new. It goes back at least to the eighteenth century Englishman/Frenchman/American Thomas Paine, who in 1797 in his *Agrarian Justice* proposed:[15]

> *To create a national fund, out of which there shall be paid to every person, when arrived at the age of twenty-one years, the sum of fifteen pounds sterling, as a compensation in part, for the loss of his or her natural inheritance, by the introduction of the system of landed property.*

The proposal of Paine for a capital element payable on reaching the age of majority has its modern counterpart in various schemes for asset-based egalitarianism (as proposed, for example, by Ackerman and Alstott, 1999). The creation of a sovereign wealth fund, as already well established in a number of countries, would offer the possibility of a minimum inheritance for all.

The fifth proposal—which also has shades of Paine—is for a citizen's income, or the payment of a guaranteed minimum income to all individuals. Such an income is sometimes described as "unconditional"; however, conditions are naturally attached. As described in Figure 5, a condition would be that of citizenship. An alternative, advocated in Atkinson (1995, 1996) is that of a *participation income*, paid not on the basis of citizenship but of participation in the society in question, through employment, past employment (on retirement), caring for dependants, being available for work when unemployed, in

[15] The text can be downloaded from the Official Web site of the U.S. Social Security Administration. The Web site carries the caution: "this is an archival or historical document and may not reflect current policies or procedures."

approved education or training, and with appropriate provisions for those who are sick, injured, or disabled. The participation income would represent a radical departure from the targeted income-tested transfers that have been the preoccupation of policymakers in recent decades. It would be individual-based, rather than involving a family means-test. It would recognize the fluidity of the employment relationship in the twenty-first century labor market.

No doubt there will be many objections to these final policy proposals, but we hope that the chapters contained in volume II of the Handbook will stimulate new ideas in this important field.

ACKNOWLEDGMENTS

In writing this Introduction, we have drawn heavily on the Handbook chapters. This will be evident from the frequency of cross-references, although we have tried to stop short of the point at which such references become tedious to the reader. We are most grateful to Rolf Aaberge, Facundo Alvaredo, Andrew Berg, Andrea Brandolini, Daniele Checchi, Pierre-André Chiappori, Andrew Clark, Koen Decancq, Jean-Yves Duclos, Francesco Figari, Michael Förster, Marc Fleurbaey, Stephen Jenkins, Salvatore Morelli, Dominique Meurs, Brian Nolan, Jonathan Ostry, Alari Paulus, Sophie Ponthieux, Thomas Piketty, Victor Rios-Rull, Wiemer Salverda, Tim Smeeding, Frederick Solt, Holly Sutherland, István Tóth, Alain Trannoy, and Daniel Waldenström for their very helpful comments on the draft of the Introduction, but none of them should be held responsible in any way for its contents. We thank Maarit Kivilo for her help with the bibliography. Atkinson's research for the Introduction was carried out as part of the EMoD program supported by INET at the Oxford Martin School.

ACKNOWLEDGMENTS

First, we would like to thank Ken Arrow and Mike Intriligator for having persuaded us back in 2010 that the time was ripe for a new volume. How prescient their advice was!

In the course of preparing the new Handbook volume, we have incurred many debts. Without the—more than 50—authors, there would be no Handbook, and we would like to thank them sincerely for the cooperative spirit in which they have produced such excellent chapters. We much appreciate the way in which they responded to several rounds of comments from the editors and (usually) met deadlines. Part of preparation took the form of an Author's conference, entitled "Recent Advances in the Economics of Income Distribution" that was held on April 4–7, 2013 at the Paris School of Economics. We are most grateful for the support that was provided to this conference by the Agence National de la Recherche (Projet INDURA INEG 2011), Cornell University, the UK Economic and Social Research Council and DFID (Grant ES/1033114/1), Ouvrir la science économique (Opening Economics), and the Paris School of Economics.

Throughout all this, a key organizing role has been played by Véronique Guillotin of the Paris School of Economics, and we thank her most warmly.

Tony Atkinson
François Bourguignon

CHAPTER 1

The Principal Problem in Political Economy: Income Distribution in the History of Economic Thought

Abstract

This chapter considers the history of theories of income distribution, from the time of Adam Smith until the 1970s. It is divided into two main parts. Part I considers the positive theory of income distribution, beginning with the classical economists' analysis of the functional distribution of income between wages, profits, and rent. It goes on to present the new theories that emerged with the marginalist revolution and which were based on maximizing behavior and market equilibrium. The main focus during the early stages of the new developments was on the markets for consumer goods and the role of marginal utility in price determination. The later neoclassical economists, including Alfred Marshall and Knut Wicksell, paid more attention to the special features that characterized the labor market and the role of marginal productivity in wage formation. In the twentieth century, the neoclassical theory was extended to include analysis of the role of imperfect competition, human capital, and risk-taking. Also included in this part of the chapter is a discussion of statistical and institutional approaches. Part II covers normative theories of income distribution and their implications for redistributive policy. It begins with a consideration of the value judgments implicit in the policy recommendations of the classical economists and continues with the attempts to establish an analytical foundation for welfare economics. The rise of Paretian welfare theory with its emphasis on the impossibility of interpersonal comparisons of utility made it difficult to draw conclusions regarding income redistribution, but the older utilitarian approach, including equal sacrifice theories, continued to live on in the modern analysis of optimal redistribution. A short Part III contains some concluding reflections on the position of income distribution theory within economics as a whole.

1.1. INTRODUCTION

Theories of the distribution of income between individuals and classes in society have been advanced in the literature of economics from before Adam Smith to the present day. Nevertheless, although David Ricardo in the preface to his *Principles of Political Economy and Taxation* (1817; 1951, p. 5) said that the determination of the laws of distribution was “the principal problem in Political Economy,” the field has at times led a somewhat modest existence on the outskirts of mainstream academic research. One of the reasons for this may have been that the study of income distribution is so tied up with normative issues of equity and justice that many economists, keen to pursue a value-free version of their subject, have tended to shy away from it. Others, however, have found this connection to be a particularly attractive feature of the field and have risen to the challenge of clarifying the distinction between the positive and normative aspects of the analysis of income distribution, in other words, separating explanation from justification. Both aspects of the study of income distribution are reflected in this chapter, which covers the positive theory of income distribution as well as the attempts that have been made to evaluate the distribution of income from the point of view of justice and equity. The development of normative theories of income distribution is intimately tied up with the analysis of redistributive policies, which in addition also have to take account of the positive analysis of income distribution. This chapter focuses on *theories* of income distribution, while no attempt has been made to cover the large empirical literature in the area, including the statistics of income distribution. Some thoughts on the relationship between theory and empirical work in the area are presented in Section 1.4.

Taking this broad view of the field of income distribution, the literature that is relevant for this chapter becomes so large that its history cannot possibly be covered in its entirety. This is especially so because many economic theories—in areas like international trade, public finance, labor, economic growth, and so on—have implications for income distribution, although the distributive aspects are not the main concern of the researchers involved. The treatment must therefore by necessity be selective, with main emphasis on the contributions of the most important and influential economists among those who have been concerned with the theory of income distribution.

For this reason as well as for reasons of space, this chapter does not by any means attempt a complete coverage of the literature. For further references and more detailed treatment, there are fortunately a number of other sources that the reader may consult and that offer complementary perspectives on the field. They include classics like Cannan (1893, 1914) and Dalton (1920) and a number of more recent surveys like Atkinson (1975), Sahota (1978), Ranadive (1978), Asimakopulos (1987), Atkinson and Bourguignon (2000), and Goldfarb and Leonard (2005). Although not all of these have their main attention on the history of thought, they include a lot of relevant historical material. The same is true of Ravallion’s contribution to this Handbook.

All accounts of the history of thought face two fundamental questions: When to begin and when to stop. In this chapter, I have decided to start with Adam Smith, as he is arguably the first economist in whose work we begin to see the contours of modern theories. The line at the other end is drawn where the literature is still being regarded as part of the contemporary set of references. This cannot be located with a great deal of precision but has been drawn roughly at some time in the 1970s.

The chapter is divided into two main parts. Following Section 1.1, Part 2 is concerned with positive theories of income distribution, whereas Part 3 covers value judgments and redistribution; in addition, a short Part 4 contains some concluding observations. This division means that the treatment of some economists has been split in two, e.g., Pareto is discussed first in the context of the debate over Pareto's law and second in relation to his contribution to welfare economics. Although this may in some respects be unfortunate, it should be kept in mind that the main purpose here is not to give well-rounded pictures of individual economists but rather to trace the development of thought within the main areas of income distribution theory. A broader treatment of the history of economic thought, including biographical sketches of the lives of the more important economists, has been given in Sandmo (2011).

1.2. THE POSITIVE ECONOMICS OF INCOME DISTRIBUTION

It has sometimes been claimed that one of the fundamental questions that has motivated the systematic study of economics is "Why are some countries rich and some poor?" This may well be correct when we consider the motivations of some of the leading economists. But for the large majority of mankind who, at least until fairly recent times, had little opportunity to obtain firsthand knowledge of the economic conditions in foreign countries, one would have thought that a more obvious question would have been "Why are some *people* rich and some poor?" This question might naturally have come to mind as individuals went about their everyday business in a world of large inequalities of income and standard of living. On the other hand, to what extent people did reflect on this question would presumably depend on whether they thought of the inequality of income as a basic and unalterable feature of the society in which they lived or as something that followed from man-made institutions and policies that were subject to change through the political process.

It took in fact considerable time before this question moved to the forefront of economics; indeed, it may be asked whether it has ever reached the forefront. Some thoughts on this question are contained in Part 4.

1.2.1 The Classical School: Factor Prices and the Functional Distribution of Income

By the classical school of economics, we shall, in line with standard usage in the history of economic thought, refer to the economists from Adam Smith to John Stuart Mill who dominated economics during the century from the 1770s to the 1870s. The members of this school were chiefly English and Scottish, although there were also economists in Germany, France, and other countries who felt a strong affinity to Adam Smith and his successors.[1]

[1] Among the prominent followers of Smith and Ricardo in continental Europe was Jean-Baptiste Say in France. In fact, Say is the only economist outside the British Isles who is mentioned by name in O'Brien's listing of "the personnel of classical economics" (O'Brien, 2004, pp. 3–9).

Regarding the positive study of the distribution of income, the theoretical approach of the classical economists focused mainly on the *functional distribution* of income, i.e., the distribution of income between the main factors of production, and it was doubtless this distribution that Ricardo had in mind when he made his remark about "the principal problem." How these "main factors" were to be defined was of course a matter of judgment, but the classical economists saw them as being labor, capital, and land, whose incomes were wages, profits, and rent. The fact that this definition of the three main categories of income should have met with such general acceptance among economists must be seen as a reflection of the fact that this particular functional distribution represented the main class division of society in the late eighteenth and early nineteenth centuries into workers, capitalists, and landowners. Although as we shall see, there are elements in classical economic theory that go some way toward explaining the personal distribution of income, to a large extent the functional distribution was also considered an important component for the understanding of the distribution of income between persons.

The theory of the functional distribution did not, in contrast to the neoclassical theory that was developed a century later, build on a unified theoretical structure. It is therefore natural to present the theory in three parts, corresponding to the three main categories of income.

1.2.1.1 Wages

In Adam Smith's great work, *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776), the first chapter presents us with his famous example of technical progress and division of labor in a pin factory. In a factory that he has seen, the complicated process of the production of a pin has been broken down into "about 18" separate operations, with the result, according to his calculations, that each of 10 men can produce 4800 times as many pins in a day as a single worker operating on his own without specialization and division of labor. One might think that this dramatic increase of productivity would lead to a corresponding increase in wages, but this is a conclusion that Smith is in fact unwilling to draw. He points out, first, that the division of labor depends on the extent of the market. Although specialization may by itself be expected to lead to higher productivity and wages, the demand side of the market limits the extent of specialization. In the highlands of Scotland, the typical farmer is often miles away from the nearest artisan and therefore has to be his own butcher, brewer, and baker, and even the artisans who are located in the small towns cannot afford to be highly specialized. Second, the mobility of labor between industries would ensure that the potential increase in the wages of the workers employed in pin production would in fact be spread thinly over the wages of workers in all industries. Third, and even more important, Smith emphasized a point that was to become a crucial component in the teaching of the whole of the classical school, viz, that any increase in the general level of wages would lead to an increase of population and therefore of the workforce, and this would tend to reverse the initial increase of wages.

This idea seems to have been part of the conventional wisdom among economic and social writers at Smith's time. In a passage that reminds one of the later work of Malthus, Smith said that "every species of animals naturally multiplies in proportion to the means of their subsistence" (Smith, 1776; 1976, p. 97). In this connection, he refers to Richard Cantillon, who in his book *Essai sur la nature du commerce en général* (1755) had argued that the standard of subsistence toward which the level of wages would gravitate must be sufficient for a working family to have four children. For experience shows, Cantillon said, that only two out of four children will be able to survive into adulthood and on average two new adults are required to ensure the reproduction of the working class.

The theory of subsistence wages received its most famous statement in the work of Thomas Robert Malthus, whose *Essay on the Theory of Population* (1798) became one of the most influential books on economics ever written.[2] Among the public at large, the book became best known for its dramatic representation of the race between population and economic progress. This was illustrated by on the one hand the natural tendency of population to grow as a geometric series, whereas food production, due to decreasing returns in agriculture, would only be able to grow as an arithmetic series. Thus, the increase of population would be held down by the shortage of food, and the income of workers would accordingly converge to the subsistence level. This was to be understood as a long run theory of wages. Malthus did not deny that wages for a limited period of time could rise above the subsistence level, but this would lead to an increase in the number of births, which over time would drive wages back to the long-run equilibrium level of subsistence.

Malthus's theory was widely accepted by the other classical economists. Gradually, however, it came to be modified regarding the essential content of the concept of subsistence. According to later thinking, a temporary increase of wages might not actually revert to the initial equilibrium level because psychological and social adaptation to a higher level of income might dampen the desire for larger families. The level of subsistence would then have to be reinterpreted as a social rather than a biological minimum amount of income, and this could well be imagined to rise over time. Technological progress, on the other hand, had no place in Malthus's view of the determination of wages.

[2] Malthus's *Essay* came out in six editions during his lifetime. The most substantial changes in its contents occurred with the publication of the second edition, which in many respects must be considered a new book. Among Malthus scholars it has therefore been common to refer to the first edition as the "First Essay" and to the second and subsequent editions as the "Second Essay."

The Malthusian theory of wages emphasized the supply side of the labor market, and little was said about labor demand. However, the reason why wages might temporarily rise above subsistence must be seen as being caused by shifts in demand, so that in an expanding economy, a series of shifts in demand might cause wages to be above subsistence even for long periods of time. The classical economists' favorite example of an expanding economy was the United States (which at the time when Smith wrote was referred to as the British colonies in North America), where the extension of the country's territory implied a continually increasing demand for labor and therefore an upward pressure on wages. The general conclusion that they drew from this example was that it was not the amount of a country's wealth that caused wages to be high; rather, it was the *growth* of the economy that was the basic cause of a high level of wages.

According to the modern way of thinking about wage determination, wages, at least in a competitive economy, are determined by the intersection of the supply and demand curve for labor. This analytical apparatus was unknown to the classical economists, but their theory can nevertheless be interpreted in these terms. The long-run equilibrium can be characterized by the intersection of a horizontal supply curve and a downward-sloping demand curve, whose position depends on the supply of other factors of production. If there is an increase in the supply of capital or land, the labor demand curve shifts to the right. In the short run labor supply is approximately inelastic, so that wages rise. But the rise in wages calls forth increased supply through an expanding population. The labor force accordingly increases until a new long-run equilibrium is reached where wages have come back to the level of subsistence, sometimes referred to as the natural price of labor. This dynamic process was described by Ricardo as follows:

> *It is when the market price of labour exceeds its natural price, that the condition of the labourer is flourishing and happy, that he has it in his power to command a greater proportion of the necessaries and enjoyments of life, and therefore to rear a healthy and numerous family. When, however, by the encouragement which high wages give to the increase of population, the number of labourers is increased, wages again fall to their natural price, and indeed from a re-action sometimes fall below it.*
>
> **Ricardo (1817; 1951, p. 94)**

1.2.1.2 Profits

Profit was regarded by the classical economists as the rate of return on capital, defined as the rate of interest plus a risk premium that varied with the nature of the capital. Actually, Ricardo gave a more general version of this definition when he stated that a capitalist would take into consideration all the advantages that one type of investment possessed over another:

> *He may therefore be willing to forego a part of his money profit, in consideration of the security, cleanliness, ease, or any other real or fancied advantage which one employment [for his funds] may possess over another.*
>
> **Ricardo (1817; 1951, p. 90)**

This is very similar to Adam Smith's theory of compensating wage differentials (to be discussed later), implying a symmetric treatment of equilibrium in the markets for labor and capital. But this broad concept of the rate of return does not in fact play much role in the work of Ricardo or any other classical economist.[3]

Although there were considerable differences among individual economists in their treatment of profits, we can still piece together a fairly unified theory from their writings. One basic question that the classical economists discussed was what it was in the working of the economic system that gave rise to a positive rate of profit. Nassau Senior (1836) provided a theory that combined the assumptions of a positive rate of time preference and the higher productivity of more roundabout methods of production. In equilibrium, capital must earn a rate of profit that compensates the investor—who is assumed to be identical to the saver—for his abstinence from current consumption. This is a formulation that foreshadows the later neoclassical theory of the rate of interest, in particular that of Böhm-Bawerk (1884–1889). In addition, the rate of profit contains a compensation for the risk undertaken by the investor. On the assumption that the investor is averse to risk, the risk premium must be positive, but because the degree of risk varies between projects and industries, the risk premium, and therefore the rate of return on capital, will show considerable variation, even assuming pure competition.

According to the classical theory, therefore, profit must be seen as the reward per unit of capital that accrues to the individual capitalist. But for a complete theory of the distribution of income from capital, one would also need a theory of the individual distribution of the ownership of capital because the income from capital accruing to the individual capitalist will be equal to the rate of return times the amount of capital owned. The determination of the ownership structure was an issue that did not receive much attention from the classical economists, and therefore their theory of the distribution of income within the capitalist class must be considered to be incomplete. On the other hand, this was an issue that did not seem to be of much concern to them. The question that formed part of Ricardo's "principal problem" was the determination of capital's share of national income, not the subdivision of this share among individual capitalists.

[3] It should be noted that there is no mention in Ricardo's *Principles* of Smith's theory of wage differentials. But this does not indicate any disagreement; Ricardo makes it clear that he limits his analysis to areas where he has something new to contribute.

1.2.1.3 Rent

Rent was the income of the landowners, defined as the rental rate per unit of land times the number of units in the possession of the individual landowner. The most influential statement of the theory of rent was contained in Ricardo's *Principles* (1817). Land varies in terms of its quality or productivity. The price of corn (Ricardo's term for agricultural produce more generally) is determined by the cost of the labor and capital required to produce a unit of corn on the land with the lowest quality, i.e., the land on the margin of cultivation. On this land rent is zero. But because the nature of the product that is grown on this land is assumed to be the same as on lands of higher quality, all corn will sell at the same price, so that a positive rent will exist on all inframarginal units of land. Rent is determined by the cost of labor and capital used on the margin of cultivation, and the position of this margin is determined by the price of corn. Therefore, Ricardo concluded, "Corn is not high because a rent is paid, but a rent is paid because corn is high" (Ricardo, 1817; 1951, p. 74). An increase in the demand for corn would imply an extension of the margin of cultivation, an increase in the labor and capital cost of production, and consequently a higher corn price. This would increase total rental income in the economy.

As in the case of profits, the theory of the functional distribution of income is of limited use when it comes to the analysis of the distribution of income within the group of landowners. An increase in the demand for corn will raise the rental rate for all landowners, but the distribution of the rental income between them will depend on the distribution of the ownership to land. On this distribution, regarding both capital and land, the classical theory is mostly silent.

What is likely to happen to the functional distribution of income in a growing economy? Ricardo's view of this issue is best explained by starting from his theory of rent. Beginning with a time when wages are above the level of subsistence, population will expand, the demand for corn will increase, and the margin of cultivation will be extended. The share of rent in national income will accordingly go up, and so will the share of labor, even after the wage rate has returned to its level of subsistence. The implication of this is that profits will fall and eventually, because of a weakening of the incentive to invest, bring the process of expansion to a halt. The economy will then have reached its stationary state, but the process toward this state may be delayed because of "improvements in machinery . . . as well as by discoveries in the science of agriculture" (Ricardo, 1817; 1951, p. 120). Thus, Ricardo saw technology as an essential determinant of the functional distribution of income, and to this would have to be added the social adaptation of the level of subsistence income if, during a process of expansion, workers became adjusted to a higher standard of living.

1.2.1.4 The Structure of Wages

In the classical theory of factor prices and the functional distribution of income, the factors of production were mostly treated as homogeneous so that the analysis could be carried out at a high level of aggregation. At the same time, it was recognized that the assumption of homogeneity was a theoretical abstraction that was particularly severe when it came to the distribution of wage income because it was obvious that wages were not in fact uniform across different professions. There could in principle be two reasons for this. On the one hand, differences in wages could be caused by competitive forces. On the other hand, they could be caused by the absence of competition, either by private restraints on the process of competition or by government regulations, the "policies of Europe," as Adam Smith used to call them.

Adam Smith's competitive theory of the wage structure is now known as the theory of compensating variations. The general idea is that wages will reflect the particular circumstances pertaining to different professions. For any particular line of work, these circumstances could be such as to imply that the wage is either above or below the average for all professions. Smith mentioned several causes of wage inequality. One of these is the "ease or hardship" of the employment. A blacksmith earns less in the course of a 12-h day than a miner does in 8 h, for the work of a blacksmith is less dirty and dangerous, and it is carried out in daylight and above the ground. Some professions are particularly honorable, and because honor is part of the reward, wages are correspondingly lower. Other professions are held in general disgrace, which has the opposite effect. The most detested of all workers is the public executioner, but relative to the hours worked, no one is better paid than he.

Smith also argued that wages will vary with how difficult and expensive it is to learn the profession, with "the constancy or inconstancy of employment," and with the amount of trust placed in the worker. His fifth and final cause of wage inequality is the probability of succeeding in one's profession. If one trains to become a shoemaker, it is virtually certain that one will be able to earn one's living by making shoes. But if one is educated as a lawyer, Smith claimed, only one in 20 will be able to do well enough to live by it. To aim at the profession of a lawyer is accordingly a lottery, and because there are so few winning tickets, these must carry very high prizes. However, the wage differences in this respect are in fact less than a rational consideration of the probabilities would imply because most people, and particularly the young, have a tendency to overestimate the probability of success. Smith suggested that this explains why so many of the young among "the common people" are ready to enlist as soldiers or go to sea.

Regarding the wage implications of education and training, Smith compared education to investment in machinery:

> *A man educated at the expence of much labour and time to any of those employments which require extraordinary dexterity and skill may be compared to one of those expensive machines. The work which he learns to perform, it must be expected, over and above the usual wages of common labour, will replace to him the whole expence of his education, with at least the ordinary profits of an equally valuable capital.*
>
> **Smith (1776; 1976, p. 118)**

This is a remarkable early statement of the main idea underlying human capital theory, which was yet to take almost 200 years to be developed more fully.

Smith's theory of the wage structure is based on the assumption of perfect competition or, in his terminology, "the system of perfect liberty." But he recognized that this was not in every respect a realistic description of actual labor markets. The guild system that regulated the entry of labor into some occupations as well as government regulations that limited the regional and industrial movement of labor could lead to wage differences that were larger than they would have been under perfect competition.

It is not entirely clear how the theory of the wage structure can be reconciled with the long-run tendency toward subsistence wages. Smith's theory of the wage structure must obviously be interpreted as one of equilibrium wage differentials. But then, if the subsistence wage is to be interpreted as the average wage, some wages must be permanently below the subsistence wage, which hardly makes sense. On the other hand, if the subsistence wage is to be understood as a long-run minimum level, it must be the case that the average wage for all workers will actually be above the subsistence level, and this conclusion is not easy to fit in with the classical theory of the long-run equilibrium theory of wages.

Smith's theory of the competitive wage structure came in for a good deal of criticism and modification by a later generation of classical economists, in particular by John Stuart Mill (1848). Mill argued that although Smith's theory might be a realistic one for the case of perfectly free competition with "employments of about the same grade" and "filled by nearly the same description of people," this case is very far from the labor markets that one actually observes:

> *The really exhausting and the really repulsive labours, instead of being better paid than others, are almost invariably paid the worst of all, because performed by those who have no choice. . . . The more revolting the occupation, the more certain it is to receive the minimum of remuneration, because it devolves on the most helpless and degraded, on those who from squalid poverty, or from want of skill and education, are rejected from all other employments.*
>
> **Mill (1848; 1965, p. 383)**

Mill concluded that Smith's hypothesis that wages tended to rise with the net disadvantages associated with different occupation was wrong, and that, on the contrary, the true relationship rather was one where "the hardships and the earnings" stood in an inverse relationship to each other. In a similar vein, John Cairnes (1874) coined the term "noncompeting groups" to describe a situation in which individuals in the labor market were prevented by lack of education and skills and the constraints imposed by their class background to compete for positions over a wide range of occupations. In other words, inequality of opportunity led to inequality of wages as well as of net advantages, i.e., wages adjusted to take account of other characteristics of the different employments.

1.2.1.5 The Laws of Distribution

We have seen that the classical economists possessed a fairly sophisticated theory of the functional distribution of income. Their theory of the personal distribution was less advanced and restricted mainly to the framework of compensating wage differentials as developed by Smith and criticized by Mill. Regarding nonlabor income, their ability to analyze the personal distribution of income was limited by the absence of a theory of the distribution of ownership. A common attitude seems to have been that the distribution of ownership to capital and land was determined by historical processes that lay outside the scope of economic science. Thus, Mill claimed that in regard to the subject of Book I of his *Principles*, which is concerned with production, the "laws and conditions of the production of wealth partake of the character of physical truths." By contrast, Book II on distribution is concerned with a subject of a quite different nature:

> *The distribution of wealth . . . depends on the laws and customs of society. The rules by which it is determined, are what the opinions and feelings of the ruling portion of the community make them, and are very different in different ages and countries. . . . But the laws of the generation of human opinions are not within our present subject. They are part of the general theory of human progress, a far larger and more difficult subject of inquiry than political economy.*
>
> **Mill (1848; 1965, p. 200)**

It is clear from the context that Mill meant this statement to apply to all aspects of the distribution of income and wealth. However, he was also careful to emphasize that although the causal factors behind the distribution of income had to be studied in a broad context, including noneconomic considerations, the *consequences* of different distributional arrangements "must be discovered, like any other physical or mental truths, by observation and reasoning."

1.2.1.6 The Marxian Perspective

The basic structure of Karl Marx's positive economic theory is consistent with the teaching of the classical economists, especially Smith and Ricardo. As in their work, his main interest in the theory of income distribution lay in the functional distribution of income and less in the distribution of income between persons. He adopted the theory of subsistence wages but added an additional component, which was absent in the work of Smith and Ricardo, viz, the existence of unemployment. According to Marx, even the subsistence level of wages would not be low enough to secure full employment in the capitalist system, and the result of this was the development of what he named "the industrial reserve army" of the unemployed who live in extreme poverty and misery. He also argued that the existence of this reserve army is in fact in the interest of the capitalists. The reason is that there are significant fluctuations in economic activity that also imply large fluctuations in the demand for labor. The reserve army serves as a depository of labor on which the capitalists can draw without having to bid up wages, which they would have been led to do in a situation of full employment. Inequality and poverty therefore serve the interests of the ruling class, i.e., the capitalists.

Marx emphasized strongly that a central feature of the capitalist system was its ability to accumulate capital and generate economic growth. So what happens to the reserve army of the unemployed with the accumulation of capital? There are two effects that work in opposite directions. On the one hand, a more capital intensive technology increases the productivity of workers and tends to push wages up. On the other hand, the new technology also increases industrial concentration, and this effect lowers labor demand and pushes wages down. In the context of an increasing population, the net result of these effects may well be that employment increases, but the industrial reserve army will also increase, both in absolute and relative terms:

> *The greater the social wealth, the functioning capital, the extent and energy of its growth, and, therefore, also the absolute mass of the proletariat and the productiveness of its labour, the greater is the industrial reserve army. The same causes which develop the expansive power of capital, develop also the labour-power at its disposal. The relative mass of the reserve army increases therefore with the potential energy of wealth.*
>
> **Marx (1867-1894; 1995, pp. 360–361)**

According to Marx, therefore, and in sharp contrast to the view commonly held by the classical economists, unemployment was a permanent feature of the capitalist economic system and was central for a proper understanding of the distribution of income and wealth.

Apart from the emphasis on unemployment, a central concept of Marx's analysis of the distribution of income is *exploitation*. At the bottom of this concept is the view that labor is the fundamental factor of production in the sense that all nonlabor inputs can be derived from past labor: "As values, all commodities are only definite masses of congealed labor time" (Marx, 1867-1894; 1995, p. 16). The worker's productivity is a reflection of his labor-power. But he is only paid the subsistence wage, which is less than the value of what he produces. The difference between the two is the worker's unpaid work for the benefit of the capitalist. This is the profit or surplus value that defines the capitalist's exploitation of the worker.

Regarding the distribution of income from capital, a central element in Marx's theory is the tendency—or the law, as he calls it—of the rate of profit to fall as capital accumulates. The effect of this would be to diminish the importance of capital income. On the other hand, Marx also believed that this would go together with increasing concentration in industry and a strengthening of the monopoly element in capital income, and this would serve to counteract the first effect. Monopoly also explains his emphasis on absolute rent in addition to the Ricardian differential rent. Absolute rent arises because the absence of competition in landed property prevents rent from being brought down to zero on land at the margin of cultivation.

Marx did not limit himself to the presentation of his arguments in terms of abstract reasoning but also provided vivid examples of the living conditions in contemporary industrial society, above all in England where he lived during the last three decades of his life and where he wrote *Capital*. In this he was also able to draw on the insights and knowledge of his friend and collaborator Friedrich Engels. Engels's study of the conditions of the English working class (Engels, 1845) provided important material for Marx's own work, but is also a significant contribution in its own right. Engels, who worked as a manager in an industrial firm in Manchester that was partly owned by his father, was appalled by the living conditions of the workers that he saw in the industrial towns in England. In his book, he attempted to give a detailed description of their incomes, housing, and health, arguing that at least at this stage of the Industrial Revolution, workers were worse off than they had been before. He based his work both on his own observations and on various contemporary reports, and the book is notable for its extensive use of statistical data to describe social and economic conditions among the working-class poor.

1.2.2 Neoclassical Economics: The Marginalist Approach to the Distribution of Income

The marginalist revolution and the birth of neoclassical economics marked a new style of economic theorizing in which, in contrast to the classical writers, the new generation of economists attempted to anchor their analysis in the behavior of individual economic agents, using the theory of optimization and the mathematical tools of the differential calculus. But it also marked a new view of the workings of the market economy. Particular stress has traditionally been laid on the greater attention to demand as a determinant of prices, but the differences were also substantial when it came to the study of income distribution. To a large extent, the development of a new approach to income distribution was driven by the internal logic of theoretical innovation, but there can be little doubt that it was also motivated by the social and economic development that became increasingly visible toward the end of the nineteenth century. As an example we may take Léon Walras, who criticized Malthus for the lack of logic in his theory of population, in particular for his neglect of the role of technological progress. He also pointed out the failure of Malthusian theory to explain the actual increase in living standards for all classes in society. Thus, after having been impressed by the progress demonstrated at the World Exhibition in Paris in 1867, he wrote an article where he emphasized the benefits that advances in technology had brought to the working class and confronted them with the "ridiculous theory" of Malthus, predicting the workers' eternal poverty and misery.

1.2.2.1 The Marginalist Revolution and Its Forerunners

Although the marginalist revolution is usually identified with the early 1870s, there were important forerunners of neoclassical economics who in some respects were actually more advanced in their analytical approach than their successors. Foremost among the early champions were Johann Heinrich von Thünen and Herrmann Heinrich Gossen in Germany and Antoine Augustine Cournot and Jules Dupuit in France. In the present context, it is von Thünen and Gossen that have a special claim to our attention.

Von Thünen's main work *Der Isolierte Staat* (*The Isolated State*, 1826, 1850) is remarkable in this connection particularly for his early formulation of marginal productivity theory, which he applied both to capital and labor use. Thus, for a producer who attempts to maximize profits, he derived the conditions that the value of the marginal productivities of labor and capital must be equal to the wage rate and interest rate, respectively, and he used this approach to study geographical variation of the choice of capital intensity in a spatial economy. Von Thünen considered the result of equality between marginal value productivities and factor prices also to be a theory of income distribution, but as such it is obviously incomplete in that it takes no account of the supply side of factor markets, thus leaving the formation of factor prices unexplained (except for the special case where factor supplies are given). Nevertheless, this was an important building block for the theory of factor prices that was to be developed later.[4]

Hermann Heinrich Gossen's long-neglected book on economic theory (Gossen, 1854) is famous mainly for its early formulation of the theory of the utility-maximizing consumer and its derivation of "Gossen's law" that at the optimum the ratio between marginal utility and price must be the same for all consumer goods. In the central version of his theory, income is taken as given so that it does not include any theory of factor supply, but he did in fact present an extension of his model in which he claims that the supply of labor can be derived from the condition that the marginal utility of consumption is equal to the disutility of work. Together, von Thünen and Gossen provided important elements for the theory of factor price formation and income distribution, but it was yet to take a long time before their approach had been developed into a logically consistent theory of income distribution.

What historians of economic thought commonly refer to as the marginalist revolution is associated with three authors and three books: William Stanley Jevons's *Theory of Political Economy* (1871), Carl Menger's *Grundsätze der Volkswirtschaftslehre* (1871), and Léon Walras's *Eléments d'économie politique pure* (1874–1877). The central concern of the three main protagonists of the marginalist revolution in the 1870s was to establish the theory of subjective value as the main causal factor for the understanding of price formation. This led them to focus first of all on the determination of prices for consumer goods, but they also extended the theory to apply to the formation of factor prices. The equality of marginal value productivities and factor prices as following from profit maximization is

[4] Von Thünen has become particularly famous for the formula for "the natural wage," which is equal to the square root of the product of the existence minimum and worker productivity. There is general agreement that in the history of thought this should be treated as a curiosity rather than a substantive contribution (although von Thünen thought sufficiently highly of it to have it inscribed on his gravestone).

particularly explicit in Walras (1874–1877; 1954, Lesson 36). Walras also emphasized that a theory of the average rate of wages—which he considered to be the main focus of the classical economists—is not very useful; the analysis of wages must be based on a disaggregated view of the labor market with occupation-specific wage rates. However, neither Walras nor the other two went very far in the analysis of income distribution. Although they considered the application of the marginalist method to the analysis of wages and interest rates, they did not proceed to a study of how the theory could be used to explain inequality in society. For this we have to wait for the work of a later generation of marginalist or neoclassical economists, and in the coming decades, a number of writers made important contributions. Here, we shall focus on the work of Alfred Marshall and Knut Wicksell, who both in different ways left their mark on the development of economics during the next century.

1.2.2.2 Alfred Marshall

The contrast between the work of Léon Walras and Alfred Marshall has frequently been characterized as that between general and partial equilibrium theory. That is clearly true regarding their style of theoretical analysis. But in addition, it is striking how much their great treatises differ with regard to the reliance on institutional and empirical material. Thus, when Marshall approached the issue of what determines the demand for labor, he did it by way of a numerical example in which a sheep farmer decides how many shepherds to hire at a given rate of wages, hiring more workers as long as an additional shepherd's marginal value product exceeds the wage rate. He emphasized that the theory that "the wages of every class of labor tend to be equal to the net product due to the additional labor of the marginal laborer of that class" does not in itself constitute a complete theory of wages because a number of other aspects both of factor and product markets need to be taken into account.[5] On the other hand, "the doctrine throws into clear light the action of one of the causes that govern wages" (Marshall, 1890; 1920, p. 518).

As Walras before him, Marshall also argued that phrases such as "the general rate of wages" were apt to be misleading, for

> *... in fact, there is no such thing in modern civilization as a general rate of wages. Each of a hundred or more groups of workers has its own wage problem, its own special set of causes, natural and artificial, controlling the supply-price, and limiting the number of its members; each has its own demand-price governed by the need that other agents of production have of its services.*
>
> **Marshall (1890; 1920, p. 533)**

There is an interesting contrast here to the work of Adam Smith and John Stuart Mill in that the wages of labor are analyzed from the start within the framework of multiple

[5] For a discussion of the relationship between the concepts of net and marginal product as used by Marshall, see Whitaker (1988). For the case of perfect competition and full substitutability of the factors of production the two concepts coincide.

(although interrelated) labor markets, whereas the classical economists discussed the general rate of wages, later adding on a somewhat ad hoc discussion of wage differentials. The supply and demand framework instead provided a general approach to the study of wage formation, which could be used to analyze both the general level of wages (assuming, contrary to Marshall, that there is such a thing) and the wage differentials between occupations. However, Marshall also discussed the theory of compensating wage differentials, blending elements from the partially conflicting views of Smith and Mill.

Although Marshall must clearly be considered to be one of the founding fathers of the marginal productivity theory of wages,[6] his theoretical perspective was much wider than this terminology may indicate. Among his significant theoretical innovations in the study of wages and the distribution of labor income should be counted his early formulation of the theory of human capital. He noted that

> *[t]he professional classes especially, while generally eager to save some capital* for *their children, are even more on the alert for opportunities of investing it* in *them.*
>
> ***Marshall (1890; 1920, p. 533)***

Although investment in children by means of education and training will increase their productivity and thereby their opportunity to earn good wages, there are some serious imperfections in the market for human capital. One of these is the weakness of employers' incentives to invest in human capital. This capital becomes the property of the worker, so that the employer's opportunities of reaping the gains of any investment that made in the worker is severely limited, hence arises the crucial role of the parents, which is limited by "their power of forecasting the future, and by their willingness to sacrifice themselves for the sake of their children" (Marshall, 1890; 1920, p. 561). But although the parents play an important role in overcoming the adverse incentives of employers, this role has also other and more unfortunate consequences. Because the opportunities and insights of the professional classes are not shared by the members of the "lower ranks of society," their investment in their children is inadequate, and this evil is cumulative:

> *The worse fed are the children of one generation, the less will they earn when they grow up, and the less will be their power of providing adequately for the material wants of their children; and so on to following generations.*
>
> ***Marshall (1890; 1920, p. 562)***

Another point that Marshall repeatedly stressed is the dependence of productivity on wages. High wages lead workers to be better fed and better educated and so increase their productivity. Marshall suggested that this mechanism may be an important part of the

[6] This term has become a standard one among historians of economic thought, although Marshall himself would no doubt have objected to it as being an incomplete description of his own theory of wage formation.

explanation of the historical increase in wages, contrary to the predictions of at least the simple version of the Malthusian theory.

Both his emphasis on a disaggregated view of the labor market and his early insistence on the importance of human capital and efficiency wages make Marshall a very important contributor to the theory of income distribution, at least as regards the distribution of labor income. About the distribution of income from capital he has less to say. He applied marginal productivity theory to the study of the rate of interest, but because he did not offer any theory of the distribution of the ownership of capital (and land), the distribution of income from capital becomes an unsolved issue. The contrast to labor income is an interesting one: Because the discussion of the marginal productivity of labor is usually framed in the context of man-years of labor (as in the shepherd's example), and because the measurement of the distribution of labor earnings uses annual income as its basis, the distribution of wages becomes identical to the distribution of earnings. Thus, the marginal productivity theory becomes a much more important element in the theory of the distribution of labor income than in the study of the distribution of income from capital.[7]

1.2.2.3 Knut Wicksell

The Swedish economist Knut Wicksell is an important figure in the history of the marginalist revolution and the rise of the neoclassical school of economic theory. Whereas the earlier marginalists—apart from von Thünen—had focused most of their attention on the analysis of consumption, Wicksell's main interest was in production and investment decisions. It is worth noting that his initial interest in economics was kindled by his concern for social problems and the issues raised by unchecked population growth. In Volume 1 of his *Lectures on Political Economy* (1901–1906), he argued that virtually every problem in economics had to be studied in the context of a changing population; however, the population issue in fact plays relatively little role in his more formal academic writing.

Wicksell is especially well known for the first clear and precise formulation of the production function as a central tool in the analysis of production and investment decisions (including the original introduction in economics of what became known as the Cobb–Douglas function). He made explicit the idea of factor substitution, and the assumption of continuous substitution between factors of production was adopted by later economists as a defining characteristic of neoclassical economics. In a more rigorous fashion than his contemporaries, he showed that profit maximization involved the equality between marginal value products and factor prices. Like Marshall, he stressed the incompleteness of marginal productivity theory as a theory of income distribution because it did not take the supply side into account. He did not really manage to

[7] The shortcomings of marginal productivity theory in explaining the distribution of income from capital and land were strongly emphasized both by Cannan (1893) and Dalton (1920).

integrate supply and demand in a formal analysis of income distribution, but in his discussion of practical issues, he showed a clear understanding of the nature of their interaction. Although he emphasized the role that technological progress had played in increasing the marginal productivity of labor, he held the view—in sharp contrast to Walras—that it was doubtful whether real wages had shown any increase during the preceding 200 years, whereas rent in his opinion had "successively doubled and redoubled." The explanation for this he found in the growth of population during the same period:

> *Such an increase [in population] must, other things being equal, continually reduce the marginal productivity of labour and force down wages; or—what comes to the same thing, though the connection is easily overlooked on a superficial view—*prevent *the otherwise inevitable* rise *in wages due to technical progress.*
>
> ***(Wicksell (1901-1906; 1934, p. 143)***

As a purely theoretical proposition, this statement shows a very clear understanding of the respective roles played by supply and demand in the determination of wages. On the other hand, its empirical connection with actual economic developments during Wicksell's lifetime is highly questionable and can only be interpreted as being strongly colored by his neo-Malthusian convictions.[8]

A further important theoretical issue in the neoclassical analysis of production and distribution concerns the problem of product exhaustion: Would the payments to the factors of production according to marginal productivity theory exhaust the value of output? Earlier, Philip Wicksteed (1894) had shown with reference to Euler's theorem of homogeneous functions that this would happen if firms' production functions were linearly homogeneous. The problem with this application of the theorem was that it implied constant marginal and average cost, so that the scale of production for each firm was indeterminate. Wicksell pointed out that the problem would be solved by the assumption that production functions went through phases of increasing, constant, and decreasing returns to scale. This corresponds to the case of an average cost function, which first decreases and then increases. At the minimum point of the U-shaped cost curve there are constant returns to scale, and this is in fact the point to which the long-run equilibrium of the industry will converge, given the assumption of free entry. Factor prices correspond to marginal value productivities, and the payments to the factors of production exhaust the value of the product with pure profits being zero. But even in the case where product prices are given, as when they can be taken to be determined in world markets, this theory of distribution is incomplete in the absence of a theory of factor supply.

[8] For a more general discussion of the relationship between theory and statistical evidence in the work of income distribution theorists, see Part 4.

1.2.2.4 General Equilibrium Theory

The work of the neoclassical economists—from that of the early pioneers to the first and second generation of the marginalists in the closing decades of the nineteenth century—became consolidated in the later version of the theory of general equilibrium that was developed around the middle of the next century. The main achievements of this development have often been associated with the introduction of new methods of mathematical methods in economics and with the analysis of existence and stability of equilibrium, but in a broader perspective one must also include the deeper understanding of the general interdependence in the economy that it led to. A particularly important aspect of this interdependence was the relationship between the prices of consumer goods, factor prices and the distribution of income and wealth. But the connection between resource allocation and the distribution of income was not given much attention in modern general equilibrium theory; in the influential presentation of the theory by Debreu (1959), the term *distribution* does not even appear in the index. In one respect, however, the modernized version of the Walrasian system provided a more satisfactory treatment of distribution. Dalton (1920) had criticized the marginal productivity theory of distribution for not giving a satisfactory account of the distribution of income from capital and land. The theory treated only the determination of the rate of interest and the rent from land, but the distribution of capital and rental incomes had to be concerned with the interest rate *times* the ownership of capital and with the rental rate *times* the holdings of land.[9] This shortcoming of the theory is resolved in the modern theory by the introduction of the notion of endowments. Consumers are assumed to be endowed with initial resources (in principle both consumer goods and factors of production) as well as shares of the profits of the different firms in the economy, so that prices do indeed determine the distribution of income or wealth. On the other hand, part of Dalton's criticism remains valid because endowments and profit shares are taken to be exogenous, and no account is provided of their origin.

One reason why the new mathematical formulation of general equilibrium theory paid little explicit attention to the problem of income or wealth distribution was that in its ambition to achieve a high degree of generality, it rid itself of the distinction between consumer goods and factors of production. Formally, consumer goods were defined as commodities that entered the budget constraints as positive numbers, whereas factors of production were commodities represented by negative numbers. Moreover, the focus of the theory was on the competitive case, so that there was no scope for treating the formation of factor prices, e.g., wages, as being any different from the formation of

[9] Cannan (1893) had directed a similar criticism against the classical economists, calling the functional distribution of income with which they were chiefly concerned a "pseudo-distribution" because it was only concerned with wages per head, profits per cent, and rent per acre.

prices for consumer goods. Labor was just like any other commodity and wages no different from all other prices.

In applications of the general equilibrium framework the situation was different. In international trade theory, the effect of international trade on the domestic distribution of income had long been a central focus of the theory, and in the 1940s and 1950s, the analysis of the connection between the prices of factors and goods moved to the forefront of the theoretical development in the field; the classic contributions were Stolper and Samuelson (1941) and Samuelson (1953). The focus of this literature was on the functional distribution of income, in particular on the shares of labor and capital, whereas the analysis of the personal income distribution was mostly by implication, as in the study of sectoral shifts following changes in world market prices.

Another field in which one might expect the general equilibrium framework to be important for the study of income distribution is public economics. But this has hardly been the case. One explanation for this is that in contrast to international trade theory, public economics has always had a strong concern with the effect of taxes on factor supply, whereas in international economics one has often been content with assuming factor supplies to be given. The extension of the framework of analysis to incorporate variable factor supply leads to significant complications, and this may be the main reason why the best-known use of the general equilibrium approach in public economics is Harberger's (1962) analysis of the incidence of the corporation income tax. Harberger's model turned out to be a fruitful one for analyzing a number of problems in tax incidence analysis. On the other hand, the reason why it was easy to use was precisely because, in analogy with international trade theory, it ignored the study of the effects of taxation on the supply of capital and labor, issues that have otherwise been treated as central in the theory of public economics.

1.2.2.5 Imperfect Competition

The early neoclassical economists and the later general equilibrium theorists focused their analysis of the market economy on the case of perfect competition. In the case of the labor market, the assumption was that both workers and employers took the equilibrium market wage as given, whereas the forces of competition made any out-of-equilibrium wage rate adjust until the supply of labor was equal to demand. It was within this framework that theorists discussed the dual role of wages—and more generally of factor prices—in allocating factors of production among alternative uses and determining the distribution of factor incomes.

That the case of perfect competition was not a realistic one particularly in the labor market was already acknowledged by Adam Smith in his discussion of the determinants of wages (Smith, 1776, Book I, Chapter VIII). He emphasized that wages are influenced both by private and public restraints on competition. The guild system limits the access to certain occupations and thereby pushes up the level of wages relative to that of other lines of employment, and the government tolerates these regulations. Another point that he makes is that in bargaining over an employment contract, the natural advantages are with the employers. There are fewer employers than workers, so that it is easier for the employers to collude to keep wages low than it is for workers to combine to push wages up. Smith wrote long before the time of strong trade unions, and he remarked that although there are many laws that forbid workers to organize themselves for the purpose of obtaining higher wages, there are none that prevent employers in colluding for the opposite purpose. He also pointed out that if a conflict occurs, the employers can hold out much longer than the workers. A factory owner will often be able to live well without workers for a year or two, whereas a worker will find it difficult to survive for a week or a month if not employed. The implication is evidently that in many labor markets wages will be lower than they would have been in a situation of perfect competition with bargaining power being symmetrically distributed.

It took a long time before Smith's insights were taken into account in the neoclassical theory of the market economy. Pigou's *Economics of Welfare* (1920) discussed the functioning of the labor market with careful attention to the role of various institutions that interfere with competition in one way or the other. Because the relationship of the parties in the labor market is one of imperfect competition, there is an unavoidable indeterminateness in regard to the level of wages. In Appendix III to his book (Pigou, 1920; 1952, pp. 813–814), he provided a diagram that shows the deviation of the equilibrium wage from the competitive level,[10] but he did not attempt to identify exactly what determines the imperfectly competitive wage level.

The year 1933 saw the publication of the two books that moved the concepts of monopolistic and imperfect competition into the core of economic theory. *The Theory of Monopolistic Competition* by Edward Chamberlin had its focus on the markets for consumer goods, whereas Joan Robinson's *Economics of Imperfect Competition* also contained an analysis of imperfectly competitive labor markets with obvious implications for the distribution of income (which, however, she did not discuss except in passing). Pigou's indeterminateness was removed by the assumption of completely asymmetric bargaining power by the two parties to the labor contract: Employers were assumed to be monopsonists, and workers took wages as given. This led to an equilibrium in which wages were in general below the level of the marginal value products, with the gap between them reflecting the elasticity of supply. The larger the value of the elasticity of supply, the smaller would be the gap between the two, and the less would be the degree of exploitation. The implications of imperfect competition in the labor market were also considered by Hicks (1932), whose book among a number of other issues also contained an extensive discussion of the role of trade unions. In regard to the theory of income

[10] He also used the deviation between the perfect and imperfect competition level of wages to measure what he called unfairness and exploitation.

distribution, however, Hicks's main interest was in the functional rather than the personal distribution of income. Thus, one of his most influential contributions in the book was the analysis of the effects of various types of technical progress on labor's share of national income.

The general indeterminateness of the outcome of wage bargaining, which was stressed by Pigou, also played a central role in the theory developed by the Danish economist Frederik Zeuthen in his book *Problems of Monopoly and Economic Warfare* (1930).[11] His theory is set in the framework of a bilateral monopoly model in which a firm bargains with a trade union and where neither party has any outside option; the employer has no alternative use of his capital, and workers have no alternative employment opportunities. While recognizing the basic indeterminacy of the equilibrium solution, Zeuthen explored the factors that would determine the features of the bargaining process and the likely outcome. Both parties realize that failure to reach agreement will result in a conflict—a strike or a lockout—that will be costly to both of them. Zeuthen saw the bargaining process as a series of proposals and counterproposals, where proposals of high wages would make employers willing to risk a conflict, and this would put downward pressure on wages. Proposals of low wages, on the other hand, would make the union more willing to risk a conflict and thereby tend to push wages upward. At some intermediate wage level, both parties will consider the risk of pushing for a better alternative to be equally large, and this will be the equilibrium wage. Zeuthen's theory was an important contribution to better understanding of the role of bargaining and labor conflicts and a significant extension of the neoclassical theory of labor markets and income distribution.[12]

1.2.2.6 Human Capital Theory

An unsatisfactory aspect of the marginal productivity theory of distribution—quite apart from its neglect of the supply side of factor markets—was that it offered little explanation of why some factors of production were more productive than others. One might argue that this was simply a question of technology and the way that factors were combined in the production process, but particularly in the case of labor, it is hard to escape the belief that some individuals are in some sense inherently more productive than others. However, some of the differences in productivity might be due to education and training. This point was already made by Adam Smith, and we have also seen that Alfred Marshall suggested a possible explanation for this in the investment that parents made in their children, both with the time that they themselves devoted to them and with the resources that they

[11] Actually, the theory had been presented two years earlier in his doctoral dissertation, published in Danish (Zeuthen, 1928), which is a broad theoretical and empirical study of the income distribution in Denmark.

[12] As pointed out by Harsanyi (1955a), it was also, together with the analysis by Hicks (1932), a forerunner of the game theoretic approach to bargaining associated with John Nash (1950).

spent in giving the children a good education. This would result in higher wages for the children who benefited but possibly also in increased inequalities of wage income.

Another writer who pursued the idea of investment in human beings was the German statistician Ernst Engel. In his 1883 book on the cost value (Kostenwerth) of human beings, he calculated the cost of training a boy to practice his father's profession in the lower, middle, and upper classes of society (corresponding to lower, middle, and higher education).[13] However, he did not have a theoretical framework that allowed him to explore the analogy between investment in human and physical capital, and he did not discuss the implications of his approach for the distribution of income, implicitly ruling out the possibility of mobility between income classes.

In the twentieth century, the ideas of Smith and Marshall were taken up by the economists of what came to be called the human capital school. Although important contributions were made by Theodore Schultz (1961), the theoretical foundations were laid by Gary Becker (1962, 1964). In particular, Becker's 1964 book marked the beginning of an extremely influential line of research, which also took up important issues regarding the distribution of income. As set out in Becker and Chiswick (1966), the amount of investment in human capital at the individual level is determined by the intersection of the supply and demand curve (or the marginal benefit and the marginal cost curve). Both supply and demand curves must be expected to vary among individuals. Different supply curves may reflect the income and wealth of parents and access to capital markets, whereas the position of the demand curve may represent individual characteristics like inherent ability and attitudes to risk. In Becker and Tomes (1979), the framework is extended to an intergenerational setting where children's endowments are partly determined by the investments made in them by their parents. This is clearly related to the ideas of Marshall regarding the long-term effects of investment in children.

As with all theoretical innovations, the growth of the human capital field can to some extent be explained by developments internal to the discipline of economics. However, it is also natural to point out explanations that reflect changes in the economy. Studies of economic growth had led to increased attention to changes in the efficiency of labor as a determinant of growth. Perhaps, more to the point in the present connection are the consequences of an increasing level of education in the labor force, which made the distinction between income from capital and labor seem a less central element in a realistic theory of income distribution. A society in which an increasing number of workers had become human capitalists required a new perspective on the distribution of income.

[13] Engel also considered the costs of education for girls, but in their case, he did not include a calculation of the cost of higher education.

1.2.2.7 Risk Taking and Income Distribution

The difference of riskiness of income between occupations figured as one element in Adam Smith's theory of compensated wage differentials. In the choice between a safe and a risky occupation (shoemaker and lawyer in Smith's example), the expected wage in the risky occupation would have to be higher than in the safe one to compensate individuals for their additional risk bearing. To the extent that individuals assessed the probabilities correctly, these *ex ante* expectations would be translated into *ex post* income inequality: The incomes of lawyers would have a higher average but greater variance than the wages of shoemakers.

The possibility of formal modeling of choice in risk-taking situations was greatly stimulated by the axiomatic foundation of expected utility theory developed by von Neumann and Morgenstern (1947). Although it took some time for the theory to find applications in the analysis of real economic problems, its use in the theory of income distribution was one of the earliest. The classic article in the field is by Milton Friedman (1953), who used his earlier work with Leonard Savage (Friedman and Savage, 1948) to explain income distribution as the result of rational choice under uncertainty. A distinctive feature of the Friedman–Savage theory is the assumption that they make about attitudes to risk. Although the assumption of risk aversion is a natural one for explaining real-world features like portfolio diversification and insurance, it does not explain the simultaneous existence of gambling. To resolve this difficulty, Friedman and Savage assumed that the utility function of income had both concave and convex segments, i.e., ranges of both decreasing and increasing marginal utility. In Friedman's income distribution theory, individuals at the beginning of their lives choose between alternative income streams; at the level of abstraction of Friedman's analysis, these streams could be generated from labor as well as capital income. Although individuals have equal opportunities *ex ante*, the income lotteries in which they engage imply that some will find themselves *ex post* with high incomes, and some will end up in low-income groups. The special shape of the utility function gives rise to a distribution of income that, Friedman argued, is consistent with observed patterns, in particular as documented in his own empirical work with Kuznets (Friedman and Kuznets, 1945). He also argued that individuals will be motivated as participants in a democratic society to introduce redistributive mechanisms that insure them against the consequences of the most adverse outcomes. According to this theory, therefore, both income inequality and redistributive policies emerge as results of individuals' free choice in a situation of equality of opportunity and will reflect their attitude to risk, in particular the relative importance of risk averters and risk lovers. The less risk-averse individuals are, the greater will be the inequality of income in society.

A further development of this framework is due to Kanbur (1979), whose analysis builds on a much more specific structure than that used in Friedman's article. In Kanbur's framework, risk-averse individuals choose between the safe occupation of a worker and the risky occupation of an entrepreneur. In equilibrium, the two occupations must be equally attractive, i.e., have the same expected utility, and this implies that the expected income of the entrepreneur must be higher than that of the worker. Kanbur explored the comparative statics of the model and showed that when account is taken of general equilibrium effects on the distribution of individuals between occupations, there is no longer any simple connection between risk aversion and inequality. In a companion paper, Kanbur (1981) studied the role of taxation in the determination of the equilibrium distribution of the population between the two occupations.

On this point, Kanbur's study is related to the older analysis of taxation and risk taking that goes back to the classic article by Domar and Musgrave (1944). Their analysis of a model of portfolio choice showed that under certain assumptions, particularly that of full loss offset, income taxation induces individuals to take more risk than they otherwise would have done. Their choice of more risky portfolios obviously has the implication that their wealth *ex post* will have a larger variance than it would have had in the absence of income taxation.[14] With full loss offset, income taxation functions in part as insurance against variations in capital income, and this insurance acts as an encouragement to risk taking. *Ex post*, therefore, one would expect higher taxation to generate more inequality in the distribution of income from capital.

1.2.3 Nonmarginalist Approaches

The marginalist revolution of the 1870s left its mark on the style of economic theorizing for a long time; indeed, it remains a dominating influence on contemporary economics. As we have seen, it also played a central role in the theory of income distribution. But at the same time, other contributions were made that do not easily fit into the marginalist framework. A common feature of the alternative approaches is that they pursued an inductive rather than a deductive line of investigation. Some of these will be discussed later.

1.2.3.1 Statistical Approaches: The Pareto Distribution

Although the marginalist theory held out the promise of a theoretically more firmly based theory of the personal distribution of income, the late nineteenth century also saw the introduction of a more inductive theory of income distribution, founded not on *a priori* theorizing but on inference from statistical data. The pioneering contribution was due to Pareto, whose work caused a good deal of discussion and controversy during several decades after its initial publication.

Vilfredo Pareto was Walras's successor in the chair of economics at the University of Lausanne. Like Walras, he was a firm believer in the mathematical method, and he saw it

[14] The Domar–Musgrave article did not use the expected utility hypothesis. For a reformulation and sharpening of their theory along expected utility lines, see Mossin (1968).

as his main task to extend and refine the general equilibrium approach that Walras had developed, including the theory of factor price formation. When it comes to income distribution, however, Pareto's fame rests not on his refinements of Walrasian theory but on his formulation of what has become known as Pareto's law.[15] Many economists only know Pareto from footnotes in textbook treatments of utility theory and welfare economics and may be forgiven for thinking of him as a pure theorist. But Pareto was an immensely productive researcher who wrote on a wide variety of topics, both theoretical and empirical, and not only in economics. He is a significant figure in the history of sociology and wrote also on statistical theory, economic history, and political science. His studies of income distribution, set out in a number of articles and in his book *Cours d'économie politique* (Pareto, 1896–97) drew on his knowledge both of economics and mathematical statistics and, in the matter of interpretation, also on his insights in sociology.

What posterity has come to know as Pareto's law was not derived from a theoretical model; instead, it was based on a detailed study of incomes statistics for a number of countries and time periods. Pareto's analysis of these data led him to the hypothesis that all statistical income distributions have a common shape that one can characterize as follows. Suppose that we draw up a list of all incomes in society from the lowest to the highest. Starting from the median income, we know that 50% of the income earners have an income above the median. We then move up to a level of income that is 1% higher than the median and ask what percentage of the population has an income above this level. Obviously, the percentage is <50, but how much less? Pareto found that the answer was 1.5%; in other words, as the level of income goes up by 1%, the number of individuals with an income above this level falls by 1.5%. In general, mathematical terms Pareto wrote his law as:

$$\log N = \log A - \alpha \log y.$$

Here, N is the number of individuals who have an income of at least y, and A is a parameter that reflects the size of the population. α is Pareto's constant that he estimated to be approximately equal to 1.5. The relationship has the interesting property that the average income of those whose incomes are greater than y will be equal to $\alpha/(\alpha-1)$ times y. Thus, once again assuming that $\alpha=1.5$, the average income of those with incomes above 10,000 francs should be equal to 30,000 francs. In the economies that Pareto studied, it turned out that the fit of the function was remarkably good, although less so at the lower tail of the income distribution. Later work has tended to establish that the fit is particularly good for the upper ranges of the distribution, i.e., for the right end of the income distribution curve.

[15] His other claim to fame is of course his role in the development of welfare economics, which will be considered later.

Pareto's law came in for a good deal of controversy. Thus, a long discussion involving several participants arose regarding Pareto's claim that the parameter α could be used as an index of inequality. That this claim should turn out to be controversial will come as no surprise to the modern economist, who from the work of Atkinson (1970), Sen (1973), and others has been made aware that any particular index of inequality is implicitly based on some ethical judgment about the nature of inequality. The question of the conditions required for social welfare to be written as a function of mean income and inequality as measured by Pareto's α (increasing in the former, decreasing in the latter) was settled by Chipman (1974). Having this issue clarified is of obvious interest. However, there were other aspects of the controversy that are arguably of greater general importance.

One question that naturally arises concerns the empirical validity of the law. Did Pareto actually claim the law to be one of universal validity? Here, his statements do not provide an unambiguous answer. On the one hand, he noted in a comment on his empirical findings that

> *[t]hese results are very remarkable. It is absolutely impossible to assume that they are due solely to chance. There must certainly be a* cause *which produces a tendency for incomes to be distributed along a certain curve. The form of this curve seems to depend only slightly on different economic conditions of the countries considered, since the effects are about the same for countries in which economic conditions are as diverse as those of England, Ireland, Germany, Italian cities and even Peru.*

However, he went on to issue a word of caution:

> *True, since we are dealing only with empirical laws, we cannot be too prudent. In any case, the consequences we shall draw from this law will at least always be valid for peoples for whom we have seen that they are confirmed.*
>
> ***Pareto (1896-97), vol. II; quoted from Chipman (1976, p. 151)***

Despite this and other cautionary statements Pareto was frequently interpreted as claiming universal validity for his law. Such a claim naturally proved provocative to many who believed that governments should see it as one of their objectives to bring about a more egalitarian distribution of income. On the one hand, Pareto seemed to claim that the distribution of factor incomes was given; on the other hand, he also went out of his way to point out that, given the skewness embedded in the Pareto distribution of incomes, progressive taxation could only be counted on to provide a rather insignificant redistribution of income in favor of the poor. This was seen by many as proof of Pareto's alleged reactionary attitudes, although this view is not supported by statements such as

> *. . . even with taxes at an equal percentage of incomes, the rich contribute far less to public expenditures than the poor, whereas they benefit much more from them. For whom, if not for the vain rich, are funds expended on armaments and the like?*
>
> ***Pareto (1895); quoted from Chipman (1976, p. 115)***

However, it was the early presentation of Pareto, rather than his later and more cautious statements, that caught the attention of other economists, and a considerable amount of work was devoted to examining and criticizing his law of income distribution. Thus, in his *Economics of Welfare* (1920), Pigou devoted a whole chapter (Part IV, Chapter II) to a critical examination of Pareto's law. In the preceding short chapter, Pigou had sketched the principles underlying the equity–efficiency trade-off (to use a more modern expression), arguing from a utilitarian perspective that any cause that increases the "national dividend" without lowering the absolute share of the poor, or increases the absolute share of the poor without reducing the national dividend, must increase welfare. By contrast, the welfare effect of any measure that increases one of these quantities but diminishes the other is ambiguous:

> *Plainly, when this kind of disharmony exists, the aggregate effect upon economic welfare, brought about by any cause responsible for it, can only be determined by balancing in detail the injury (or benefit) to the dividend as a whole against the benefit (or injury) to the real earnings of the lower classes.*
>
> **Pigou (1920; 1932, p. 645)**

Pigou then went on to point out that, according to one "interesting thesis," there was no need to be concerned about these cases of disharmony: Pareto's alleged law of income distribution implied that because the relative shares of the different income groups were at least approximately constant, the only way to ensure an increase in the absolute share of the poor was to increase the national dividend. Pigou was clearly skeptical of the conclusion and also expressed strong doubts with respect to several aspects of Pareto's work. He criticized the empirical basis for Pareto's generalization, but a more important point that he raised concerns the basis for assuming a given distribution relating to all sources of income. Pareto's distribution is skewed to the right, and Pigou argued that in the case of labor income one would rather like to assume that the distribution of "capacities" follows the normal distribution.[16] He also pointed out, however, that capacity is a multidimensional concept, and that although manual and mental capacity might both be normally distributed, their joint distribution would not be, and this fact might go some way toward explaining the form of the Pareto distribution. On the other hand, the reference to capacity, whether manual or mental, does not explain the distribution of income from capital or property, which is largely determined by inheritance, the importance of which depends in a crucial manner on the nature of legal and political institutions. The view

[16] If capacity is taken to mean marginal productivity it is, of course, not sufficient to argue that the normal distribution of capacity is reflected in a corresponding normal distribution of wages. According to marginal productivity theory, wages correspond (under competitive conditions) to the value of the marginal products, so that the distribution of wages also depends on the distribution of product prices and accordingly on the distribution of workers between industries.

that the distribution of income, and in particular the share of the poor, cannot be affected by measures of economic policy therefore becomes untenable.

Toward the end of the chapter Pigou quotes Pareto as remarking about his own distribution that

> *[Some] persons would deduce from it a general law as to the only way in which the inequality of incomes can be diminished. But such a conclusion far transcends anything that can be derived from the premises. Empirical laws, like those with which we are here concerned, have little or no value outside the limits for which they were found experimentally to be true.*
>
> **Pigou (1920; 1932, p. 655)**

So it appears that Pigou's criticism of Pareto to some extent missed its target. That it still was felt to be necessary to devote a chapter to it in 1920 must be explained by the popular attention that Pareto's original formulation had attracted. The idea that the distribution of income was determined by a sort of immutable law appeared to have far-reaching consequences for the feasibility—or rather infeasibility—of redistributive policies.

Pigou was not the only economist to be critical of Pareto's law of income distribution. Edgeworth (1896) at an early stage of the debate argued that Pareto's contribution bore strong similarities to previous work by the English statistician Karl Pearson. Pareto reacted strongly to what he saw as an accusation of plagiarism and gave a heated reply in which he remarked that "it must have displeased Mr. Edgeworth to see me poach on territory which is apparently reserved for Professor Pearson, just as political economy is reserved for Professor Marshall" (Pareto, 1896). Further exchanges did little to soften the tone of the debate, and as late as 1926, 3 years after Pareto's death, Edgeworth wrote about Pareto's reaction that it "is of interest as throwing light not only on the character of the curve, but also on that of its discoverer" (Edgeworth, 1926; 2003, p. 492).

Pareto's formulation of his law as well as the later controversies to which it gave rise constitute an interesting episode in the history of economic thought, and the Pareto distribution continues to play a role in the empirical study of income distribution. Although it has received a good deal of criticism, it has also been hailed as a milestone in the empirical study of income distribution.[17]

1.2.3.2 Other Statistical Approaches

The tradition established by Pareto's work to look for regularities or empirical laws in the distribution of income was continued by a number of later writers. A characteristic feature of this literature is that the authors do not attempt to found their hypotheses on the neoclassical theory of factor market equilibrium but start instead from

[17] For a survey of the statistical literature that, although critical, takes an overall positive view of Pareto's contribution, see Bresciani-Turroni (1939). A balanced survey of the controversy surrounding Pareto's law is the article by Chipman (1976).

some observed empirical regularity, just as Pareto did. Just a few examples of this approach will be given here.

Roy (1950, 1951) claimed that observed earnings distributions could be reasonably approximated by the lognormal distribution and argued, echoing Pareto, that "[t]here must be some rational explanation of the fact that all these earnings' distributions have such similar shapes" (Roy, 1950, p. 490). He attempted to discover this explanation by studying a number of industrial cases in which workers performed a standard and identical task and where individual output was easy to measure. These included tasks like packing boxes of chocolate, stitching shoes, and pressing gramophone records. Altogether, for the 12 different cases studied, it turned out that the lognormal distribution performed slightly better than the normal. To the extent that people are paid according to output, this result could go some of the way toward explaining the earnings distribution in terms of the distribution of individual skills. In Roy (1951), he studies the theoretical case of a "primitive" society in which people can choose to work in two or more occupations and where their skills differ between occupations. He then discussed how different skill correlations give rise to different statistical earnings distributions (always assuming that earnings are proportional to output), emphasizing the central role played by the lognormal distribution. Champernowne (1953) considered a dynamic model in which it is assumed that every income earner has a probability of a rise or fall in income between one period and the next, which is proportionate to his income in the first period. He showed that over time this will result in convergence toward the Pareto distribution. In a comment on this article, Lydall (1959) argued that this stochastic process was implausible for labor incomes and showed that the Pareto distribution could be generated on the alternative assumption that in an industrial firm each supervisor controls the same number of persons and is paid according to the total income of those below him. A similar assumption about the pyramidal structure of organizations was employed by Herbert Simon (1957) in his analysis of the compensation of executives.

A different and more macroeconomic approach was taken by Kuznets (1955), whose goal was to explain the long-term trends in the inequality of income in the economy as a whole. Although on the basis of data for the United States, England, and Germany, he found that income inequality had decreased after the end of the First World War, he suggested that this period had been preceded by one of increasing inequality. In his view, the period of widening income gaps began with the Industrial Revolution in the late eighteenth century; for England he suggested that it ended around the middle of the nineteenth century and for the others a few decades later.[18] His explanation for this development was based on the shifts from the agricultural or traditional sector of

[18] Setting the date of the change from the first to the second phase at roughly 1850 for England, Kuznets suggested that Marx's view of the inevitable rise of inequality of income under capitalism may have been an overgeneralization from observations of the last stages of the first phase.

the economy to the nonagricultural or modern sector, where income from capital plays a larger role for the distribution of income. Initially, inequality is larger in the modern sector than in the traditional one, and this generates an increased inequality of income for society as a whole as the modern sector expands. Over time, however, as the modern sector becomes more mature a variety of forces combine to reduce inequality there, particularly through an increased share of the lower-income groups and a lowering of the income from capital. Consequently, overall inequality diminishes. In his own words:

> *One might thus assume a long swing in the inequality characterizing the secular income structure; widening in the early phases of economic growth when the transition from the pre-industrial to the industrial civilization was most rapid; becoming stabilized for a while; and then narrowing in the later phases.*
>
> **Kuznets (1955, p. 18)**

This hypothesis is what has become known as the Kuznets curve in the form of a bell-shaped curve describing the relationship between per capita income and the degree of inequality. It should be emphasized, however, that Kuznets was careful to point out the inadequacy of the empirical evidence for the hypothesis, particularly in regard to the earlier phase of economic growth.

The various statistical approaches to the study of income distribution are attempts to rationalize the observed distribution of income by using some stylized facts or assumptions about the generation of income to explain observed patterns of the distribution of income. To call these approaches, nontheoretical might be somewhat misleading; however, it is clearly the case that they are not founded on theories of optimizing behavior and market equilibrium.

1.2.3.3 Institutional Theories of Income Distribution

There have always been economists who were skeptical of the central role played by formal models in economic theory. In the area of income distribution, we have seen that even a prominent theorist like John Stuart Mill argued that "the laws of distribution" must be understood in a political and social context, and because this context was determined by institutions, the understanding of the distribution of income and wealth would have to take proper account of institutions in addition to the mechanism of demand and supply. Karl Marx emphasized that the distribution of income in the society of his time reflected the particular phase of social development that he called capitalism. Along similar lines, the German historical school, led by Wilhelm Roscher and Gustav Schmoller, downplayed the role of theory in favor of an approach based on a detailed study of historical data. If successfully carried out, this line of research would presumably be less able than, e.g., the marginal productivity theory to offer explanations with a claim to universal validity; on the other hand, it might hold out a promise of generating more insights with relevance for the particular society being studied.

It was especially in the United States that institutional approaches to the study of the economic system received a position that made many regard it as an important alternative to the theoretical approach of the neoclassical school of economists. Thorstein Veblen is widely regarded as the founder of American institutional economics, but his approach—more satirical than analytical—in books like *The Theory of the Leisure Class* (1899) and *The Theory of Business Enterprise* (1904) was too idiosyncratic to attract many direct followers.[19] Neither he nor the other most prominent members of the institutional school, John R. Commons and Wesley C. Mitchell, paid particular attention to the distribution of income except for a general emphasis on the importance of power relations and evolutionary processes. The chief importance of the institutional school may have been as critics of the neoclassical theory in its focus on rational behavior and competitive equilibria. But the lack of general propositions in the work of the institutional school contributed to its gradual decline as an influence on modern economics.

An interesting question that arises in the study of the effects of institutions on the economy is: What constitutes an institution? Here, Veblen adopted a broad definition that encompassed "settled habits of thought common to the generality of men." A modern version of this idea came with Gary Becker's work on the economics of discrimination (Becker, 1957), in which racial discrimination in the labor market is assumed to arise from a common preference for not working alongside people with a different skin color. In pursuing the implications of this idea, Becker may be said to have followed the guidelines for economic research recommended by the institutional economists; however, the tools that he used in this work were entirely neoclassical.

Regarding the inequality of wage income, important contributions have been made by specialists in labor economics and industrial relations. It is natural to group these with the institutional economists because like them they emphasize the crucial role of institutions for the understanding of the distribution of income, specifically the distribution of wage income. In the United States, the work of Dunlop (1944, 1958) described wages as determined by the interaction between company owners, management, and workers as represented by trade unions.[20] The book by Phelps Brown (1977) collects a number of his studies of wage inequality in different countries and under different economic systems.

[19] The closest that one may come to such a follower is perhaps John Kenneth Galbraith, whose satirical style and skepticism toward mainstream economics are in many ways reminiscent of Veblen. His book *The Affluent Society* (1958) contains several discussions of issues of income distribution with criticism of mainstream views but does not offer any alternative explanations of observed patterns of inequality.

[20] It should be noted that Dunlop's work is not institutional in the sense of showing aversion to theoretical modeling. As an example, in his 1944 book, he discussed the formal mathematical modeling of trade union behavior in a situation of unemployment, analyzing the relationship between the union's wage claim and the rate of unemployment compensation and thereby the distribution of income between the employed and the unemployed. This analysis foreshadows the numerous contributions to the theory of trade union behavior in the 1970s and 1980s.

His work is notable for the attempt to explain inequality of pay by drawing both on economic and sociological approaches, paying attention to such factors as social class and status, discrimination, intergenerational mobility, and mental ability.

1.2.3.4 The Role of Property Ownership and Inheritance

The role of inheritance as a determinant of income distribution has received relatively little attention in the theoretical literature. In the world of the early neoclassical economists and the later general equilibrium theorists, the subject did not fit easily into their models. The time dimension—essential to get a grip on inheritance—could indeed be added through the introduction of time-dating consumer goods as well as factors of production, but this failed to provide a convincing picture of the nature of inheritance. In the world of general equilibrium theory, as described, e.g., in the book by Arrow and Hahn (1971), property ownership was represented by "endowments," initial holding of goods and factors of production that were taken as exogenous. But models of this type are unable to explain the passing on of property from parents to children and the persistence of inequality between generations. The nature of these intergenerational transfers is determined by the rules of inheritance, which will therefore have an important influence on the distribution of income and wealth. But as Dalton remarked almost a century ago,

> *Many thinkers of high reputation still talk, or remain silent, about the law of inheritance, as though it had fallen immutable from heaven into the Garden of Eden.*
>
> **Dalton (1920, p. 285)**

Meade (1964) considered the development of the personal distribution of wealth on the background of what he saw as the likely development of the functional distribution of income. In his view, the dominating technological trend was toward "automation," which would imply a significant reduction in the demand for labor and falling wages. This would lead to a shift in the functional distribution of income away from labor and in favor of income from property. Because, as he pointed out, income from property is much more unequally distributed than income from labor, this shift would imply a greater overall inequality in the population. This trend toward increased inequality in the distribution of income might in Meade's view be reinforced by demographic factors, such as higher rates of growth for large than for small fortunes (due to better opportunities for diversification), the genetic inheritance of earning power, and the tendency toward assortative mating (the rich marrying the rich). As later pointed out by Stiglitz (1969), it could also be influenced by the rules governing inheritance, either by law or custom. If all wealth goes to the firstborn (primogeniture), this leads to a more unequal distribution of wealth than the alternative of dividing wealth equally among one's children.

Inheritance is of obvious importance not only for material wealth but also for human capital. We have seen that this point had already been emphasized by Marshall (1890), and some decades later Cannan argued that the individual qualities required both to earn a good income from labor and to manage one's property wisely were passed on from one generation to the next, so that this tended to stabilize the degree of inequality over time. However, this tendency was not without exceptions:

> *The able members of the poorest class are constantly rising to the top, and the particularly incompetent members of the richest class are constantly falling to the bottom; but all the same, among the bulk of mankind there is a continuous hereditary transmission of inequality of income, the importance of which it is foolish to ignore.*
>
> **Cannan (1914; 1928, p. 217)**

The role of inheritance in determining the degree of inequality in the ownership of property is obviously an important one and requires attention to the broader subject of what Mill called "the laws and customs of society." Perhaps, his warning, that this was a much larger and more difficult subject than economics, played some role in the development that led economists largely to neglect this important aspect of the distribution of income and wealth.

1.3. VALUE JUDGMENTS AND REDISTRIBUTION

The interest in the question "Why are some people rich and some poor?" has always been motivated by something more than pure intellectual curiosity. A notable feature of the observed distribution of income has always been that it is unequal, and a natural second question is therefore "Can inequality be justified?" A possible response to this question is that it is one that should be answered by moral philosophers and not by economists, whose science does not provide them with the tools needed to answer it. There are indeed some economists who have taken this position, but there are also a large number who have not, and this includes many of the most prominent characters in the history of the subject. The reasons for this are not difficult to see. On the one hand, there is the fact that many economists—from Adam Smith to Amartya Sen—have had a foot in the camp of the moral philosophers, so that crossing the borders between the two fields has come naturally to them. On the other hand, there is the existence of the borderland between the two fields, which is the study of the effects of redistribution policy. To understand the design and consequences of redistribution policy, one must know something both about economics and moral philosophy, and the attempts to combine them constitute the normative part of the study of income distribution.

1.3.1 The Normative Economics of the Classical School

The natural starting point for economic theories of distributive justice is the distribution of income that is generated by the market economy. Although the main concern of the classical economists was with the positive analysis of income distribution, they were also concerned with ethical issues and with the evaluation of redistribution policy.

1.3.1.1 Adam Smith

A point of reference for the classical view of this issue is Adam Smith's theory of the invisible hand. In the most famous single passage in the *Wealth of Nations*, he claims that each individual, by pursuing his self-interest also promotes the interest of society:

> *He intends only his own gain, and he is in this, as in many other cases, led by an invisible hand to promote an end which was no part of his intention. Nor is it always the worse for the society that it was no part of it. By pursuing his own interest he frequently promotes that of the society more effectually than when he really intends to promote it.*
>
> **Smith (1776; 1976, p. 456)**

The most common interpretation of this passage is that private incentives operating in the context of a market economy promote an efficient use of resources in the sense of maximizing "the annual revenue of society," although this interpretation is not undisputed.[21] Does it also promote a just distribution of income? There is no systematic discussion of this in the *Wealth of Nations*, although most readers of the book will find it reasonably clear that this was not his view. It is remarkable, therefore, to find in Smith's other main work, *The Theory of Moral Sentiments* (1759), a paragraph in which he makes the claim that the rich, without intending to do so, promote the interests of the poor. His statement of this claim is also of interest because it contains the second of his three uses of the metaphor of the invisible hand.[22] The rich, he says

> *... in spite of their natural selfishness and rapacity, though they mean only their own conveniency, though the sole end which they propose from the labours of all the thousands whom they employ, be the gratification of their own vain and insatiable desires, they divide with the poor the produce of all their improvements. They are led by an invisible hand to make nearly the same distribution of the necessaries of life, which would have been made, had the earth been divided into equal portions among all its inhabitants, and thus without intending it, without knowing it, advance the interest of the society.*
>
> **Smith (1759; 1976, pp. 184–185)**

The proposition that the distribution of necessaries is almost the same as if the economic system had been designed with a view to an equal distribution is certainly a striking one, although one should note that there is no claim that the income that finances the consumption over and above that level is distributed in a similar fashion. The self-interest of the rich is claimed to guarantee a certain minimum income to the poor, but not to the extent of leading to equality of living standards. Almost regardless of one's interpretation of the substantive content of this proposition, it is difficult to see that Smith provides any convincing support for it, and it is hardly surprising that this version of the invisible hand has had little influence on subsequent thinking about income distribution.

[21] For a discussion of alternative interpretations of the meaning of Smith's statement of the invisible hand, see Chapter 2 of Sandmo (2011).

[22] The third use occurs in his essay on the history of astronomy.

Going back to *The Wealth of Nations*, although it does not contain any systematic discussion of the normative aspects of the distribution of income, there are many passages in the book that demonstrate Adam Smith's concern with inequality and poverty as well his sympathy for the poor. One example is his positive attitude toward trade unions, which leads him to suggest that it is an inconsistency of economic policy to allow employers to collude while forbidding workmen to form trade unions (Smith, 1776; 1976, pp. 83–85). Another example that, although in itself of minor importance, is suggestive of his attitude, is his discussion of the system of the tolls that should be charged for different types of public transport. The principle that was most commonly used at Smith's time was that of charging according to the weight of the carriage. He argued against this principle and in favor of the alternative of charging higher rates for luxury carriages and lower rates for carriages of necessity. Such a reform, he argued, would have the effect that "the indolence and vanity of the rich is made to contribute in a very easy manner to the relief of the poor, by rendering cheaper the transportation of heavy goods to all the different parts of the country" (Smith, 1776; 1976, p. 725).

A clearer statement of Smith's more general perspective on the distribution of income between rich and poor comes in a passage that follows a discussion of the effects of lower prices of necessities:

> *Is this improvement in the circumstances of the lower ranks of the people to be regarded as an advantage or as an inconveniency to the society? The answer seems at first sight abundantly plain. Servants, labourers and workmen of different kinds, make up the far greater part of every great political society. But what improves the circumstances of the greater part can never be regarded as an inconveniency to the whole. No society can surely be flourishing and happy, of which the far greater part of the members are poor and miserable. It is but equity, besides, that they who feed, cloath and lodge the whole body of the people, should have such a share of the produce of their own labour as to be themselves tolerably well fed, cloathed and lodged.*
>
> ***Smith (1776; 1976, p. 96)***

It is clear from the context that Smith meant this statement to apply even to the case where the improvements in the standard of living of the lower ranks were achieved at some cost to the higher ranks of society.

What consequences did Smith draw for redistributive policy? Here, we must keep in mind that the instruments available for redistributive policy were limited in number in Smith's time, so that his policy recommendations were mostly incidental, as in the preceding passage concerning charges for public transport. His discussion of taxation in Book V of the *Wealth of Nations* is not very explicit when it comes to the redistributive effects of the tax system as a whole; he is content to discuss the main categories of taxes one by one with apparently little regard for the overall impact of the tax system. However, this discussion is introduced by the presentation of four normative "maxims" of taxation, and in the first of these we find the following principle:

> *The subjects of every state ought to contribute towards the support of the government, as nearly as possible, in proportion to their respective abilities; that is, in proportion to the revenue which they respectively enjoy under the protection of the state. In the observation or neglect of this maxim consists what is called the equality or inequality of taxation.*
>
> **Smith (1776; 1976, p. 825)**

The principle may not be entirely clear to the modern reader and could be interpreted in two different ways. The first part of the passage indicates that the principle is one of ability to pay, whereas the second part might suggest that we should read it as a recommendation of the benefit principle, according to which taxes should be seen as payment for services rendered by the state. However, the most reasonable interpretation of the term "revenue" is "income"; a central service that the state provides is security of private income, so that income is both a measure of ability to pay and benefits received. Thus, the tax system as a whole should be as nearly as possible proportionate to income. It is important to note that this is not a recommendation for the form of an income tax—about which Smith has little to say—but for the more general design of the tax system as a whole.

1.3.1.2 Malthus and Ricardo on the Poor Laws

Although redistributive taxation played little role at the time of the early classical economists, the form that support for the poor should take was a major issue of public policy.[23] There was widespread concern over the established system of poor relief, which provided assistance both to those too sick or too old to work and to those who were able to work but found it difficult or impossible to earn a living. Malthus applied his theory of population to this issue and argued that support for the poor would not in the long run improve their position in society. Because the provision of a minimum standard of living would encourage the poor to have more children, in the long run they would not be better off on an individual basis; there would simply be a larger number of poor people in society. In addition, the resulting increase of population would drive up the price of food and cause more workers to rely on poor relief:

> *They [the poor laws] may be said, therefore, to create the poor which they maintain; and as the provisions of the country must, in consequence of the increased population, be distributed to every man in smaller proportions, it is evident that the labour of those who are not supported by parish assistance will purchase a smaller quantity of provisions than before, and consequently more of them must be driven to apply for assistance.*
>
> **Malthus (1803; 1992, p. 100)**

Malthus therefore recommended the abolition of the poor laws to increase the incentives of the able-bodied poor to provide for themselves through their own work. In this he

[23] The history of thought regarding public policy toward the poor is discussed both more broadly and in more depth in Martin Ravallion's chapter in the present *Handbook*.

received strong support from other prominent economists, in particular from his friend David Ricardo. According to Ricardo, "the comforts and well-being of the poor" cannot be secured without some effort of their own, especially to regulate the increase in their numbers. But, he argued,

> *The operation of the system of poor laws has been directly contrary to this. They have rendered restraint superfluous, and have invited imprudence, by offering it a portion of the wages of prudence and industry.*
>
> *The nature of the evil points out the remedy. By gradually contracting the sphere of the poor laws; by impressing on the poor the value of independence, by teaching them that they must look not to systematic and casual charity, but to their own exertions for support, that prudence and forethought are neither unnecessary nor unprofitable virtues, we shall by degrees approach a sounder and more healthful state.*
>
> **Ricardo (1817; 1951, p. 107)**

In a stark form the critique of the poor laws introduced a theme that was destined to become a major issue in the economic analysis of poverty and redistribution: The possible conflict between the objectives of justice (poor relief) and efficiency (labor supply). Later classical economists, in particular Nassau William Senior, who was chairman of the 1832 Royal Commission on the poor laws, strongly recommended a reform of the system that ensured that poor relief would never be organized in such a way as to make it more attractive than to earn one's living by regular work.

1.3.1.3 Mill

John Stuart Mill is known as one of the most prominent spokesmen for the philosophy of utilitarianism, which he expounded in particular in his book *Utilitarianism* (1863). One might expect then that in his *Principles* he would use the utilitarian approach to evaluate income inequality, but this perspective is in fact absent from his analysis.[24] Like in the case of Adam Smith, we search in vain for a unified theoretical principle that can be used to evaluate income distribution from a normative point of view. On the other hand, there are numerous opportunities to gain insight into his views on distribution from his discussion of more specific issues.

On such issue is that of inheritance. Although Mill supports each individual's rights to the fruits of his own labor and property, he draws a line when it comes to income from inherited property. In a passage that may have been more controversial to his readers than he indicated (Mill, 1848; 1965, p. 218), he wrote that "although the right of bequest, or gift after death, forms part of the idea of private property, the right of inheritance, as distinguished from bequest, does not." He therefore supported restrictions regarding inheritance in the form of limits on how much an individual may be allowed to receive. His

[24] The last edition of the *Principles* that appeared during Mill's lifetime was the 7th, which came out in 1871. Thus, he clearly had the opportunity to use material from *Utilitarianism* for this purpose.

arguments for such restrictions run partly in the form of incentives: Although restrictions on how much a parent is allowed to leave to his children may weaken the parent's desire to accumulate wealth, this is outweighed by the adverse incentives to work and save that arise for children who receive large amounts of wealth that they have done nothing to deserve. But he also defended the proposed restrictions by its distributional consequences. If children's inheritance were to be limited to some maximum amount,

> *. . . the benefit would be great. Wealth which could no longer be employed in "over"-enriching a few, would either be devoted to objects of public usefulness, or if bestowed on individuals, would be distributed among a larger number.*
>
> ***Mill (1848; 1965, p. 226)***

According to Mill, therefore, there is a social benefit associated with a more even distribution of wealth.[25]

Another issue is that of the most desirable form of taxation. In his chapter "On the General Principles of Taxation" (Mill, 1848; 1965, Book V, Chapter II), Mill cited with approval Adam Smith's four maxims on taxation. After having quoted them *in verbatim*, he commented that although their meaning is mostly clear, the maxim that is concerned with equality in taxation (and which was cited earlier) requires further examination because it is concerned with a concept that is often imperfectly understood. He then stated that the fundamental principle of equality in taxation is equality of sacrifice, which means ". . . apportioning the contribution of each person toward the expenses of government, so that he shall feel neither more nor less inconvenience from his share of the payment than every other person experiences from his" (p. 807). He then went on to discuss the consequences of this general principle for the design of the income tax. Although expressing some sympathy for the idea of a graduated income tax, he concluded in favor of a linear tax in which, e.g., the first 50 pounds of income is tax exempt, whereas the excess income is taxed at a constant rate. He also recommended that saving be exempt from taxation, the main argument being that taxing the parts of income that are devoted to consumption and saving at the same rate involves a "double taxation of saving" and therefore a disincentive to saving and investment.

Mill's tax policy recommendations emerge as a compromise between the abstract idea of equal sacrifice and more *ad hoc* considerations, but it is difficult to see to what extent his conclusions can be derived from the philosophical principles of utilitarianism. In his book *Utilitarianism* (Mill, 1863; 1969, pp. 254–255), there is a brief discussion of alternative concepts of justice in taxation, but the text is rather inconclusive: Mill described alternative points of view that give support to a head tax, a proportional tax, or progressive taxation. He then stated that "[f]rom these confusions there is no other mode of

[25] A century later, Mill's recommendations were echoed by Meade (1964), who proposed progressive taxes both on wealth and inheritance for the purpose of achieving a more equal distribution of the ownership of property.

extrication than the utilitarian." However, he did not conclude as to the form of taxation that would follow from the application of utilitarian principles, and as we have seen this connection is not clear in his discussion in the *Principles* either.

It may seem surprising that John Stuart Mill, an intellectual known for his radical sympathies, should not have come out more strongly in favor of redistributive taxation. The main explanation is probably that he saw taxation as being of secondary importance in this regard in comparison to structural reforms aiming to expand the range of choice open to all layers of society. Such reforms would include better education for the lower classes, ending the restrictions on entry into various occupations as well the discrimination of women in the labor market. The latter issue was one that he considered to be of special importance. He wrote the influential book *On the Subjection of Women* (Mill, 1869), and in the *Principles* he wrote,

> *Let women who prefer that occupation [as a wife and mother]; adopt it, but that there should be no option, no other* carrière *possible for the great majority of women, except in the humbler departments of life, is a flagrant social injustice.*
>
> ***Mill (1848; 1965, p. 765)***

It is notable that it was to take more than a century for the gender issue once again to make its appearance in the normative economics of inequality and income distribution.

1.3.2 The Neoclassical Economists: Efficiency and Justice

With the emergence of marginalism and the neoclassical school of economic theory there began a more systematic exploration of the optimality properties of the market allocation of resources and in particular the relationship between on the one hand the efficiency of the market economy and on the other hand the distributive justice of its allocation of resources. In the long-run perspective of the history of ideas, the neoclassical interest in these issues may be seen as a desire to clarify Adam Smith's proposition that the invisible hand of the market led to a result that was in conformity with "the public interest."

1.3.2.1 Walras

The three main protagonists of the marginalist revolution paid little attention to the role of the competitive market system in the determination of income distribution and even less to the ethical aspects of it. Among the three, however, Léon Walras is notable for raising an issue that goes back to Adam Smith's theory of the invisible hand and the ability of the market mechanism to function in a way that is consistent with the public interest. Toward the end of his detailed analysis of exchange in a two-commodity world he wrote that

> *[the] exchange of two commodities for each other in a perfectly competitive market is an operation by which all holders of either one, or of both, of the two commodities can obtain the greatest*

> *possible satisfaction of their wants consistent with the condition that the two commodities are bought and sold at one and the same rate of exchange throughout the market.*
>
> **Walras (1874-1877; 1954, p. 143)**

The context makes it clear that Walras meant the conclusion to apply beyond the simple case of two commodities and pure exchange, so it must be understood as a more general characterization of a competitive economy.

The characterization can be read as a modernized version of Smith's statement about the invisible hand; however, it can be interpreted in two different ways. Several economists have taken the view that the expression "the greatest possible satisfaction of their wants" refers to the collective society of all individuals; according to this interpretation, Walras said that the competitive equilibrium generates the greatest possible satisfaction of wants for society as a whole. In this perspective, Walras came out as a rather naïve apologetic for the free market system. The other interpretation is obviously that each individual can obtain the greatest possible satisfaction of wants *for himself*. There can in fact be no doubt that the second interpretation is the correct representation of Walras's position. On the one hand, he insisted that his analytical description of the competitive market has no broader normative significance:

> *Though our description of free competition emphasizes the problem of utility, it leaves the question of justice entirely to one side.*
>
> **Walras (1874-1877; 1954, p. 257)**

On the other hand, he emphasized the noncomparability of utility, so that he must have rejected the notion that there exists such a thing as wants satisfaction for society as a whole.

On the latter point, however, we have evidence that for Walras, at least in this case, old habits of thought died hard. In a letter to the German economist Wilhelm Launhard in 1885 Walras defended himself against the charge that he had maintained that competition necessarily led to maximum satisfaction for society as a whole. Suppose, he argued, that commodities can be sold at a low price to the poor and a high price to the rich. The rich would then have to give up some consumption of "superfluous" goods, whereas the poor would be better able to afford necessities. "Consequently, there would be a large increase in utility" (Jaffé, 1965, vol. II, p. 50). Here, utility evidently refers to aggregate or social utility; hence, there is an assumption, contrary to the statement in the *Eléments*, that individual utilities can be compared and aggregated.

In addition to this lapse from theoretical consistency, the modern economist might also question Walras's use of the example of price discrimination for consumer goods to illustrate redistribution policy. Clearly, an example that would both be more striking and more realistic would be redistribution of *income* from the rich to the poor. The consequences in terms of the consumption of luxuries and necessities would be the same, and the connection with policies that were within the realm of the feasible would be much stronger.

In modern terminology, the conclusion to which Walras came close, although he did not manage to state it with great clarity, was that the market equilibrium was efficient although it did not necessarily result in a just distribution of resources and income. Although imperfectly formulated, this insight was a step forward in the understanding of the connection between the market mechanism as a system for efficient resource allocation and as a determinant of the distribution of income and welfare between individuals in society. The insight was to be further studied and clarified by the next generation of marginalist thinkers of whom the most important were Alfred Marshall and Walras' successor in Lausanne, Vilfredo Pareto.

1.3.2.2 Marshall

What were Marshall's views regarding the normative aspects of income distribution? In welfare economics, Marshall is chiefly remembered for his invention of the partial equilibrium concept of the social surplus (the sum of producers' and consumers' surplus), which can be measured as the area between the demand and marginal cost curves. Because this area achieves its maximum at the point of intersection between the two curves, i.e., at the competitive equilibrium, Marshall was able to conclude that

> *a position of (stable) equilibrium of demand and supply is a position also of* maximum satisfaction*.*
>
> **Marshall (1890; 1920, p. 470)**

This is a conclusion very similar to that of Walras, although Marshall was more careful in qualifying it to avoid misunderstandings. It is obvious that he meant the conclusion to apply beyond the simple case of an individual commodity to the general equilibrium of demand and supply, including the markets for the factors of production. And although the term *maximum satisfaction* was meant to apply to society as a whole, Marshall emphasized that it is an aggregate measure that is built on the assumption that

> *all differences in wealth between the different parties concerned may be neglected, and that the satisfaction which is rated at a shilling by any one of them, may be taken as equal to one that is rated at a shilling by any other.*
>
> **Marshall (1890; 1920, p. 471)**

He then argued that if, e.g., it were the case that the producers as a class were much poorer than the consumers, "aggregate satisfaction" might be increased by a restriction of supply that would, assuming demand to be inelastic, increase the income of the producers. The terminology here is apt to be confusing because it seems strange to argue that aggregate satisfaction can be increased by moving away from a position of maximum satisfaction. But quite apart from the terminology, the underlying argument is clearly based on the utilitarian assumption of decreasing marginal utility:

> *It is in fact only a special case of the broad proposition that the aggregate satisfaction can* primâ facie *be increased by the distribution, whether voluntarily or compulsorily, of some of the property of the rich among the poor.*
>
> **Marshall (1890; 1920, pp. 471–472)**

In his concluding chapter on "Progress in relation to the standards of life" he became at the same time more explicit and more cautious regarding the desirability of less inequality:

> *The drift of economic science during many generations has been with increasing force towards the belief that there is no real necessity, and therefore no moral justification for extreme poverty side by side with great wealth. The inequalities of wealth though less than they are often represented to be, are a serious flaw in our economic organization. Any diminution of them which can be attained by means that would not sap the springs of free initiative and strength of character, and would not therefore materially check the growth of the national dividend, would seem to be a clear social gain.*
>
> **Marshall (1890; 1920, pp. 713–714)**

This is a forceful expression of the view that excessive inequality is a social evil, and one notes also Marshall's claim that this moral judgment can claim the support of economic science. On the other hand, the desirability of a move toward increased equality must take account of the possibility that it might weaken productivity and economic incentives, a point of view that would become a cornerstone in the analysis of welfare state policies that was to occupy the work of many economists in the coming generations.

What would be the means that could be used to achieve reduced inequality? On this topic Marshall's *Principles* has less to contribute. There is the emphasis on education as a means of improving one's position in society but little attention to the possibility of compulsory redistribution that he alludes to. Foremost among the instruments of such redistribution is taxation, but there is hardly any systematic discussion of the principles of taxation in Marshall's book, and what mention there is, is mostly incidental and for the most part relegated to footnotes or appendices. This is in marked contrast to the treatises of Smith, Ricardo, and Mill, in which issues of taxation (as well as public expenditure) occupied a major part of their presentation of the principles of economics. A possible explanation of this neglect on the part of Marshall is that he initially saw his *Principles* as the first of a work in two volumes, where the second volume was to contain the application of theory to several areas of economic policy; a sketch of the proposed contents of Volume 2 dated in October 1887 lists "Taxation" as one of six such areas, whereas in 1903, "Public finance" had become one of nine areas. When his *Industry and Trade* was finally published in 1919, these topics were no longer parts of the content of the book.[26]

[26] An interesting study of Marshall's plans for a second—and a third and possibly a fourth—volume of the *Principles* is Whitaker (1990).

1.3.2.3 J. B. Clark

John Bates Clark was a pioneer of the modern marginalist thinking in the United States who introduced the concepts of marginal productivity and marginal utility both in academic and more popular writings. But his 1899 book, *The Distribution of Wealth*, has become less known for its restatement of marginal productivity theory (which is its main focus) than for what Stigler (1941) referred to as its "naïve productivity ethics." In Clark's view, the equality between factor prices and marginal value productivity was not just a descriptive theory of how the market worked; it was also the manifestation of a natural law. This view is expressed already on the first page of the preface:

> *It is the purpose of this work to show that the distribution of the income of society is controlled by a natural law, and that this law, if it worked without friction, would give to every agent of production the amount of wealth which that agent creates.*
>
> **Clark (1899, p. v)**

This statement may be read simply as a characterization of factor market equilibrium under perfect competition, although it raises the issue of how an agent's marginal productivity can be identified with "what he creates." Clark maintained that this problem was less complex than many people thought, for it was essentially of the same nature as that which arose in a simple frontier society:

> *In particular, it is necessary to know that the primitive law which puts a man face to face with nature and makes him dependent on what he personally can make her yield to him is still, in essence, the law of the most complex economy.*
>
> **Clark (1899, p. 37)**

A further and crucial issue is whether the distribution that results from the operation of the law is just. On this point, there is a certain ambivalence in Clark's exposition. On the one hand, he said that this question lies outside his enquiry, "for it is a matter of pure ethics" (p. 8). On the other hand, he argued that what he creates belongs to the agent by right, and that nobody can complain if he is paid according to what he creates. The competitive distribution of income is therefore both fair and consistent with social stability, for if some agents are paid less than what they create,

> *there would be at the foundation of the social structure an explosive element which sooner or later would destroy it.*
>
> **Clark (1899, p. 9)**

Although most modern economists will no doubt find Clark's "productivity ethics" unconvincing, there are also elements in his thought that have been taken up by others. The most obvious parallel is the analysis by the philosopher Robert Nozick in his book *Anarchy, State, and Utopia* (Nozick, 1974). Nozick's basic idea is what he calls the entitlement theory of distributive justice. Any distribution that reflects an acquisition of income or wealth that is considered to be fair, i.e., to have been fairly acquired according to certain axiomatic criteria, is just. Moreover, given such a distribution, there is no case for public redistribution of income. Although it is not linked to the marginal productivity theory of income distribution, Nozick's theory evidently has some elements in common with the ideas of Clark.[27]

1.3.2.4 Pareto

We have already encountered Pareto as an empirical researcher on income distribution. Although his influence in that area was significant, his contribution to welfare economics was more fundamental and of more lasting significance. It had important consequences for the way that economists thought about normative issues, including their views on income redistribution as a goal of economic policy.

The starting point for Pareto's welfare economics was his study of utility and demand. Arguing in his *Manual of Political Economy* that only an ordinal concept of utility was required as a foundation for the study of consumers' demand,[28] he went on to point out that this concept of utility did not lend itself to interpersonal comparisons:

> *The utility, or its index, for one individual, and the utility, or its index, for another individual, are heterogeneous quantities. We can neither add them together nor compare them ... A sum of utility enjoyed by different individuals does not exist; it is an expression which has no meaning.*
>
> **Pareto (1909; 1971, p. 192)**

From this it would seem to follow that the search for a criterion of aggregate utility or welfare would be in vain. However, Pareto went on to introduce his own criterion of social welfare or efficiency that we now call Pareto optimality:

> *We will say that the members of a collectivity enjoy* maximum utility *in a certain position when it is impossible to find a way of moving from that position very slightly in such a manner that the utility enjoyed by each of the individuals of that collectivity increases.*
>
> **Pareto (1909; 1971, p. 261)**

"Maximum utility" was clearly not a good name for this concept because it suggested precisely the type of aggregation that Pareto sought to avoid, but he may be excused for not inventing the term "Pareto optimality."

Pareto showed that a competitive equilibrium satisfied the conditions for optimality in this sense. From the assumption of incomparability, it followed that his optimality criterion was unable to judge the welfare effects of a redistribution of income that led to diminished incomes for the rich and increased incomes for the poor because this would make the rich enjoy less utility and the poor more. If the economy were to find itself in a competitive equilibrium both before and after the redistribution of income, both states of

[27] Ideas similar to those of Nozick had also been advanced by Friedrich Hayek; see in particular Hayek (1973).

[28] To distinguish this concept from that of cardinal utility, he even coined a new word, *ophelimity* (*ophélimité*), to represent it—a word that never caught on. In the quotations that follow, I have substituted "utility" for Pareto's "ophelimity."

the economy would satisfy the conditions for Pareto optimality, but the optimality criterion would not be able to rank the two situations relative to each other. Judgments about income distribution and redistribution in terms of justice or fairness should, according to this view, be regarded as occupying a position outside the field of economics as a scientific discipline. Although this interpretation is not very explicit in Pareto's own work, it became a central proposition in the further elaboration of Paretian welfare economics that was carried out by a number of twentieth-century economists. But the acceptance of Pareto optimality as an important concept of welfare economics took a long time. As late as 1947 Paul Samuelson, after having presented the definition of Pareto optimality, could write that "it has not yet received attention from economists commensurate with the importance which he [Pareto] attached to it" (Samuelson, 1947, p. 212).

1.3.3 Utilitarianism and the Economics of Redistribution

The insistence by Walras and even more strongly by Pareto on the subjective nature of utility might have been expected to lead to the total banishment of utilitarian philosophy from the normative analysis of income distribution. However, this did not happen. There were several reasons for this. One is that the work of Walras and especially Pareto did not become widely known in the international community of economists until well into the twentieth century. Another was that utilitarianism continued to hold a strong attraction for economists in search of a philosophical foundation for their egalitarian convictions and for the design of redistributive policy, particularly in the tax field.

1.3.3.1 Maximizing the Sum of Utilities

A good example of such an economist is Francis Ysidro Edgeworth. He adopted the view of the older utilitarians that social welfare should be seen as the sum of individual utilities but was critical of the use that they made of it, pointing out that it was difficult to see, in the absence of mathematical formalization, how their conclusions followed from their ethical premises. In his book *New and Old Methods of Ethics* (Edgeworth, 1877) he built on the analogy with the Weber–Fechner law in psychology, which stated that the perception of a sensual stimulus increases less than proportionally with the strength of the stimulus, to argue that utility must increase less than proportionally with income. From this he drew strong conclusions for the socially optimal distribution of income. In the case of a given total income to be divided between all members of society the optimal distribution would be one of complete equality, assuming that all individuals had the same utility function of income. He also analyzed the case of variable work effort and found that under certain assumptions those with the greatest capacity should do the most work.

A related approach was that of Pigou. In his *Economics of Welfare* (1920), he used an explicit utilitarian argument—although without reference to the Weber–Fechner law—to argue in favor of redistribution of income from the rich to the poor:

> *... it is evident that any transference of income from a relatively rich man to a relatively poor man of similar temperament, since it enables more intense wants to be satisfied at the expense of less intense wants, must increase the aggregate sum of satisfaction. The old "law of diminishing [marginal] utility" thus leads securely to the proposition: Any cause which increases the absolute share of real income in the hands of the poor, provided that it does not lead to a contraction in the size of the national dividend from any point of view, will, in general, increase economic welfare.*
>
> **Pigou (1920; 1932, p. 89)**

In other words, it is assumed that there exists a utility function of income that is concave and the same for everybody. In the following pages, the proviso of "similar temperament" is spelled out further. Pigou admits that under existing social conditions a rich man may in fact be able to produce more utility from any given amount of income than a poor man. But this advantage has come about through past inequalities of income and the standard of living and cannot therefore be used to argue against income equalization: In the long run, the poor who experience increased incomes will be as able as the current rich to generate utility from their income. The last part of the quotation introduces an important qualification: Policies that aim to redistribute income from the rich to the poor may have an adverse effect on incentives, in particular on the incentives to work and save. This may lead to a reduction of the national dividend or national income so that there will be less income available for distribution.

In analytical terms, we might restate this argument as saying that if there are no incentive effects of redistribution it should be carried to the point where the marginal utility of income is the same for all; in the case of identical tastes, this would imply complete equalization of incomes, as in the analysis of Edgeworth. If incentive effects are present, the optimal amount of redistribution would stop short of this point, with the gap between the marginal utility of income between rich and poor determined by the strength of the incentive effects.

1.3.3.2 Critique of Utilitarianism

The assumptions of identical utility functions, decreasing marginal utility, and interpersonal comparability of utility all became the subject of critical scrutiny as Pareto's work on demand theory and welfare economics became more widely known. Because these assumptions had been shown to be unnecessary for the study of consumer demand, they were also held to be inappropriate for making welfare judgments. Justifications of income redistribution such as that advanced by Pigou gradually came to be viewed as nonscientific and simply subjective expressions of one's personal taste for income equality. On the desirability of redistribution, economics as a science would have to remain silent. This view was particularly forcefully put in the influential book by Lionel Robbins (1932).

Robbins's influence is clearly discernible in the New Welfare Economics that was developed by several writers during the 1930s and 1940s. In the reformulation of welfare theory by Bergson (1938) and Samuelson (1947), a crucial role was played by the social welfare function that depicted social welfare as an increasing function of individual utility levels, represented by ordinal utility functions. The conditions for social welfare maximization could then be stated as two set of conditions. One set described the conditions for Pareto optimal allocation of factors of production and consumer goods, whereas the other represented the conditions for optimal distribution between consumers as requiring equality of the social marginal utility of income—i.e., the increase in social welfare following an increase in income—between individuals.[29] Although the new formulation made clear the distinction between welfare judgments related to efficiency on the one hand and distributive justice on the other, the generality of the conditions that Samuelson (1947) referred to as the interpersonal optimal conditions was such that it became virtually impossible to draw any conclusion regarding the socially desirable form of income redistribution. At the most general level of analysis, the only conclusion that could be drawn from the analysis was that the desirable extent of redistribution was determined by one's ethical beliefs. Regarding the *form* of redistribution, however, the analysis had rather strong implications: To achieve a full optimum of social welfare, redistribution ought to be carried out by means of instruments that did not lead to violation of the efficiency conditions. The only instruments that could achieve this were individualized lump sum taxes and transfers (although some economists, e.g., Hotelling (1938), implicitly assumed that the income tax was at least approximately equivalent to lump sum taxation).

1.3.3.3 A Comeback for Utilitarianism

Although the new welfare economics helped to clarify the relationship between economists' statements regarding efficiency and distributive justice, one might still ask whether the representatives of the new approach went too far in their rejection of the old welfare economics, which was based on a cardinal definition of utility and interpersonal utility comparisons. This view has been argued by Cooter and Rappoport (1984), who maintained that the concepts of utility used by the post-Pareto ordinalist school and the older economists whom they refer to as the material welfare school were fundamentally different. The concept of utility employed by the material welfare school was not intended to represent the individual's tastes but his needs, and these needs were assumed to be objectively observable as for instance in the form of physical fitness. To use this concept for interpersonal comparisons did not involve a comparison of subjective preferences but of empirically observable standards of living. The consumption goods that were bought using the individual's income were used to produce his standard of living, but like other factors of production the goods obeyed the law of diminishing returns,

[29] The implication is that Pareto optimality is a necessary but not sufficient condition for a maximum of the social welfare function. This follows directly from the assumption that the social welfare function is increasing in individual utilities.

which in this case was translated into the concept of diminishing marginal utility of income. It was this concept of utility that was used by economists like Edgeworth[30] and Pigou to justify the recommendation of transfers to the poor and progressive taxation. The concreteness of the concept is well brought out in Hugh Dalton's (1920) comment on Jevons's (1871) discovery[31] of the law of diminishing marginal utility.

> *From this law a practical conclusion of the greatest importance follows, namely, the extreme wastefulness from the point of view of economic welfare of large inequalities of income. It is obvious to the modern economist that, from this point of view, a considerable equalization of incomes is desirable, provided that production is not checked thereby. But before Jevons wrote, this was by no means obvious, or at any rate it was not widely perceived.*
>
> **Dalton (1920, p. 90)**

Dalton's use of the word *wastefulness* is suggestive. In the new welfare economics framework, this term would be meaningless, but in the approach taken by the material welfare school, it has a concrete interpretation in terms of a smaller quantity of aggregate welfare, which is due to the inequality of income. Given the way that income is distributed, it produces a smaller amount of material welfare or standard of living than that which would result from a more equal distribution.

A new justification for the utilitarian social welfare function arose in the early postwar period. It started with an article by William Vickrey (1945), which was apparently concerned with the possibility of measuring the marginal utility of income on the basis of the von Neumann–Morgenstern expected utility hypothesis. But in the middle of the article, Vickrey changed his focus to that of discussing the question of the socially optimal distribution of income. His approach is nicely summed up in the following statement:

> *If utility is defined as that quantity the mathematical expectation of which is maximized by an individual making choices involving risk, then to maximize the aggregate of such utility over the population is equivalent to choosing that distribution of income which such an individual would select were he asked which of various variants of the economy he would like to become a member of, assuming that once he selects a given economy with a given distribution of income he has an equal chance of landing in the shoes of each member of it.*
>
> **Vickrey (1945, p. 329)**

The idea was developed further by several writers, including Marcus Fleming (1952) and John Harsanyi (1955b), neither of whom, however, referred to Vickrey's work. Harsanyi's article in particular showed how a utilitarian social welfare function, additive in individual utilities, could be derived from a set of axioms governing individual and social welfare judgments. Using this approach, one could go back to the issue raised by the earlier utilitarian economists and ask which distribution of a given amount of

[30] Samuelson (1947, p. 206) said that "to a man like Edgeworth, steeped as he was in the Utilitarian tradition, individual utility—nay social utility—was as real as his morning jam."

[31] Jevons was in fact not the first to formulate this principle. As he was later to acknowledge, Gossen (1854) had done so before him. Even earlier, although in a different context, the principle had been formulated by Bernoulli (1738). For references and further discussion, see Sandmo (2011).

income would maximize social welfare. If social welfare can be expressed as an unweighted sum of individual utility functions, and if these functions are concave (representing risk-averse attitudes), the answer would once again be that the optimal distribution would be one of complete equality.

This implication was not emphasized by Harsanyi, whose interests centered on the logical foundations for this particular social welfare function, not in its implications for social organization and economic policy. Vickrey, on the other hand, developed these implications in some detail, pointing out both the optimality of equal distribution if total income could be taken as fixed and the qualifications needed when one takes account of the objection that the total amount of income cannot in practice be taken as independent of the way it is distributed.[32] Therefore, he argued, "some degree of inequality is needed in order to provide the required incentives and stimuli to efficient cooperation of individuals in the production process" (Vickrey, 1945, p. 329). From this observation, he proceeded to an attempt to determine the welfare maximizing amount of redistribution by calculating an optimal income tax function using the calculus of variations. He succeeded in deriving the Euler equation for this problem but concluded that "even in this simplified form the problem resists any facile solution" (Vickrey, 1945, p. 331).

There is a direct line from Vickrey's analysis to the modern theory of optimal income taxation as pioneered by James Mirrlees (1971). Mirrlees also adopted the utilitarian assumption of social welfare as the sum of individual utility functions (which he also assumed to be identical) but without the choice theoretic foundation adopted by Vickrey and Harsanyi; it is also notable that he does not refer to Vickrey's (1945) article. In the Mirrlees model, individual utility functions depend on consumption (or income) and leisure. Lump sum taxation is ruled out as infeasible, and redistribution has to be carried out by means of a nonlinear income tax that distorts the choice between leisure and consumption. The shape of the optimal income tax function accordingly has to reflect the trade-off between equality and efficiency. By adopting some additional assumptions relative to Vickrey's model, Mirrlees was in fact able to characterize the optimal income tax function, although in rather general terms. More specific results were derived by a simulation analysis of special cases. A surprising feature of the optimal tax schedule that emerged from these numerical experiments was that although the average tax rate was increasing in income, the marginal tax rate tended to stay approximately constant and if anything showed a tendency to decline with income.[33] Mirrlees's contribution has led to a long line of refinements and extensions of his analysis, including a critical examination of the utilitarian foundations of the social welfare function. In the 1970s, the book

[32] Vickrey's argument is strongly reminiscent of that of Pigou in the *Economics of Welfare*, but he made no reference to Pigou or any of the other early utilitarian economists.

[33] Later work by several economists demonstrated that under certain assumptions the optimal marginal rate of income tax at the top of the income schedule should be equal to zero. For an interpretation of this result and further references, see, e.g., Sandmo (1999).

by the philosopher John Rawls (1972) created a great deal of interest among economists who were interested in public policy analysis, and Rawls's "maxi-min" criterion, by which the welfare criterion to be maximized is the utility of the least fortunate person in society, was applied to the problem of optimal income taxation by Atkinson (1973). His numerical results indicated that with this criterion the marginal tax rates and the degree of progression were likely to be considerably higher than in the case considered by Mirrlees.

As an aside, it may be noted that a different argument for low marginal tax rates had earlier been discussed by Ragnar Frisch in an article published in Norwegian (Frisch, 1948). Frisch based his argument on the distinction between what he called the internal and external marginal productivity of labor. The external marginal productivity in a particular sector refers to the effect on output in other sectors that is not taken into account in the employment decision. Frisch believed that this effect as a rule was positive, so that work effort tended to be too low in a market economy. This might call for a negative marginal tax rate,[34] which, however, was not practically feasible, "at least not at the present time." Instead, he suggested a zero marginal tax rate on the part of income that was directly related to effort, and the remainder of the individual's income could be taxed according to a progressive scale.

1.3.4 Sacrifice and Benefit Theories

There are other ways to analyze the normative problems of redistribution than via social welfare maximization, and in this section, we consider two of these. Equal sacrifice theories caught the attention of economists around the end of the nineteenth century and were for a time influential in policy debates. Benefit theories of taxation whereby taxes are seen as payment for benefits received from the state have traditionally had a strong appeal to those who look for fairness in the relationship between the individual and the state.

1.3.4.1 Equal Sacrifice

The utilitarian approach to income distribution and taxation is sometimes referred to as an equal sacrifice theory. In the simple case that forms the starting point for the utilitarian analysis, pretax incomes are given and the government aims to collect a given amount of revenue by using individualized lump sum taxes to maximize the sum of identical and concave utility functions of income. The resulting optimal distribution of after-tax incomes is one of complete equality of income where the marginal utility of income is the same for all. The solution represent a minimum of aggregate sacrifice because the outcome with equal marginal utilities of income is the maximum of total utility that can be obtained relative to the tax revenue that is to be collected. It is a solution of equal sacrifice between persons only in the sense of equal *marginal* sacrifice: The sacrifice of the last dollar paid in taxes is the same for all.

[34] Or in other words a Pigouvian subsidy to work effort, although Frisch does not use this terminology.

It might be expected that some economists who thought about the just distribution of the tax burden should come to think that this notion of equal sacrifice had limited appeal. In the case of substantial inequality of pretax incomes, the loss of utility from going from the pretax to the after-tax situation will obviously differ between individuals, and if one thinks that this is unjust it is natural to look for some alternative notion of equal sacrifice that could be applied to such nonmarginal changes in the distribution of income. This led to the development of equal sacrifice theories in the more specific sense, and in particular the theories of equal absolute and equal proportional sacrifice; theories that were first discussed analytically by Cohen-Stuart (1889) and Edgeworth (1897). The criterion of equal absolute sacrifice)[35] can be formalized as:

$$U(Y) - U(Y - T) = k.$$

Here, Y is pretax income and T is the amount of tax, while k is a constant that is the same for all taxpayers,[36] so that the sacrifice of utility that results from taxation is the same for all individuals. To see how the amount of tax varies with income according to this principle, one may take the derivative of the left-hand side of the equation with respect to Y, treating T as a function of Y. Solving for the marginal tax rate, we obtain:

$$\mathrm{d}T/\mathrm{d}Y = [U'(Y - T) - U'(Y)]/U'(Y - T).$$

One sees immediately that the assumption of decreasing marginal utility of income implies that the marginal tax rate is positive, but the assumption does not take us any further in supplying an argument for progressive taxation. To study the implications for progressivity, one can use the result to derive the elasticity of income after tax with respect to income before tax. For progressivity, this should be less than one, but whether this is the case or not turns out to depend on whether the elasticity of the marginal utility of income is less than or greater than -1. For the logarithmic function, where the elasticity is just -1, equal sacrifice in this sense implies proportional rather than progressive taxation, as pointed out by Samuelson (1947, p. 227). From the point of view of the history of public finance, this conclusion is of particular interest because it was for some time widely believed that the principle of equal sacrifice combined with the assumption of decreasing marginal utility of income was sufficient to justify progressive taxation.[37]

35 The central contributions of Cohen-Stuart and Edgeworth have been reprinted in Musgrave and Peacock (1958). The criterion of equal relative or proportional sacrifice, whereby the difference in utility levels is related to the before tax utility level, leads to slightly different conditions for progressive taxation but does not raise any new issues of principle. See Musgrave (1959, p. 96).

36 k must reflect the government's revenue requirement, so that T is higher, the higher is k.

37 Cohen-Stuart (1889; 1958) surveyed a number of earlier studies of this issue by German and Dutch writers who claimed that progressive taxation could be rationalized along these lines. See also the book by Blum and Kalven (1953), which surveys both economic and legal discussions of tax progressivity with emphasis on the arguments derived from equal sacrifice theories.

Although the principle of equal sacrifice may have some appeal to economic intuition, the main reason that it has disappeared from the modern discussion of optimal redistribution must be that its assumptions are difficult to reconcile with the maximization of a social welfare function. From that perspective, the straightforward utilitarian approach is much more appealing. In addition, the equal sacrifice theory lends itself less easily to generalizations incorporating variable labor supply and the second best considerations introduced by the work of Mirrlees and others into the utilitarian framework. From this point of view, the equal sacrifice theory of income redistribution proved to be a sidetrack.[38]

1.3.4.2 The Benefit Principle of Taxation

The utilitarian and related approaches to the issue of optimal income distribution considered the question of the just or fair distribution of income in isolation from the distributive effects of public expenditure. In the older literature, we have seen that Adam Smith recommended that the contributions of taxpayers should be in proportion to "the revenue which they respectively enjoy under the protection of the state," and one interpretation of this rule is that taxes should be levied so as to correspond to the benefits that people received from the activities of the state. However, the further elaboration of the benefit principle of taxation mainly took place in the writings of a number of continental European economists during the late nineteenth and early twentieth centuries. Two different types of claims were made for the implementation of the benefit principle of taxation. The first was that taxes levied on individuals according to the benefits that they received from the provision of public goods would somehow establish a price system for public goods or publicly provided goods that would correspond to competitive prices for private goods with similar efficiency properties. This idea suffers from the weakness that at least for public goods in the proper sense these prices do not provide individuals with the incentives to reveal their true preferences so that they cannot fill the functions of the price mechanism in the private goods part of the economy. The second claim, which is the one that is relevant for the normative analysis of redistribution policy, is that the benefit principle represents justice in taxation and that it therefore is important for normative judgments about income distribution in a mixed economy. The best known statement of this position is that of Knut Wicksell (1896).[39]

The concept of just taxation as used by Wicksell is quite different from that employed by economists in the utilitarian tradition. Wicksell sees the relationship between government and citizens as basically one of exchange, and one that should be carried out on

[38] Or, as put by Edgeworth (1897, p. 566): ". . . whatever view we take of the relation of the principle of like sacrifice to pure utilitarianism, the sphere of its action independently of that supreme principle appears to be insignificant."

[39] The collection of translations edited by Musgrave and Peacock (1958) contains many of the most important contributions to this line of analysis by German, Italian, and Swedish economists, including a central extract from Wicksell's book.

terms that are fair. The starting point for his argument is that no public project should be carried out unless society's aggregate willingness to pay is at least as high as its costs. Given that this condition is satisfied, it ought to be possible to distribute the costs in such a manner that every citizen makes a gain from the exchange, and this is the principle of justice in taxation: "No-one can complain if he secures a benefit which he himself considers to be (greater or at least) as great as the price he has to pay" (Wicksell, 1896; 1958, p. 79). From this he drew the conclusion that any political proposal about public projects should be voted on as a balanced budget tax-expenditure "package," and that it should only be passed on the basis of a unanimous vote.

It may seem surprising that Wicksell with his reputation for political radicalism should favor a system that seems to exclude the possibility of income redistribution through the public budget. It is at this point that one has to keep his peculiar definition of "just taxation" in mind. Wicksell said explicitly that the principle does not take account of distributional issues. Given the distribution of income in society, Wicksell's principle, as described here, does nothing more than assure that the adoption of any new public project does not harm any citizen.[40] He also emphasized that this principle, if adopted in the Swedish society of his own time, would be in the interests of the lower classes who in his view were exploited by the higher income groups to contribute to the financing of public projects that involved little or no benefit to themselves.

However, Wicksell recognized that for this principle to be fully convincing both from an economic and ethical point of view, it would have to be embedded in a broader framework of distributive justice: "It is clear that justice in taxation tacitly presupposes justice in the existing distribution of property and income" (Wicksell, 1896; 1958, p. 108). On this broader concept of justice, however, he has actually little to say, although he emphasized that too much redistribution may harm the upper classes in a way that is harmful to society as a whole because these classes "undeniably include a significant share of a nation's intelligence and economic initiative" (Wicksell, 1896; 1958, p. 117).

Wicksell's analysis was followed up by his countryman Erik Lindahl, whose monograph on the theory of taxation introduced the concept that later came to be known as Lindahl prices (Lindahl, 1919). In a later article, he discussed in more detail the argument that the benefit principle had a claim to be considered a standard of justice in taxation. Here, on the one hand, he emphasized the broader concept of distributive justice in which the benefit principle had to be embedded[41]:

[40] The principle is closely related to the Pareto principle, which identifies a social improvement with the case where no one becomes worse off. Wicksell later modified the unanimity requirement to apply to groups rather than individuals.

[41] The term *property* should here be interpreted in a broad sense as including all individual economic resources, including income.

> *. . . justice in taxation is inextricably linked with justice in the distribution of property, since it would obviously be nonsense to speak of "a just portion of an unjust whole."*
>
> **Lindahl (1928; 1958, p. 227)**

On the other hand, Lindahl also argued that there did not necessarily exist any contradiction between the principles of benefit and ability to pay because ability to pay could often be taken as a good indication of the benefit derived from public expenditure. On this point, Lindahl's argument is reminiscent of Adam Smith's first maxim of taxation, which indicated that it would be possible for taxation simultaneously to reflect both the individual taxpayers' ability to pay and the benefits that they received under the protection of the state.

1.4. CONCLUDING REFLECTIONS

A chapter of the history of economic thought regarding income distribution theories does not lend itself easily to a summary in the way of a few main conclusions. Looking back on a two-hundred-year-long history, however, it does induce one to offer a few general reflections on the nature of the field and its development. Accordingly, I will make a few remarks on two general issues. The first concerns the relationship of economic theory to empirical evidence, in particular before the time when econometrics was established as the main framework for empirical study. The second set of remarks relates to Ricardo's characterization of income distribution as the principal problem of economics: Does the history of economic thought confirm his view of the importance of the subject?

1.4.1 Theory and Evidence

This chapter has been primarily an account of *theories* of income distribution; to include also the statistical and empirical work that has been done over the two centuries covered by the survey would be impossible within the confines of a single article. However, a brief discussion may be in order regarding the connection between theoretical and empirical work during the period. Thus, an interesting question to consider is to what extent the theorists of income distribution were aware of and were influenced by the empirical work that was undertaken at about the same time. In particular, the nineteenth century witnessed the growth of official statistics covering both the development of national income and its distribution.

The questions of awareness and influence are very general, and it is not easy to provide clear and simple answers. One reason for this is that the influence of empirical knowledge on economic theorists may have been rather indirect; some characteristics of the real economy may have been considered to be common knowledge, so that theorists saw no need to provide exact documentation. But one should realize that there was not always agreement about what that supposedly common knowledge actually was. A case in point is John Stuart Mill's disagreement with Adam Smith regarding the structure of wages. As we have seen, Smith believed that labor market competition would ensure that occupational wage rates would tend to compensate for noneconomic advantages and disadvantages, whereas Mill claimed that quite to the contrary, wage differentials reinforced the inequalities arising from different working conditions. In the eighteenth century, empirical data on this issue were presumably hard to come by; nevertheless, Smith did refer to empirical observations in support of his hypothesis, although by modern standards these references are both incomplete and unsystematic. By the middle of the next century, however, the situation had changed, and it would have been possible for Mill to provide if not direct evidence at least some empirical illustrations that could throw light on this matter and more generally on the distribution of income. But he obviously felt no need to do this. Well into the next century, Hicks (1932) wrote about the effects of competition on the structure of wages with hardly any reference to empirical relationships. In fact, the only instance in which he did refer to empirical evidence is where he cited data for wages of agricultural laborers in Lancashire in 1794, showing how they vary with the distance to the nearest manufacturing center.[42]

To blame the economists of the eighteenth and nineteenth centuries for not supplying formal statistical tests of their theories would of course be pointless because at that time econometrics was not even in its infancy (see Morgan, 1990). What one might nevertheless have expected was a greater interest in drawing on data that could illustrate the importance and relevance of theoretical reasoning.

From this point of view, a more striking instance of the lack of connection between theoretical and empirical work is Knut Wicksell's belief that real wages had not risen significantly over the past two centuries, as seen from the perspective of 1901. At that time, there had actually accumulated a large amount of statistical data documenting the significant rise in real wages during the nineteenth century in countries such as Germany, Italy, Great Britain, and the United States (see, e.g., Bresciani-Turroni, 1939) as well as the Scandinavian countries. The data for Germany were particularly extensive and at Wicksell's time had been used in academic studies by several German economists. Wicksell read (and wrote) German, but for whatever reason this work had little or no influence on his own thinking. If he had utilized it, he would have seen that his belief was firmly rejected by the empirical evidence.[43] But at least on this particular issue, he must have felt no need to confront his theoretical conclusions with statistical evidence.[44]

[42] These data were drawn from Redford (1926).

[43] In the case of Sweden, later economic historians have found that real wages increased at an annual rate of more than 2% during the period 1860–1895 (Phelps Brown and Browne, 1968). Although these particular statistics were not available to Wicksell, it is hard to imagine that this growth was not noticeable for people living at the time.

[44] Wicksell must also have known several economists and statisticians who had personal experience of the empirical work. Thus, he had extensive contacts with Norwegian economists, among whom was Anders Nicolai Kiær, who was an acknowledged expert on income and wealth statistics.

The history of the interaction—or lack of it—between theorists and empirical researchers in the study of income distribution is a large topic in itself that cannot be surveyed here, particularly because it cannot be separated from the broader issue of the connection between theoretical and empirical research in economics more generally. The present examples of the lack of such a connection should simply be taken as an indication that at least in the preeconometric age, there were sometimes large gaps between theoretical and empirical insights.

1.4.2 The Principal Problem of Political Economy?

Toward the end of this review of the development of theories of income distribution, it is natural to reconsider the quotation from Ricardo with which we began. Is Ricardo's view reflected in the actual importance that the theory of income distribution has had in the history of economics? It may well have been true that Ricardo in this way expressed his conviction of the nature of economics, but his vision must be interpreted in light of the state of the science at the time in which he lived as well as the nature of society. To a modern economist, the proposition that the functional distribution of income between workers, capitalists, and landowners should be considered the most important problem in economics will hardly be a convincing one. One of the reasons why Ricardo gave such emphatic priority to the problem may have been a conviction that the analysis of this issue also went far to explain the personal distribution in a society with a modest degree of mobility between social and economic classes. Another reason may have been that he did not see the economic theory of his day as providing a set of analytical tools and concepts that would be useful in a more disaggregated analysis of the personal distribution of income.

All this has of course changed. With the marginalist revolution of the late nineteenth century, economists acquired a set of theoretical tools that gradually came to improve their opportunities for analysis of both the positive and normative aspects of income distribution. But to what extent did they exploit these opportunities? When one reads the contributions of the early marginalists, it becomes obvious that they applied their new theories mainly to the explanation of price formation in the market for commodities and less so in the markets for factors of production. When the general equilibrium followers of Walras put the finishing touches to the neoclassical theory of competitive markets, commodities and factors were treated symmetrically with the result that less attention was given to the special features of the markets for labor, capital, and natural resources. Labor economics was for a long time considered to be a field on the outskirts of theory-based economics, and the literature on financial markets paid little or no attention—and continues to pay little or no attention—to the study of the personal distribution of income and wealth. Only in recent decades has formal economic theory begun to catch up on its neglect of the determination of income distribution. But this neglect is still visible in the allocation of space in introductory textbooks and books on microeconomic theory.

These remarks pertain in particular to the positive economics of income distribution. But the attention to normative issues has fluctuated even more. Questions of distributive justice were certainly discussed by the classical economists but without the benefit of a formal theoretical structure. With the breakthrough of marginal utility theory the situation changed, and many economists saw no objection to utilizing the hypothesis of decreasing marginal utility both to explain consumer demand and to justify the utilitarian argument in favor of income equality. This approach suffered a setback in the early nineteenth century with the adoption of ordinalism and the ideas of a value-free science. Later on, it once again became accepted that welfare economics could make an important contribution in clarifying the borderline between statements of facts and values, whereas since the 1960s, as Atkinson (2001) has pointed out, many modern textbooks seem to have adopted the view that the basic elements of welfare economics do not form a central part of the training of the modern economist. In regard to the theory of income distribution, many economists seem be held back from a discussion of distributive justice, presumably because it will lead them into areas where they have to confront issues that are of an ethical or philosophical nature.[45]

The desirable awareness of the relationship between positive and normative approaches to issues of income distribution may also be promoted through better knowledge of the history of thought in the area. Here, there is definitely room for improvement. History provides many examples of how new theories have been formulated without apparent awareness of the work of earlier economists. As an example, the modern theory of optimal income taxation could probably have been developed and presented with a broader appeal to the general economics profession if it had been set in the context of the work by earlier utilitarian economists such as Edgeworth and Pigou. It is undeniable that economics has many of the features of a cumulative science in which new theories replace old ones because of their higher explanatory power or because they lead to better insights in the problems that arise in the design of economic policy. But even a cumulative science can benefit from awareness of its roots.

ACKNOWLEDGMENTS

I am indebted to Tony Atkinson, Branko Milanovic, Martin Ravallion, and the participants in the authors' conference in Paris for many helpful comments and suggestions.

[45] A reviewer of my book on the history of economic thought (Sandmo, 2011) wrote, "I hate the word *social justice* because I do not know what it means."

Abstract

Individual well-being depends not only on income but also on other dimensions of life, such as health, the quality of social relations and of the environment, employment, and job satisfaction. In this chapter we survey the economic literature on how to construct such overall measures of well-being. We distinguish three approaches: the capability (and functionings) approach, the use of subjective life satisfaction measures, and the calculation of equivalent incomes. We discuss the normative assumptions underlying these three approaches, focusing on two issues: the degree to which individual preferences are respected and where in each approach the boundaries of individual responsibility are drawn. We compare the measurement of inequality in well-being with the use of multidimensional inequality measures. We illustrate the general theoretical issues in three domains of application: measuring the effects of household size and composition in the literature on equivalence scales, valuing publicly provided goods and services, and making international comparisons of well-being involving international purchasing power parity comparisons.

2.1. INTRODUCTION

The economic literature on inequality has traditionally focused on income inequality. One reason to be interested in income inequality is that it may be linked to potential economic growth, to aggregate consumption, and to the occurrence and size of cyclical movements (see Chapter 14). From this perspective, income (in)equality is instrumental to reach other social objectives. A second reason is a normative one, considering the distribution to be a matter of social concern in itself, independent of its effects on other variables. In this chapter, we focus on the latter reason, leaving the instrumental concerns aside.

One normative reason to be concerned with income distribution is that we are ultimately interested in the distribution of well-being and that we consider income as a proxy for well-being. A related argument emphasizes the right of everyone to have access to a minimum level of resources, income then being an indicator of these resources. These two approaches are closely related if we define well-being directly in terms of resources, but they may differ if one adopts alternative definitions of well-being, for instance, in terms of functionings or capabilities or in terms of subjective satisfaction with life. A third normative reason why people are interested in income distribution has to do with the fairness of the process through which income is acquired. There are strong convictions in society that individuals should be paid in a fair way and that effort should be somehow rewarded. There is more discussion about the ethical desirability of remunerating productivity differences stemming from differences in innate talent or in socioeconomic background. These considerations are linked to the debate about the content of "desert" and "merit" and their relevance for evaluating the income distribution. At first sight, such a focus on the process of income formation is very different from a concern for the final distribution of well-being. Yet, although the latter is the connecting thread of this chapter, fairness judgments will also play an important role at some points in our discussion.

It is not obvious that income is indeed an adequate proxy for well-being. It is well accepted that the same monetary amount may yield a different level of well-being for individuals with different needs. Moreover, individuals do not care only about their income. A consensus seems to be emerging that information on other dimensions of life (such as health, job quality, the natural and social environment in which people are living) should be integrated into a richer view of well-being (see Stiglitz et al., 2009, and the references therein). This broadening of the perspective on well-being has led to a growing aversion against the use of (even a "corrected" or "extended") income metric to measure well-being on the ground that this would reflect a kind of "resource fetishism." Yet, from an applied viewpoint, monetary measures have the obvious advantage that they yield an operational and cardinal measure.

This brings us to the main question for this chapter: is it possible to formulate an ethically attractive notion of individual well-being that is richer than monetary income and that is still sufficiently operational to be used in applied welfare analysis?[1]

The concept of individual "well-being" can be approached from many different perspectives. One could, e.g., take a psychological perspective and investigate what is the best measure of well-being for describing and explaining the emotion of "feeling well" (Kahneman and Krueger, 2006). However, according to the welfare economic perspective taken in this chapter, the choice of an adequate measure of individual well-being is not a psychological, but rather a normative question. An adequate measure of well-being makes interpersonal comparisons such that redistribution from a better-off individual to a worse-off individual yields a better state of affairs as seen from the social welfare point of view.[2] In other words, an adequate measure of well-being serves as equalizandum for an egalitarian policy.

[1] In a macro setting, the criticism of "income fetishism" is voiced even more loudly against the use of GDP (growth) as an indicator of welfare. We do not go into the debate on sustainability or on the different ways of "correcting" GDP to include distributional issues. A critical discussion of different approaches can be found in Fleurbaey and Blanchet (2013). In this chapter we focus on the derivation of a measure of well-being at the individual level. However, in Section 2.5 we will discuss some of the implications of our discussion for international welfare comparisons.

[2] When we talk about redistribution here, we refer to redistribution of well-being. This is not necessarily restricted to income redistribution, but may also take place through spending more or less on health care or education for specific groups in the population.

The choice of a particular metric of well-being is inevitably a matter of value judgments. Selecting income as the measure of well-being, or deciding to go beyond the income dimension is a normative choice. Indeed, the argument that we should include other dimensions than income because people care about these other dimensions, for instance, is only valid if we accept the normative position that society should care about what people care about.

Because defining an adequate concept of well-being is a normative choice, it is no surprise that opinions differ about what is the best measure of well-being. As soon as one moves beyond the single income dimension to describe well-being, at least two sets of issues come to the fore. First, what additional dimensions should be included? Or, more fundamentally, what justification can or should be given for this choice of dimensions? Second, should these different dimensions be seen as incommensurable, or is it possible to aggregate them into one measure of individual well-being? If one takes the former position and sticks to a vector representation of well-being, how should one handle interpersonal comparisons involving a trade-off between the different variables? If one takes the latter position, what should be the normative logic underlying the aggregation across dimensions?

In this chapter, we will describe the answers proposed by different approaches to these two sets of questions, and we will discuss their normative implications. In particular, we will look at the different approaches from two specific perspectives. First, we focus on the extent to which the proposed measure of individual well-being respects individual preferences. The principle of individual sovereignty has always been one of the main tenets of economics and remains a hotly debated issue (see, among others, Hausman and McPherson, 2009). One of the difficulties in the debate is that different interpretations have been given to the concept of preferences. In this chapter, we will interpret preferences as reflecting people's well-informed and well-considered ideas about what is a good life. The recent literature has documented many behavioral anomalies and has convincingly shown that these well-informed preferences are not always revealed in actual choice behavior (see Della Vigna, 2009, for an overview). Preferences as the representation of a life project therefore do not coincide with the traditional economic concept of revealed preferences. We will come back to these distinctions later.

Second, we will focus on the implications of selecting a specific measure of well-being for the delineation of the domain of personal responsibility. If we start from the idea that a redistribution from someone with a higher level of well-being to someone with a lower level of well-being is an improvement from the social point of view, this implies (even when this is not made explicit) that the person at the lower level of well-being is not held responsible for this lower level of well-being. This responsibility perspective helps to interpret some of the normative differences between the various approaches. As responsibility and freedom are closely related concepts, a focus on responsibility will also allow us to comment on the different interpretations of freedom embedded in the different approaches.

The chapter is structured as follows. Section 2.2 gives a brief historical sketch of the development of the literature. Section 2.3 is the core of the chapter. It contains a critical discussion of the three prominent proposals for a measure of well-being capturing nonincome dimensions: the capabilities approach, the subjective well-being approach, and the equivalent income approach. In Section 2.4 we consider the literature on multidimensional inequality measurement and on multidimensional stochastic dominance, which has taken up a direct concern for the distribution in multiple dimensions without introducing explicitly a measure of individual well-being. We refer to Chapter 3 in this volume for more details on the different indices that have been proposed, and we focus on their theoretical foundations in the light of our normative criteria. In Section 2.5, we apply the general insights from Sections 2.3 and 2.4 to a series of issues that have played a prominent role in the applied literature: the use of equivalence scales to deal with heterogeneous households, the inclusion of the value of public and nonmarketed goods and services in the measurement of inequality, and the measurement of inequalities at the world level. This last point will also give us the opportunity to link the discussion on the limitations of gross domestic product (GDP) as a measure of aggregate social welfare to the normative issues discussed in the previous sections.

Before starting, we make two remarks. First, this chapter is about evaluating states of affairs. For such a broad evaluation, the income distribution is not sufficient; it is necessary to work with a broader concept of well-being. This does not mean that it would not be relevant to argue in favor of a *re*distribution of income. In fact, as soon as we define well-being to include personalized and nontransferable characteristics (such as health), a direct redistribution of well-being is not feasible. If income has a positive effect on well-being, a redistribution of income can be an effective instrument to realize a more equal distribution of well-being. Yet, this will not necessarily be a redistribution from the (income-)rich to the (income-)poor because the income-rich can be at a lower level of well-being than the income-poor. This is precisely where different approaches to well-being will make a difference.

Second, we will focus on inequality rather than on poverty. The two concepts are complementary, but may still involve different ethical intuitions, especially if one accepts that poverty has an absolute component. It is probably not a coincidence that the concept of multidimensional deprivation has traditionally played a more important role in poverty than in inequality research. Poverty researchers are generally more sympathetic toward rights-based approaches. They are also less inclined to accept the idea that different life dimensions can be traded off. We will discuss these issues where needed.

2.2. A BRIEF HISTORICAL SKETCH

As we defined the quest for a measure of well-being ultimately as a quest for an attractive equalizandum for egalitarian policy, our discussion is related to the large welfare economic literature on consequentialist versus nonconsequentialist approaches and within the consequentialist approach on welfarist versus nonwelfarist criteria. Although this literature is rich and inspiring, it is also plagued by some terminological confusion. This problem is, e.g., very acute for the (for our purposes essential) notion of "welfarism." We will therefore briefly situate our topic against the background of the debate around Arrow's (1951) impossibility theorem. We will do so in an informal way without going into technical details.[3]

As a matter of fact, the initially dominant interpretation of Arrow's theorem was that it was impossible to define a nondictatorial social ordering of social states, satisfying the Pareto principle of respect for individual preferences. It was soon realized, however, that the independence condition, which was necessary to arrive at the impossibility result, was a strong one. It basically stated that the social ranking of any pair of two alternatives should depend only on the ordinal noncomparable individual preferences over these two alternatives. The so-called informational approach to social choice (d'Aspremont and Gevers, 1977; Sen, 1970)[4] showed that the impossibility is lifted as soon as one accepts that it is meaningful to represent individual preferences with an interpersonally comparable utility function. Depending on the specific informational assumptions made, a whole range of social orderings can then be defined, ranging from the utilitarian sum of utilities to the leximin ordering giving priority to the worst off. The lesson seemed to be that the only way to escape from Arrow's impossibility was to work with such an interpersonally comparable notion of utility (i.e., to go beyond ordinal noncomparable individual preferences).

Amartya Sen, who was one of the main contributors to this literature, later became one of the main critics of what he coined as welfarism (i.e., the approach in which the social evaluation is based solely on individual but interpersonally comparable levels of subjective well-being; see, e.g., Sen and Williams, 1982). Important social philosophers had already rejected the welfarist approach. Rawls (1971, 1982) stated that individuals have life projects and that these life projects should be respected, but that it does not make sense to reduce them to the objective of reaching the maximum level of welfare. What matters to individuals is the content of their project, not the satisfaction following from its realization. These projects are incommensurable. Dworkin (1981a) emphasized the problem of expensive tastes; according to him, someone with expensive tastes (e.g., for "prephylloxera claret and plover's eggs," as in Arrow's (1973) famous example)

[3] Pattanaik and Xu (2012) offered a conceptual framework to structure the various approaches. See also Fleurbaey (2003) for a more formal treatment.

[4] See d'Aspremont and Gevers (2002) for a survey.

cannot claim that he should be compensated for his ambitions at the expense of those with more modest tastes. Sen (1985) reformulated similar arguments in an elegant way by pointing out that subjective welfarism suffered from two problems. The first he calls "physical-condition neglect": Utility is only grounded on the mental attitude of the person and does not sufficiently take into account the real physical conditions of the person. This has two aspects. One is the issue of expensive tastes; the other is that persons may adapt to their objective circumstances or realistic expectations: "A person who is ill-fed, undernourished, unsheltered and ill can still be high up in the scale of happiness or desire-fulfillment if he or she has learned to have 'realistic' desires and to take pleasure in small mercies" (Sen, 1985, p. 21). The second problem is "valuation neglect." Valuing a life is a reflective activity in a way that "being happy" or "desiring" need not be (Sen, 1985, p. 29). An acceptable approach to well-being should explicitly take into account this valuational activity by the persons themselves.

In a long series of books and papers, Sen proposed his own concept of well-being in terms of functionings and of "advantage" in terms of capabilities. This approach is the first notion of well-being that we discuss in more detail in Section 2.3. It is definitely non-welfarist in Sen's own original meaning of the word, as it does not interpret well-being in terms of subjective welfare. It is even explicitly formulated as an alternative to subjective welfare. Yet, it does evaluate social states in terms of the individual achievements (the individual advantage levels) in these social states. It is therefore consequentialist and individualist. And here the terminological confusion starts. Some authors (e.g., Pattanaik and Xu, 2012) claim that it is natural to use the term *welfarist* also for such approaches that are centered on personal well-being, even if they use a well-being concept that is *not* subjective utility. Although we prefer the original (narrower) use of the term by Sen, we will try to avoid confusion by adding the word *subjective* each time we use the notion of welfarism in this original meaning.

At a time when the criticism on subjective welfarism was winning ground among welfare economists, there was a surprising and spectacular growth of the interest in the measurement of happiness in other domains of economics. Advances in survey research suggested more and more convincingly that happiness and/or life satisfaction could be measured and that interpersonal comparisons of these measured concepts yielded meaningful results. A rapidly growing stream of empirical papers showed that life satisfaction is not exclusively determined by income but is also strongly influenced by nonmonetary dimensions of life (such as health, social interactions, and job market status). The econometric results were reasonably robust. Although a large part of this literature is meant to be only explanatory, the implicit suggestion that what contributes to happiness must per se be good is very strong. Moreover, some authors (Frey and Stutzer, 2002; Kahneman et al., 1997, 2004; Layard, 2005) have been explicit about the normative implications of their empirical work: Now that we know how to measure utility, why not go back to Bentham? This position reflects a remarkable revival of subjective welfarism, and it is striking that the happiness literature has largely disregarded the arguments against subjective welfarism of the philosophical and welfare economic literature. The life satisfaction approach is the second notion of well-being that will be discussed in Section 2.3.

The third notion of well-being that we will explore in detail is that of "equivalent income," or money-metric utility. It also has a somewhat surprising history. Money-metric utility was introduced as a representation of preferences by Samuelson (1974) and Samuelson and Swamy (1974) and had some impact on the applied welfare economic literature during the eighties (see Deaton and Muellbauer, 1980; King, 1983, for instance). It lost popularity, however, as authors argued that it relied on an arbitrary choice of reference values and could have nonegalitarian implications (Blackorby and Donaldson, 1988). Although it slowly disappeared from the applied welfare economic literature, it was (more or less independently) developed within the social choice literature in what is called the theory of fair allocation. This theory looked for a social ordering that was based only on noncomparable ordinal preferences (i.e., noncomparable life projects). At first sight, this attempt may look hopeless because it should run against Arrow's impossibility result. However, closer investigation shows that Arrow's independence axiom can be decomposed in two components (Fleurbaey and Mongin, 2005; Roemer, 1996): The first is "ordinal noncomparability," stating that the only information that can be used is information about individual ordinal preferences; the second is "binary independence," requiring that the ranking of two alternatives should depend only on the individual evaluation of these two alternatives (see Fleurbaey and Blanchet, 2013, p. 139). The welfarist approach relaxes the first component, the fair allocation approach the second. Going beyond binary independence makes it possible to use information about the indifference curves for the two alternatives. Moreover, it turns out that the theory of fair allocation has a (more or less convincing) reply to the criticism that had been raised against the use of money-metric utilities. We summarize this debate in Section 2.3.

Note that the equivalent income is yet another concept of individual well-being that does not coincide with subjective welfare, but is based on individual preferences. Again, some authors claim that "respecting individual preferences" boils down to welfarism. This is then a third possible interpretation of the term (the first relating to the use of comparable subjective utility levels, the second to any measure of personal well-being). As mentioned already, we will not follow this line of thinking, and we will reserve the use of the term *subjective (non)welfarism* to its original meaning.

Although the three approaches that we sketched until now can be related more or less explicitly to the welfare economic literature on the measurement of well-being, this is much less the case for another strand of economic research that aimed at broadening the concern for income inequality to include other dimensions. This literature deliberately remains agnostic about the formulation of an individual measure of well-being and focuses directly on Pigou–Dalton axioms in a multidimensional space. We will discuss the relationship between this approach and the welfare economic literature in Section 2.4.

2.3. INEQUALITY OF WHAT?

We first discuss the approach that defines well-being in terms of functionings and capabilities, then consider the normative interpretation of happiness and life satisfaction data and, finally, turn to the equivalent income approach. In each case we investigate whether the well-being concept respects individual preferences and what the underlying (implicit or explicit) delineation of individual responsibility is.

It is useful to introduce some notation. Let ℓ_i denote the vector of m aspects of life that may matter to individual i. Examples are consumption or income, health, longevity, leisure, status, and job characteristics. One of the variables in ℓ_i is income (or consumption) y_i. Individuals have a life project (i.e., an informed judgment about what makes a life good or bad). We represent this life project for each individual i by a preference ordering R_i over the vectors ℓ_i: $\ell_i R_i \ell_i'$ if i weakly prefers the life described by ℓ_i to the life described by ℓ_i'. Let $\ell_i P_i \ell_i'$ denote strict preference and $\ell_i I_i \ell_i'$ denote indifference. These well-informed preferences are individual specific. We do not assume that these preferences are always revealed in actual choices. Subjective individual satisfaction is given by a "satisfaction function" $S_i\,(\ell_i)$.[5]

We assume that, from a normative point of view, individual i's situation is completely described by the triplet (ℓ_i, R_i, S_i), that consists of the vector of life dimensions ℓ_i, the preference ordering R_i and the satisfaction function S_i. This means that personal characteristics (e.g., cognitive capacities) are only relevant insofar as they influence preferences or satisfaction, or if they are part of the vector of relevant life dimensions for individual i. A method of interpersonal well-being comparisons must be able to rank such triplets (ℓ_i, R_i, S_i). Because ℓ_i by definition describes all the aspects of life that matter to individual i, measuring i's well-being involves constructing an interpersonally comparable index in which the various elements of ℓ_i are weighted. Different well-being concepts are represented by a well-being measure WB. The value $WB(\ell_i, R_i, S_i)$ is to be interpreted as the well-being of individual i with life ℓ_i, preference ordering R_i and satisfaction function S_i.

2.3.1 Functionings and Capabilities

The origins of the capability approach within welfare economics are to be found in a series of influential papers and monographs, written by Amartya Sen in the 1980s (Sen, 1980, 1985; Sen et al., 1987). He developed and discussed the approach further

[5] We do not use the term *utility function* here because this refers to *any* representation of the ordinal preference ordering. The "satisfaction function" is one choice out of all the possible utility functions. As we will see, the equivalent income function is another.

in some widely read books (Nussbaum and Sen, 1993; Sen, 1992, 1999, 2009). On the philosophical side, important contributions have been made by Nussbaum (2000, 2006, 2011). Both authors, and the many papers following in their wake, are explicit about the normative purpose of the approach. Their aim is to define individual well-being so that it can be used in a meaningful way as the equalizandum for an egalitarian policy. The important question is: "Equality of what?" (Sen, 1980).

Sen's own answer to this question starts from the rejection of two extreme alternative approaches. We have seen in the previous section that Sen considers subjective welfarism unacceptable because of the problems of "physical condition-neglect" and "valuation neglect." But focusing exclusively on either income or material resources would not do justice to the heterogeneity among human beings, he argued. What does matter to define well-being is the vector of functionings of a person (i.e., achievements): what this person manages to do or to be (such as being well nourished, well clothed, mobile, or able to appear in public without shame).

These functionings have to be distinguished from the resources or commodities that are used to achieve them. Personal and environmental characteristics, to a large extent, determine what people can achieve with a given amount of resources. How well nourished a person is does not only depend on the amount of food eaten, but also on the biological characteristics of the person's body and the work that person does; books do not contribute to the personal development of persons who were never taught to read; whether a person is mobile does not only depend on whether that person owns a bicycle, but also on the availability of safe road infrastructure, and so on. The well-being of person i can be seen as the person-specific valuation of the vector of functionings ℓ_i:

$$\mathrm{WB}^{\mathrm{F}}(\ell_i, R_i, S_i) = v_i(\ell_i), \tag{2.1}$$

where the superscript F refers to the functionings approach. The crucial question is, of course, how to interpret the valuation function v_i. We return to this question later in this section.

In a further step, Sen claimed that a description of well-being in terms of achieved functionings is not sufficient because it does not integrate the essential notion of freedom. His classical example involves the comparison between two individuals who are both undernourished. For the first person, the undernourishment is the result of material deprivation. The second person, on the contrary, is wealthy but freely chooses to fast for religious reasons. Although their achievements in terms of the "being well-nourished" functioning are exactly identical, it is intuitive to say that their situations are not the same in terms of well-being. Therefore Sen introduced the notion of "capabilities" to capture the real opportunities of persons. The capabilities of person i are given by the set of functionings vectors that are accessible to the person (i.e., the set from which he or she can choose). Loosely formalized, we can represent the set as $Q_i = \{\ell_i | \ell_i \text{ is feasible for individual } i\}$. The "advantage" of person i is then the evaluation of the capability set Q_i.

We will now first discuss the implications of moving from functionings to capabilities (i.e., from achievements to opportunities).[6] This will allow us to discuss the interpretation of freedom and responsibility within the capability approach. We then move to the issues of choosing the relevant dimensions to be included in the vector ℓ_i, and whether and how to aggregate them in a single well-being indicator. This will clarify the position of the capability approach with respect to the other normative criterion (i.e., respecting individual preferences).

2.3.1.1 Capabilities, Responsibility, and Freedom

Capabilities, defined as the opportunity set from which people can choose, are a reflection of the real (positive) freedom of individuals and are definitely not restricted to the securing of negative freedoms alone. People should not only have the legal right to provide themselves with food, but they should also have the economic possibilities to do so. Equalizing capabilities also goes beyond eliminating discrimination, although the latter is an important element of it. This integration of positive freedom issues in the measurement of well-being is an attractive idea. However, it also raises some difficult questions.

A first issue was raised by Basu (1987) in his review of Sen (1985) and was taken up again in Basu and Lopez-Calva (2011). It can best be illustrated in the usual Edgeworth box of a two-person two-good exchange economy (see Figure 2.1). This figure depicts a general equilibrium situation (point e), in which relative prices are given by the slope of the line AB, and the initial endowments of persons 1 and 2 are given by point a. In this setting it might seem straightforward to say that individuals choose within their budget sets (i.e., the areas O_1CAB for person 1 and O_2DBA for person 2). But the figure immediately shows that their freedom to choose within the budget set is illusory: What is open to one person depends on what the other person chooses. If person 2 sticks to the bundle in e, it is impossible for person 1 to pick bundle b. In fact, in that case person 1 can only choose bundles from the rectangle O_1FeG. In general terms, changes in the choices by one person (induced by changes in preferences, for instance) will change relative prices and, therefore, the opportunity set of the other person. Figure 2.1 represents the very peculiar case of a two-person two-good exchange economy, but the point made by Basu is more general. The achieved functionings of any person do not only depend on the choices made by that individual, but also on actions taken by other individuals. How to define the capability set of any person in such a situation?[7]

[6] There is some terminological confusion in the literature. Although the distinction between "functionings" and "capabilities" is clear in Sen's approach, other authors have later used the term (*basic*) *capabilities* to refer to functionings. In this chapter we aim to remain as close as possible to the original meaning of the terms.

[7] Basu's example of the Edgeworth box loses some of its relevance in a many-person society, but the issue of social interdependencies is a more general one. See Pattanaik and Xu (2009) for a discussion leading to the conclusion that none of the solutions proposed for this problem is entirely satisfactory.

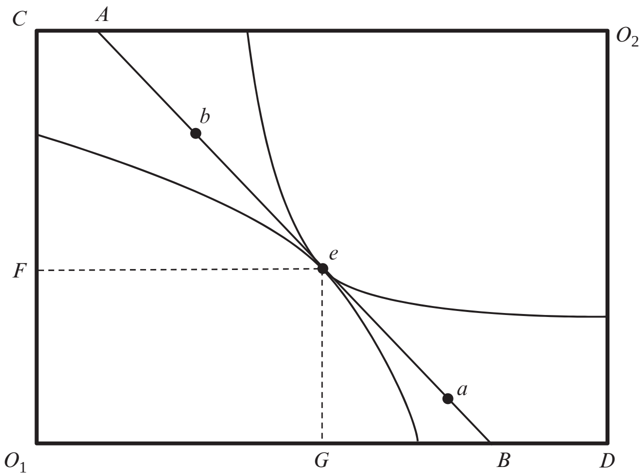

Figure 2.1 Capabilities and social interactions.

In general, defining well-being in terms of opportunity sets requires that one can put a value on these sets in a normatively attractive way. This is a difficult problem, as demonstrated by the formal (and abstract) literature on the topic (see, among others, Barbera et al., 1998; Foster, 2010). If one does not include information about preferences, a set of reasonable axioms soon leads to the unattractive solution of evaluating opportunity sets by simply counting the number of its elements without taking any account of the "quality" of these elements (Pattanaik and Xu, 1990). Yet, introducing preferences does not lead to easy solutions either. One of the proposals by Sen (1985) is to evaluate sets by the value of their best element. He called this the "elementary evaluation," but immediately acknowledged that this method does not do justice to the idea of freedom. Another proposal would be to say that the set Q is "better" than Q' if there is an element in Q that is considered by all individuals to be better than all elements in Q'. This is a very strict criterion that leaves many sets incomparable when there is sufficient interpersonal heterogeneity in preferences. At this moment, there seems to be no single proposal that has gained enough theoretical support to become the prime candidate to be implemented in applied work. As a matter of fact, except for the simple proposals such as elementary evaluation, none of the proposed methods appears easy to operationalize. This lack of practical applicability is worrying if we opt for "advantage" as our preferred measure of well-being.

An even more fundamental problem with the proposals to value sets that have been made in the literature until now is that the proposed methods go against a compensation principle that has been a cornerstone of the theory of equality of opportunity (Fleurbaey and Blanchet, 2013, p. 218). This principle says that individuals that are at the same level of individual responsibility (say, effort) should also obtain an equally valuable outcome. The literature on equality of opportunity is surveyed in Chapter 4.

Another important question is the following. If we want to measure well-being, is it then sufficient to look at opportunity or capability sets while neglecting completely the realized achievement or functioning? Fleurbaey (2006a) argued that focusing exclusively on capability sets suffers from two problems. First, it leads to a loss of information. Consider the following example. Two individuals, Ann and Bob, face the capability sets Q and Q', respectively, with $Q \subset Q'$. Bob has all the opportunities that Ann has, and he even has some opportunities that are not feasible for Ann. In such a case of set inclusion, it seems reasonable to say that Bob's opportunities are at least as good as Ann's. But now suppose that Ann selects option a in Q, while Bob picks option b in Q', such that $a \gg b$. Then it seems reasonable to say that Ann's achievement is "better" than Bob's. Such an example is not irrelevant within the capability approach, as many of its advocates stress that individuals do not necessarily choose within their capability set the functioning vector that would give them the highest level of individual well-being. Whatever conclusion one wants to draw from this example in terms of who is worse off, it is clear that limiting our attention to sets and neglecting actual achievements leads to a loss of information. Comparing sets and knowing the selected option is not the same as comparing sets without knowing the selected option.

Second, an evaluation purely on the basis of capability sets may reflect a harsh attitude about individual responsibility, given the well-documented limitations of individual decision-making capacities. With capabilities as the measure of well-being, individuals are held responsible for their mistakes when selecting a particular option from their capability set. The question gets even more pressing when considering choices over the life cycle. The opportunity sets of older people are determined by their decisions when they were young, and the question arises for how long individuals have to remain responsible for potential "mistakes" committed earlier in life.

The previous discussion raises the question of whether focusing on capability sets is indeed the best way to introduce freedom considerations into the measurement of well-being. From his first writings on the topic, Sen has hinted that an alternative is to work with so-called refined functionings or comprehensive outcomes, where the "refinement" refers to the operation of including additional information on the available alternatives or on the process of choice itself. Let us reconsider the example of the two individuals who are fasting and starving. The fasting person is choosing to eat less; the poor starving person is exercising no choice at all. These can be seen as two different "refined" functionings—choosing a when b is also available is a different refined functioning than choosing a when b is not available (Sen et al., 1987, pp. 36–37). Alternatively, in addition to the functioning of being well nourished, one could consider another functioning "exercising choice with respect to what one eats."

Fleurbaey (2009) extends this idea and argues that all the relevant aspects of freedom can be captured through refined functionings. Basic freedoms of thought, speech, political activity, travel, and so on are clearly part of the functioning vector. The freedom from avoidable disease can be approximated in terms of the achieved health functioning, of the accessibility of the health care system, and of the environmental and social factors influenced by public health policy. These examples immediately show that the refined functionings approach too raises formidable challenges. Understanding the "process of choosing" is not straightforward. As soon as one has to resort to indirect indicators (such as education, income, social relations, accessibility of the health care system), it is important to carefully consider the specific social, environmental, and individual variables that determine the influence of these indicators. In moving from "capability sets" to "refined functionings," we replace the problem of evaluating sets with the challenge of understanding the process of "producing" refined functionings. However, it seems that the notion of refined functionings is better suited for a careful empirical analysis, which is needed to answer these questions about choice, well-being, and differences in opportunities.

2.3.1.2 Choice of Dimensions

Whether we prefer a definition of well-being based on capabilities or (refined) functionings, inevitably we face the question of how to select the list of relevant dimensions. It follows from a focus on freedom and agency that only dimensions that people have reason to value should be included. Yet, this notion of "reason to value" can be interpreted in different ways.

A natural choice in a freedom perspective is to include all dimensions that are considered by the individuals themselves to be relevant within their own personal life projects. This matches the normative purpose of respecting individual preferences. From the applied point of view, however, it raises the question how one should collect the necessary information about these preferences. There is a conceptual distinction between very specific dimensions (such as "not suffering from malaria") and more encompassing dimensions (such as "having a good overall health situation"). Although a consensus could perhaps be reached on the relevant dimensions at a more encompassing level, substantial disagreement may remain about the dimensions to be included at a more specific level. Direct surveys should therefore be structured carefully.[8]

Most researchers within the capability approach do not follow this preference-based approach. Their suspicion toward preferences can at least partly be explained by the

[8] Clark (2005) investigated through a small number of high-quality interviews how the South African poor perceive "development" (a good form of life). He concluded that the intrinsic value of material things matters a lot. A challenging example is Coca-Cola, which turns out to be very important to many poor respondents. Although the nutritional value of Coca-Cola is low, it is "perceived as a superior first world product" (Clark, 2005, p. 1353) and is important "to achieve other important functionings such as relaxing, facilitating social life and enhancing friendships" (Clark, 2005, p. 1354). But is "having the opportunity to drink Coca-Cola" really a crucial dimension of life?

multiplicity of preference concepts that coexist in the literature. If preferences are interpreted as revealed through actual choice behavior, a dose of suspicion is indeed justified based on the well-documented behavioral anomalies that individual choices display in real life. However, in an approach that puts great emphasis on freedom and agency, it seems less easy to discard preferences understood as reflecting the individual's well-considered life projects. One possible justification is that one considers it unrealistic to assume that individuals have such well-defined preferences. We will come back to this viewpoint later in the chapter.

Let us now describe the two alternative ways of selecting the list of relevant dimensions that have been proposed by Nussbaum and Sen, respectively. Inspired by Aristotle, Nussbaum (2000, 2006, 2011) started from an "objective" view about what constitutes human flourishing and defined a list of abstract essential capabilities (or functionings). She presented the list as universal, but is well aware of the fact that the translation of the abstract capabilities in implementable terms will depend on the specific social, cultural, and economic context. Sen, on the other hand, prefers to leave the definition of the list of functionings deliberately open, as he believes that the list should be drawn up in a democratic process through public reasoning (see, e.g., Sen, 2004). This dynamic process creates room for participation of the people concerned—which in itself is already a crucial functioning. Sen's focus on public reasoning is inspired by an activist perspective that aims at implementing the capability approach by means of social change. From an analytical and ethical point of view, however, it seems to raise many questions. If one reaches an agreement through a public deliberation process, is this agreement a kind of compromise between the different preferences of the individuals involved? If so, how is the compromise to be interpreted? Does the process not induce the risk of a tyranny of the majority or of the most outspoken personalities? If we were to accept that preferences are not given ex ante, but are formed in and through the deliberation process itself, one could perhaps even aim at a real consensus rather than a compromise. Yet, without a good understanding of (and arguably well-defined conditions imposed on) these public deliberations, it is not clear what the normative status of such a consensus should be.

Although the conceptual differences between these different approaches are important, the problem seems less acute when it comes to practical applications. Alkire (2002) gives an extensive overview of different lists of dimensions that have been proposed in the literature and reaches the following—perhaps surprising—conclusion. Despite the large variety of approaches and the differences in opinion about the underlying logic, the specific proposals are strikingly similar. As a matter of fact, the same is true for the lists of dimensions that have been proposed for practical applications by, e.g., the Organisation for Economic Co-operation and Development (OECD, 2011), the European Statistical System (2011), or Stiglitz et al. (2009). All proposals include material consumption and housing quality, health, job market status and leisure, the quality of social interactions, and the quality of the natural environment. To be precise, this consensus is about the first layer of encompassing dimensions and dissipates when we turn to a second layer of more specific dimensions. However, even at that lower level the similarities are sufficiently reassuring, if one accepts the ultimate aim of arriving at a single synthetic indicator of well-being. Indeed, (partial) overlap can be taken care of through the choice of the weights used to get at the synthetic indicator (see Decancq and Lugo, 2013 for an overview on setting weights in synthetic well-being indicators). Let us now turn to this aggregation step.

2.3.1.3 Aggregation and Respect for Preferences

Note first that the construction of a synthetic indicator of well-being is not really necessary, if the purpose of the analysis is to construct a richer description of individual well-being than is possible with a one-dimensional approach in terms of monetary income alone. In fact, for this purpose, a simple observation of the vectors ℓ_i is sufficient, and any aggregation procedure may be interpreted as leading to a loss of information. Yet, as soon as one wants to make interpersonal comparisons of well-being between all individuals of society (for instance, when computing inequality) it is necessary to go beyond the simple description in terms of vectors. In this section, we therefore focus on the construction of synthetic well-being indicators. In Section 2.4 of this chapter, we will consider approaches that introduce a multidimensional version of the Pigou–Dalton transfer principle directly at the level of the vectors of relevant life dimensions.

An influential stream within the capability approach emphatically rejects the idea that the different life dimensions are commensurable. Again, Nussbaum (2000, 2006, 2011) is the main proponent of this view. There is an immediate normative reason for this position. Nussbaum focuses on capabilities as basic needs, and she accepts the "union" identification strategy to the measurement of multidimensional poverty, in which someone is considered poor as soon as he or she does not reach a minimum level for at least one dimension. A union approach to identify the multidimensional poor is closely related to a "rights-based" view on poverty measurement. One can interpret this approach as implying a very simple ranking of individuals in which only two groups are distinguished, the poor and the nonpoor, and no further comparisons are made within these groups. This approach may be sufficient for some purposes (such as identifying the poor) but is too coarse if we want to derive conclusions about inequality in society, for instance.

If we want to derive a measure of individual well-being that can be used for the measurement of inequality, the possible trade-offs between the different dimensions can no longer be neglected. This brings us back to the interpretation of the valuation function v_i in expression (1). If individuals indeed have a continuous preference ordering over life dimensions and if one accepts the normative relevance of this preference ordering, then v_i could be a representation of their preference ordering:

$$\ell_i R_i \ell_i' \Leftrightarrow v_i(\ell_i) \geq v_i\left(\ell_i'\right).$$

Note, however, that different individuals may have different valuation functions (each representing their own personal preference ordering about what is a good life) and that, moreover, for each preference ordering there is an infinity of valuation functions that represent it (indeed, any monotonic increasing transformation of v_i is also a representation of R_i). This raises a fundamental question of interpersonal comparability. We return extensively to that problem in Section 2.3.3.

On the other hand, in the capability approach (with its suspicion for individual preferences), researchers typically aim to use a common valuation function v, which is the same for all individuals. If we do not rely on personal preferences, the question becomes how to construct such a function. Here again, we can rely on public deliberation, but this raises issues similar to those encountered when discussing the choice of relevant dimensions. Alternative, more analytical, proposals have been discussed in Sen (1985). The most prominent of these proposals is the so-called intersection approach, which makes use of a dominance principle. We can write this principle more formally, using the notation that was introduced at the beginning of this section[9]:

Dominance Principle: (ℓ', R', S') *is at least as good as* (ℓ'', R'', S'') *if* $\ell' R \ell''$ *for all* R, *and strictly better if* $\ell' P \ell''$ *for all* R.

This principle states that if a situation ℓ' is preferred to a situation ℓ'' for *all* admissible individual preference orderings (and hence also by all individuals in society), then we consider the individual in ℓ' to be better off (from a normative perspective) than the individual in ℓ'', *irrespective* of the differences in the actual preference orderings or the satisfaction functions of the individuals.[10] With monotonic preference orderings the dominance principle implies that (ℓ', R', S') is better than (ℓ'', R'', S'') whenever $\ell' \gg \ell''$.

One immediate problem with this approach (acknowledged explicitly by Sen) is that the resulting partial ordering may be very coarse. Not many triplets can be effectively ranked with respect to well-being. The deeper question, however, is why it is so difficult to obtain a more complete ordering. One answer is to say that well-being and advantage are objective concepts, and that the incompleteness follows from the fact that it is intrinsically difficult to define what a good life is. We mentioned already that this perfectionist idea is prominent in the work of philosophers in the Aristotelian tradition (most notably Martha Nussbaum). An alternative answer would be that the valuation of functionings bundles should be at least partly based on the valuations by the persons themselves (which seems to be more in line with the idea of freedom) and that the difficulty of defining a common valuation function v reflects the fact that it is not straightforward to find a kind of "overlapping consensus" on what is a good life (see, e.g., Sugden, 1993).

This difficulty is indeed fundamental. At first sight, the dominance principle appears to be in line with the respect for personal preferences. However, this first impression is misleading, as has been shown by Brun and Tungodden (2004), Fleurbaey (2007), and Pattanaik and Xu (2007) (see Weymark, 2013, for a survey). The underlying intuition is

[9] Assuming anonymity, we drop the individual subscripts to simplify notation.

[10] This latter conclusion is natural because the capability approach does not take into account subjective satisfaction for the ranking of well-being levels if it is not part of the vector ℓ.

that the dominance principle implies that (ℓ, R, S) is at least as good as (ℓ, R', S') for all ℓ and all R, R', S, S', so that preferences can play *no* role in the evaluation of (ℓ, R, S). We further illustrate the difficulty by making use of the following principle:

Personal-Preference Principle: (ℓ, R, S) *is at least as good as* (ℓ', R, S) if $\ell R \ell'$ *and strictly better if* $\ell P \ell'$.

The personal-preference principle requires that the (normative) evaluation of well-being in two situations should follow the preferences of the individual involved. As this principle only involves intrapersonal comparisons, it is a weak requirement of respect for preferences, but even this weak requirement is already incompatible with the weak form of the dominance principle stating that (ℓ, R, S) is strictly better than (ℓ', R', S') whenever $\ell \gg \ell'$. This incompatibility is shown by the following example. Figure 2.2 illustrates. Take $\ell_i, \ell_j, \ell_i', \ell_j'$ and R_i, R_j such that $\ell_i \gg \ell_j, \ell_j' \gg \ell_i', \ell_i' P_i \ell_i$, and $\ell_j P_j \ell_j'$ The personal-preference principle implies that (ℓ_i', R_i, S_i) is strictly better than (ℓ_i, R_i, S_i) and that (ℓ_j, R_j, S_j) is strictly better than (ℓ_j', R_j, S_j), whereas the dominance principle implies that (ℓ_i, R_i, S_i) is strictly better than (ℓ_j, R_j, S_j) and that (ℓ_j', R_j, S_j) is strictly better than (ℓ_i', R_i, S_i). By transitivity, this is impossible.

This incompatibility confronts us with a deep clash between two different normative principles. If one constructs a partial well-being ordering based on the idea of dominance (or consensus), one almost immediately gets a conflict with even a minimal form of respect for individual preferences. Later in this chapter we will show that it is possible to operationalize the concept of a valuation function that respects preferences and therefore necessarily violates the dominance principle. If one endorses a more objective view of well-being, this may be seen as a bridge too far.

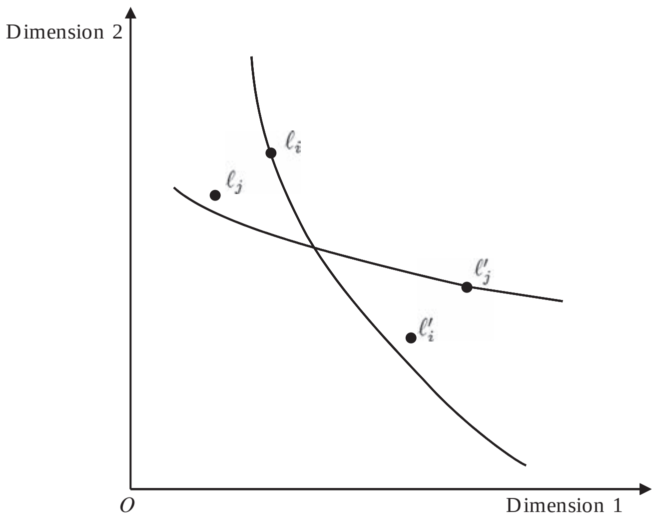

Figure 2.2 The dominance principle and personal-preference principle are incompatible.

Moving from the basic theoretical discussion to the applied work, a large number of empirical applications are focusing only on a description of functionings vectors. At the other extreme, we can find some examples in which one synthetic well-being index is constructed in an explicit way. The best known example of a synthetic well-being index (at the country level) is the Human Development Index (HDI) of the UNDP that will be described in more detail in Section 2.5. As a matter of fact, we will argue that this popular measure presents a good illustration of the problems raised with an objective approach.

2.3.2 Utility and Happiness

In the recent decades there has been a strong upsurge of economic research on happiness. Given the traditional reluctance of economists about the use of subjective information obtained through questionnaires, this is a somewhat surprising phenomenon. Data on subjective well-being have by now been collected for thousands of respondents throughout the world with large-scale surveys. Many variants of the subjective well-being question have been studied, all being relatively simple.[11]

It is useful to distinguish between two broad categories of subjective well-being questions. We illustrate both categories using the European Social Survey. The first question refers to life satisfaction and goes as follows: "All things considered, how satisfied are you with your life as a whole nowadays? Please answer using this card, where 0 means extremely dissatisfied and 10 means extremely satisfied." The second question refers to happiness: "Taken all together, how happy would you say you are? Please use this card." Analysis suggests that the results for both questions are generally highly correlated and that they can be explained to a large extent by the same set of correlates. Not surprisingly, many economists have concluded that both questions measure the same underlying concept—which is then equalized with the traditional notion of utility. This interpretation is not supported by psychologists, however, who make a clear distinction between affective and cognitive components in the experience of life satisfaction. As a matter of fact, there is growing evidence that affective scores are less sensitive to objective conditions of life, such as income, and more prone to adaptation.[12] We will return to this distinction and to its normative consequences in the first subsection, but for the moment we do as if both questions reflected the same underlying concept of utility that can either be measured by questions on happiness or by questions on life satisfaction and that we will label generically as "subjective well-being."

It is not our ambition here to give an extensive overview of the large empirical literature on the topic (see Chapter 14). We will only draw attention to three key findings

[11] We focus in this chapter on the questions concerning "overall" satisfaction or happiness with life. Many surveys include in addition questions on satisfaction with specific life domains, such as health or job market status.

[12] A more complete discussion of the issue can be found in Chapter 4 of Fleurbaey and Blanchet (2013).

that are relevant to our quest for an attractive measure of individual well-being. First, the answers to the subjective well-being questions are empirically robust and show regular patterns that are intuitively reasonable. This is not a trivial finding in the light of the traditionally dominant view that interpersonal comparisons of utility are necessarily normative and can have no empirical basis (Robbins, 1938).

Second, the literature convincingly shows that answers to subjective well-being questions are not only, perhaps not even mainly, determined by monetary income or material consumption. The life dimensions that have been found to be relevant for subjective well-being almost coincide with the lists of functionings that were described in the previous section: in addition to income, also health, job market status, quality of relations and social interactions, and even political rights and freedom of speech have been shown to have a significant impact (Frey and Stutzer, 2002). The initial interest in subjective well-being in economics has largely been driven by the striking findings of Easterlin (1974), showing that despite the strong economic growth since the Second World War, subjective well-being has remained almost constant. Recent work (e.g., by Stevenson and Wolfers, 2008) has questioned the empirical validity of the so-called Easterlin paradox, but has not shaken the consensus that subjective well-being is crucially influenced by nonmaterial factors.

A third finding is also related to the Easterlin paradox. Respondents rate their subjective well-being by comparing their actual situation with a set of variable reference standards. They compare their own life conditions with those of their reference groups. Moreover, there is a dynamic process of adaptation of standards through which people lower their aspirations when things go badly and raise their standards when things go well. The empirical literature on subjective well-being now offers plenty of examples showing that adaptation is indeed a pervasive real-world phenomenon. The most striking examples of adaptation are found in the sphere of health, but they also occur in other dimensions of life. Deaton (2008) finds that countries with higher rates of HIV prevalence do not systematically report a lower life (or even health) satisfaction, whereas individuals (and countries) care about HIV and would prefer not to suffer from it. Individuals who have lost a limb may, after adaptation, recover a good subjective well-being score—but still express a strong aversion to disability (Loewenstein and Ubel, 2008; Oswald and Powdthavee, 2008). Interestingly, the recent work on subjective well-being has produced convincing empirical evidence confirming Sen's concern about physical-condition neglect.

The literature on subjective well-being is largely descriptive and seldom engages in an explicit normative discussion. Yet, even if there are no explicitly normative conclusions drawn, often it seems implicitly understood that a higher subjective well-being is better. Using subjective well-being as a measure of individual well-being is understandable given the dominance of subjective welfarism in (applied) economics. A successful measurement of utility allows shortcutting the use of its imperfect monetary approximations (such as the consumer surplus). Moreover, the data on life satisfaction are readily available and easy to collect.[13] If one is willing to accept the answers as an interpersonally comparable measure of utility, one obtains a ready-to-use one-dimensional measure of well-being expressed on a convenient scale, which can then be plugged into a social welfare function. All relevant nonmonetary dimensions are included in the measure, based on the personal evaluation of the individuals themselves. Relying on the earlier notation, this approach uses the subjective well-being scores as aggregator of the various life dimensions and therefore as the measure of individual well-being:

$$WB^{SA}(\ell_i, R_i, S_i) = S_i(\ell_i), \tag{2.2}$$

where the superscript SA refers to satisfaction.

Using subjective well-being as the measure of well-being (i.e., returning to subjective welfarism) implies that it is ethically desirable to redistribute from someone with a high level of subjective well-being to someone with a low level of subjective well-being. It is regrettable that the happiness and welfare economic literature have developed largely in separation, so that there is little debate in the former literature on Sen's original—but very topical—arguments of "physical-condition neglect" and "valuation neglect" against this subjective welfarist position (see also Section 2.2). This separation may partly be caused by a difference in focus because the happiness literature is more interested in "average" or "aggregate" results at the level of the whole society and less on inequality and redistribution. Yet, this different focus offers only a partial explanation, as there is by now a growing number of papers focusing on inequality in happiness (see Dutta and Foster, 2013; Van Praag and Ferrer-i-Carbonell, 2009, for instance).

Before turning to the central questions of this chapter about respect for preferences and responsibility, we first have to return to the question of whether happiness and life satisfaction indeed measure a single concept of utility.

2.3.2.1 Feelings of Happiness and Hedonic Welfarism

The conclusion that there is one concept of utility, underlying both happiness and life satisfaction measures, is contested by most psychologists. They emphasize that "well-being" is a multifaceted experience, and that it is at least essential to distinguish two of its components: affects (feelings, emotions) and cognitions (Diener et al., 1999; Kahneman and Krueger, 2006). For the cognitive component, individuals take some distance to formulate a judgment over their lives. Positive and negative emotions, on the other hand, come in a permanent flow when individuals are awake. They are related to Bentham's pleasures and pains. If one accepts this distinction, the finding that the answers to questions on happiness and life satisfaction are highly correlated becomes worrying rather than reassuring. It suggests that what is measured by the questionnaires is a kind of hybrid mixture of feelings and cognitions without much psychological relevance.

[13] Pragmatic arguments are emphasized, e.g., by Oswald (1997).

In fact, this is precisely the judgment of psychologists like Kahneman, who argue that to measure the affective experience of happiness, other methods (such as experience sampling or day reconstruction) should be used (Kahneman and Krueger, 2006). Application of these methods shows that adaptation is even stronger for feelings than for judgments of satisfaction. Individuals seem to be characterized by a (largely genetically determined) baseline level of happiness, to which they return after having experienced positive or negative shocks.

The distinction between affects and cognitions is not only psychologically relevant but also resonates with welfare economic arguments. It is common to distinguish two variants of welfarism. "Hedonic welfarism" bases the evaluation of individual well-being on feelings of happiness; "preference welfarism" starts from judgments about what is a valuable life and aims at respecting these preferences. There is a clear link with the distinction between affects and cognitions.

Let us first comment on "hedonic welfarism," a modern version of traditional Benthamite utilitarianism. Influential advocates of this variant of welfarism are Kahneman et al. (1997, 2004) and Layard (2005). This approach argues that only feelings of happiness matter for well-being.[14] One of the main reasons for adopting hedonic welfarism is skepticism about the idea that preferences over life dimensions can be meaningfully defined. This skepticism toward preference welfarism leaves hedonic welfarism as the only feasible approach if one cares about individual well-being as experienced by the individuals themselves. Yet, it seems a quite radical position to state that human beings have no single idea about what is valuable in their lives.[15] Rejecting this extreme position, we turn to the central questions of this chapter on respect for preferences and responsibility.

Defining individual well-being in terms of feelings of happiness alone does *not* respect preferences. Such feelings may be very important to individuals, but they are not the only consideration entering the assessment of life (Benjamin et al., 2012; Nussbaum, 2008). Individuals may consider Vincent Van Gogh's life to be more valuable than that of another person who had only pleasant feelings but did not leave any trace after his death. Moreover, using feelings of happiness as the measure of well-being for inequality measurement implies that individuals are not to be held responsible for any factor that influences these (after all extremely subjective) feelings. One immediately runs into the issue of expensive tastes, which is nicely illustrated by Sen's colorful story of the unhappy millionaire:

[14] Layard (2005), p. 121) writes: "Ethical theory should focus on what people feel, rather than what other people think is good for them."

[15] One can easily admit that the preference relation R_i is incomplete, or that there may be inconsistencies in individual evaluations of what is a good life. We will come back to these issues in the next section.

> *I haven't seen you for many years-since I was chucked out of school in fact. I run into you one day in the West End waving at me from your chauffeur-driven Rolls-Royce, looking shockingly prosperous and well-heeled. You give me a ride, and invite me to visit you at your mansion in Chelsea. I remark that I am pleased to see what a high standard of living you are enjoying. 'Not at all', you reply, 'My standard of living is very low. I am a very unhappy man.' 'Why so?' I have to probe. 'Because', you reply, 'I write poems - damn good ones too - but nobody likes my poems, not even my wife. I am always depressed about this injustice, and also sorry that the world has such deplorable taste. I am miserable and have a very low standard of living.' By now I can see no reason to doubt that you are indeed unhappy, but I feel obliged to tell you that you don't know the meaning of 'standard of living'. So you drop me off at the next Tube station (remarking: 'My standard of living high/What a plebeian lie!', adding to the set of people who don't think much of your poetry).*
>
> ***Sen (1984, p. 75)***

Arguably, it is not ethically attractive to compensate the unhappy millionaire for his lower level of subjective well-being. As a matter of fact, given the strong adaptation of happiness feelings, it is even unlikely that any redistribution of income would contribute to a higher level of social welfare. Hedonic welfarists therefore emphasize the importance of investing more in the mental health of the citizens (see, e.g., Layard, 2005)—to the point perhaps of convincing the unhappy millionaire that he is on the wrong track.

While "hedonic welfarism" reduces the scope of individual well-being to feelings of happiness, a broader scope on well-being does not necessarily discard these feelings completely. Indeed, "it would be odd to claim that a person broken down by pain and misery is doing very well" (Sen, 1985, p. 17). It is easy to integrate this intuition in other approaches to well-being, by treating emotions as aspects of life over which individuals may have preferences. In our formal notation, they are then seen as one (but definitely *not* the only) component of vector ℓ_i.[16] In this interpretation, hedonic welfarism respects preferences only under the unrealistic assumption that the only thing that individuals ultimately care about is their own feelings (i.e., a subset of ℓ_i). Yet, including feelings in the list of dimensions of life raises some additional hard questions. Here are some examples. The CEO of a large firm may "need" a certain material lifestyle to be respected in his group of peers, whereas a university professor in a philosophy or welfare economics department may perhaps earn more prestige through a sober lifestyle (Robeyns, 2006). Do we accept these "needs" in our definition of well-being? And, what about feelings of depression that are not obviously linked to physical conditions? Where should we draw the line between real psychiatric problems (which most observers would include in the definition of well-being) and overly subjective reactions, which can be easily manipulated and are situated within the sphere of private information? Leaving these questions aside, we now move to "preference welfarism."

[16] See, among others, Kimball and Willis (2006), Loewenstein and Ubel (2008), and Rayo and Becker (2007).

2.3.2.2 Life Satisfaction, Experienced and Decision Utility

Rather than interpreting subjective well-being as an expression of emotions, one can also see it as reflecting a cognitive judgment about the extent to which one is leading a good life. The satisfaction function S_i is then basically an aggregation function, giving a synthetic evaluation of the complete vector ℓ_i of relevant life dimensions (as we have just seen, this vector may include some pleasant and unpleasant feelings). Various authors in the literature argue that using the satisfaction function means that one evaluates well-being with the value system that is used by the respondents themselves. "If we accept the Marxist idea of 'false consciousness,' we play God and decide what is good for others, even if they will never feel it to be so" (Layard, 2005, p. 121). The argument seems straightforward: If we care for what people care about, we should care for their own perception of life satisfaction. Even if this reasoning may seem convincing at first sight, it requires some further scrutiny.

To do so, let us first consider the relation between the satisfaction function S_i and the preference relation R_i. Clearly, the idea of respecting preferences is only meaningful if one accepts that individuals have well-considered ideas about the good life that can be represented by a (possibly incomplete) preference relation R_i. The precise interpretation of R_i is somewhat ambiguous in the literature, however. Happiness researchers have introduced a distinction between "experienced utility" and "decision utility" (Kahneman and Sugden, 2005; Kahneman et al., 1997). Although decision utility is linked to prospective choices, experienced utility would be better reflected in survey questions that are answered ex post. It turns out that there is frequently a discrepancy between experienced utility and decision utility, in the sense that individuals apparently misperceive the effects of their choices on their future experienced utility (see, e.g., Gruber and Mullainathan, 2005; Layard, 2005; Stutzer and Frey, 2008). In such cases, it is argued, the focus should be on experienced utility.

It is possible to interpret the limitations of decision utility in two different ways. The first interpretation is that stable preferences do not exist. Preference welfarism then is simply not meaningful, and we are back in the hedonic welfarist approach of the previous subsection, albeit possibly with some (undesirable) confusion between affects and cognitions. The second interpretation is that the relevant preferences about life dimensions should involve correct information and proper deliberation and that they therefore are not always revealed in actual choice behavior—and hence in decision utility. The difference between decision utility and experienced utility then justifies skepticism about the use of *revealed* preferences as a criterion for evaluating well-being and does not exclude the interpretation of S_i as a representation of the true underlying preferences of individuals. As we have stressed already before, R_i does not necessarily coincide with revealed preferences in our formal framework. In fact, if psychological feelings of happiness are part of ℓ_i, and insofar as decision utility suffers from imperfect forecast of the psychological effects of choices, we suggest that R_i should not be equated to decision utility, but should be corrected for mistakes and misperceptions.

With this caveat in mind, we can now put forward the obvious point that a necessary condition for S_i to respect preferences is that it is a representation of the preference ordering R_i:

Consistency Assumption $S_i(\ell_i) \geq S_i(\ell_i')$ *if and only if* $\ell_i R_i \ell_i'$.

The formal analogy between the satisfaction function S_i and the valuation function v_i that was introduced before is obvious. Yet, the interpretation of satisfaction as a cardinally measurable and interpersonally comparable variable, which is common in the applied literature, implies that the satisfaction function is more than a general representation of ordinal preferences. Satisfaction scores select one particular "utility" function from the set of all positive monotonic transformations representing the same preference ordering.

Selecting a particular cardinalization imposes a particular scaling. This scaling will reflect comparisons with reference situations such as the worst possible and the best possible situation, the situation one expected at some earlier stage in life (aspirations or expectations), the situation of one's parents, the situation of reference groups such as one's peers or one's fellow citizens. We can call all such components of the judgment the scaling factors. Obviously, scaling factors may differ across individuals and change over time, as aspirations and the choice of reference groups may change. Moreover, the specific scaling may depend on the way the satisfaction question is formulated, or even on its location in the overall questionnaire. It is crucial to realize that the consistency assumption only refers to ordinal preferences and not to these scaling factors. This immediately implies that preferences R_i, which, as discussed before, do not necessarily coincide with revealed preferences, do not necessarily correspond to experienced utility either. Experienced utility as it is typically observed with empirical methods may incorporate a shift in scaling factors and therefore a change from an initial function S_i to another function S_i'. The consistency assumption says nothing about inequalities of the form $S_i(\ell_i) \geq S_i'(\ell_i')$. We will explore the implications of this insight in the following subsection.

It is hard to test the consistency assumption empirically because in practice it seems almost impossible to make sure that preferences and scaling factors remain fixed when an individual moves from ℓ_i to ℓ_i'. We propose to interpret the assumption as a requirement on the measurement of $S_i(\ell_i)$. In other words, we assume that the satisfaction question is sufficiently well crafted so that the answers reflect the individual's views about what is good in life, as embodied in R_i. This is not an innocuous assumption,[17] but from now onward, we will accept that it holds, as it is a necessary condition for subjective well-being measures to respect preferences.

[17] See Fleurbaey and Blanchet (2013) for a discussion. The authors discuss problems related to *scope* (what part of ℓ_i is relevant), *ranking* (how does ℓ_i stand in the set of relevant possible lives), and *calibration* (how does a position in the ranking translate into a category of the questionnaire).

2.3.2.3 Respect for Preferences

Using life satisfaction as a measure of individual well-being does respect preferences, provided that the consistency assumption holds. Indeed, combining the latter assumption with expression (2) immediately confirms that a measure of well-being directly based on $S_i(\ell_i)$ satisfies the personal-preference principle that was introduced in the previous section. Note that this necessarily implies that such a measure will not satisfy the dominance principle.

However, one can argue that respecting preferences for the measurement of well-being requires going beyond intrapersonal comparisons at one point in time (this is the scope of the personal-preference principle). For evaluating inequality, the idea of respecting preferences needs to be extended to situations where scaling factors are different. Such cases can reflect interpersonal comparisons between a pair of individuals who share the same preferences but have different scaling factors, or comparisons over time for a given individual with stable preferences and shifting scaling factors. Consider two triplets (ℓ_i, R_i, S_i) and $(\ell_i' \ R_i, S_i')$ such that $\ell_i \ P_i, \ \ell_i'$ but $S_i(\ell_i) \le S_i' \ (\ell_i')$. There is a preference for ℓ_i against ℓ_i', but the situation (ℓ_i', R_i, S_i') exhibits a greater or equal level of satisfaction. This configuration is not a mere theoretical curiosum. The empirical happiness literature contains many examples of shifting scaling factors. Recall the earlier example of the individuals who express a preference for not being disabled but, after having lost their limbs, recover a good satisfaction score because their aspirations have been adapted to their actual situation (Loewenstein and Ubel, 2008; Oswald and Powdthavee, 2008). Graham (2009) insists that the diversity of scaling factors across individuals generates "happy peasants and miserable millionaires." Her findings do not imply that the poor would prefer to remain poor above getting rich, neither that the rich would prefer to be thrown into poverty. All these examples can be understood as cases of shifts or differences in scaling factors with common preferences in the background. In these examples there is a clear echo of Sen's criticism of "physical-condition neglect" toward subjective welfarism.

It is therefore not obvious that using life satisfaction as a measure of well-being does indeed respect preferences. If one endorses the value judgment that the happy poor are worse off than unhappy millionaires, and hence that redistribution from the millionaire to the poor would lead to an improvement from a social welfare point of view, one has to give priority to the information about (common) preferences over the information about satisfaction levels. This idea is embodied in the following principle, which logically strengthens the personal-preference principle:

Same-Preference Principle: (ℓ, R, S) *is at least as good as* (ℓ', R, S') *if* $\ell R \ell'$, *and strictly better if* $\ell P \ell'$.

Clearly, the same-preference principle is not satisfied by an approach that uses life satisfaction scores as individual well-being measures.

2.3.2.4 Responsibility and Freedom

The discussion in the previous subsection also addresses our second central question on responsibility and freedom. Using life satisfaction as the measure of well-being and as the equalizandum in egalitarian policy implies that redistributing from i to j is ethically desirable if $S_i(\ell_i) > S_j(\ell_j)$. We have seen, however, that in this case it is possible that both individuals prefer ℓ_j to ℓ_i, so that the difference between the life satisfaction scores would only reflect a difference in scaling factors such as aspirations. By choosing this well-being measure, individuals are not held responsible for their aspirations and are compensated for them. Redistributing from a poor peasant to a rich millionaire would then be ethically desirable if the rich millionaire were less satisfied with life because the millionaire would not be held responsible for his ambitious aspirations.

As another example, consider two individuals occupying the same job. The first individual comes from a poor family and has received little education: he is satisfied to have found a job. The other individual has rich parents and a university degree: he is dissatisfied because he is convinced that he was entitled to a "better" job.[18] Because using life satisfaction scores as the measure of well-being does not question the higher aspirations of the rich person, some redistribution of income from the modest to the ambitious individual is socially desirable. This is a conclusion that will appear counterintuitive to many.

2.3.3 Respecting Preferences: Equivalent Income

We have seen that neither the capability approach nor the happiness approach (in its hedonic or its satisfaction interpretation) respects the same-preference principle. The third approach covered in our survey, that of equivalent income or money-metric utility, does.[19] The somewhat surprising history of the concept has been sketched in Section 2.2. We will first introduce the approach and then turn to the most prominent points of criticism.

2.3.3.1 The Equivalent Income

Let us write the vector of relevant life dimensions for individual i as $\ell_i = (y_i, x_i)$, where x_i contains all the nonincome dimensions and y_i his income.[20] Now, choose reference values $\widetilde{x}$ for all the nonincome dimensions. The choice of reference values is a crucial question, to which we will return in the following subsection, but let us first assume that

[18] The empirical relevance of this example is supported by data on Belgian school-leavers in Schokkaert et al. (2011).

[19] The equivalence approach, as it has been introduced in the recent welfare economic literature, is broader than the concept of equivalent income, on which we focus in this chapter (see Fleurbaey and Blanchet, 2013; Fleurbaey and Maniquet, 2011). First, the choice of equivalent income with reference values for all nonincome dimensions is a special case of an approach in which the well-being levels of individuals are ranked on the basis of the intersections of their indifference curves with any monotone path (see, e.g., Fleurbaey et al., 2009). Second, the model can even be further extended to include the notion of equivalent *sets*. In this chapter, we will not elaborate on these generalizations.

[20] In the original literature on money-metric utility, the focus was on comparing consumption bundles, and the nonincome variables then referred to the price vector $\widetilde{p}$. This is just a special case of our approach. Indeed, the vector x may contain the prices of the commodities as one feature of the environment of the individuals.

we can take them as given. The equivalent income y_i^* for individual i is then defined as the solution to the equation

$$(y_i, x_i) I_i (y_i^*, \widetilde{x}). \tag{2.3}$$

In other words, the equivalent income is the level of income that would make the individual indifferent (as judged by his own preferences) between his current situation and the hypothetical reference situation where he would be at the reference values for all nonincome dimensions of life. We then take this equivalent income as the measure of individual well-being:

$$\mathrm{WB}^{\mathrm{EI}}((y_i, x_i), R_i, S_i) = y_i^*.$$

The function that gives the equivalent income for individual i for each combination of (y_i, x_i) is the so-called equivalent income function $y_i^*(y_i, x_i)$.[21]

The concept is illustrated in Figure 2.3 for the case of income–health combinations. Suppose we have to compare the situation of Ann (in A) and Bob (in B). Taking normal health as the reference for the health dimension (we will see in the next section that this is indeed an attractive choice), we can define the equivalent income y_A^* for Ann as the income that would bring her in situation A' (i.e., the income, normal health bundle) that is just as good for her as her actual bundle A. Similarly, we obtain for Bob an equivalent income of y_B^*. We see that Bob's well-being (in B), as measured by y_B^*, is larger than Ann's well-being y_A^* (in A). Conveniently, the equivalent income is expressed in monetary terms. It has all the operational advantages of a cardinal and interpersonally comparable measure, so that it can be used in traditional inequality measures. On the other hand, however, it takes into account all the relevant dimensions in the vector ℓ_i, weighted according to the preferences of individual i herself.

To see this, note first that the equivalent income is a representation of the preference ordering. Indeed if preferences are monotonic in income, it follows immediately that

$$\ell_i R_i \ell_i' \Leftrightarrow y_i^* \geq y_i^{*'}.$$

This shows that, just like subjective well-being under the consistency assumption, the equivalent income function is one possible "utility" function from the set of all positive monotonic transformations representing the same preference ordering. Contrary to life satisfaction scores, however, this specific cardinalization of the utility function does respect the same-preference principle. This is immediately clear from Figure 2.3. The equivalent income uses only ordinal information about the shape of the indifference curves and is not sensitive to differences in aspirations or expectations captured by the satisfaction function S.

[21] As can be seen from expression (3), the equivalent income depends on the choice for the reference value $\widetilde{x}$. To avoid notational clutter, we suppress this dependency in the notation, however.

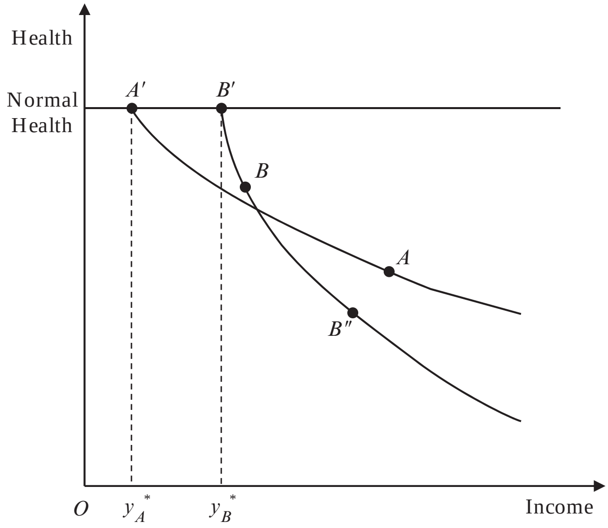

Figure 2.3 Equivalent income.

Recall that a measure that satisfies the personal-preference principle (and, a fortiori, the same-preference principle) does not satisfy the dominance principle. If, in Figure 2.3, Bob were in situation B'' rather than in B, his equivalent income would not change (because B and B'' are on the same indifference curve). He would still be better off than Ann, whereas B'' is dominated by Ann's situation A. The figure also shows why this result is obtained: With his indifference curves, which are "steeper," Bob gives a smaller weight to health than Ann and therefore suffers less from the fact that his health is not at the reference value.

Another way of interpreting the equivalent income refers to willingness-to-pay. It follows from expression (3) that

$$y_i^* = y_i - \mathrm{WTP}_i(x_i \to \tilde{x}; y_i, x_i), \tag{2.4}$$

where $\mathrm{WTP}_i(x_i \to \tilde{x}; y_i, x_i)$ denotes the willingness-to-pay of individual i for a move from x_i to $\tilde{x}$. It is clearly conditional on the level of the actual income level y_i and the level of other life dimensions contained in x_i. Because this willingness-to-pay can be large, it is obvious from expression (4) that the ranking of individuals on the basis of equivalent incomes can be very different from the ranking on the basis of their incomes. This is also illustrated in Figure 2.3, where Bob obtains a larger equivalent income than Ann, despite the fact that his income is smaller.

2.3.3.2 Concavity Failures and Choice of Reference Values

One of the reasons why the equivalent income approach lost popularity in the applied welfare economic literature was the finding by Blackorby and Donaldson (1988) that the equivalent income function $y_i^*(y_i, x_i)$ is not necessarily concave in income. As expression (4) shows, this will occur if $\partial^2 \mathrm{WTP}_i / \partial y_i^2 < 0$. In general, the problem is avoided if preferences are homothetic. Blackorby and Donaldson (1988) then argued that using y_i^* as an indicator of individual well-being in a social welfare function may lead to undesirable redistributive consequences. A regressive income transfer (i.e., a transfer of income from someone with a low equivalent income to someone with a high equivalent income) might be seen as a welfare improvement. Of course, this point only concerns income transfers: A "transfer" of equivalent income itself will lead to an increase in the value of any social welfare function that is concave in equivalent incomes (and to a decrease in inequality with any inequality measure satisfying the Pigou–Dalton transfer principle).

A similar result has been found in the theory of fair allocation, stating that any approach—and not only an approach based on the equivalent income function—that evaluates well-being on the basis of individual indifference curves may clash with a multidimensional Pigou–Dalton transfer principle (see Fleurbaey and Maniquet, 2011). We return to this issue in Section 2.4, but note here already that the only way to avoid the problem is to work with a social welfare function that is of the leximin type (i.e., gives absolute priority to the worse off).

A second point of criticism relates to the dependency of the equivalent income method on the choice of the reference parameters $\tilde{x}$. The dependency is clear: if one moved the reference line in Figure 2.3 sufficiently downward, the relative well-being positions of Ann and Bob would change. Yet, the fact that reference values have to be chosen does not mean that they are necessarily arbitrary (which is the position taken by Blackorby and Donaldson, 1988 and Donaldson, 1992). Given that we are looking for an answer to the normative question "equality of what?" normative choices are inevitable. It is then better to make them explicit, so that they are open to debate and scrutiny. This is precisely the approach taken in the literature on fair allocation. Fleurbaey and Maniquet (2011) provide many examples of applications of money-metric utility in which the reference is selected on the basis of clear normative principles. We will focus here on the choice of references for the calculation of equivalent incomes.

Suppose we want to compare the well-being of two individuals who are in the reference situation for all the nonincome dimensions (e.g., in Figure 2.3 we would consider Alice in A' and Bert in B'). By definition, their equivalent income then coincides with their actual income—implying that the comparison of well-being levels for Alice and Bert reduces to a comparison of their actual income levels, despite the fact that they have different preferences (Bert cares less about health). This example suggests a general criterion for choosing the reference situation. Reference values should be set in such a way that we can accept the implication that when all individuals are in the reference situation for the nonincome dimensions, differences in preferences do not matter to determine who is worse or better off. Namely, if all individuals are in the reference situation, we can focus on income only.

When there exists a "normal" level for the nonincome dimensions to which all individuals aspire, it seems natural to take this normal value as the reference. An obvious example is health because we may assume that, despite some interpersonal differences, there is a large degree of consensus about what is a normal, unproblematic health level. Return to the example of Alice and Bert. It appears counterintuitive to claim that a Pigou–Dalton transfer of income from Bert to Alice would lead to a more *un*equal distribution of well-being on the grounds that Bert cares less about health because they are both in normal health anyway. On the contrary, redistributing income may increase inequality when comparing two individuals at the same health level, when this health level is not the normal one. Indeed, it may happen that the richer individual cares more about health and therefore suffers more from this health condition than the poorer individual. Recall that a similar reasoning has already led us to the conclusion that deviations from the dominance principle can be justified when preferences differ. With this choice of reference, the equivalent income measures the welfare loss that results from deviations from the "normal" level, and this loss is dependent on preferences, which can also be seen from expression (4).

However, it is not possible to define a normal level to which everybody would aspire, for all life dimensions. First, the idea of a "normal" level may be different for different individuals. Leisure (or hours worked) offers a challenging example. Although it may be safe to assume that employment is desirable for everybody (and hence that being employed is a good choice for the reference), people are likely to have different ideas about what is a normal amount of hours of work (and hence of leisure time). Some individuals (academics?) love their work. Others only have access to unpleasant jobs—and although they prefer having a job to being unemployed, they would prefer to have to work as few hours as possible. As shown in Fleurbaey and Blanchet (2013), such differences can be accommodated by selecting individual-specific "normal" values as the reference. Although this complicates the calculations, the interpretation still holds that the difference between income and equivalent income is the welfare loss that results from deviations from the normal level.

Second, even this personalized approach does not work well when the nonincome dimension is unbounded and people have monotonic preferences over it. It is not interesting in this case to take the "best" or a very large reference value because this would lead to extremely small equivalent incomes. A practical solution is then to pick some upper bound (or a variable such as the median) as the reference, but this remains rather ad hoc. More theoretical work is needed to solve this issue.[22]

[22] Difficult questions also arise if the commodity prices are part of the vector x. Fleurbaey and Blanchet (2013, Appendix A) suggest that it would be good to have a reference situation that is as close as possible to the actual market situation faced by the individuals. This intuition is indeed closely related to that of a "normal" value. They then suggest to take as a reference the so-called Scitovsky reference price, defined as the supporting price of the bundle λX (where X is the total actual consumption vector) that belongs to the lower boundary of the Scitovsky set (which contains the vectors of total consumption that can be distributed to keep all individuals on their current indifference curve). Although they show that there are good reasons to pick this reference, the normative justification may appear less compelling than in the cases of health or (un)employment.

2.3.3.3 Freedom and Responsibility

As was emphasized earlier, the most significant feature of the equivalent income approach is that it satisfies the same-preference principle. It is important to note that this respect for preferences is in line with the perspective on personal responsibility that has been put forward by some prominent social philosophers. Rawls (1971, 1982) argued that treating persons as autonomous moral agents necessarily implies that they should assume responsibility for their goals and their conception of the good life. Dworkin (1981a,b, 2000) stressed that individuals should be held responsible for their preferences: In his view, an individual cannot sensibly identify with his own preferences about how to conduct his life and at the same time request compensation on the grounds that his preferences are a sort of handicap.

This view on responsibility for preferences is not beyond criticism, however. In the literature on equality of opportunity and responsibility-sensitive egalitarianism, it has been attacked by authors such as Arneson (1989), Cohen (1989), and Roemer (1998). They claim that preferences are often the product of upbringing and social influences, for which individuals cannot be held responsible, and they instead advocate the "common sense" view that individuals should be held responsible only for what they have genuinely chosen. This, however, raises similar questions as the ones that were encountered earlier when discussing the opportunity-set approach to capabilities. Choices are also determined by factors that are not under the control of the individuals. An attractive theory of responsibility as choice seems to require that one corrects for interpersonal differences in the environment and also for differences in the choice-making abilities of the individuals. Yet, this brings us on a slippery slope. Is there any room left for individual responsibility in a deterministic world, if we better and better understand and explain behavior? The question is especially acute within the paradigm of rational choice (Fleurbaey, 2008). In this paradigm, genuine choice is an elusive notion, as individual decisions result from a mechanical optimization exercise with a given objective (preferences) and a given set of options (determined by the budget set and possibly additional constraints). On the other hand, the equivalent income approach makes use of the preferences that are one of the essential building blocks of the economic model. Recall, however, that one should be careful about equating "revealed" preferences with the authentic views of the good life that have to be respected.

Rawls (1971) already made the connection between respecting different conceptions of the good life and the notion of real freedom. In the same spirit, Fleurbaey (2008) defends the view that individuals should be put in good conditions of autonomy and freedom so that they can be the masters of their lives and participate fully in social interactions. He argues that respect for freedom implies respect for personal preferences. In this view, a policy that is successful in reducing inequality in well-being, defined as equivalent income, can also be seen as reducing inequalities in the real freedom of the individuals.

2.3.3.4 Measurement of Preferences

Compared to the other methods proposed in this section, the equivalent income approach requires additional information. More specifically, for each individual one needs to know not only his actual situation in terms of the relevant life dimensions, ℓ_i, but also his preferences, R_i. Although recovering this information may be hard, it is not a hopeless task. Nor is it a new problem. Economics has a long tradition in identifying preferences, both for market and for nonmarket goods. Three methods have been proposed and applied in the literature on equivalent income, each of them with its own strengths and weaknesses.

2.3.3.4.1 Revealed Preferences

The first method uses revealed preferences (i.e., preferences that are derived from an analysis of observed choice behavior). This approach is common in consumption and labor supply analysis. In fact, the first applications of money-metric utilities made use of it. As an example, King (1983) analyzed the welfare implications of housing subsidies with equivalent incomes that are derived from observations of choices on the housing market. Recently, Decoster and Haan (2013) and Bargain et al. (2013) have estimated preferences over consumption–leisure combinations on the basis of a discrete labor supply model. The authors then derived estimates of equivalent incomes for different choices of the reference values.

Within the perspective of the measurement of equivalent income, an important challenge for this approach is to incorporate preference heterogeneity in an adequate way. More generally, the method only works if individuals have a real choice and can be assumed to choose rationally. This observation points at two limitations. First, the revealed preferences approach cannot give information on the relative value of dimensions that are not chosen by the individual. An example is health: Although it can be influenced by lifestyle choices to some extent, health remains largely outside the sphere of private decisions. Second, choice behavior does not always reveal the informed and authentic preferences of individuals. Human beings make mistakes or take decisions under imperfect information or under social pressure. Behavioral economics has shown that it is not always possible to identify preferences in such situations because the outcomes of two different behavioral models (with different underlying preference relations) may be observationally equivalent in terms of choices (Bernheim, 2009; Bernheim and Rangel, 2009).

2.3.3.4.2 Stated Preferences

The second method is based on stated preferences and makes use of the contingent valuation methods that are typically used in environmental economics and in health economics to measure the subjective willingness-to-pay for goods that cannot be bought on a market.[23] The contingent valuation method consists of asking people to evaluate the income they would need to be as well off in different reference scenarios as they are currently. As expression (4) shows, as soon as the actual income of individuals and their willingness-to-pay to be in the reference situation is known, equivalent income can be computed easily. This method is indeed the most direct way to make the notion of equivalent income operational.

To analyze policies, it is generally not sufficient to register the willingness-to-pay and the equivalent income of the individuals. One also would like to derive information about their entire indifference map. Because the equivalent income function $y_i^*(y_i, x_i)$ is a representation of the preference ordering, observations on y_i^* (or on WTP_i) can be used to estimate the parameters of a utility function. Fleurbaey et al. (2013) have used this method to calculate equivalent incomes for income–health combinations with survey data collected in Marseilles.[24] The authors use the estimated parameters to derive a set of distributional weights that could be implemented in a cost-benefit analysis of medical interventions.

It is fair to say that within the economic literature there is no consensus about the validity of these stated preferences techniques. There are strong believers and at the same time ruthless critics. Two titles in a recent symposium of the *Journal of Economic Perspectives* summarize the debate. Carson (2012) claimed that contingent valuation is a practical alternative when prices are not available, whereas Hausman (2012) argued that the results range from dubious to hopeless. This is not the place to settle this debate. Let us simply note that the applications in the context of equivalent income may be among the least contested because they are based on realistic and understandable alternatives, with which the respondents may have had some previous experience (like being in good health), rather than more esoteric alternatives (like the survival of a particular whale) with which they are not familiar.

2.3.3.4.3 Using Satisfaction Data

The third method for estimating preferences makes use of the answers to a "satisfaction with life" (or happiness) question. At first sight, this may seem a surprising venture, given our earlier emphasis on the fact that the answers to these satisfaction questions do not satisfy the same-preference principle. Yet, we have seen that the satisfaction function S_i can be interpreted as one utility function representing the preference ordering of individuals, provided the consistency assumption holds. By modeling carefully the effects of aspirations and expectations on subjective well-being, one can retrieve the ordinal information about preferences that is embodied in the satisfaction answers. This method is in

[23] Other stated preferences methods (e.g., discrete choice analysis) could in principle also be useful to estimate preferences.

[24] A similar analysis with data from a representative survey in France is presented in Fleurbaey et al. (2012).

line with a growing body of research that estimates willingness-to-pay for nonmarket goods through their effects on subjective satisfaction (see, e.g., Clark and Oswald, 2002; Van Praag and Ferrer-i-Carbonell, 2007).

Denoting by π_i the individual characteristics of individual i, which are not seen as life dimensions but as factors that do influence life satisfaction (the scaling factors), we can rewrite the satisfaction function as $S(y_i, x_i; \pi_i)$. The equivalent income can then be computed by solving

$$S(y_i, x_i; \pi_i) = S(y_i^*, \widetilde{x}; \pi_i)$$

for y_i^*. If we adopt a log-linear approximation (which is the dominant model in the empirical happiness literature), this yields

$$\ln y_i^* = \ln y_i - \sum_j \left(\frac{\partial S/\partial x_{ij}}{\partial S/\partial \ln y_i} \right) \left(\widetilde{x}_j - x_{ij} \right), \tag{2.5}$$

where the subscript j refers to the different life dimensions. Expression (5) shows that interpersonal variation in the psychological characteristics π_i will only influence the value of the equivalent income if it influences the marginal rates of substitution. Differences in scaling factors that only influence the satisfaction level, without affecting the relative weights given to the different dimensions, will not influence the estimated y_i^*. The satisfaction method has been used to calculate equivalent incomes by Fleurbaey et al. (2009) and by Schokkaert et al. (2011). In both papers it is shown that the ranking of well-being on the basis of subjective satisfaction differs considerably from the ranking of equivalent incomes.

Like the stated preferences approaches, the use of satisfaction data allows for the incorporation of nonchoice dimensions in the evaluation. However, the precise specification of the function $S(y_i, x_i; \pi_i)$ and the identification of the relative effects of x_i and π_i raise difficult issues.[25] Most important, the method rests on the acceptability of the consistency assumption. To be useful, the satisfaction question should be formulated in such a way that it can safely be assumed to capture the respondent's cognitive views on what constitutes a good life.[26]

2.3.3.5 What If Preferences Are Incomplete?

The equivalent income approach, as described until now, rests on the assumption that well-defined individual preferences exist. Many researchers expressed their skepticism

[25] The treatment of education illustrates the problem. Having a good education may be seen as an important dimension of life (it is, e.g., emphasized by Nussbaum, 2000). At the same time, however, education may also have a direct influence on aspirations (e.g., with respect to job characteristics, as in Schokkaert et al., 2011). With the satisfaction approach it is impossible to disentangle the two effects.

[26] See Fleurbaey and Blanchet (2013) on the wording of subjective satisfaction questions.

about the use of preferences. We have already seen that, in the light of the many instances of differences between "decision utility" (the perceived utility on which decisions are based) and "experience utility" (the real after-decision utility), some researchers from the subjective well-being approach suggest focusing on the latter in case of conflict. Their skepticism seems to be supported by the recent findings of behavioral economics that a large number of "behavioral anomalies" make it difficult to interpret individual choice behavior as the maximization of well-defined preferences. We have argued before that the latter point urges a focus not on revealed, but on "authentic" preferences.

Other researchers reject the idea that individuals "authentically" have a complete preference relation over all possible lives. The assumption of a complete preference relation over all possible lives is indeed a strong one, implying that individuals can order states with which they may not be familiar at all. The psychological uncertainty about preferences may be expected to be larger further away from the actual situation. To calculate healthy-equivalent incomes as depicted in Figure 2.3, for instance, one needs nonlocal information on the indifference curve. Is someone who has been chronically ill for a long time (or is handicapped since birth) able to evaluate trade-offs in a situation of normal health? And, even if individuals have clear ideas about what a good life is for them, the available techniques to recover these preferences are still in their infancy and far from perfect. In fact, it is quite likely that different techniques will lead to conflicting results.

If one does not believe that authentic preferences do exist or can be recovered, one could conclude that the equivalent income approach to measuring well-being is not meaningful and that one has to go back to either more "objective" applications of the capability approach or the direct use of subjective satisfaction measures. An alternative approach, however, is to keep individual preferences as the underlying foundation for measuring individual well-being, but to accept that the preference relation is not complete if choices (or stated preferences) are conflicting and context-dependent. This route has been explored by Fleurbaey and Schokkaert (2013) who implement the notion of incomplete preferences (or choices) that was suggested by Bernheim and Rangel (2009) in the context of the measurement of individual well-being. They show that incomplete preferences can be accommodated by introducing upper and lower bounds to equivalent income. Figure 2.4 illustrates the suggested method for the example that was already used in Figure 2.3. Suppose the individual has the income–health combination depicted in Z. Imagine that his preference relation is incomplete: bundles in the region UC are seen as better by him, bundles in the region LC are worse, but bundles in the region NC are noncomparable to bundle Z. This way of modeling preferences embodies the natural assumption that individuals have finer preferences when comparing closer alternatives. Figure 2.4 then immediately shows (using the same assumption about the choice of the reference situation as discussed before) that it is possible to derive an upper limit $y_i^{*\sup}$ and a lower limit $y_i^{*\inf}$ for the equivalent income. One can then argue that individual i is better off than individual j if $y_i^{*\inf} > y_i^{*\sup}$. Arguably, this condition is a

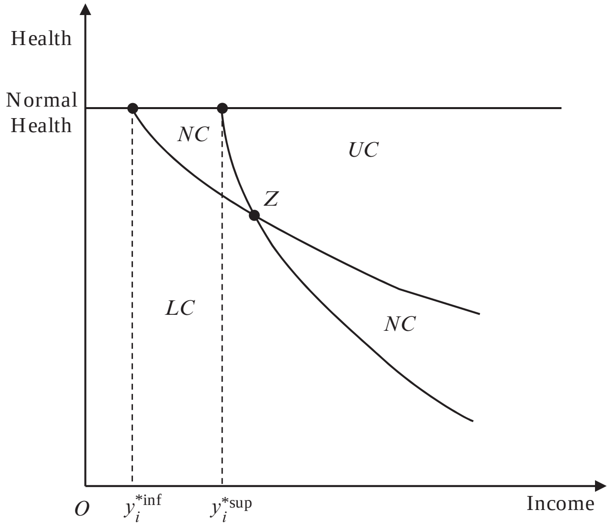

Figure 2.4 Equivalent income with incomplete preferences.

stringent one, and Fleurbaey and Schokkaert (2013) show how it is possible to weaken it to be able to compare more individual situations. The less-stringent conditions do not preclude mistakes in interpersonal comparisons, but they prevent the evaluator from missing a situation in which the worse off is really badly off.[27]

2.3.4 Conclusion

Choosing a meaningful measure of individual well-being for the analysis of inequality is a normative exercise. The underlying value judgment is the following: when is it ethically acceptable to say that one individual is worse off than another, in the sense that redistribution is desirable from a social perspective?

In this section, we focused on the normative foundations of the three most popular approaches for measuring well-being in a multidimensional setting: the capability approach, the subjective well-being approach (with its two variants: hedonic and preference welfarism), and the equivalent income approach. If one interprets the capability approach in terms of (refined) functionings and one opts for a measurement tool that respects preferences, one arrives at the equivalent income approach. Yet, most followers of the capability model are skeptical about respecting preferences and the idea of trading off different life dimensions against each other. In these concluding remarks, we will follow this dominant perspective on the capability approach.

[27] The idea is that if the evaluator is wrong about the worse off in a pairwise comparison, the true worse off is not as badly off as he could be if the mistake was in the opposite direction.

A first ethical requirement for a measure of well-being could be that individual *i* is said to be better off than individual *j*, if he has higher achievements in all life dimensions compared to individual *j*. This is the so-called dominance principle. We have seen that this seemingly innocuous principle cannot be reconciled with respect for preferences and that it is therefore not satisfied by the happiness and equivalent income approaches. It can be satisfied by the capability approach, on the other hand, if the latter is implemented with an aggregation procedure that gives objective weights to all dimensions. This observation immediately implies that the capability approach in this interpretation cannot respect preferences.

Respect for preferences comes in a weak and a strong form. The personal-preference principle is satisfied by the subjective well-being approach, provided that the answers to satisfaction questionnaires are consistent with preferences. The personal-preference principle is also satisfied by the equivalent income approach. Only the equivalent income approach satisfies the stronger same-preference principle, which extends respect for preferences to interpersonal comparisons. The crucial difference between the two approaches is the treatment of aspirations and expectations, and hence of adaptation. These phenomena are taken up in the life satisfaction measure of well-being, whereas they are corrected for by the equivalent income approach. The hedonic version of the subjective well-being approach goes very far in its rejection of the relevance of preferences by putting forward that only ex post feelings should matter to determine who is worse off. This appears to be a radical position, given the widespread observation that people care about more than their subjective feelings.

The choice of a metric of well-being has implications for the implied cut between personal and social responsibility. In its opportunity set interpretation, the capability approach holds people responsible for their choices. This can be harsh in the light of significant differences in the decision-making capacities of individuals. Correcting for these differences is probably easier when we turn to an interpretation in terms of refined functionings. The satisfaction approach compensates individuals with expensive tastes (high aspirations) and will not compensate them if they adapt to poor physical conditions. The equivalent income approach evaluates individual achievements. However, because it evaluates these achievements on the basis of the own conceptions that individuals have about what is a good life, individuals are held responsible for these conceptions.

For practical purposes it is important to realize that the different perspectives on well-being also impose different informational requirements. If one deems that life satisfaction questionnaires yield meaningful answers, this approach is the easiest to implement. The hedonic approach requires that feelings be registered, ideally with a day reconstruction or an experience sampling method. Both the capability and the equivalent income approaches need information about the different life dimensions at the level of the individual. To calculate equivalent incomes one moreover has to know individual preferences. We discussed three methods to retrieve these preferences.

A final word of caution. The happiness literature has looked at the effect of economic inequality on life satisfaction (see also Chapter 13). To give one example, Alesina et al. (2004) show that respondents report a lower level of happiness when inequality is high. This effect is larger and statistically more significant in Europe than in the United States. More strikingly, there are also differences across groups. In Europe mainly the leftist and the poor suffer from inequality, while in the United States the strongest negative effect is on a subgroup of leftist rich. This fascinating result might be explained by differences in perceived mobility. However, for our purposes it is important to be clear about the normative status of these findings. One interpretation is that people care about their social environment, i.e., that perceived inequality (or injustice) is one of the relevant dimensions influencing the quality of their life. This can be easily incorporated in all three approaches in this section. Only the life satisfaction approach would go further, however, and would claim that inequality only matters from an ethical point of view if it influences satisfaction—which would imply that the fact that it is felt as less important in the United States would also imply that it is indeed less important from an ethical perspective. This conclusion is not acceptable for the two other approaches. Both for the capability and for the equivalent income approach, inequality is a problem of justice, and justice remains ethically important, even if people do not (seem to) care.

2.4. MULTIDIMENSIONAL INEQUALITY AND DOMINANCE

The route taken by most welfare economists to evaluate the multidimensional distribution of well-being consists of two steps. In a first step, an appropriate measure of individual well-being is derived by answering the question "equality of what?" In the previous section we studied three prominent answers to that question. In a second step, social welfare or inequality is measured consistently with the analogue of the Pigou–Dalton transfer principle defined in the space of the well-being measures, which have been obtained in the first step. As a consequence, the ethical attractiveness of the Pigou–Dalton transfer principle and the well-being measure are intimately linked.

An alternative, more direct route has been followed in the recent literature on multidimensional inequality. It consists of first generalizing the Pigou–Dalton transfer principle toward a multidimensional framework and then imposing this principle directly in the multidimensional space of achievements. At first sight, this route appears to be shortcutting the problem of constructing a well-being measure in the initial step. We have seen indeed that a number of authors within the capability approach are reluctant to construct one single index of well-being. We will investigate whether the methods developed in the literature on multidimensional inequality allow studying the multidimensional well-being distribution without constructing such an index.

For this section, we introduce some additional information. Consistent with the previous section we assume that a social situation can be described as $(\ell_i, R_i, S_i)_{i=1}^{n}$. In addition, it will turn out to be convenient to summarize only the achievements of all individuals by means of a so-called distribution matrix. Next we give an example of a distribution matrix L of a society with n individuals and m dimensions of life. Let ℓ_i^k be the achievement of individual i in dimension k. As before, ℓ_i refers to the m-dimensional vector of all achievements of individual i (a row of the matrix), and ℓ^k refers to the n-dimensional vector of achievements of all individuals in dimension k (a column of the matrix).

$$L = \begin{array}{cc} \begin{bmatrix} \ell_1^1 & \cdots & \ell_1^m \\ \ell_2^1 & \cdots & \ell_2^m \\ \vdots & \vdots & \vdots \\ \ell_n^1 & \cdots & \ell_n^m \end{bmatrix} & \begin{array}{l} \leftarrow \text{Individual } 1 \\ \leftarrow \text{Individual } 2 \\ \qquad \vdots \\ \leftarrow \text{Individual } n \end{array} \\ \begin{array}{ccc} \uparrow & \cdots & \uparrow \\ \text{Dim. } 1 & \cdots & \text{Dim. } m \end{array} & \end{array} \tag{2.6}$$

The literature on multidimensional inequality studies how to summarize the information in a distribution matrix by means of a single numerical value.[28] By taking a distribution matrix as the only information basis, it is clear that the standard multidimensional social welfare measures proposed in the literature are not sensitive to the preferences held in the society. We return to this topic in the next subsection.

2.4.1 Two-Step Aggregation and Cumulative Deprivation

Although the aggregation of a distribution matrix into a numerical value is not always performed by an explicit two-step procedure, most of the existing multidimensional measures combine two one-dimensional aggregations. One aggregation is across the n individuals in the society. The other aggregation is across the m dimensions of well-being. Different multidimensional measures of social welfare differ in the functional specifications of both aggregations and in the sequencing of both steps.

Let us describe two procedures to sequence this two-step aggregation. In the first procedure, we first aggregate across the different individuals in each dimension. In this step we obtain for each dimension a single summary statistic, so that an m-dimensional vector of summary statistics is generated. In the second step, this vector is further aggregated across dimensions. Kolm (1977) calls this procedure a specific one. Pattanaik et al. (2012) refer to it as the column-first two-step aggregation procedure. In the second

[28] We refer the reader to Chapter 3 or Weymark (2006) for detailed surveys on the literature on multidimensional inequality. Following Kolm (1977), a measure of multidimensional inequality can be derived from a measure of multidimensional social welfare as the fraction of the aggregate amount of each dimension that could be destroyed if every dimension of the matrix were equalized while keeping the resulting matrix socially indifferent to the original matrix. We will focus primarily on measures of social welfare in this section.

procedure, the order of aggregation is reversed: in the first step one aggregates for each individual i the dimensions of well-being, which generates a measure of well-being. All the obtained well-being measures generate an n-dimensional vector of individual well-being measures. In the second step, this vector is aggregated across individuals. Following Kolm (1977) this second procedure will be referred to as an individualistic one, or a row-first aggregation procedure according to Pattanaik et al. (2012).

In general the two procedures lead to different results (see Decancq and Lugo, 2012; Dutta et al., 2003; Kolm, 1977). Most theoretical multidimensional inequality measures follow the individualistic procedure and aggregate first across dimensions and then across individuals. Some authors have followed the other track, however. A notable example is provided by Gajdos and Weymark (2005), who impose separability between dimensions. Imposing this requirement brings them to a specific procedure. Specific procedures have the operational advantage that they allow the use of different information sources for the different dimensions of well-being. The summary statistic of one dimension may come from one survey, whereas the summary statistic of another dimension may be based on a different survey. A prominent example of such an approach is the HDI, which will be discussed in more detail in the next section.

The flexibility of the specific procedure with respect to the data sources comes at a (high) price, however. The second aggregation function used in a specific procedure aggregates across the different dimensionwise summary statistics. This aggregation may appear to be largely arbitrary. Contrary to an aggregation across dimensions of well-being at the individual level, a theoretical framework for aggregation of summary statistics is indeed missing. This arbitrariness probably underlies the reluctance of various researchers and statistical agencies to pursue an aggregation of summary statistics. A portfolio or dashboard of separate summary statistics, which each can be monitored in separation, is often presented as an alternative. This method is consistent with the view that different dimensions of life are incommensurable, as we have encountered, e.g., in our overview of the capability approach.

Irrespective of the choice whether and how the summary statistics are aggregated in its second step, a specific procedure has an additional drawback. An important aspect of the information on well-being is lost, namely the correlation between the positions of the individuals across the different dimensions (see Decancq, 2013, for a discussion). When the dimensions of life are correlated, deprivations in one dimension are cumulated with deprivations in other dimensions. Compare, for instance, the following two distribution matrices L and L':

$$L = \begin{bmatrix} 10 & 10 \\ 20 & 70 \\ 70 & 20 \end{bmatrix} \quad L' = \begin{bmatrix} 10 & 10 \\ 20 & 20 \\ 70 & 70 \end{bmatrix}.$$

In both matrices, there are two dimensions of life (columns) and three individuals (rows). It is easy to see that each of the four dimensionwise distributions is the same and hence that each specific aggregation across individuals should lead to exactly the same result. Yet, in the distribution matrix L', there is one individual who is bottom-ranked in both dimensions of life, another individual who is second-ranked in all dimensions, and still another individual who is top-ranked in all dimensions. This society is arguably more unequal than the society represented by L with exactly the same distributional profile in each dimension, but where the achievements of individuals two and three are more mixed. It seems natural to require that the multidimensional evaluation is at least sensitive to the degree to which deprivations in each dimensions are cumulative across dimensions. Pogge (2002, p. 11), for instance, writes: "Consider institutional schemes under which half the population are poor and half have no access to higher education. We may plausibly judge such an order to be more unjust when the two groups coincide than when they are disjoint (so that no one bears both hardships)."

The preceding example illustrated that all measures obtained through a specific procedure are blind to the correlation between the dimensions of life. It follows that a concern for correlation or an aversion to cumulative deprivation rules out the specific (or column-first) sequencing of both aggregations as well as dashboard approaches.[29] This brings us to the alternative, individualistic sequencing in which the dimensions of life are first aggregated for each individual and then across all individuals. Interestingly, this procedure coincides with the welfare economic approach surveyed in the previous section. Although the literature on multidimensional inequality measurement offers a coherent axiomatic justification for the functional specification of the various measures, the link between the formal axioms used (such as homotheticity or separability) and the normative foundations of the implied well-being measure is usually not explained in detail, however.

2.4.2 Multidimensional Pigou–Dalton Transfer Principles and Respect for Preferences

A central question in the literature on multidimensional inequality deals with the generalizations of the standard one-dimensional Pigou–Dalton Transfer Principle and the restrictions that each of these generalizations impose on the functional specifications of the aggregation across dimensions and individuals.[30] In this section we are particularly concerned with the question whether such generalizations can be reconciled with a general respect for individual preferences.

2.4.2.1 Multidimensional Pigou–Dalton Transfer Principle(s)

In a one-dimensional setting, a Pigou–Dalton transfer consists of transferring a positive amount of income from a richer to a poorer individual without reversing the ranking

[29] See Dardanoni (1995), Gajdos and Weymark (2005), and Pattanaik et al. (2012) for formal discussions.
[30] See Weymark (2006) and Fleurbaey (2006b) for surveys.

between both individuals. A natural generalization into a multidimensional framework is the following (see Fleurbaey, 2006b; Fleurbaey and Maniquet, 2011).

Pigou–Dalton Transfer Principle $(\ell_i, R_i, S_i)_{i=1}^n$ *is strictly better than* $(\ell_i', R_i, S_i)_{i=1}^n$*, if for all individuals* $k \neq i, j$*, we have that* $\ell_k' = \ell_k$*, and for individuals i and j, we have that for* $\delta \in \mathbb{R}_+^m \setminus \{0\}$

$$\ell_i' = \ell_i + \delta \leq \ell_j - \delta = \ell_j'. \tag{2.7}$$

A positive bundle δ is transferred from a donor j to the recipient i, where the donor has achievements that are at least as good as the recipient in all dimensions of life. In the axiomatic literature on multidimensional social welfare, on the other hand, it is more common to work with transfers where the transferred bundle is a fraction of the difference between the achievement vector of donor and recipient of the transfer, so that $\delta = \lambda(\ell_j - \ell_i)$. Moreover, often expression (7) is replaced by the following expression,

$$\ell_i' = \ell_i + \lambda(\ell_j - \ell_i) \text{ and } \ell_j' = \ell_j - \lambda(\ell_j - \ell_i), \tag{2.8}$$

for $\lambda \in (0,1)$.[31] The most important difference between expressions (7) and (8) is the fact that the achievements of the donor of the transfer should no longer be larger than the achievements of the recipient in all life dimensions. Consequently, the transfers may go in opposite directions for different dimensions. Consider the following distribution matrices L and L'' for example, where

$$L = \begin{bmatrix} 10 & 10 \\ 20 & 70 \\ 70 & 20 \end{bmatrix} \quad L'' = \begin{bmatrix} 10 & 10 \\ 50 & 40 \\ 40 & 50 \end{bmatrix}. \tag{2.9}$$

One easily checks that a transfer of 30 units is carried out between individuals 2 and 3 in distribution matrix L to reach matrix L''. In the first dimension the units are transferred from individual 3 to individual 2, whereas in the second dimension the 30 units are transferred in the other direction from individual 2 to individual 3.

This example illustrates a fundamental problem with using expression (8) in a richer setting where individuals may have different preferences (Fleurbaey, 2006b). Distribution matrix L'' is obtained from L by a multidimensional transfer. Yet, individual 2 may prefer his bundle in the distribution L to the one in L'', as he may give more weight to the second dimension. Also individual 3 may prefer his bundle in the distribution L, if

[31] Any sequence of these transfers can be written as a bistochastic matrix (see Weymark, 2006, for details). The converse of this statement does not always hold. When $n \geq 3$ and $m \geq 2$ not all bistochastic matrices can be obtained as a sequence of transfers described by expression (8) (Marshall and Olkin, 1979, p. 431). The class of multidimensional transfers that can be expressed by means of a bistochastic matrix is the workhorse of many (axiomatic) studies of multidimensional inequality. It has the advantage of imposing a clear structure on the functional specifications of the aggregation across dimensions and individuals (see, e.g., Kolm, 1977; Tsui, 1995).

he cares more about his achievement in the first dimension. The transfers may therefore go against unanimous individual opinions on the change in well-being. At first sight, this problem seems to be avoided by restricting the transfers to cases where the donor vector dominates the recipient, as in the definition of a multidimensional Pigou–Dalton transfer based on expression (7), so that there is an unambiguous recipient who benefits from the transfer and an unambiguous donor whose well-being is worsened. Yet, we will now see that even these transfers are incompatible with a respect for preferences.

2.4.2.2 The Impossibility of a Paretian Egalitarian

Let us assume, as in the previous section, that all individuals have an informed judgment about what a good life is. Respect for these individual opinions may in this context be expressed by the following Pareto condition:

Weak Pareto Principle $(\ell_i, R_i, S_i)_{i=1}^n$ *is strictly better than* $(\ell_i', R_i, S_i)_{i=1}^n$ *if for all* $i, \ell_i P_i \ell_i'$

The (weak) Pareto principle and the multidimensional Pigou–Dalton transfer principle conflict as soon as at least two individuals have different preferences. This impossibility result is intuitive. The Pareto principle requires that individual preferences are respected, whereas the multidimensional Pigou–Dalton transfer principle advocates some transfers irrespective of the individual preferences. Figure 2.5 illustrates a simple graphical proof (see Fleurbaey and Maniquet, 2011, Theorem 2.1, and also Fleurbaey and Trannoy, 2003). The Pareto principle requires that distribution matrix L^1 is strictly better than L^4 because for all individuals the achievement vector in L^4 is below the indifference curve containing the achievement vector in distribution matrix L^1. Similarly, L^3 is strictly better than L^2. On the other hand, the multidimensional Pigou–Dalton transfer principle requires that L^2 is strictly better than L^1, and L^4 is strictly better than L^3, which creates a cycle.

This impossibility reflects a deep tension between two ways of interpreting what it means to respect unanimous preferences. As the donor of the transfer has a higher achievement in all dimensions of life than the recipient, all individuals with monotonic preferences will agree that the donor is indeed better off, so that a transfer from the donor to the recipient is a social improvement. On the other hand, it may be the case that all individuals are indifferent between the current distribution and a new one, where the initial donor now has a lower achievement in all dimensions of life than the initial recipient. Note that the same tension is underlying the incompatibility between the personal-preference principle and the dominance principle that was discussed in the previous section.

The impossibility result brings us to a crossroad. We can take two directions from here. Either we give priority to the Pareto principle and look for appropriate weakenings of the multidimensional Pigou–Dalton transfer principle. This route is taken by Fleurbaey and Maniquet (2011), among others. A natural weakening of the multidimensional Pigou–Dalton transfer principle is to impose the additional requirement that both donor and recipient of the transfer should have the same preferences (i.e., agree on the

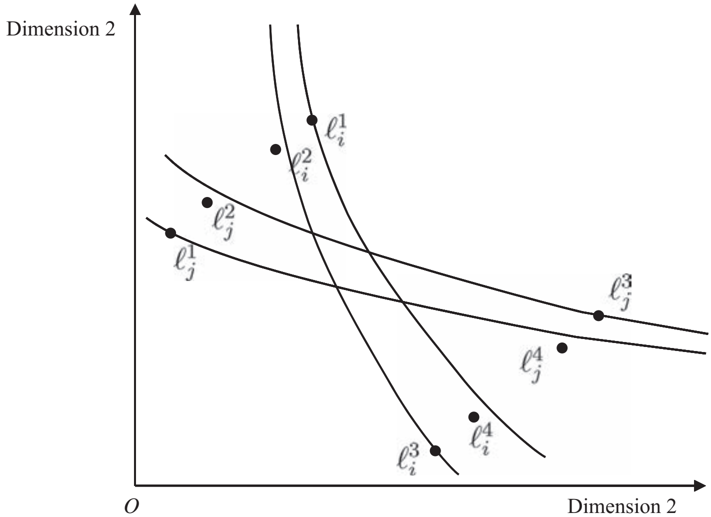

Figure 2.5 Weak Pareto principle and multidimensional Pigou–Dalton principle are incompatible.

good life). This restricted transfer principle is arguably a weak one (as it remains silent on the evaluation of all transfers where donor and recipient disagree on the good life), yet in terms of implications on the social welfare function, it turns out to be very strong. Together with the Pareto principle and the requirement that the comparison of two allocations only depends on the indifference curves at these two allocations, it imposes a leximin aggregation across individuals that gives priority to the worse off. This result echoes our earlier findings when we described the problems with the nonconcavity of the equivalent income in the previous section.

Alternatively, one can give priority to the multidimensional Pigou–Dalton transfer principle. This implies that the resulting social evaluation procedure will not be able to respect individual preferences. The literature on multidimensional inequality measurement has taken this second route by assuming that the well-being of a society can be described using information on achievements alone (i.e., a distribution matrix), disregarding information on the preferences of the individuals themselves.[32] This assumption imposes the requirement that the social welfare function is anonymous in the achievement space (see, for instance, Kolm, 1977; Tsui, 1995; Weymark, 2006). A social welfare function is anonymous in the achievement space whenever permuting individual achievement vectors is a matter of social indifference. As a consequence, the well-being measures used to aggregate across dimensions are identical for all individuals. This assumption is defended as requiring equal treatment of all individuals i with the same achievement bundle ℓ_i either because the observer is unable to distinguish between other

[32] For a more subtle weakening, see Sprumont (2012).

possibly relevant individual characteristics (such as the individual opinions on what constitutes a good life) or because the observer considers the other individual characteristics to be ethically irrelevant.

In his seminal article Kolm (1977) suggested that a common well-being measure can be seen as "the observer's evaluation of the individual welfare." Alternatively, the common objective opinion on the good life is rooted in some "reasoned social agreement on basic components of well-being and on the relative "urgency" of claims to different goods" (Scanlon, 1975). These options are closely linked to the perfectionist approach and the focus on public reasoning that we found within the capability approach by Nussbaum and Sen, respectively.

2.4.3 Dominance and Agnosticism on Preferences

Whether a social agreement on the components of well-being can effectively be reached is doubtful. Yet, even if it is hard to reach a social agreement on which common well-being measure to use, it may be possible to reach an agreement on some of its basic features while remaining agnostic on other features. This agnosticism comes at a price, as the social evaluation criterion will become incomplete and indecisive on the comparison of some social situations.

The dominance approach studies these incomplete orderings. In their seminal contribution, Atkinson and Bourguignon (1982) extended the existing one-dimensional dominance approach to a multidimensional framework.[33] A distribution matrix is said to dominate another one if the sum of well-being measures is greater for each and every well-being measure in a given set of measures that satisfy certain sign-restrictions on its partial derivatives.

In general, the class of measures that satisfy given sign restrictions contains infinitely many members, so that checking for dominance involves checking infinitely many inequalities. Luckily, dominance with respect to classes of well-being measures can be shown to be equivalent with implementable criteria. In a two-dimensional framework, Atkinson and Bourguignon (1982) showed, for instance, that dominance with respect to the class of increasing well-being measures with a negative cross-derivative is equivalent to first-order stochastic dominance in terms of the joint distribution functions corresponding to the distribution matrices. Various statistical tests have been developed to test whether distribution functions first-order stochastically dominate one another (see Chapter 6). By imposing a negative cross-derivative, the marginal increase in well-being from having a small increase in the achievement of the first

[33] Related approaches focus on the measurement of inequality, rather than social welfare. These approaches start from a multidimensional generalization of the Lorenz criterion, based on the so-called zonotope (Koshevoy, 1995). Unfortunately, the equivalence between second-order stochastic dominance and the Lorenz criterion breaks down in the multidimensional case.

dimension decreases with the level of the achievements in the second dimension. In other words, if some manna would become available in the first dimension, the social planner prefers it to go to the worse-off individual in the second dimension. This restriction introduces again some aversion to correlation and cumulative deprivation between the two dimensions of well-being. Atkinson and Bourguignon also looked for the consequences of imposing further restrictions on the partial derivatives, and later work has extended these results (see Trannoy, 2006, and the references therein). The more sign-restrictions are imposed, the more complete the ordering becomes. However, the results become arguably harder and harder to interpret, as higher-order cross-derivatives are involved.

The dominance approach moves us away from the perfectionism that is implicitly underlying approaches that impose a single well-being measure for all individuals. Yet, the unanimous judgment of a class of social welfare functions remains based on a common well-being function for all individuals, so that the dominance approach ignores the diversity of individual preferences. Whether one finds this problematic or not depends on the attitude one takes toward the idea of respecting preferences. Multidimensional inequality measures and dominance approaches are arguably the best way to proceed if one believes that individuals do not have well-defined conceptions of the good life, or that, even when they exist, it is impossible to know them, or that, even when they exist and one can approximate them, one should not do so but rather implement an objective conception of the good life. Again, this is an essentially normative debate.

2.5. APPLICATIONS

Although our discussion so far has remained at an abstract level, the different positions described suggest different approaches to many applied issues that are of great importance for measuring inequality. An important application is the booming literature on socioeconomic inequality and racial disparities in health, in which the issue of cumulative deprivation (with respect to income and health) plays a crucial role. Because this literature has been discussed in great detail in Fleurbaey and Schokkaert (2012), we will not repeat this analysis here. We will illustrate the practical relevance of the previous sections by focusing on three applications. We first discuss the issue of household equivalence scales and (related to that) the measurement of intrahousehold inequality. We will then look at the different methods that have been proposed to include the value of public goods and services into the analysis of inequality. Our third application is the analysis of world inequalities, including a discussion of purchasing-power parity (PPP) indices. In each of these subsections, we do not go into the technical details but focus on the relationship with the normative analysis in the previous sections.

2.5.1 Household Equivalence Scales

It is widely agreed that the quality of social relations is one of the most important dimensions of life. For many people this is particularly true for their relationship with a partner and the quality of their family life. Also the presence of children changes life deeply (for better or for worse). Therefore, it seems natural to include these family-related dimensions in a broader view of well-being. Family relations have been introduced in the capability approach, often with a focus on gender issues (see, for instance, Nussbaum, 2000; Robeyns, 2003). Moreover, family relations have been shown to have a strong effect on happiness or life satisfaction. A famous example is offered by Blanchflower and Oswald (2004). The authors estimate that a lasting marriage (compared to widowhood as a natural experiment) is worth \$100,000 a year. As far as we know, there are no applications in the equivalent income tradition yet.[34] It would not be difficult to derive equivalent incomes on the basis of a life satisfaction equation, however, and the marginal rate of substitution estimated by Blanchflower and Oswald shows that the willingness-to-pay for a good family life is likely to be considerable.

In these studies, the ultimate goal is to measure well-being as an aggregate over many dimensions. This has also been the perspective of Section 2.3. It is instructive to compare this perspective to that taken by the large body of literature that tries to calculate so-called equivalence scales. The basic question to be answered by this approach is the following: "How much income does a household with characteristics z need to reach the same level of well-being as a reference household?" where the latter is usually—but not always—taken to be a single. Therefore, the proclaimed ambition of this literature is also to compare the well-being of different households. The problem that researchers working in this field want to tackle is that income (and consumption) are usually reported at the level of the household and not at the level of the individual. Yet, it is obvious that living in a household involves returns to scale, including the consumption of household public goods. Think about housing or about the use of a car, for instance. It is natural to assume that a couple needs less than twice the income of a single to reach the same level of well-being. The challenge is then to try to correct reported incomes at the household level to take into account differences in household composition.

This is a very old problem, about which no consensus has been reached yet. As a matter of fact, despite the large academic literature on the topic, most practitioners are still using equivalence scales without a coherent theoretical foundation. A typical example is the so-called modified OECD scale used by Eurostat, in which the first adult counts for 1, the second adult and each subsequent person aged 14 and over counts for 0.5, and for each additional child under 14 one adds 0.3. The household income is then divided

[34] Household size plays an important role in the application of Fleurbaey and Gaulier (2009), but this application is at the country level—see Section 2.5.3.

by this scale to get the "equivalized income."[35] Alternatively, the OECD divides the household income by the square root of the household size. In both cases the reference household (for which the equivalized income equals the original income) is a single. The lack of consensus about the exact scale to be used has also stimulated the use of stochastic dominance approaches (Atkinson and Bourguignon, 1987; Bourguignon, 1989; Fleurbaey et al., 2003; Ooghe and Lambert, 2006). We will not summarize the large literature on equivalence scales here, but rather focus on the differences and similarities with the approaches to measuring well-being that are the topic of this chapter.

Using the cost function $C(u, p, z)$ to denote the minimum expenditure needed by a household with characteristics z to reach utility level u if prices are p, and denoting the reference household characteristics by $\bar{z}$, the equivalence scale is defined as

$$\mathrm{ES}(u, p, z) = \frac{C(u, p; z)}{C(u, p; \bar{z})}, \tag{2.10}$$

and the equivalized income as

$$y_E(u, p, z) \equiv \frac{y}{\mathrm{ES}(u, p, z)} = y\frac{C(u, p; \bar{z})}{C(u, p; z)} = C(u, p; \bar{z}).$$

By far most attention went to the derivation of equivalence scales on the basis of observed consumption behavior. Traditionally, the analysis of consumption behavior was based on the assumption of a "unitary" household, with preferences and optimization behavior defined at the level of the household. To go beyond the household level and compute individual well-being, it was then commonly assumed that all household members experience the same well-being level. It is clear that in this approach the calculation of equivalence scales requires interpersonal comparisons of well-being between households of different sizes. It is not easy, however, to give an intuitively attractive interpretation to well-being at the level of the household. More important, it is immediately obvious that consumption data do not yield sufficient information to allow for such interhousehold comparisons of well-being. More specifically, what we can (under some conditions) identify are different sets of indifference curves (one for each household type), but observed consumption does not give us any clue about how to link these indifference curves to utility levels. Stated more formally, the cost functions $C(u, p, z)$ and $C(\delta(u, z), p, z)$ will induce exactly the same consumption behavior—where the transformation $\delta(u, z)$ may depend on z.

Identification of the equivalence scales can only be achieved by introducing additional assumptions. The most famous of these is the so-called IB assumption, where IB stands for "independence of base" (Lewbel, 1989).[36] This assumption states that

[35] We use the term *equivalized income* to denote the income divided by an equivalence scale. This is to be distinguished from the equivalent income that was introduced in Section 2.3.

[36] The same assumption has been proposed by Blackorby and Donaldson (1993) under the name "equivalence-scale exactness." It has later been generalized by Donaldson and Pendakur (2003), but this generalization does not solve the basic issue described here.

the equivalence scale is independent of utility, i.e., $C(u, p; z) = C(u, p; \overline{z})\mathrm{EB}(p, z)$, where $\mathrm{EB}(p, z)$ refers to an equivalence scale that satisfies the IB assumption. This assumption implies a restriction on the cost functions and therefore leads to testable restrictions on the consumption behavior of different households. A crucial part of the identifying assumption is not testable, however, notably the assumption that all households with the same value for $y/EB(p, z)$ indeed reach the same level of utility.

How to interpret this approach in the light of our broader questions about well-being? First, the concept of well-being used is a restricted one. In fact, as argued in the short but influential paper by Pollak and Wales (1979), equivalence scales as derived from consumption behavior do not include the direct effects of z on utility—and unless one includes choice of household size in the analysis, choice behavior can never reveal any information about preferences with respect to household size. Pollak and Wales draw a distinction between *situation comparisons* and *welfare comparisons*. Situation comparisons are based on the conditional cost function, giving the minimum expenditures needed to reach a given utility level u, conditional on having characteristics z. Welfare comparisons, on the other hand, require the estimation of an unconditional cost function, giving the minimum expenditures needed to reach a given utility level u, taking into account the direct effect of the characteristics z on utility. In fact, Pollak and Wales are critical of the traditional approach and state that "conditional equivalence scales estimated from observed differences in the consumption patterns of families with different demographic profiles cannot be used to make welfare comparisons" (Pollak and Wales, 1979, p. 220). Unconditional utility (or cost) functions are the representation of preferences over bundles of life dimensions, with household characteristics z as elements of those bundles. Pollak and Wales therefore reject the relevance of traditional equivalence scales and advocate the use of the methods that have been described in the previous sections.

Many (or even most) authors studying equivalence scales take a less-negative position and argue that situation comparisons, despite their limitations, are meaningful on their own. They do not yield real welfare comparisons because they do not take into account the direct effect of family life (having a partner and children) on well-being. However, they do make sense in a resource-based approach, focusing on incomes and material consumption only. Some would even claim that inequality in material welfare, as measured by equivalized incomes, is more relevant for policy purposes than inequality in overall well-being, as it is not generally accepted that households should be compensated, e.g., for the fact of having children or not. The relevant question then becomes whether the IB-assumption that the equivalence scale is independent of utility is attractive from a normative point of view. This turns out to be a difficult question as the concepts of preferences and utility are difficult to interpret when applied at the level of the household.

As a matter of fact, this issue extends beyond the problem of correcting for household size. Similarly, one can calculate equivalence scales for other characteristics z. As an example, Jones and O'Donnell (1995) presented equivalence scales for disability, focusing on "the extra expenditure required by a household with a disabled person to achieve the same level of welfare as a reference household without any disabled individuals." In such a context of disability, the distinction between situation and welfare comparisons seems even more relevant, although (as noted by the authors) in this setting one can consider these extra expenditures as a lower bound on the welfare loss resulting from disability.

A major drawback of the traditional approach is its assumption that preferences and welfare can be defined at the level of the household. It is much more natural to see the household as consisting of individual members, each with their own individual preferences and deciding jointly about household consumption.[37] In this respect, an important recent breakthrough has been the move from the "unitary" to the "collective" model of household behavior (Apps and Rees, 1988; Chiappori, 1988). Some goods are purely private (food or clothing), others are public, and some may be mixed (a car can be used by all household members to make a trip jointly, but it can also be used by only one member of the household). Household resources are allocated to the consumption of each of the household members on the basis of a sharing rule. This rule reflects the relative power positions of the different household members. Finding the restrictions needed to identify the individual preferences of the household members and the sharing rule on the basis of observed consumption behavior in a setting with joint consumption and externalities is a very active and rapidly expanding field of research. This literature is discussed extensively in Chapter 16. Here we focus on the crucial relevance of this work for measuring individual well-being. Indeed, moving from the unitary to the collective model is an important advance in this regard.

A first approach to measuring individual well-being focuses on the sharing rule. If one reasons within a resource-based approach, the share of resources devoted to the consumption of individual *i* (as influenced by the distribution of power within the household) is an important indicator of his relative well-being level. Identification of the level of the sharing rule is not easy and requires additional restrictions, but Cherchye et al. (2013) show that upper and lower boundaries can be identified in a nonparametric setting. Applying their method to observations in the 1999–2009 Panel Study of Income Dynamics on childless couples, where both adult members participate in the labor market, leads to some interesting insights. As an example, while 11% of their restricted sample have incomes below the two-person poverty line; between 16% and 20% of individuals are below the individual poverty line. Using semiparametric restrictions, Dunbar et al. (2013) identified the resource shares of different household members, including children. Using data for Malawi, they found that the overall poverty rate calculated at the household level understates the incidence of child poverty.

The sharing rule-approach defines well-being in terms of income. For our purposes, another application of the collective approach is more relevant, however. Given that

[37] Early examples of this approach are Manser and Brown (1980) and McElroy and Horney (1981).

(under some assumptions) it is possible to identify individual preferences, one can formulate an answer to the question: "How much income would an individual living alone need to attain the same indifference curve over goods that the individual attains as a member of the household?" (see, e.g., Browning et al., 2013; Lewbel, 2003). There is an essential difference between this question and the one that was formulated earlier in the context of traditional equivalence scales. To answer this question, one just needs information about the indifference map of the individual, without having to label them. The resulting so-called individual indifference scales are closely related to the notion of equivalent income because they obviously are a form of money-metric utility that can be calculated on the basis of ordinal preference information only. Indifference scales will depend on these preferences, on the "consumption technology" used by the household (in terms of private, public, and mixed goods), and on the sharing rule, i.e., the distribution of power within the household. Applications of this approach have focused, among others, on the adequate compensation in case of wrongful death (Lewbel, 2003) and on poverty among the elderly (Cherchye et al., 2012).

Although the introduction of the collective model constitutes an important step forward, it does not bridge the gap between welfare and situation comparisons. Indifference scales do not capture the direct utility effects of partnership and children and remain therefore situated within a resource-based approach. They therefore do not yield a complete measure of well-being taking all relevant life dimensions into account. Whether one considers this to be a problem or not depends on whether one thinks that resource-based (situation) comparisons are relevant from a policy point of view.

Until now, we have discussed the approach to equivalence scales that focuses on observed consumption behavior. Because the focus is on identifying individual preferences, this approach is close to the intuitions underlying the equivalent income approach. Let us now see how the two other approaches to well-being measurement have been applied to tackle the equivalence scales problem.

There are almost no applications within the capabilities framework. Lelli (2005) calculated the equivalence scale of a household with characteristics z as the income needed to reach the same level of functioning (in her case housing) as the reference household. Her application thus remains limited to one functioning—and the resource-based perspective underlying this analysis goes in fact against the basic inspiration of the capability approach.

The subjective (or satisfaction) approach has been used more extensively for the construction of equivalence scales. The pioneering work in this field has been done by Van Praag (1971) and Kapteyn and Van Praag (1976). Originally, these authors assumed that there was a cardinal utility function of income $U(y; z)$, where z represents—as before—all relevant nonincome variables. They assumed (on the basis of a theoretical reasoning) that this utility function takes the form of a lognormal distribution function $U(y; \mu(y^A, z), \sigma(y^A, z))$, with the mean and the standard deviation dependent on z and on the actual income y^A of the household. The parameters of that function were estimated on the basis of the answers obtained from what was called the "Income Evaluation Question" (Van Praag, 1971). This question goes as follows:

> *Please try to indicate what you consider to be an appropriate amount for each of the following cases. Under my (our) conditions I would call a net household income per week/month/year of:*
> *about__________________very bad*
> *about__________________bad*
> *about__________________insufficient*
> *about__________________sufficient*
> *about__________________good*
> *about__________________very good.*

Giving specific values to the labels allowed them to estimate the utility function and hence to derive equivalence scales as in expression (10). This original Van Praag approach has never become very popular, partly because of the strong assumptions of cardinality and lognormality.

In later work (e.g., Van Praag and van der Sar, 1988), the cardinality assumption was dropped and the only assumption that was retained was that the different labels (from "very bad" to "very good") correspond to the same utility values for all individuals (i.e., that they were interpersonally comparable). Denoting the answers given by individual i for label k by c_{ik}, Van Praag and van der Sar (1988) then specified and estimated a (loglinear) function $c_{ik}(y_i, z_i)$:

$$\ln c_{ik} = \beta_{0k} + \beta_{1k} \ln z_i + \beta_{2k} \ln y_i + \epsilon_{ik},$$

where z_i is the size of individual i's household and ϵ_{ik} is an error term. The coefficients β_{2k} turn out to be highly significant. Respondents with a higher income evaluate the income needed to reach a given utility level as significantly higher than respondents with a lower income. Van Praag talks about a "preference drift" effect, and there is clear echo of the phenomenon of adaptation that has been discussed before. Taking this preference drift into account, one can derive that the "true" cost level needed to reach utility level k is found where $c_{ik} = y_i$, i.e.,

$$\hat{c}_k(z) = \exp[(\beta_{0k} + \beta_{1k} \ln z_i)/(1 - \beta_{2k})].$$

The equivalence scale at level k can then be calculated as $\hat{c}_k(z)/\hat{c}_k(\overline{z})$, where $\overline{z}$ again denotes the reference household. In their sample of eight European countries and the United States, the equivalence scales are reasonably similar at the different k levels, which gives some support for the IB assumption used in the consumption approach.

Other authors (e.g., Koulovatianos et al., 2005) have implemented a similar method with different formulations of the subjective question. A few papers have combined consumption data and subjective questions (de Ree et al., 2013; Kapteyn, 1994). This is a promising approach because it allows identification of preference parameters on the basis of the subjective information. As an example, de Ree et al. (2013) rejected the IB assumption (and its generalizations) for a sample of Indonesian households.

The question arises of whether the subjective method yields welfare or situation comparisons. Surely, the analyses on the basis of overall life satisfaction that we discussed in the beginning of this section yield welfare comparisons. This is much less clear for the subjective questions used in the literature on equivalence scales, however. Do individuals responding to the income evaluation question take into account the direct effect of household size on well-being? They probably do not, but it is not fully clear for the income evaluation question given earlier. Koulovatianos et al. (2005) confront their respondents with hypothetical household situations and then ask: "Given that someone has an extra child, how much would they need to reach the same level of well-being?" They argue that this yields conditional scales. The subjective information used by de Ree et al. (2013) is even more related to adequacy of resources. The subjective approach to equivalence scales estimation therefore also yields only situation comparisons—and deliberately so.

We can conclude that most of the studies within the equivalence scale approach do *not* aim at comparisons of well-being, taking into account at the same time the effects of income and of the quality of family life. On the contrary, they aim at needs-corrected values of income, i.e., at conditional comparisons of well-being. They are therefore rooted in a resourcist view on well-being. However, the methods that have been used to calculate equivalence scales are similar to the methods that we described in Section 2.3. The capability approach has hardly been used in this context. Equivalence scales derived from consumption behavior are based on preferences. Although the traditional literature based on the unitary model requires arbitrary assumptions about interpersonal comparability, the recent work with the collective model derives indifference scales using only ordinal preference information. The intuition underlying this approach is closely related to that behind the concept of equivalent income. Subjective evaluations have also been used, and in some of the work there is explicit consideration of the adaptation phenomenon. We will see in the next section that the issue of welfare versus situation comparisons is also relevant to interpret the literature on publicly provided services and benefits.

2.5.2 Publicly Provided Services and Benefits

Countries differ in the extent to which services are provided publicly rather than through the private market, for instance. Comparing the income distribution of two countries, one where health services are primarily covered by private out-of-pocket payments and another where such services are provided free of charge, may result in misleading conclusions on which country is preferable from a social welfare point of view. In addition, publicly provided services and benefits may have an impact on the inequality within a country.[38]

[38] The publicly provided services that are typically covered in the applied literature include educational benefits, health care, social housing, food stamps, and child care. On average across OECD countries, the first two listed services are estimated to add up to about 13% of GDP, ranging from 8% in Turkey up to 20% in Denmark and Sweden (Verbist et al., 2012).

As a starting point, it is fruitful to recall the distinction between functionings and resources. We argued that what matters to define well-being are the functionings of a person, i.e., that person's "beings" and "doings." Resources, on the other hand, can be used to achieve certain functionings. These two concepts are different, as individuals may differ in how they convert resources into functionings. An analysis of well-being inequality using a broad set of functionings as the relevant space of well-being includes automatically the publicly provided services, insofar as they contribute to the functionings of the individuals. This approach seems natural in view of the discussions of this chapter. Yet, to the best of our knowledge, examples of this direct method to include publicly provided services into distributional analysis are scarce. Instead, a resource-based approach is standard practice in the literature. In this method, disposable income is extended with a monetary valuation of the publicly provided services. The resulting measure of extended income uses a monetary valuation of the external resources that individuals have at their disposal to obtain functionings and to reach well-being. The inspiration of this approach is therefore closely related to that of equivalence scales as described in the previous section.

In this section, we will first shortly survey the popular approach to extend disposable income with information on publicly provided services. Then we will discuss the issue of the valuation of public services and the adjustment for needs in view of the normative issues discussed in this chapter.[39]

2.5.2.1 The Extended Income Approach

The extended income approach consists of three steps. In a first step, one *selects* the government services to be included. Then, second, these services are *valued* at their production cost for the government. Finally, the value of the service is *allocated* to the beneficiaries based on their actual consumption or the insurance value, depending on the benefit at hand.[40] The obtained value of the monetary value of the publicly provided service is added to the disposable income of the household to obtain its extended income. The distribution of extended income is then analyzed with standard inequality measures.

Applying an extended income approach, the OECD flagship report "Growing Unequal?" (OECD, 2008; Chapter 8) has obtained the following findings. First, the inclusion of publicly provided services reduces income inequality within countries

[39] More extensive surveys can be found in Smeeding (1982), Marical et al. (2008), and Verbist et al. (2012). In this section we do not discuss intergenerational equity concerns involving publicly provided services (see Bourguignon and Rogers, 2007, however).

[40] The insurance value method is commonly used in the case of health care services, where the allocation is based on the average spending on the relevant age-sex group irrespective of the actual use that was made of the service. This method interprets health care as an insurance benefit received by all covered individuals. The value of the insurance benefit approximates an actuarially fair insurance premium assuming that all individuals with the same age-sex characteristics are paying the same premium.

because of their predominantly uniform character. Yet, this reduction is typically lower than the inequality reduction obtained by tax and cash benefits. Second, the differences in income inequality between countries are reduced as well, but the ranking of the countries with respect to extended income inequality remains similar to the ranking according to income inequality (affirming earlier findings of Smeeding et al., 1993).

The extended income approach has the advantage of being implementable for many countries. It requires income data that are readily available in standard household surveys and some additional macroestimates of the production cost of public services. Yet, in view of the normative issues raised in this chapter, the extended income approach appears to take an overly pragmatic view on the valuation of the contribution of publicly provided services to well-being.

2.5.2.2 Valuing Publicly Provided Services and Respect for Preferences

How a publicly provided service should be valued depends arguably on the purpose of the valuation exercise. Whereas valuing the benefit by means of its production cost may give a good estimate of its budgetary cost, this valuation method seems less appropriate for the purpose discussed in this chapter (i.e., an analysis of the distribution of individual well-being).[41]

An example illustrates why this is the case. Imagine that the value of publicly provided education benefits is determined by their production cost. An increase in the wages of teachers increases the production cost, but it seems counterintuitive to say that the value of the service for the recipients has increased *because* the production cost has increased. Indeed, this valuation method neglects the efficiency of the production process and potential quality differences between equally expensive services. A valuation by means of the production cost can therefore best be seen as an approximation when no other information is available. Alternative valuation methods have been proposed that are more closely related to the preferences of the population.[42]

A first alternative would be to use the *market value* of the public services rather than the production cost. Under some circumstances market prices may indeed give an indication of willingness-to-pay. Of course, this method can only be applied to the publicly

[41] Note that in an approach that values publicly provided services by the production costs, the measured productivity growth is always equal to zero (because productivity equals the ratio of output to input). The so-called Atkinson Review (see Atkinson, 2005; Pont, 2008) provides some general principles for an improved measurement of aggregate government output that captures productivity and quality improvements.

[42] See Smeeding (1982) for a more extensive survey. In the 1980s, the market valuation and cash equivalent valuation have played a central role in the computation by the U.S. Census Bureau of an "experimental" poverty measure for the United States, including the value of publicly provided services (Fisher, 1997). More recently, the production cost approach seems to have become the gold standard in the applied literature, as can be witnessed from the survey by Marical et al. (2008).

provided services for which a private market exists. For food stamps and social housing, for instance, the market value can either be inferred directly or obtained by a hedonic regression. However, the prices of privately provided services do not always reflect the valuation of the recipients either. Stiglitz et al. (2009, p. 99) give an example in the market for privately provided medical services where informational asymmetries disconnect market prices from marginal valuations and preferences.

A second alternative valuation method relies directly on the preferences of the recipients and measures the value of the publicly provided service by its so-called cash-equivalent. That is the amount of cash needed to induce an individual to forgo a particular publicly provided service (see, Smeeding, 1977, for instance). Insofar as the individual's own preferences (her own willingness-to-pay) are used to compute these cash equivalents, this method respects the same-preference principle. Figure 2.6 illustrates the cash-equivalent valuation method graphically in the income-health space. Consider two individuals, Alexandra and Benny, who are equally rich (their income equals OA on the graph). Alexandra is in better health than Benny (their health is respectively OG and OE). Both individuals receive publicly provided health services, without which Alexandra's health would be OF, whereas Benny's health would be only OD. It is clear from the figure that the publicly provided health services generate a larger increase in the health of Benny than they do for Alexandra. However, Benny cares relatively less about his health than Alexandra does (as Benny's indifference curve is "steeper"). Benny's cash equivalent for the health service is AB, as Benny is willing to forgo the publicly provided health service for an additional income of AB. Alexandra's cash equivalent, on the other hand, equals AC. Even if the health service generates a smaller health increase for Alexandra, her cash equivalent is larger, as she cares more about health than Benny does.

Estimating a cash equivalent requires additional information compared to the production cost approach. As illustrated by the preceding example, one needs to know the preferences of Alexandra and Benny because the magnitude of their cash equivalent is determined by the shape of their indifference map. To obtain the necessary information on preferences, the methods surveyed in Section 2.3 can be used, i.e., revealed preferences, stated preferences, and satisfaction data. The revealed preferences method seems to be favored in the applied literature. Typically, the preferences are derived from consumption behavior by means of an estimated system of demand equations (Slesnick, 1996; Smolensky et al., 1977). Life satisfaction data can also be used to estimate willingness-to-pay for publicly provided services. Levinson (2012), for instance, estimated the willingness-to-pay for air quality and computes the compensating variation for air pollution.

Typically the cash-equivalent method is not formulated in the space of functionings (or life dimensions), and it does not yield an overall measure of well-being that is based on a coherent ethical reasoning. We will come back to this issue in the following subsection. However, because it focuses on the individual willingness-to-pay, its inspiration remains

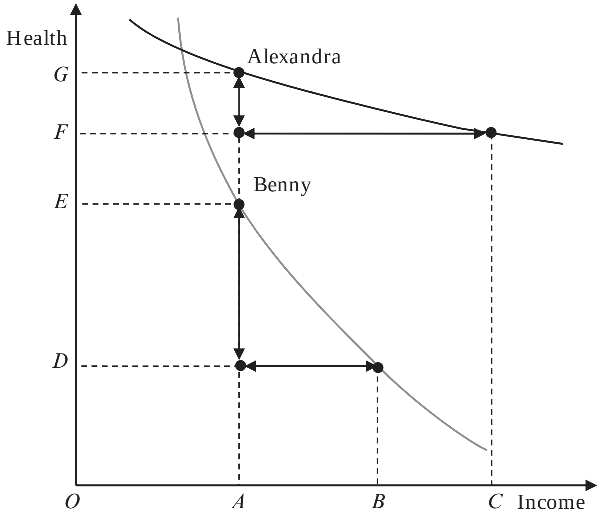

Figure 2.6 Cash equivalent income.

similar to that of the equivalent income approach to well-being as defined in Section 2.3.3. Other approaches reject completely the idea that individual preferences and willingness-to-pay provide the best guidelines to value publicly provided services.

Governments may provide these in-kind services exactly because they are inspired by paternalistic motives or by a concern about consumption externalities (see Currie and Gahvari, 2008, and the references therein for a detailed discussion). The paternalistic motivations reflect Musgrave's (1959) idea that some goods are merit goods, which leads to an immediate conflict with the idea of respecting individual preferences. A paternalistic government values the publicly provided services according to an objective valuation function, which requires arguably a perfectionist or objective theory of well-being. As suggested before, the gap between these two approaches may be bridged to some extent by introducing a distinction between informed and uninformed preferences.

2.5.2.3 Adjusting for Needs and Individual Responsibility

Because extended income focuses on the willingness-to-pay for the services, it does not at all take into account the functioning levels that the individuals would obtain in absence of any publicly provided service. This can be seen using Figure 2.7, depicting the functionings and indifference curves of Alexandra and Charlotte in the income-health space. Alexandra and Charlotte have the same income (OA) and obtain the same increase in their health from the publicly provided health services ($ED=FG$). Moreover they have the same preferences, so their cash equivalents are equal to AC.[43] Hence, the extended

[43] The argument does not depend on the choice for a particular valuation method for the publicly provided service.

income of both individuals is equal (OC). Consequently, when extended income would be used as a measure of well-being, both individuals would be considered as equally well off. Yet, no account is taken of the fact that the health levels that the individuals would obtain in absence of any publicly provided health service may be very different (Alexandra is in much better health than Charlotte, $OF > OD$). Radner (1997) illustrated a similar issue by showing how the well-being of elderly (Charlotte in Figure 2.7) would be overestimated as the value of publicly provided services is included in their extended income without taking account of their needs. This observation led Paulus et al. (2010, p. 263) to doubt whether results derived using the extended income approach can have a straightforward welfare interpretation.

This discussion echoes the distinction that was introduced in the previous section between welfare and situation comparisons. As a matter of fact, in the recent applied literature, the solution has been sought in adjusting the equivalence scales of the recipients for differences in needs.[44] Paulus et al. (2010) adopted a "fixed cost" approach, in which the needs of a recipient are assumed to be equal to a specific fixed monetary amount. In particular, it is assumed that the per capita amounts spent for age-specific population groups on public services accurately depict the corresponding needs of these groups. Under this assumption an equivalence scale for extended income can be inferred for each household. The authors then performed a sensitivity analysis of the inequality reducing

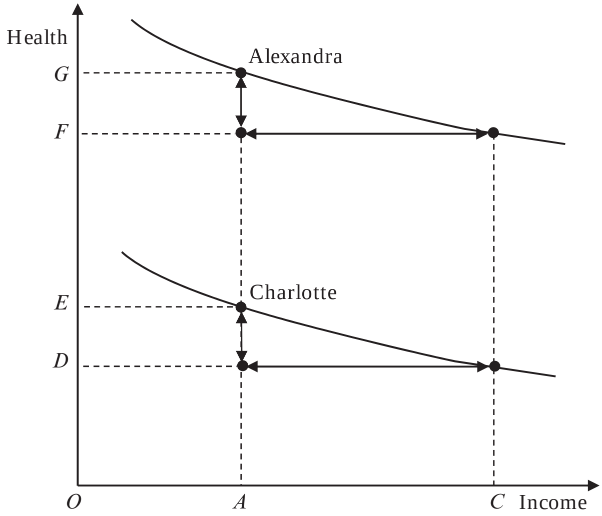

Figure 2.7 Cash equivalent income and needs.

[44] It should be noted that Smeeding et al. (1993) applied different equivalence scales to disposable income and the value of the publicly provided services. A standard equivalence scale based on household size and number of children is applied to disposable income. The publicly provided services received by the household, on the other hand, are distributed on a per capita basis over all its members.

effect of public services from changing the amount of received publicly provided services to the European average for the age-specific groups.

Aaberge et al. (2010) derived needs-adjusted equivalence scales consistent with their preferred allocation method of the production costs across target groups (i.e., a model of spending behavior of local governments). The equivalence scale for noncash income is obtained from the estimates of the relative needs of different target groups that are derived from the minimum expenditures identified in the spending model. Using data from Norway, they find that including publicly provided services reduces income inequality considerably, but that adjusting for needs offsets about half of the inequality reduction.

The method hinges on two strong assumptions on the interpretation of the spending model for the local governments (Aaberge et al., 2010, p. 552). First, the estimated minimum expenditures are to be interpreted as originating from an implicit consensus among local governments about how much spending the different target groups need minimally. Second, the functional form of the individual well-being measure derived from public services is assumed to coincide with the functional form used by local governments to decide the spending on public services. A priori, it seems hard to square such a (heroic) assumption with the idea of respecting individual preferences.

Both approaches to compute a needs-adjusted extended income rely on a two-step procedure. In a first step, the extended income is computed by adding a monetary value of the publicly provided services to the disposable income of the individual. Then, in a second step, these extended incomes are adjusted for differences in individual needs by means of an equivalence scale. A natural alternative would be to measure well-being directly in the desired space, i.e., functionings or capabilities themselves. For that purpose, a well-being measure should be developed along the lines described in Section 2.3 of this chapter. The relationship between these broader measures and the resource-based measures that are used now deserves a deeper exploration.

2.5.3 International Comparisons

The international comparison of living standards is fraught with many difficulties (see also Chapter 11). Because the focus in this literature has often been on comparing real incomes, we will first discuss the difficulties related to differences in prices for market commodities, and we will show how they are linked to the normative issues discussed in the previous sections. We will then show the relevance of introducing nonmarket dimensions into the evaluation of living standards.

2.5.3.1 PPP Indexes

International comparisons of living standards involve the search for price deflators that make it possible to compute comparable real incomes.[45] Pragmatic convenience

[45] Good introductions to this field are offered by Neary (2004), Deaton (2010), and Deaton and Heston (2010).

motivates approaches in which indexes are computed directly from prices and quantities, without depending on an estimation of consumer preferences. The theory of index numbers initiated by Fisher (1922) and developed by Diewert (1976, 1992a,b) is an important source of inspiration for such indexes. Pragmatic convenience also encourages seeking formulae that make the comparison of two countries independent of data from third countries.

Consistency is akin to transitivity in the comparison of real incomes, but a cardinal form of transitivity (involving orders of magnitude) appears desirable, not just an ordinal form. For instance, if Q_{ij} is a quantity index that compares real income in country i to country j, consistency is achieved when the chain relation $Q_{ij} = Q_{ik}Q_{kj}$ holds for every third country k. A popular way of achieving consistency computes real income as the value of quantities consumed at reference prices $\bar{p}$, so that $Q_{ij} = \bar{p}q_i/\bar{p}q_j$, where q_i is the vector of total consumption in country i.

All approaches have a connection with consumer preferences, but the conditions required are more or less restrictive, and the connection therefore more or less loose. There seems to be near consensus, in the PPP literature, that "in so far as data on real income have any meaning, it is that they provide an answer to the question: 'How well off would the same reference consumer be in different countries?'" (Neary, 2004, p. 1425). In other words, even if heterogeneous preferences may be the fact of the matter, there is no real attempt to formulate indexes that reflect this diversity of preferences. The main implicit underlying argument seems to be that ordinal preferences do not allow for interpersonal comparisons, unless arbitrary assumptions are made. In particular, money-metric utilities are not considered a possible option, although very similar notions are sometimes used, as explained later. This observation again suggests that the focus is not on welfare comparisons, but on situation comparisons.

Let us first briefly describe the two most popular PPP methodologies. The Eltetö–Köves–Szulc (EKS) quantity indices, used by the OECD and Eurostat are multilateral extensions of the Fisher index:

$$Q_{ij}^{\mathrm{EKS}} = \prod_{k=1}^{n}\left(Q_{ik}^{F}Q_{kj}^{F}\right)^{1/n},$$
$$Q_{ik}^{\mathrm{F}} = \sqrt{\frac{p_i q_i}{p_i q_k}\frac{p_k q_i}{p_k q_k}}.$$

They satisfy consistency in the form of the chain relation, but depend on third country data. They do not require estimation of preferences, and the link to consumer preferences is usually made by referring to Diewert's (1976) argument that the Fisher quantity index Q_{ik}^{F} is equal to the exact index $e(p_k, u(q_i))/e(p_k, u(q_k))$ of a flexible expenditure function $e(p, u)$, i.e., a function that approximates any twice differentiable expenditure function to the second order. Along a similar vein, Neary (2004) proved that Q_{ij}^{EKS} is equal to the ratio of utilities when utility is quadratic $u = \sqrt{q'Aq}$, for some suitably chosen symmetric matrix A. Again, a quadratic utility is a flexible form. These approximation results, however, are compatible with the index being sometimes wrong in the first order even for small changes—as must happen with any index that ignores preferences.[46]

Another popular approach, used by the U.N. International Comparison Project and the Penn World Table (PWT), relies on the Geary–Khamis (GK) indices, which compute PPP expenditures as the value of consumption at reference prices, $\bar{p}q_i$, and the reference prices are derived from the system

$$\bar{p}_k = \frac{\sum_i s_{ik}\bar{p}q_i}{\sum_i q_{ik}}, \tag{2.11}$$

where s_{ik} is the budget share of commodity k in country i. If one defines $\bar{s}_{ik} = \bar{p}_k q_{ik}/\bar{p}q_i$, one sees that the GK system can be written as

$$\sum_i \bar{s}_{ik}\bar{p}q_i = \sum_i s_{ik}\bar{p}q_i.$$

This approach obviously satisfies consistency. It depends on third country data, but only in the computation of $\bar{p}$. The link with consumer preferences is tenuous because $\bar{p}q_i$ provides a good index only for Leontief preferences (which would imply that all countries' consumption vectors should be proportional to one another). Neary (2004) then proposed, as a variant, to estimate world consumer preferences and substitute compensated demands q_i^* to actual quantities q_i for the computation of reference prices in system (11). Taking $\bar{p}q_i^* = e(\bar{p}, u(q_i))$ as the real income values is then truly faithful to the estimated preferences—but not necessarily to the population's actual preferences if they are heterogeneous, as noted in van Veelen and van der Weide (2008).

Interestingly, nothing in expression (11) as modified by Neary requires identical preferences, so that one could apply Neary's methodology to a population with country-specific estimated preferences, in which case the real incomes $\bar{p}q_i^* = e_i(\bar{p}, u_i(q_i))$ would be money-metric utilities at the country level. This idea is not considered in van Veelen and van der Weide (2008) or in the reply by Crawford and Neary (2008). As mentioned earlier, Fleurbaey and Blanchet (2013) proposed to take other reference prices for the computation of money-metric utilities, namely, prices $\bar{p}$ that maximize $\sum_i e_i(\bar{p}, u_i(q_i))/\sum_i \bar{p}q_i$. This minimizes the aggregate Gershenkron effect[47] and renders $\sum_i q_i^*$ proportional to $\sum_i q_i$.

van Veelen (2002) proved an impossibility theorem that is similar to the incompatibility between the personal-preference principle and the dominance principle discussed earlier in this chapter. This theorem says that there is no measure of real income (based on

[46] See Fleurbaey and Blanchet (2013, p. 95) for more details.

[47] The Gershenkron effect is the observation that the more p_i differs from $\bar{p}$ and q_i differs from q_i^* the more $\bar{p}q_i$ overestimates $\bar{p}q_i^* = e_i(\bar{p}, u_i(q_i))$.

prices and quantities in all countries) that is continuous, is not independent of prices, satisfies dominance ($q_i > q_j$ implies that real income is greater in i), and such that pairwise comparisons are independent of third countries.[48] The EKS and GK methods satisfy all conditions except the last one. A money-metric approach that estimates preferences on the same data may, in addition, fail to satisfy dominance in the case of heterogeneous estimated preferences. We know that this is a necessary consequence of respecting heterogeneous preferences.[49]

In a recent paper, Almas (2012) considers exploiting preference data by estimating budget coefficients with household surveys, but retains the assumption of identical preferences. Instead of estimating a complete system of demand functions to compute expenditure functions and money-metric utilities, she focused on food and assumed that the equation of food share, conditional on demographic characteristics, is the same everywhere. Estimating it with the PPP price indexes from the PWT, she included country dummies and assimilated these dummies to a bias in the PPP indices. This method relies on the assumption that preferences for food versus other goods are identical all over the world, and it is not indicative of welfare because incomes deflated with the corrected indices are *not* money-metric utilities for the AIDS model that is estimated.[50]

Deaton (2010) and Deaton and Heston (2010) studied the difficulties created by the fact that different countries in fact consume different lists of commodities, with great differences between countries with very unequal standards of living. The worst configuration would, of course, be the case in which every country consumes its own specific list, that has no intersection with the list of other countries. In this case, it is hard to imagine how to perform comparisons on the basis of observed market demand data. But even when all pairs of countries have a nonempty intersection of lists, the imperfect overlap creates difficulties. Practical methods that single out identical but often nonrepresentative goods appear unsatisfactory (a popular example, however, is the so-called Big Mac Index, published yearly by the *Economist*). Using proximate countries to compute chained indexes may lead to compounding errors as one compares distant countries. Deaton (2010) suggested that nondemand data, such as well-being questionnaires, may provide useful additional information for comparisons across countries. On the theory side, Fleurbaey and Tadenuma (2007) showed that imperfect overlap of commodity lists generates Arrow-like impossibility theorems, even if one only relies on the weak independence axiom stipulating that the evaluation of two allocations should only depend on

[48] See Quiggin and van Veelen (2007) for a further analysis of similar ideas.

[49] Note that if preferences were known on the basis of other data, then a money-metric approach with a fixed reference price would satisfy the last condition but would fail the price-dependence condition, as quantities would provide all needed information about welfare.

[50] In fact she does not estimate the AIDS model, but only the equation of food share in which the deflator of income is the PWT PPP index rather than the AIDS deflator.

preferences over the commodities that appear in either allocation. As a way out, they suggested focusing on lists of functionings that have a common set of core components, which is not very different from Deaton's suggestion to go beyond market data. Of course, these suggestions immediately bring us the more general topic of introducing nonmarket dimensions.

2.5.3.2 Nonmarket Dimensions

The recognition that living standards incorporate public goods of many sorts (e.g., the environment), as well as nonmarketed goods and "functionings" (e.g., health), has played an important role in the motivation to go "beyond GDP" not just for the evaluation of growth and public policy in a given country, but also in international comparisons. In fact, all three approaches that were reviewed in Section 2.3 have been applied in empirical work on intercountry comparisons.

The simplest approach consists in aggregating indices of the different dimensions of life into a single composite indicator. This approach follows the objective interpretation of the *capability approach*. The most popular example is the HDI that aggregates three indices (which are normalized between 0 and 1 from the range of achievements by the various countries of the world): national income, life expectancy, and education. Although the initial version of the index made a linear aggregation (UNDP, 1990) and therefore implied perfect substitutability between the dimensions, the geometric mean has recently been adopted to reflect the greater importance of a dimension when its level is low compared to the others (UNDP, 2010). In a variant of the new index, the average indices per domain can be adjusted for inequality, so as to make each index a geometric mean of individual achievements. In this fashion, the global index can then also be written as the geometric mean of individual Cobb–Douglas indexes, due to the following identity (where I_i, L_i, E_i denote income, life expectancy, and education for individual i):

$$\prod_i \sqrt[3]{I_i L_i E_i} \equiv \sqrt[3]{\left(\prod_i I_i\right)\left(\prod_i L_i\right)\left(\prod_i E_i\right)}.$$

This variant alleviates the criticism raised against specific composite well-being indicators, that they fail to take the correlations between the dimensions or cumulative deprivation into account as they start from dimension-by-dimension summary statistics (see Section 2.4). In the preceding formula, the same elasticity of substitution is applied in the aggregation across dimensions and across individuals, so that the sequencing of both aggregations does not matter. This makes the index impervious to correlations between dimensions. Moreover, the present version of the HDI is clearly an objective index which—according to some—implies troubling trade-offs between the dimensions (see Ravallion, 2012, for instance).

There are many composite indicators that mimic the HDI methodology.[51] Some focus on social issues, whereas others focus on sustainability issues. The key difficulty for such indices is the choice of the weighting system for the various dimensions. It is quite common to perform sensitivity analysis to ascertain the robustness of conclusions to the weights (Decancq and Ooghe, 2010; Foster et al., 2013), which boils down to a dominance analysis. Another approach is to give up the aggregate index altogether and immediately apply multidimensional inequality indices to the same data (Decancq et al., 2009). Of course, as we saw in Section 2.4, none of these approaches allows to respect international preference heterogeneity.

The *happiness approach* has also been used for international comparisons, although much of the literature on cross-country data has focused on the link between happiness and income (Deaton, 2008; Diener et al., 2010; Stevenson and Wolfers, 2008). The great variations in average satisfaction with life at any given level of income may reflect differences in nonmarket dimensions of life, but also cultural variations. Helliwell et al. (2010) studied a large sample of countries and derived two conclusions. First, nonmarket dimensions play a large role in econometric regressions of life satisfaction. Such dimensions include having a partner, being able to count on friends, having freedom to choose, not perceiving corruption around oneself, having been generous, and practicing religion. These dimensions play a role at the individual level, but for some of them the national average also plays a role (including healthy life expectancy, which is not observed at the individual level). The second conclusion is that once one incorporates these social dimensions in the analysis, in a single equation of satisfaction with the same coefficients for all countries, the difference between predicted and actual values for the average level of satisfaction per country is small for most countries and has no systematic pattern, with one exception: the Latin-American countries in general have a higher well-being than predicted.

However, the results of country and regional equations also show that the coefficients of income and social dimensions vary substantially, revealing that the association between life satisfaction and the various dimensions of life is heterogeneous over the world. One can suspect that interpersonal heterogeneity may be even more important. If the satisfaction equations can be interpreted as giving some evidence on population preferences, this raises the interesting issue of comparing the situations of populations with different preferences—an issue that has been central in this chapter. Helliwell et al. (2010) proposed to compute income equivalent variations via the ratios of coefficients of social dimensions over the income coefficient. This method is one of those that have been introduced in Section 2.3 to estimate preferences necessary to calculate equivalent incomes.

[51] Surveys can be found in Gadrey and Jany-Catrice (2006), Stiglitz et al. (2009), and Fleurbaey and Blanchet (2013).

The method of *income equivalent variations* has been used by Becker et al. (2005) to estimate the income growth that would have been equivalent to the observed increase in life expectancy for various countries of the world. Their main finding is that the large increase in life expectancy in developing countries, once converted into a monetary equivalent, produces a much rosier picture of world inequalities than standard income measures. They assumed homogeneous preferences in the world, and their estimation of preferences relied on U.S. data on revealed preferences about job risks.

A combination of equivalent variations and compensating variations has been used by Jones and Klenow (2010), with a preference relation similar to that used in Becker et al. (2005), but extending the list of nonincome dimensions to include leisure time and inequalities. Letting I and Q denote income and quality of life (life expectancy, leisure, inequalities) and V a utility function representing the preference ordering (assumed to be common across countries), the equivalent variation approach solves the following equation, for each country i:

$$V(I_i, Q_i) = V\left(\lambda_i^{\mathrm{EV}} I_{\mathrm{USA}}, Q_{\mathrm{USA}}\right),$$

while the compensating variation approach solves the equation

$$V(I_{\mathrm{USA}}, Q_{\mathrm{USA}}) = V\left(I_i/\lambda_i^{CV}, Q_i\right).$$

They then propose to take $\sqrt{\lambda_i^{\mathrm{CV}}\lambda_i^{\mathrm{EV}}}$ as the index for comparisons across countries. A difficulty with the compensating variation approach, as they implement it, is that one may have $V(I_i, Q_i) > V(I_j, Q_j)$ but $\lambda_i^{\mathrm{CV}} < \lambda_j^{\mathrm{CV}}$. This problem is avoided with their equivalent variation approach because $\lambda_i^{\mathrm{EV}} I_{\mathrm{USA}}$ is a money-metric index based on quality of life in the United States as the reference.

Compensating and equivalent variation approaches are in general problematic when they make references vary with the object of comparison. Money-metric indexes avoid that difficulty by taking a fixed reference. Fleurbaey and Gaulier (2009) adopted a money-metric approach for international comparisons of OECD countries, with nonincome dimensions including leisure, life expectancy, unemployment risk, household composition, and income inequalities. They allowed for heterogeneous preferences for leisure only and relied on the Becker et al. (2005) preference ordering otherwise. Although the approach is in theory compatible with heterogeneous preferences at the individual level and the computation of a distribution of equivalent incomes within each country, they only focused on average levels for each country. Decancq and Schokkaert (2013) calculated individual equivalent incomes on the basis of the life satisfaction data from the European Social Survey with as nonincome dimensions health, employment status, quality of social interactions, and personal safety. They introduced these equivalent incomes into a concave social welfare function and compared the social welfare of 18 European countries for the years 2008 and 2010, taking into account the distribution of individual well-being. The ranking of the different countries in terms of equivalent incomes is different from the ranking of countries in terms of income. A striking example is the dramatic fall in the well-being of Greece and Spain as a result of the economic crisis. Bargain et al. (2013) studied heterogeneous preferences over consumption and leisure in various European countries and the United States and computed several money-metric indexes for the analysis of welfare level and inequalities. In their analysis also, preference heterogeneity plays an important role in the welfare rankings.

2.6. CONCLUSION

Egalitarian thinkers are usually concerned about the distribution of well-being. Individual well-being depends not only on income but also on other dimensions of life, such as health, the quality of social relations and of the environment, employment, and job satisfaction. In this chapter we have surveyed the economic literature on how to construct such overall measures of well-being. We distinguished three approaches: the capability (and functionings) approach, the use of subjective life satisfaction measures, and the calculation of equivalent incomes. We argued that the choice of measure ultimately is a normative issue, and we discussed the normative assumptions underlying the measurement of individual well-being, focusing on two issues: the degree to which individual preferences are respected and where in each approach the boundaries of individual responsibility are drawn. The three approaches take a different stance on these issues. We also compared the measurement of inequality in well-being with the use of multidimensional inequality measures. The latter only fit in a perfectionist perspective, completely neglecting interpersonal preference differences.

In most of the applied work on inequality measurement the ambition is more limited. One keeps focusing on resource-based measures, which are then extended to include other considerations: household size and composition (and other needs) in the literature on equivalence scales, the value of publicly provided goods and services, or differences in prices in the contect of international PPP comparisons. In each of these cases one usually does not aim at constructing an overall measure of well-being. One neglects (respectively) the direct effects of family relations on well-being, the attainment of functionings as a result of the public provision of goods and services, and the effect of international preference heterogeneity. In all these three domains one focuses on situation rather than welfare comparisons. However, the most common approaches are not really satisfactory, even from this more limited perspective, and the proposals to improve on these existing measures (the construction of indifference scales, the use of subjective satisfaction information, the introduction of willingness-to-pay and differences in needs in the context of public service provision, the introduction of preference differences in international comparisons) move the approaches in the direction of the construction of more global well-being measures and use methods that have also been explored and developed for the latter purpose. In fact, in some cases, the informational requirements become similar. Analyzing the exact relationship between "extended (or corrected) incomes" and overall measures of well-being is a fruitful area for further research.

ACKNOWLEDGMENT

We are grateful to the editors and John Roemer, Tim Smeeding, Tom Trimpeneers, Aki Tsuchiya, Gerlinde Verbist, and Frederic Vermeulen for helpful comments and suggestions on an earlier version.

Abstract

This chapter examines different approaches to the measurement of multidimensional inequality and poverty. It first outlines three aspects preliminary to any multidimensional study: the selection of the relevant dimensions, the indicators used to measure them, and the procedures for their weighting. It

then considers the counting approach and the axiomatic treatment in poverty measurement. Finally, it reviews the axiomatic approach to inequality analysis. The chapter also provides a selective review of the rapidly growing theoretical literature with the twofold aim of highlighting areas for future research and offering some guidance on how to use multidimensional methods in empirical and policy-oriented applications.

3.1. INTRODUCTION

Few people would question that well-being results from many different attributes of human life, and the level of income, or expenditure, is only a crude proxy of the quality of living that a person enjoys.[1] Should we then account for the multiple facets of well-being in the social evaluation of inequality and poverty? If so, how can we do it?

Acknowledging the multidimensional nature of well-being does not necessarily imply that the social evaluation must also be multidimensional. Some argue that a single variable can still subsume all various dimensions of well-being. This is typically the case in the utilitarian approach, which employs a single indicator represented by "utility," or the level of well-being as assessed by individuals. Individuals themselves reduce the vector $\boldsymbol{x}$ of the different constituents of well-being to the level of utility $u(\boldsymbol{x})$. The social evaluation may then consider estimated utility levels as revealed by individuals, either directly through their answers to questions on subjective well-being and life satisfaction, as in the happiness literature,[2] or indirectly through their consumption patterns, as suggested by Jorgenson and Slesnick (1984a,b). Apart from requiring analytical restrictions (e.g., shape of indirect utility functions, integrability of demand functions), these approaches run into the difficulty that individual utilities must be assumed to be interpersonally comparable. Alternatively, the reduction of multiple dimensions to a single indicator can be

[1] Throughout the chapter, we interchangeably use terms such as "well-being", "quality of life," and "standard of living," without adopting any precise definition, except for the recognition of their multidimensional nature. The ensuing ambiguity is not a problem for our presentation, but it might be in a different context. For a discussion of this point, see the exchange between Williams (1987), Sen (1987), and Sen (1993). Likewise, we use terms such as "attributes," "dimensions," and "domains" to indicate the components of a multivariate notion of deprivation or well-being, although we acknowledge that, in certain areas of the literature on social indicators, they may be used to indicate different concepts.

[2] Well before the recent surge of interest in happiness research among economists, the "Leyden approach" to the measurement of poverty proposed exploiting the information on people's subjective evaluation of their own economic condition to identify poverty thresholds. See, for instance, Goedhart et al. (1977), van Praag et al. (1980), Danziger et al. (1984), van Praag et al. (2003), and van Praag and Ferrer-i-Carbonell (2008).

considered to be carried out by a social evaluator. This composite indicator would then represent a "utility-like function of all the attributes received," as put by Maasoumi (1986, p. 991), to which standard univariate techniques could be applied. Maasoumi suggests applying information theory to find the utility-like function with a distribution as close as possible to the distributions of the constituent attributes, but other approaches can lead to the definition of analogous individual-level functions. The common practice of adjusting household income for the household size and the age of its members by an equivalence scale is another example of this type of multidimensional analysis, for which command over resources (income) and individual needs (varying by age and living arrangements) are the two dimensions reputed to be relevant in assessing well-being. The chosen equivalence scale is assumed to represent the preferences of the social evaluator.

At the opposite extreme are those who argue, on philosophical or practical grounds, that dimensions must be kept distinct in the social evaluation. If well-being domains are characterized by specific criteria and arrangements, some might adhere to Walzer's (1983, p. 19) view of "complex equality" whereby "no citizen's standing in one sphere or with regard to one social good can be undercut by his standing in some other sphere, with regard to some other good." If inequalities in certain domains (e.g., basic life necessities or health) are less acceptable than they are in others (e.g., luxury goods), it might be justifiable to adopt a piecemeal approach informed by the "specific egalitarianism" advocated by Tobin (1970).[3] The intrinsic incommensurability of domains may then imply that "no simple ordered indicator of level of living can be constructed, either on an individual or on an aggregate level," as asserted by Erikson (1993, p. 75) in summarizing the Swedish approach to welfare research. Or, the need to avoid the "*ad hoc* aggregation" and the unexplained trade-offs between domains, which are implicit in any composite or "mashup" index, might advise us "to derive the best measure possible for each of a logically defensible set of grouped dimensions—such as 'income poverty,' 'health poverty' and 'education poverty'" (Ravallion, 2011a, p. 240; see also Ravallion, 2012a). In all these cases, the recognition of the inherent autonomy of each dimension, however motivated, leads to a piecewise social judgement that does not need any unitary measurement of human well-being. The elements of the vector $\boldsymbol{x}$ of the attributes of well-being are examined one by one, without attempting to reduce complexity by a summary index. It is the "dashboard" approach. The straightforwardness of this strategy is appealing, but it is tempered by the difficulty of drawing a synthetic picture, especially in the presence of a rich information set.

[3] Slesnick (1989) assesses how pursuing equalization in separate domains affects the inequality of overall utility (specific egalitarianism vs. general egalitarianism) by comparing the inequality of main consumption components with the inequality of total expenditure.

There are reasons to take an intermediate position between these two extremes, however. This may be because the above-described conditions for reducing well-being to a single variable may not hold: we might differ in our views about the appropriate equivalence scale or the weights to be placed on different goods, we might not have access to individual well-being measures, or we might reject the individual valuations altogether. Or, we may worry that the inequalities in different spheres accumulate and that the combination of multiple deprivations makes life much harder than just the sum of such deprivations. In these cases, we may need a social evaluation of poverty and inequality that is multidimensional and accounts for the joint distributions of all the elements of the vector $\boldsymbol{x}$ of well-being attributes.

Our aim in this chapter is to explore this intermediate route. We do not argue further whether we should or should not have a multidimensional social evaluation. We take it for granted, and we concentrate on how we can carry it out in a sound way. More precisely, we examine the analytical and ethical foundations of methods for the multidimensional measurement of inequality and poverty, whether it be for descriptive, normative, or policy-making purposes. All these methods require numerous arbitrary, and hence debatable, assumptions. Elucidating their foundations helps us to unveil these assumptions and understand their normative content. Taking this perspective, we pay little attention to the many multivariate techniques that have been developed in statistics and efficiency analysis. They provide valuable information, but their aggregation of multiple attributes is based on empirically observed patterns of association among the variables, and, thus, it lacks any clear ethical interpretation. We may legitimately hesitate to entrust a mathematical algorithm with an essentially normative task such as deriving an index of well-being.

The theoretical literature on the multidimensional measurement of inequality and poverty has been growing very rapidly in the last quarter of a century, and it is still far from consolidation. Rather than engaging in a systematic rationalization of this literature, we provide a selective reading of it with the twofold objective of, first, identifying areas worthy of further investigation and, second, offering some guidance on how to use the rich and sophisticated machinery now available for empirical and policy-oriented applications. As the multidimensional view of well-being has gained momentum in the policy discourse, its practical implementation has turned into an active battlefield where contenders passionately argue for opposing approaches—a good example being the Forum on multidimensional poverty in the 2011 volume of the *Journal of Economic Inequality* (see Lustig, 2011, for an introduction). We attempt to provide a balanced account of alternative positions, as well as their strengths and weaknesses.

The chapter is divided into three parts, plus a closing section. In the next section, we briefly review three questions that are preliminary to any multidimensional analysis of well-being: the selection of the relevant dimensions, the indicators used to measure them, and the procedures for their weighting. These questions are theoretically intriguing and of considerable importance in empirical analyses, but we only outline their main features. Importantly, the choice made with regard to these issues may condition the analytical methods reviewed later. For instance, the fact that many variables used in multidimensional poverty analysis are dichotomous suggests paying particular attention to methods based on counting deprivations. The assumption that inequality does not change after proportionate variations of the variable under examination (scale invariance) may be reasonable for income, but much less so for life expectancy, impinging on the axiomatic measurement of multidimensional inequality. We then move to the core of the chapter: the methods for the multivariate analysis of poverty, in Section 3.3, and of inequality, in Section 3.4. In the remainder of this introduction, we offer a brief account of the historical developments in the research summarized in these two sections, while providing a tour of the main themes discussed in the chapter.

3.1.1 Historical Developments and Main Themes

The multidimensional literature in economics began with seminal articles by Kolm (1977) and by Atkinson and Bourguignon (1982) on the dominance conditions for ranking multivariate distributions. A few years later, Atkinson and Bourguignon (1987) developed sequential dominance criteria for the bivariate space of income and household composition. Their aim was to impose weaker assumptions on social preferences than those implicit in the standard method of constructing equivalent incomes. Whereas the standard approach entails specifying how much a family type is needier than another one, sequential dominance criteria only require ranking family types in terms of needs, although at the cost of obtaining an incomplete ordering. This application paved the way for a specific and fertile strand of research which focuses on the possibility that one attribute (e.g., income) can be used to compensate for another nontransferable attribute (e.g., needs, health).

With the partial exception of Maasoumi (1986, 1989), who recasted multidimensional analysis into a unidimensional space by means of a utility-like function, it was not until the mid-1990s that Tsui (1995, 1999) moved on to the axiomatic approach to inequality indices in order to achieve complete orderings. The bases of the axiomatic analysis of partial and complete poverty orderings were laid down at about the same time by Chakravarty et al. (1998), Bourguignon and Chakravarty (1999, 2003, 2009), and Tsui (2002). Notably, multidimensional indices of inequality and poverty associate real numbers to each multivariate distribution, as does the univariate analysis of a composite well-being indicator, but with the important difference that they do not need to go through the aggregation of well-being attributes at the individual level. Thus, multidimensional poverty indices allow for separate thresholds for each attribute, while a utility-like indicator usually has a single threshold in the space of well-being. The trade-offs between the attributes that are built into the utility-like indicator used in the latter approach follow from the weighting structure of dimensions in the former approach.

At the turn of the twentieth century, the literature on multidimensional poverty and inequality was still in its infancy. The first volume of this *Handbook* (Atkinson and Bourguignon, 2000) did not feature any specific chapter on the topic, and the comprehensive analytical chapter on the measurement of inequality by Cowell (2000) devoted only three pages to multidimensional approaches. Ever since, the theoretical literature has grown conspicuously, however, and we can identify two main lines of research.

The first line devotes considerable effort to developing the axiomatic approach to both poverty and inequality measurement. Researchers delve into the different ways to model the patterns of association (correlation) between the variables, which is the single feature that distinguishes multidimensional from unidimensional analysis, and elaborate alternative axioms. They have also come to realize that a mechanical transposition of the properties typically adopted in the univariate analysis of income distribution may not be straightforward, and sometimes it may not even be appropriate. A case in point is the extension to life expectancy of the scale invariance property of inequality measures just mentioned. An even more cogent example is the Pigou–Dalton principle of transfers, a central tenet of income inequality measurement (Atkinson and Brandolini, forthcoming). This principle states that a mean-preserving transfer of income from a richer person to an (otherwise identical) poorer person decreases inequality. On the one hand, an interpersonal transfer might be unfeasible and even ethically debatable for a dimension such as the health status, despite being acceptable for income. On the other hand, the generalization of the principle to a multivariate framework is far from univocal, as explained in detail in Section 3.4.1.

The second line of research focuses on what Atkinson (2003, p. 51) labels the "counting approach." This multidimensional approach is at the same time the newest (in terms of theoretical elaboration) and the oldest (in terms of empirical practice). For example, the main poverty statistic adopted by a parliamentary commission of inquiry over destitution in Italy in the early 1950s was a weighted count of the number of households failing to achieve minimum levels of food consumption, clothing availability, and housing conditions (Cao-Pinna, 1953). Modern applied research on material deprivation owes much to the pioneering work by Townsend (1979) and Mack and Lansley (1985) in Britain.[4] Ever since the publication of their studies, it has had a huge

[4] Interestingly, Townsend's interest for elaborating a deprivation score was largely instrumental, being conceived as a way to reduce the arbitrariness of fixing income thresholds: "We assume that the deprivation index will not be correlated uniformly with total resources at the lower levels and that there will be a 'threshold' of resources below which deprivation will be marked" (Townsend, 1970, p. 29). There is by now an extensive literature on this subject. Some examples of studies for rich countries are Mayer and Jencks (1989), Federman et al. (1996), Nolan and Whelan (1996a,b, 2007, 2010, 2011), Whelan et al. (2001), Halleröd et al. (2006), Guio (2005), Cappellari and Jenkins (2007), Fusco and Dickes (2008), Fusco et al. (2010), and Figari (2012).

impact on the social policy debate in Ireland and the United Kingdom, and later in the European Union.[5] Nevertheless, we lack a full-fledged theoretical treatment of the normative basis of the counting approach. The recent work by Alkire and Foster (2011a,b) fills this gap, in part, by providing the axiomatic characterization of a family of multidimensional counting poverty indices. Yet, the difficulties illustrated by Atkinson (2003) in reconciling the counting approach with a social welfare approach are still unsettled. In our view, part of the problem may derive from defining welfare criteria in terms of the distributions of the underlying continuous variables rather than in terms of the distribution of deprivation scores, which is the key variable considered in the counting approach. The distribution of deprivation scores contains all the relevant information in the counting approach, which by construction implies neglecting levels of achievement in the original variables. Disagreement on this point, and on the implicit loss of information, might have some part in the recent controversies surrounding the counting approach.

The less developed analytical structure, in the face of the method's popularity in applied research, is the main reason for devoting a relatively larger space to the counting approach in this chapter. However, counting deprivations is also the simplest way to embed the association between individual-level dimensions into an overall index of deprivation. It is useful to illustrate two aspects of multidimensional measurement that recur throughout the chapter. The first is the order of aggregation. In the counting approach, the synthesis of available information begins with aggregation across single dimensions for each individual, and then across individuals. Inverting the order of aggregation by first computing the proportions of people suffering from deprivation in each dimension and then aggregating these proportions into a composite index of deprivation yields the same result only if the dimensions of well-being are "independent." If this is not the case, the composite index of deprivation misses the impact of cumulating failures in more than one dimension. The second aspect is the contrast between the "union criterion" and the "intersection criterion," which plays a

[5] Since 1997, the official poverty statistic adopted by the Irish government is "consistent poverty," which is the proportion of people who are both income-poor and deprived of two or more items considered essential for a basic standard of living (Social Inclusion Division, 2014). The British Child Poverty Act 2010 sets four policy targets, among which is a combined low income and material deprivation target (The Child Poverty Unit, 2014). One of the five European Union headline targets set by the Europe 2020 strategy for a smart, sustainable, and inclusive growth concerns the share of people "at risk of poverty or social exclusion" (European Commission 2010). This indicator combines income poverty, household joblessness, and severe material deprivation, with severe material deprivation occurring whenever a person lives in a household that cannot afford at least four out of nine amenities. For discussions of the use of indicators of material deprivation and, more generally, the multidimensional perspective adopted in the European Union's policy evaluation of social progress, see Atkinson et al. (2002), Marlier et al. (2007), Maquet and Stanton (2012), and Marlier et al. (2012).

fundamental role in the measurement of multidimensional poverty, as stressed by Atkinson (2003). The occurrence of deprivation in some dimensions does not necessarily entail a condition of overall poverty: we may define people to be poor when they are deprived in at least one dimension (union criterion) or in all dimensions (intersection criterion), or else in some fraction of the dimensions considered in the analysis. The choice of a critical number of dimensions to identify poverty status introduces an additional threshold relative to those already set for defining deprivation in each dimension, which is a central feature of the "dual cut-off" approach proposed by Alkire and Foster (2011a,b).

In Sections 3.3 and 3.4, we discuss first, the counting approach, then the axiomatic treatment of poverty, and finally, the axiomatic treatment of inequality. This sequence reflects the growing complexity of data requirements, rather than a chronological order. In this chapter we pay no attention to the assessment of data quality and the elaboration of inference tools, although they are admittedly two crucial issues in empirical analyses.

3.2. PRELIMINARIES: DIMENSIONS, INDICATORS, AND WEIGHTS

Three questions are preliminary to any discussion of the methods for the multivariate analysis of poverty and inequality: the selection of the relevant dimensions of well-being; the indicators used to measure people's achievements in these dimensions and the choice of deprivation thresholds in poverty analysis; and the weights assigned to each dimension. An in-depth examination of these issues is beyond the scope of this chapter, and our primary aim in this section is to highlight how these questions can influence the multivariate methods of analysis reviewed below. However, the actual solutions given to these questions may affect empirical findings and their substantive interpretation, and robustness and sensitivity exercises are advisable.

3.2.1 Selection of Dimensions

An established tradition of research in the study of deprivation postulates that we can better understand hardship by focusing on the individual's inability to consume socially perceived necessities because of a lack of economic resources, rather than focusing on income. Typically, this approach considers a battery of indicators concerning the ownership of durable goods; the possibility of carrying out certain activities, such as going out for a meal with friends; or the ability to cope with the payment of rent, mortgages, or utility bills. Material deprivation indicators have recently gained an official status in the monitoring of the social situation in the European Union, as well as in Ireland and the United Kingdom. The aim of the social evaluation may be broader than assessing material living conditions, however, and it may be concerned with "social exclusion."[6] According to Burchardt et al. (1999), social exclusion is associated with failures to achieve a reasonable living standard, a degree of security, an activity valued by others, some decision-making power, and the possibility of drawing support from relatives and friends. The variety of dimensions used to define the overall quality of life may be even larger. The Scandinavian approach to welfare, a long-established research program in Nordic countries, considers nine domains of human life: health and access to health care, employment and working conditions, economic resources, education and skills, family and social integration, housing, security of life and property, recreation and culture, and political resources (e.g., Erikson, 1993; Erikson and Uusitalo, 1986–87). Within the "capability approach," Nussbaum (2003) proposes a specific list of ten "central human capabilities": life; bodily health; bodily integrity; senses, imagination, and thought; emotions; practical reason; affiliation; other species; play; and control over one's environment. The Commission on the Measurement of Economic Performance and Social Progress, created at the beginning of 2008 under a French government initiative, identifies eight key dimensions: material living standards, health, education, personal activities including work, political voice and governance, social connections and relationships, environment (present and future conditions), and economic and physical insecurity (Stiglitz et al., 2009).

These examples illustrate the wide range and diversity of the domains considered in the multidimensional analysis of inequality and poverty. The choice of the dimensions that they include is mainly due to the advise of experts, possibly based on existing data, conventions, and statistical techniques.[7] It could also result from empirical evidence regarding citizen values, or it could be the product of a consultative process involving focus groups and representatives of the civil society or the public at large (Alkire, 2007). In all cases, the selection of poverty and income inequality indicators is a fundamental exercise, which has to blend theoretical rigor, political salience, empirical measurability, and data availability.

In this chapter, we simply assume that a predefined list of r attributes fully describes the well-being concept used in the analysis of poverty and inequality. We ignore all questions concerning the selection of attributes and refer the reader to Chapter 2 for a

[6] For a consideration of the somewhat elusive concept of social exclusion and its relationship with poverty, see Atkinson (1998). Ruggeri Laderchi et al. (2003) compare the empirical findings of social exclusion and capability approaches. Poggi (2007a,b) and Devicienti and Poggi (2011) empirically study the persistence of social exclusion, and Poggi and Ramos (2011) investigate the interdependency of the dimensions of social exclusion using stochastic epidemic models.

[7] For instance, Fusco and Dickes (2008) assume that poverty is a latent condition that can be identified by selecting the relevant domains from a set of deprivation indicators by applying a psychometric model.

comprehensive discussion.[8] Notice, however, that the nature of selected attributes may condition the definition of measurement tools. As noted in the introduction, we cannot mechanically export the Pigou–Dalton principle of transfers, which is central in income inequality analysis to other well-being dimensions, such as health (Bleichrodt and van Doorslaer, 2006), happiness (Kalmijn and Veenhoven, 2005), and literacy (Denny, 2002). Leaving aside the practical problem of how to transfer one unit of health from one person to another, we might doubt that imposing the principle of transfers in the health domain is ethically justified. We return to this issue in Section 3.4.1.

3.2.2 Indicators

The indicators used to measure people's achievements in the various dimensions are numerous and understandably have different measurement units. Incomes, wealth, and quantities consumed or purchased are continuous variables, but the number of durable goods owned and the frequency in the use of consumer services are discrete variables. Education can be measured by a categorical variable such as the highest school attainment of a person. Transforming it into the minimum number of years necessary to achieve each school level then provides an objective way to grade the various levels, but we might wonder whether a person who completed 14 years of school is really twice as well-educated as a person who only completed 7 years; moreover, only in a loose sense, can this type of transformed variable be interpreted as truly continuous. People's competencies and problem-solving capacity are increasingly assessed by complex exercises that produce literacy, numeracy, or skill scores generally normalized on a scale from 0 to 500. These scores are bounded, continuous, ordinal variables.[9] Individual health and physical status are measured with a host of indicators. Self-reported measures of health conditions are ordinal variables, but the information on the incidence of specific chronic illnesses is dichotomous; anthropometric indicators such as height, weight, and the body mass index are continuous variables. Subjective measures of well-being are typically collected by asking interviewees their personal degree of satisfaction on prefixed numerical scales or verbal rating scales often ranging from "not very happy" to "very happy." In either case, the outcome is an ordinal variable, which ranks the alternative

[8] The topic has attracted considerable attention within the literature on the "capability approach." See, among others, Sen (1985, 1992), Alkire (2002, 2007), Nussbaum (1990, 1993, 2003), Kuklys (2005), Robeyns (2005, 2006), and Basu and López-Calva (2011).

[9] Well-known examples are the Programme for International Student Assessment (PISA) for 15-year-old students and the Programme for the International Assessment of Adult Competencies (PIAAC), both coordinated by the Organisation for Economic Co-operation and Development (OECD). Micklewright and Schnepf (2007, p. 133) compare the cross-country inequality in learning achievement scores and call for caution in the use of the income inequality measurement toolbox, because "it is doubtful whether the measurement of the scores is on a ratio scale. Their nature is therefore quite different from that of data on income or height."

ratings without however providing any information on how much one rating is better, or worse, than another rating.

Cardinal continuous variables, such as income, probably represent a minority of available indicators of well-being. The application of measurement tools that are standard in income distribution analysis may hence need to be reconsidered if applied to nonmonetary domains.[10] This warning applies to, but is clearly not exclusive of, multidimensional analysis. One specific problem that arises in this context concerns the commensurability of the indicators when they are merged into a single index. It is generally tackled by employing procedures of standardization that, for instance, transform the original variable by taking its (normalized) distance from benchmark values (for some examples of these transformations, see Decancq and Lugo, 2013, p. 12). Alternatively, ordinal criteria might also be applied to quantitative variables (e.g., by classifying units according to the quantile to which they belong).[11] Irrespective of the specific procedure adopted, the transformation of the original values substantially affects the outcome.

Many variables are dichotomous, or binary, either by definition or after a comparison of individual achievement with some social norm: for instance, we may classify those deprived in housing conditions as all individuals living in households with less than one room per person, transforming the variable "room per person" into a binary one. The use of dichotomous variables is at the center of the counting approach examined below.

In poverty assessments, the choice of the indicators is intertwined with the definition of the respective deprivation thresholds. This problem parallels the problem for income or consumption in univariate analysis, with absolute, relative, subjective, and legal criteria being the main alternatives (e.g., Callan and Nolan, 1991). In multivariate analyses, these problems may be amplified by the consideration of intangible dimensions for which it is more contentious to identify minimum thresholds (Thorbecke, 2007). Similar to the univariate case, however, the binary distinction between a "bad state" and a "good state" may be too sharp because deprivation might occur by degrees. Moving along these lines, Desai and Shah (1988) focus on the distance of the individual achievements from modal values in each dimension, taken to represent the social norm, whereas the extensive

[10] Researchers are increasingly exploring the measurement of inequality when using qualitative ordinal variables, such as self-reported health status (e.g., Abul Naga and Yalcin, 2008; Allison and Foster, 2004; Bleichrodt and van Doorslaer, 2006; van Doorslaer and Jones, 2003) and happiness (e.g. Dutta and Foster, 2013; Kalmijn and Veenhoven, 2005). Cowell and Flachaire (2012) have axiomatically developed a class of inequality indices for categorical data, conditional on a reference point, which are based on the individuals' positions in the distribution. Zheng (2008) suggests that, when data are ordinal, stochastic dominance has limited applicability in ranking social welfare and no applicability in ranking inequality.

[11] Qizilbash (2004) discusses the sensitivity of empirical estimates of South African poverty to the transformation of indicators from cardinal to ordinal, using the Borda score, as well as to variation in the thresholds used to define deprivation.

literature on the "fuzzy sets approach" formalizes a continuum of grades of poverty by means of a "membership" function.[12] Such a membership function may assume any value between 0 and 1: the two extreme values indicate that a person is definitely nondeprived (0) or deprived (1), and all other values indicate partial membership in the pool of the deprived. The form of the membership function plays a crucial role in the construction of a fuzzy deprivation measure. Although largely seen as a distinct approach in the multivariate analysis of deprivation, there is nothing inherently multidimensional in the theory of fuzzy sets.

3.2.3 Weighting of Dimensions

Weights determine the extent to which the selected attributes contribute to well-being and the degree by which we can substitute one attribute for another, interacting with the functional form used to aggregate dimensions. This can be easily seen by defining individual well-being S_β as the weighted mean of order β of the achievements in the r dimensions, as suggested, for instance, by Maasoumi (1986),

$$S_\beta = \begin{cases} \left[\sum_{k=1}^{r} w_k x_k^\beta\right]^{1/\beta} & \beta \neq 0 \\ \prod_{k=1}^{r} x_k^{w_k} & \beta = 0 \end{cases} \tag{3.1}$$

where x_k is nonnegative and represents the level of attribute k, $k=1,2,\ldots,r$, and w_k is the corresponding weight. Notice that expression (3.1) turns into an index of deprivation if the r attributes measure hardship. The weights w_k and the parameter β jointly govern the degree of substitution between any pair of cardinal attributes. Indeed, the marginal rate of substitution between attributes b and a, which is the quantity of b that has to be given up in exchange for one more unit of a in order to leave well-being unchanged, is equal to:

$$MRS_{b,a} = \frac{\mathrm{d}x_{bi}}{\mathrm{d}x_{ai}} = -\left(\frac{w_a}{w_b}\right)\left(\frac{x_a}{x_b}\right)^{\beta-1}. \tag{3.2}$$

If $\beta=1$ well-being is simply the (weighted) arithmetic mean of the achievements in all dimensions, which are then perfectly substitutable at a rate equal to the ratio of their

[12] See Cerioli and Zani (1990), Cheli et al. (1994), Cheli (1995), Cheli and Lemmi (1995), Chiappero Martinetti (1994, 2000), Betti et al. (2002), Dagum and Costa (2004), Qizilbash and Clark (2005), Betti and Verma (2008), Betti et al. (2008), Belhadj (2012), and Belhadj and Limam (2012). Deutsch and Silber (2005), Pérez-Mayo (2007), and D'Ambrosio et al. (2011) compare empirical results for multidimensional measures of poverty based on the fuzzy sets approach with those derived from applying alternative approaches (axiomatic approach, information theory, efficiency analysis, latent class analysis). Kim (2014) studies the statistical behavior of fuzzy measures of poverty.

respective weights. In all other cases, the marginal rate of substitution also depends on relative achievements: the further away β is from 1, the more an unbalanced achievement in the two dimensions matters. When β goes to infinity (minus infinity), the attributes are perfect complements, and the well-being level depends on the highest (lowest) achievement, regardless of the values assigned to the weights.

The pattern of substitution among attributes can be more muddled than in (3.2) when the functional form of the well-being aggregator is more complex than (3.1), but it is bound to depend critically on weights, except in the extreme cases in which the attributes are perfect complements. The choice of weights might have a significant effect on the results of multidimensional analyses of inequality and poverty. For instance, Decancq et al. (2013) find that the identification of the worst-off in a sample of Flemish people is considerably influenced by the use of alternative weighting schemes of the attributes. In a comparison of the incidence of income-and-health poverty in selected European countries from 2000 to 2001, Brandolini (2009) finds that the ranking of Italy and Germany reverses as weights are shifted from one dimension to the other, although the ordering of France and the United Kingdom mostly remains unchanged. Here, we outline approaches to weighting by drawing on Brandolini and D'Alessio (1998), and we refer to Decancq and Lugo (2013) for a more comprehensive discussion.

A popular way of setting weights is to treat all attributes equally. This is the case with the Human Development Index, which assigns the same weight (one-third) to the three basic dimensions considered: a long and healthy life, access to knowledge, and a decent standard of living (e.g., UNDP, 2013). Equal weighting may result from either an "agnostic" attitude and a wish to reduce interference to a minimum or from the lack of information about some kind of "consensus" view. For instance, Mayer and Jencks (1989, p. 96) opt for equal weighting, after remarking that "ideally, we would have liked to weight [the] ten hardships according to their relative importance in the eyes of legislators and the general public, but we have no reliable basis for doing this." (In fact, there may be disagreement among the legislators and the public, let alone within the public itself.)

Some departure from equal weighting is envisaged by Atkinson et al. (2002) and Marlier and Atkinson (2010). They propose a set of principles for the design of social indicators for policy purposes, among which is the principle that the weights should be "proportionate," so that dimensions have "degrees of importance that, while not necessarily exactly equal, are not grossly different" (Marlier and Atkinson, 2010, p. 289). This criterion only sets some reasonable boundaries, without specifying how to define unequal weights.

The social evaluator can directly elicit the weighting structure from consultations with groups of experts or the public at large or from the importance assigned to dimensions of well-being by survey respondents, or the evaluator can indirectly generate the structure from estimates of happiness equations.[13] The last procedure is followed by Decancq et al. (2014) who characterize axiomatically a class of multidimensional poverty indices that are consistent with individual preferences in the aggregation of the different dimensions. In addition to standard axioms, they postulate principles for interpersonal poverty comparisons that lead to measuring individual poverty as a function of the fraction of the poverty line vector to which the agent is indifferent. The poverty threshold is therefore defined in terms of well-being using person-specific weights. In some exercises, users of statistics are allowed to build their own sets of weights. For instance, the OECD Better Life Index allows people to compare well-being across countries by means of eleven indicators of quality of life that can be rated equally or according to individual preferences (see Boarini and Mira D'Ercole, 2013 and the initiative's website http://www.oecdbetterlifeindex.org/). In all these cases, the choice of weights relies on some implicit or explicit normative criterion.

Under certain hypotheses, market prices provide weights that capture a trade-off between dimensions that is consistent with consumer welfare. Sugden (1993) and Srinivasan (1994) contend that the availability of such an "operational metric for weighting commodities" makes traditional real-income comparison superior in practice to Sen's capability approach. Ravallion (2011a, p. 243) argues that the main multidimensional poverty indices aggregate deprivations in a manner that "essentially ignores all implications for welfare measurement of consumer choice in a market economy. While those implications need not be decisive in welfare measurement, it is clearly worrying if the implicit tradeoff between any two market goods built into a poverty measure differs markedly from the tradeoff facing someone at the poverty line." On the other hand, market prices may be distorted by market imperfections and externalities, and they do not exist for many constituents of well-being and their imputation may be arduous, although various approaches estimate the "willingness to pay" in order to add the monetary value of nonincome dimensions to income (e.g. Becker et al., 2005; Fleurbaey and Gaulier, 2009; see Chapter 2). More importantly, they may be conceptually inappropriate for welfare comparisons, a task for which they are not devised (Foster and Sen, 1997; Thorbecke, 2007).

The main alternative and widely applied approach is "to let the data speak for themselves." Methods differ, but we may cluster them into two main categories: frequency-based approaches and multivariate statistical techniques. Since Desai and Shah (1988) and Cerioli and Zani (1990), many researchers assume that the smaller the proportion of people with a certain deprivation, the higher the weight that should be assigned to that deprivation, on the grounds that a hardship shared by few is more important than one shared by many. This approach raises two problems. First, it may lead

[13] See Decancq and Lugo (2013, pp. 24–26) for a discussion, and Bellani (2013), Bellani et al. (2013), Cavapozzi et al. (2013), Decancq et al. (2013), and Mitra et al. (2013) for some examples.

to a questionably unbalanced structure of weights. As observed by Brandolini and D'Alessio (1998), in 1995, the shares of Italians with low achievement in health and education were 19.5% and 8.6%, respectively. With these proportions, education insufficiency would be valued more than health insufficiency: one-tenth more according to Desai and Shah's formula, and over one-half more according to Cerioli and Zani's formula. Whether education should attain a weight so much higher than health is certainly a matter of disagreement. This criterion also makes the weights endogenous to the distributions being studied. Thus, it implies that we should take country-specific weights in an international comparison of multidimensional poverty, unless we impose a common, but arbitrary, set of weights. This observation also applies to the suggestions by Betti et al. (2008), who suggest taking weights proportional to the dispersion of the attributes in the population (adjusted for their bilateral correlations to avoid redundancy), and by Vélez and Robles (2008), who select weights that allow a set of multidimensional poverty measures to better track the dynamics of self-perceived well-being.

Several multivariate statistical techniques are employed to aggregate dimensions.[14] Maasoumi and Nickelsburg (1988), Klasen (2000), and Lelli (2005) use the analysis of principal components, on the grounds that this approach "... uncovers empirically the commonalities between the individual components and bases the weights of these on the strength of the empirical relation between the deprivation measure and the individual capabilities" (Klasen, 2000, p. 39, fn. 13). Schokkaert and Van Ootegem (1990), Nolan and Whelan (1996a,b), and Whelan et al. (2001) use factor analysis to aggregate elementary indicators into measures of well-being or deprivation. These papers tend to use this technique to identify few distinct constituents of well-being, however: as noted by Schokkaert and Van Ootegem (1990, p. 439–40), their application of factor analysis is "a mere data reduction technique," which does not provide any indication about the relative valuation of each attribute. Several authors apply latent variable models or structural equation modeling to collapse multiple indicators into indices of total or domain-specific deprivation (Ayala et al., 2011; Di Tommaso, 2007; Krishnakumar, 2008; Krishnakumar and Ballon, 2008; Krishnakumar and Nagar, 2008; Kuklys, 2005; Navarro and Ayala, 2008; Pérez-Mayo, 2005, 2007; Tomlinson et al., 2008; Wagle, 2005, 2008a,b). Dewilde (2004) uses a two-step latent class analysis, evaluating deprivation in specific domains in the first step and the latent concept of overall poverty in the second step. Lovell et al. (1994), Deutsch and Silber (2005), Ramos and Silber (2005), Anderson et al. (2008), Ramos (2008), and Jurado and Pérez-Mayo (2012) apply methods developed in efficiency

[14] For a discussion of applied multivariate techniques, see Sharma (1996). Moreover, see Ferro Luzzi et al. (2008), Pisati et al. (2010), Whelan et al. (2010), Lucchini and Assi (2013), and Caruso et al. (2014) for an application of cluster analysis to identify population subgroups homogeneous by well-being or deprivation level, and Hirschberg et al. (1991) for an analogous comparison across countries, as well as Asselin and Anh (2008) and Coromaldi and Zoli (2012) for an application of multiple correspondence analysis and nonlinear principal component analysis, respectively.

analysis to aggregate the various attributes of well-being. These methods allow estimating the level of individual achievement relative to the achievement frontier, providing implicit estimates of the values of the weights. In a related approach, Cherchye et al. (2004) construct a synthetic indicator to assess European countries' performance in achieving social inclusion, with weights being variable in order to provide the most favorable evaluation for each country. They contend that this approach preserves the "legitimate diversity" of countries in pursuing their own policy objectives, because a relatively better performance in a particular dimension is seen as revealing a policy priority.

The methods reviewed in the next sections generally allow for the possibility that weights can differ across dimensions in the social evaluation of poverty and inequality. Our brief overview suggests some ways to define them. Two comments are in order. First, multivariate statistical techniques differ from other approaches in that their aim is to estimate the level of individual achievement; weights are integral part of the aggregation procedure and have no truly independent meaning. We may then wonder whether it is appropriate to use them in conjunction with many of the methods discussed below. Second, as the weighting structure captures the importance assigned to each attribute, it is bound to reflect different views. On one side, this suggests questioning the use of techniques that may be robust from a statistical viewpoint but ignore the intrinsically normative aspect of the choice of weights. On the other side, it hints that one way to account for this plurality of views is to specify ranges of weights rather than a single set of weights, although this approach might lead to a partial ordering, as suggested by Sen (1987, p. 30; see also Foster and Sen, 1997, p. 205).[15]

3.3. MULTIDIMENSIONAL POVERTY MEASUREMENT

A long tradition in social sciences has been concerned with measuring material deprivation by looking at a number of indicators of living conditions, such as the ownership of durables or the possibility of carrying out certain activities such as going out for a meal with friends. The typical way to summarize the information has been to count the number of dimensions in which people fail to achieve a minimum standard, and, hence, this method is labeled the "counting approach." It represents the simplest way to embed the association between deprivations at the individual level into an overall index of deprivation.

In the counting approach, the synthesis of the available information begins with aggregating across the single dimensions for each individual, and then across the individuals themselves. However, we could invert the order of aggregation by computing the proportions of people suffering in each dimension and then aggregating these proportions into a composite index of deprivation. This different order of aggregation has the great advantage of allowing us to draw these proportions from various sources. This

[15] Cherchye et al. (2008) present a methodology that incorporates a range of weighting schemes in the ranking of vectors of attributes.

characteristic makes this "composite index" approach easily understandable and very popular, especially in public debates in which there is a need to summarize headline messages from sets of indicators. If the dimensions of well-being are independent of each other, the order of aggregation does not matter, and the two approaches are equivalent. However, if they are dependent and suffering from multiple deprivations has a more than proportionate effect on people's well-being, ignoring the impact of the association among the achievements in the various dimensions, as with the composite index approach, may imply overlooking an important aspect of hardship. This is not the case for an indicator such as severe material deprivation in the Europe 2020 strategy, because it would rank a society with one person suffering from four deprivations and three persons not suffering from any differently from a society in which four people fail in one dimension each.

The relationship between the two approaches can be better understood by considering the simple situation in which only two dimensions exist. Assume that X_k is equal to 1 if an individual suffers from deprivation in dimension k and 0 otherwise, with $k=1,2$. Let $p_{ij}=\Pr((X_1=i)\cap(X_2=j))$, $p_{i+}=\Pr(X_1=i)$, and $p_{+j}=\Pr(X_2=j)$. Then, assign equal weight to the two deprivation indicators and define the deprivation score $X=X_1+X_2$, which can take the values $(0,1,2)$ with associated probabilities (q_0,q_1,q_2). The parameters (q_0,q_1,q_2) of the count distribution X are determined by the parameters of the original two-dimensional simultaneous distribution in the following manner: $q_0=p_{00}$, $q_1=p_{10}+p_{01}$, and $q_2=p_{11}$. The original and derived distributions are summarized in Table 3.1.

If only the marginal distributions in the left panel of Table 3.1 were known, an overall poverty indicator P could be expressed as a function g of p_{1+} and p_{+1} only, that is $P=g(p_{1+},p_{+1})$, which is an example of a composite poverty index. If the simultaneous distribution was known, we could turn to the distribution of X in the right panel of Table 3.1, and the overall index could account for the number of deprivations that each individual suffers from. Counting deprivations highlights two possible ways of identifying someone as poor: either he fails in either single dimension ($X=1$), or he fails in both ($X=2$). In the first case, we adopt the union criterion: the poor are those with at least one deprivation and $P=g(1-p_{00})$. In the second case, we favor the intersection criterion: the poor are those with two failures and $P=g(p_{11})$. The contrast between union and

Table 3.1 The distribution of deprivations in two dimensions and the derived distribution of deprivations scores

	$X_2=0$	$X_2=1$	
$X_1=0$	p_{00}	p_{01}	p_{0+}
$X_1=1$	p_{10}	p_{11}	p_{1+}
	p_{+0}	p_{+1}	1

	$X=X_1+X_2$
$X=0$	$q_0=p_{00}$
$X=1$	$q_1=p_{10}+p_{01}$
$X=2$	$q_2=p_{11}$

intersection criteria plays a fundamental role in the measurement of multidimensional deprivation (see Atkinson, 2003). It also suggests that the occurrence of deprivation in some domains need not entail a condition of overall poverty: if we adopt the intersection criterion, only those with two failures are regarded as poor individuals, whereas those with only one failure are not. Setting a critical number of dimensions c, $1 \leq c \leq r$, to identify the poverty status introduces an additional threshold over those already set for defining deprivation in each dimension (see Alkire and Foster, 2011a,b). We return to this issue in Section 3.3.2.6.

The available information may be richer than the knowledge about the deprived/not deprived status in a number of dimensions, however. Rather than dichotomous, variables may be continuous or discrete with at least three categories. We may then want the overall poverty indicator to account not only for the occurrence of deprivation, that is, an individual achievement below the given dimension-specific threshold, but also for its intensity, that is, the shortfall of this achievement as compared to the threshold.

These observations illustrate that the reach of the informational basis conditions the multidimensional methods that can be used to measure poverty. When individual-level data on multiple attributes are not available, a composite index may be the only measure that can be calculated. When these data exist but are not publicly available, multidimensional poverty analysis may still be possible by using counting measures, if statistical offices release simple tabulations such as those discussed in the examples in Section 3.3.2. We use the complexity of informational needs as the criterion to organize the discussion of this section. We begin with the composite multidimensional poverty indices that only require information on the marginal distributions and can be estimated by gathering data from separate sources. All other multidimensional measures need an integrated database in which the information for each relevant dimension is available for each individual unit. We first consider counting measures that use minimal information: the distribution of the population by number of deprivations. With r dimensions, it is sufficient to know r values (the proportions of the population suffering from deprivation in $0, 1, \ldots, r$ dimensions). Although it is the oldest multidimensional approach in social sciences, the counting approach is arguably the least structured from a theoretical point of view, and we devote relatively more space to its examination. Due to its simplicity, the counting approach offers transparent illustrations of alternative aggregation methods, as well as the role of various normative rearrangement principles, and it helps to clarify the distinction between deprivation and poverty. Next, we turn to multidimensional poverty indices requiring the knowledge of individual achievements in each dimension. Lastly, we discuss criteria for partial ordering.

3.3.1 The Composite Index Approach

We can measure the overall poverty of a society by aggregating over the proportions of individuals suffering from deprivation in the r dimensions of well-being, whenever this is the only available information. A prominent example of this composite index approach is the Human Poverty Index (*HPI*), which was published by the United Nations Development Program from 1997 to 2009 (UNDP, 1997). As originally formalized by Anand and Sen (1997), a general version of the index with r dimensions, weighted by w_k, is defined by

$$HPI_\beta = \zeta_1(p_1, p_2, \ldots, p_r) = \left(\sum_{k=1}^{r} w_k p_k^\beta\right)^{1/\beta}, \tag{3.3}$$

where p_k is the proportion suffering from deprivation in dimension k (in the two-dimensional case of Table 3.1 $p_1 = p_{1+}$ and $p_2 = p_{+1}$), $\beta > 0$, and $w_k > 0$ for all k; if the r dimensions are equally weighted, $w_k = 1/r$. As β rises, greater weight is given to the dimension in which there is the most deprivation. UNDP (1997) paid particular attention to three dimensions related to longevity, knowledge, and a decent standard of living, and it later added a fourth dimension, social exclusion, for rich countries. In either case, β was set equal to 3 to give "additional but not overwhelming weight to areas of more acute deprivation" (UNDP, 2005, p. 342).[16]

Bossert et al. (2013) provide an axiomatic characterization of (3.3) for the case in which $\beta = 1$, based on the condition of additive decomposability in attributes as well as in individuals (see also Pattanaik et al., 2011). This case is of some interest: it assumes perfect substitutability among the components, and the index HPI_1 equals the weighted arithmetic mean of the headcount indices across all dimensions. This implies that people who suffer from k deprivations, with $0 \leq k \leq r$, are counted k times by the index HPI_1. Although rather crude and *ad hoc*, this is a simple way of giving heavier weight to people suffering from multiple deprivations. The implicit assumption is that the effect of deprivations is proportionate, however: suffering from two deprivations is twice as bad as suffering from one. If there are reasons to question this assumption, then the inability of *HPI*-type measures to discriminate between situations in which deprivations are concentrated on few people and situations where an identical total amount of deprivations is spread across many people represents a serious shortcoming.

Dutta et al. (2003) prove that composite indices can lead to the same conclusions as those that would be derived from aggregating first across dimensions and then across individuals only under very restrictive conditions on the aggregation functions. Namely, "the overall deprivation of an individual must be a weighted average of her deprivations [i.e., proportionate shortfalls relative to benchmark values] in terms of the different attributes, and society's overall deprivation must be a simple average of the overall deprivation levels of the different individuals in the society" (Dutta et al., 2003, p. 202). Both conditions may be debatable: the first because it implies that marginal rates of substitution between any pair of attributes are insensitive to the depths of deprivations; the second because it is liable to the same criticism leveled against the poverty gap by Sen (1976). Analogous

[16] Chakravarty and Majumder (2005) characterize a general family of deprivation indices that includes an index ordinally equivalent to *HPI* as a member.

results hold when the equivalence condition is set with respect to rankings rather than indices. Pattanaik et al. (2011) discuss further weaknesses of *HPI*-type measures.

Although composite indices may not be consistent with an approach that sees society's overall poverty as a function of individual poverty levels, as happens in standard welfare economics, they might be justified by taking a different set of ethical assumptions.

3.3.2 The Counting Approach

In many cases, we know more than the headcount poverty ratio for each dimension, and we observe how many people are suffering from deprivation in one dimension, two dimensions, and so forth. Counting the number of failures is well rooted in the analysis of deprivation in social sciences, but the characteristics of the underlying social judgments and the relationship with standard welfare approaches still need clarification. Atkinson (2003), for instance, draws a parallel between the difficulty of deriving dominance conditions in the counting case and the failure of the headcount poverty measure to satisfy the Pigou–Dalton principle of transfers in the one-dimensional case. However, this difficulty stems from defining welfare criteria in terms of the distributions of the underlying continuous variables across people rather than in terms of the distribution of deprivation scores. As the deprivation score counts the number of dimensions in which an individual fails to achieve the minimum standards, it is by definition a discrete variable ranging from 0 to the number of dimensions considered. The distribution of deprivation scores contains all the relevant information in the counting approach, which by construction implies neglecting levels of achievement in the original variables. Dominance conditions in the counting approach can be established following this line of reasoning. In this section, we discuss these conditions, and we show how they can yield counting measures that encompass those proposed by Atkinson (2003), Chakravarty and D'Ambrosio (2006), and Alkire and Foster (2011a,b).

As is standard in the counting literature, we assume that individuals might suffer from deprivation in r different dimensions, and then we sum the number of actual deprivations.[17] Let X_i be equal to 1 if an individual suffers from deprivation in the dimension i and 0 otherwise. Moreover, let

$$X = \sum_{i=1}^{r} X_i$$

[17] Cappellari and Jenkins (2007) observe that the practice of constructing raw deprivation sum-scores is "ubiquitous" but has weak theoretical foundations. They suggest that a promising alternative way to summarize multiple deprivations can rely on the item response modeling approach used in psychometrics and educational testing, although they find similar results in a comparison of the two approaches for British data.

be a random discrete variable with cumulative distribution function F and mean μ, and let F^{-1} denote the left inverse of F. Thus, $X=1$ means that the individual suffers from one deprivation, $X=2$ means that the individual suffers from two deprivations, and so on. We call X the deprivation count and F the deprivation count distribution. Furthermore, let $q_k = \Pr(X=k)$, which yields

$$F(k) = \sum_{j=0}^{k} q_j, \quad k = 0, 1, \ldots, r \tag{3.4}$$

and

$$\mu = \sum_{k=1}^{r} k q_k. \tag{3.5}$$

For the sake of simplicity, we are assigning equal weight to all dimensions, but this assumption can be relaxed (see Section 3.3.2.5).

In order to compare count distributions, we introduce appropriate dominance criteria to obtain partial orderings (Section 3.3.2.1) and complete orderings (Sections 3.3.2.2–3.3.2.4).[18] Although the multidimensional approaches discussed in Section 3.3.3 focus on the distribution of people's achievements, the dominance criteria formulated for the counting approach are defined in terms of the distribution F of the univariate discrete variable X.

3.3.2.1 Partial Orderings

As is standard in the income distribution literature, the first criterion regards first-degree dominance.[19]

Definition 3.1

A deprivation count distribution F_1 is said to first-degree dominate a deprivation count distribution F_2 if

$$F_1(k) \geq F_2(k) \quad \text{for all } k = 0, 1, \ldots, r$$

and the inequality holds strictly for some k.

If F_1 first-degree dominates F_2, then F_1 exhibits less deprivation than F_2. An example is given in Figure 3.1, in which we use the material deprivation indicators in five European countries in 2012 drawn from Eurostat (2014) and reported in Table 3.2. Figure 3.1 plots on the vertical axis the cumulative proportion of persons who suffer from

[18] Lasso de la Vega (2010) and Yalonetzky (2014) also identify dominance conditions to rank deprivation count distributions.

[19] The first-degree stochastic dominance relations for integer variables representing the counting of people achievements, rather than deprivations, are studied by Chakravarty and Zoli (2012).

deprivation in, at most, the number of dimensions indicated on the horizontal axis. (Figure 3.1 considers a maximum of seven deprivation items because nobody suffers from more than seven in the countries considered.) The left panel shows that Norway first-degree dominates both the United Kingdom and Italy, whereas the last two countries cannot be ordered by the criterion of first-degree dominance because their distributions intersect. The United Kingdom clearly lies ahead of Italy for up to five items, but then it exhibits a share of people suffering from six or seven deprivations that is more than twice the Italian level (1% vs. 0.4%, see Table 3.2). The right panel of Figure 3.1 shows that the cumulative distributions of deprivation scores for France and Germany also intersect, though they are much closer. The share of nondeprived is higher in Germany than in France, and the same holds true when we sequentially add those with one, two, and three deprivations; however, when we add people suffering from four deprivations, the order reverses, and it no longer changes when we consider more severe situations.[20]

This example shows that first-degree dominance might be too demanding in practice: where count distributions intersect, they can be ranked only by defining weaker dominance criteria. This implies that we have to impose stricter conditions on the preference ordering of the social evaluator, taking into account that, in the study of deprivation, we might be leaning toward either the intersection or the union criteria. In the former case, we would start aggregating "from above," looking first at the proportion of those who are deprived in r dimensions, then adding the proportion of those failing in $r-1$ dimensions, and so forth; in the latter case, we would start "from below." This distinction naturally leads to the definition of two second-degree dominance criteria, as suggested by Aaberge and Peluso (2011):

Definition 3.2A

A deprivation count distribution F_1 is said to second-degree downward dominate a deprivation count distribution F_2 if

$$\sum_{k=s}^{r} F_1(k) \geq \sum_{k=s}^{r} F_2(k) \quad \text{for all } s = 0, 1, \ldots, r$$

and the inequality holds strictly for some s.

Definition 3.2B

A deprivation count distribution F_1 is said to second-degree upward dominate a deprivation count distribution F_2 if

$$\sum_{k=0}^{s} F_1(k) \geq \sum_{k=0}^{s} F_2(k) \quad \text{for all } s = 0, 1, \ldots, r$$

and the inequality holds strictly for some s.

[20] In this example and in all subsequent empirical illustrations, we treat statistics as if they were exact, and we abstract from the fact that they are subject to sampling and other types of errors. Accounting for these errors would possibly lead us to conclude that neither the observed difference between France and Germany nor the upper tail intersection between France and Norway is statistically significant.

If F_1 second-degree dominates F_2, then F_1 exhibits less deprivation than F_2, as before, but this result is now obtained at the cost of imposing the stricter conditions on the preference ordering that will be shown below by Theorems 3.1A and 3.1B. Moreover, we have to make a choice between being more concerned with the extent to which deprivation is diffused across the population (union criterion) or the occurrence of multiple deprivations (intersection criterion). In the first case, we would adopt second-degree upward dominance. Intuitively, we can see this in Definition 3.2B from the fact that we are making comparisons on (doubly) cumulated population proportions that start by considering the share of people who do not suffer from any deprivation, $F(0)$, and we sequentially add the shares of those who suffer from one deprivation, then those who suffer from two deprivations, and so forth. In calculating the cumulative function we "go up." The opposite happens in the second case, for which we aggregate "going down," thus placing more weight on the most deprived. Formally, second-degree upward dominance parallels the dominance criterion used by Atkinson (1970) for ranking income distributions. Second-degree downward dominance has no correspondent in the income inequality literature, because it would be inconsistent with the Pigou–Dalton principle of transfers. It is, however, analogous to the criterion introduced for Lorenz curves by Aaberge (2009).

Is agreeing on whether to go up (union criterion) or to go down (intersection criterion) when we aggregate deprivation scores sufficient in empirical applications? Not always. This can be seen by reconsidering the previous comparisons of Italy and the United Kingdom, and of France and Germany, with neither country in each comparison found to first-degree dominate the other. In Figure 3.2, we plot the difference between the integrated cumulative distributions considered by Definitions 3.2A and 3.2B for each pair of countries. If we integrate going up as in Definition 3.2B, the United Kingdom and Germany second-degree (upward) dominate Italy and France, respectively: the lower proportions of people who do not suffer from any deprivation give the first two countries an advantage that is not offset by their worst results for the incidence of people deprived in many dimensions. On the other hand, if we integrate going down as in Definition 3.2A, the difference between the integrated cumulative distributions changes from positive to negative, and no country second-degree (downward) dominates the other in either comparison. The distribution of deprivation scores enables social evaluators favoring the union perspective to rank the United Kingdom and Germany ahead of Italy and France, but it does not allow social evaluators supporting the intersection perspective to draw unambiguous conclusions. In such a case, higher-degree criteria are needed, although they could still provide a partial ordering. The exploration of higher-order dominance criteria is a topic for further research. We turn instead to methods that can lead to a complete ordering.

3.3.2.2 Complete Orderings: The Independence Axioms

A complete ordering can be achieved by imposing an independence axiom for preference ordering. This allows us to weight differently certain parts of the distributions and eventually to define a summary measure of deprivation. Formally, let social preferences be

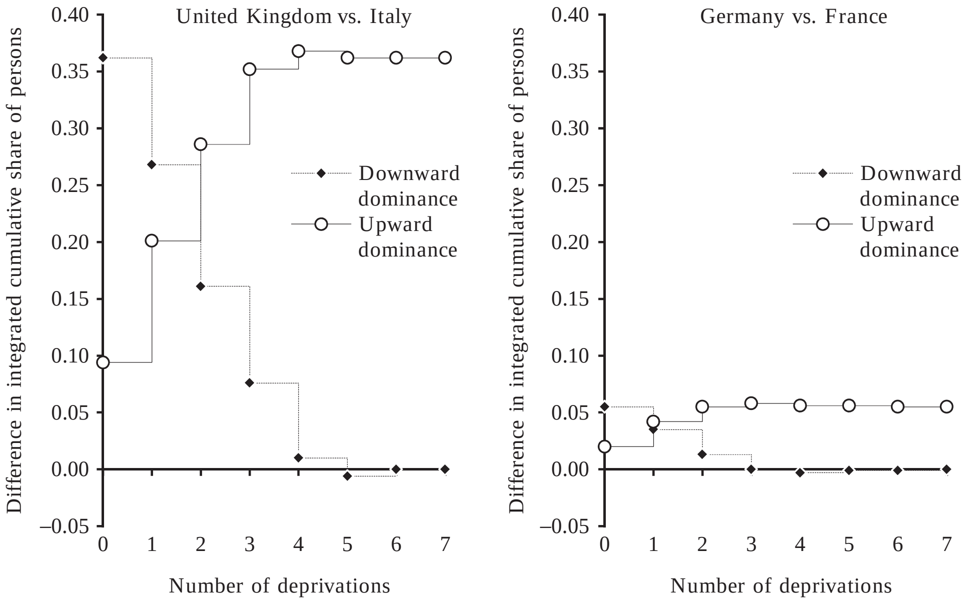

Figure 3.2 Second-degree dominance for material deprivation scores in selected European countries in 2012. *Source: authors' elaboration on data from Eurostat (2014).*

represented by the ordering $\succeq$ defined on the family of deprivation count distributions F. This preference ordering is assumed to be continuous, transitive, and complete and to satisfy the condition of first-degree count distribution dominance. As proved by Debreu (1964), a preference ordering that is continuous, transitive, and complete can be represented by a continuous and increasing preference functional. We need further conditions to give social preferences an explicit empirical content, however. We therefore introduce two alternative independence conditions, which require that the preference ordering is invariant with respect to certain changes in the count distributions being compared:

Axiom (Independence). *Let F_1 and F_2 be members of $\boldsymbol{F}$. Then $F_1 \succeq F_2$ implies $\alpha F_1 + (1-\alpha)F_3 \succeq \alpha F_2 + (1-\alpha)F_3$ for all $F_3 \in \boldsymbol{F}$ and $\alpha \in [0,1]$.*

This axiom focuses on the proportions of people suffering from given numbers of deprivations (the F). We could instead focus on the number of deprivations that is associated with a given proportion of people, that is, more technically, the rank in the count distribution (the F^{-1}). This corresponds to an alternative version of the independence axiom, as in the literatures on uncertainty and inequality:

Axiom (Dual Independence). *Let F_1 and F_2 be members of $\boldsymbol{F}$. Then $F_1 \succeq F_2$ implies $\left(\alpha F_1^{-1} + (1-\alpha)F_3^{-1}\right)^{-1} \succeq \left(\alpha F_2^{-1} + (1-\alpha)F_3^{-1}\right)^{-1}$ for all $F_3 \in \boldsymbol{F}$ and $\alpha \in [0,1]$.*

If F_1 is weakly preferred to F_2, then the independence axiom (similar to the expected utility theory) states that any mixture on F_1 is weakly preferred to the corresponding mixture on F_2: identical mixing interventions on the count distributions do not affect their ranking, which depends solely on how the differences between the mixed count distributions are judged. Thus, if the overall count deprivation is lower in country 1 than in country 2, so that $F_1 \succeq F_2$, the ranking would not change by adding to the population of either country the same group of migrants, whose deprivation distribution is F_3. The ordering relation $\succeq$ is therefore invariant with respect to the aggregation of subpopulations across deprivations.

The dual independence axiom shifts toward aggregating subsets of deprivation dimensions across proportions of people. Assume that there are only two deprivation indicators, income and health, and that two alternative tax and benefit regimes produce the two count deprivation distributions F_1 and F_2 for income. Next, match F_1 with the count deprivation distribution F_3 for health in such a way that the most deprived person in income is also the most deprived person in health, the second most deprived person in income is the second most deprived person in health, and so on. Match F_2 and F_3 in the same way. If the count deprivation distribution F_1 is preferred to F_2 for income, then the share of income-deprived people under regime 1 is lower than the corresponding share under regime 2. Dual independence means that, given any distribution F_3 of health deprivation counts, F_1 will continue to be preferred to F_2 after matching both F_1 and F_2 with F_3.[21] The dual independence axiom imposes this invariance property regardless of the shape of the count deprivation distribution for health (F_3) and of the weights used for such a matching (α).

The essential difference between the two axioms is that the independence axiom deals with the relationship between a given number of deprivations and weighted averages of the corresponding population proportions, but the dual independence axiom deals with the relationship between given population proportions and weighted averages of the corresponding numbers of deprivations. No one has so far provided a convincing justification for preferring one axiom to the other, but the choice of the axiom yields summary measures of deprivation with different decomposition properties. For instance, indices consistent with the independence axiom can be expressed as weighted averages of the corresponding indices computed for mutually exclusive population subgroups, whereas the indices satisfying the dual independence axiom cannot. By contrast, the dual measures offer a convenient decomposition by sources of deprivation, whereas the measures associated with the independence axiom cannot. Moreover, as measures of income

[21] This argument parallels the rationale offered by Weymark (1981, p. 418) for his "Weak Independence of Income Source" axiom: "if in two income distributions the incomes from all but one type of income are the same in both distributions, then the overall judgement that one distribution is more unequal than a second is completely determined by a comparison of the distributions of income from the variable source." Gajdos and Weymark (2005) call the corresponding multidimensional condition "Weak Comonotonic Additivity."

inequality, they have the convenient property of being expressed as linear functionals of the Lorenz curve, whereas the primal measures cannot.

The "primal approach," based on the independence axiom, is analogous to the inequality framework developed by Atkinson (1970), and it parallels the discussion of the headcount curves by Aaberge and Atkinson (2013). The "dual approach," based on the dual independence axiom, is analogous to the rank-dependent measurement of inequality introduced by Weymark (1981) and Yaari (1988) and to the way to summarization of the informational content of Lorenz curves by Aaberge (2001). In what follows, we draw on Aaberge and Peluso (2011) for the dual approach and Aaberge and Brandolini (2014) for the primal approach.

3.3.2.3 Complete Orderings: The Dual Approach

The dual independence axiom can be used to justify the following family of deprivation measures

$$D_\Gamma(F) = r - \sum_{k=0}^{r-1} \Gamma\left(\sum_{j=0}^{k} q_j\right) = \begin{cases} \mu + \Delta_\Gamma(F) & \text{when } \Gamma \text{ is convex} \\ \mu - \Delta_\Gamma(F) & \text{when } \Gamma \text{ is concave} \end{cases}, \tag{3.6}$$

where

$$\Delta_\Gamma(F) = \begin{cases} \sum_{k=0}^{r-1}\left[\sum_{j=0}^{k} q_j - \Gamma\left(\sum_{j=0}^{k} q_j\right)\right] & \text{when } \Gamma \text{ is convex} \\ \sum_{k=0}^{r-1}\left[\Gamma\left(\sum_{j=0}^{k} q_j\right) - \sum_{j=0}^{k} q_j\right] & \text{when } \Gamma \text{ is concave} \end{cases}, \tag{3.7}$$

and Γ, with $\Gamma(0)=0$ and $\Gamma(1)=1$, is a nonnegative, nondecreasing continuous function. Because F denotes the distribution of the deprivation count, $D_\Gamma(F)$ can be treated as a summary measure of deprivation exhibited by the distribution F. It can be seen as the social evaluation function corresponding to the social preference relation that identifies the most favorable distribution F with the one that minimizes $D_\Gamma(F)$. These social preferences are shaped by the specification of the function Γ, which can be considered as a deprivation intensity function. $D_\Gamma(F)$ can be decomposed into the mean number of deprivations, μ, and a term that captures the dispersion of deprivations across the population, Δ_Γ. By definition, Δ_Γ is always nonnegative and measures left-tail heaviness (left-spread) when Γ is concave and right-tail heaviness (right-spread) when Γ is convex. It follows that $\mu \le D_\Gamma(F) \le r$ when Γ is convex, and $0 \le D_\Gamma(F) \le \mu$ when Γ is concave. If Γ is convex, the minimum value μ of $D_\Gamma(F)$ is attained when $\Delta_\Gamma(F)=0$, that is, when each individual suffers from the same number μ of deprivations. If everybody suffers from all r deprivations, $\Delta_\Gamma(F)$ still equals 0, but $D_\Gamma(F)$ reaches its maximum value r. Conversely, $\Delta_\Gamma(F)$ is at a maximum when half of the population does not suffer from any deprivation and the remaining half suffer from all, so that $D_\Gamma(F)=r[1-\Gamma(0.5)]$. The comparison between the last two cases illustrates how the index works: a situation in which everybody suffers from r deprivations is definitely worse than one where only half of the population suffers from r deprivations. But the extent to which the two situations are valued differently depends on the convexity of Γ: the more convex it is, the more weight we give to multiple deprivations, and the closer $D_\Gamma(F)$ is to r. A similar reasoning applies, *mutatis mutandis*, for concave Γ.

Expression (3.6) shows that an exclusive concern for the mean number of deprivations implies linear (both convex and concave) social preferences: $\Gamma(t)=t$. There is indifference between a situation in which s people have one deprivation and a situation in which only one person is deprived but in s dimensions. It is the same result that we would obtain by applying the composite index approach discussed in Section 3.3.1, and it is another way to appreciate the restrictions imposed on social preferences in that approach. When there is a concern for the distribution of deprivations across the population, the critical judgement is whether this concern should prioritize the intensity or the diffusion of deprivations. In the former case, social preferences pay more attention to one person with s deprivations than to s people with one deprivation each, and the measure D_Γ should embody a convex Γ. In the latter case, social preferences take the opposite stance, and the measure D_Γ should embody a concave Γ. With Γ concave, for a given μ, D_Γ decreases as Δ_Γ increases because the distribution of deprivations across the population shifts towards people with none or fewer deprivations or, in other words, to the left tail of the distribution.

Thus, there is a correspondence between convexity and the intersection criterion on one side and between concavity and the union criterion on the other. This can be seen by taking particular specifications of the function Γ. With the union criterion, the focus is on the proportion of people who suffer from deprivation in at least one dimension $(1-q_0)$. By specifying Γ as

$$\Gamma(t)=\begin{cases} q_0 & \text{if } t=q_0 \\ 1 & \text{if } q_0<t\leq 1 \end{cases}, \tag{3.8}$$

we get $D_\Gamma(F)=1-q_0$, which means that the union measure can be considered as a limiting case of the D_Γ-family of deprivation measures in the concave case. With the intersection criterion, the focus is on the proportion of people deprived in all dimensions (q_r). The following alternative specification for Γ,

$$\Gamma(t)=\begin{cases} 0 & \text{if } 0\leq t<1-q_r \\ 1-q_r & \text{if } 1-q_r\leq t\leq 1 \end{cases}, \tag{3.9}$$

yields $D_\Gamma(F)=r-1+q_r$, which means that the intersection measure also represents a limiting case of the D_Γ-family of deprivation measures in the convex case. Although the union and intersection measures do not belong to the D_Γ-family, which is generated by continuous Γ functions, they can be approximated within this class (see Le Breton and Peluso, 2010, for general approximation results).

A Gini version of the measure of deprivation D_Γ can be obtained by taking $\Gamma(t) = 2t - t^2$ (concave) or $\Gamma(t) = t^2$ (convex), so that Δ_Γ equals the Gini mean difference. A general family of deprivation measures associated with the Lorenz family of inequality measures (Aaberge, 2000) is obtained by using the specification $\Gamma(t) = t^\tau$ for which the parameter $\tau > 0$ captures the concern for deprivation inequality, paying more attention to the lower tail when $0 < \tau < 1$ and to the upper tail when $\tau > 1$ (Aaberge and Peluso, 2011).

3.3.2.4 Complete Orderings: The Primal Approach

The independence axiom provides a justification for the following alternative family of deprivation measures,

$$d_\gamma(F) = \sum_{k=0}^{r} \gamma(k) q_k = \begin{cases} \gamma(\mu) + \delta_\gamma(F) & \text{when}\,\gamma\,\text{is}\,\text{convex} \\ \gamma(\mu) - \delta_\gamma(F) & \text{when}\,\gamma\,\text{is}\,\text{concave} \end{cases}, \tag{3.10}$$

where

$$\delta_\gamma(F) = \begin{cases} \displaystyle\sum_{k=0}^{r} (\gamma(k) - \gamma(\mu)) q_k & \text{when}\,\gamma\,\text{is}\,\text{convex} \\ \displaystyle\sum_{k=0}^{r} (\gamma(\mu) - \gamma(k)) q_k & \text{when}\,\gamma\,\text{is}\,\text{concave} \end{cases}, \tag{3.11}$$

and $\gamma(k)$, with $\gamma(0) = 0$, is a nonnegative, non-decreasing continuous function of the number of deprivations k. As with Γ in the dual case, γ can be considered as a deprivation intensity function with a curvature that determines how much we dislike increasingly severe deprivations in the convex case or growingly diffuse deprivations in the concave case. This family of deprivation measures is analogous to the family of inequality measures introduced by Kolm (1969) and Atkinson (1970). Chakravarty and D'Ambrosio (2006) provide an alternative axiomatic justification of (3.10) with a convex γ for measuring social exclusion.[22]

[22] Unlike the discussion in this section, Chakravarty and D'Ambrosio (2006) focus on the distribution of deprivation scores across people rather than on the distribution of deprivation scores itself. They also prove that second-degree downward dominance implies a convex γ and is preserved under a "favorable composite change," which is an intervention principle that is closely related to the Pigou–Dalton principle of transfers. This principle differs from the association-rearrangement principles motivated by the measurement of multidimensional poverty and discussed in Section 3.3.2.5. The index characterized by Bossert et al. (2013) is a special (linear) case of Chakravarty and D'Ambrosio's social exclusion measure. In a related paper, Bossert et al. (2007) use the counting approach to derive a further measure of social exclusion. They define axioms such that the degree of deprivation of an individual is proportional to the product of the share of people who suffer from fewer deprivations than he does and the mean difference between his deprivation score and that of all people who are better off: summation of these individual functions across individuals and then over time yields the aggregate deprivation and social exclusion indices, respectively.

As in the dual case, the primal measures $d_\gamma(F)$ can be considered as a social evaluation function for which preferences favor the count distribution F that minimizes $d_\gamma(F)$. The primal measures $d_\gamma(F)$ can be decomposed into a first term that is a transformation of the mean μ and a second term $\delta_\gamma(F)$ that measures the left- or right-tail heaviness when γ is concave or convex. By inserting $\gamma(k)=2rk-k^2$ (concave) and $\gamma(k)=k^2$ (convex) in (3.11), the term $\delta_\gamma(F)$ equals the variance. When $\gamma(k)=k$ for all k, $d_\gamma(F)=\mu$ and only the mean matters: social preferences ignore the dispersion of deprivations.[23] When the dispersion matters, as in the dual case, the judgement depends on whether social preferences give more weight to s people with one deprivation each or to one person with s deprivations, which means choosing a concave function γ in the first case and a convex function in the second. Indeed, the union criterion is a limiting case of the d_γ -family of deprivation measures for concave γ, and the intersection criterion is a limiting case for convex γ.[24] With a concave γ, the dispersion term is subtracted from the (transformed) mean and $0 \le d_\gamma(F) \le \gamma(\mu)$, whereas with a convex γ, the opposite happens, and $\gamma(\mu) \le d_\gamma(F) \le \gamma(r)$.

Unlike the dual measures, the primal measures are exactly decomposable by population subgroups, in the sense that the index computed for the overall population equals the weighted average of the measures calculated for each subgroup, with weights equal to the respective population shares of the subgroups. Note, that the dual measures may admit a different decomposition into within-group and between-group components, however, along the lines suggested by Ebert (2010).

The measure d_γ generalizes the counting measure proposed by Atkinson (2003, p. 62) for a bivariate distribution ($r=2$). Atkinson's measure A_θ can be written as

$$\begin{aligned} A_\theta &= 2^{-\theta}\left[p_{1+}+p_{+1}+2\left(2^{\theta-1}-1\right)p_{11}\right] = 2^{-\theta}(p_{1+}+p_{+1})+\left(1-2^{1-\theta}\right)p_{11} \\ &= 2^{-\theta}q_1+q_2, \end{aligned} \tag{3.12}$$

by making use of the notation of Table 3.1 and after dividing through the original formula by 2^θ. We can obtain (3.12) from (3.10) by inserting $\gamma(k)=(k/r)^\theta$ and $r=2$. The parameter θ varies from 0 to infinity and is introduced by Atkinson to capture alternative views on the importance of multiple deprivations. (Strictly speaking, both extreme values

[23] As seen, both D_Γ and d_γ can coincide with the mean μ for certain specifications of social preferences ($\Gamma(t)=t$ and $\gamma(k)=k$). From the proof of Theorem 5 in Aaberge (2001), it follows that the mean is the only measure of deprivation that satisfies both the independence and the dual independence axioms. Thus, the independence and the dual independence axioms provide, together with the conditions of transitivity, completeness, continuity, and first-degree dominance, a complete axiomatic characterization of the mean μ. In the alternative axiomatic justification for the mean offered by Bossert et al. (2013), two conditions of subgroup decomposability play a similar role as the two independence axioms.

[24] This can be seen by approximating the concave function γ with $\gamma(k)=1$ for $k=1,2,\ldots,r$ and the convex function γ with $\gamma(k)=0$ for $k=1,2,\ldots,r-1$ and $\gamma(r)=1$, which yield $d_\gamma(F)=1-q_0$ and $d_\gamma(F)=q_r$, respectively.

are inconsistent with the assumed continuity of the function γ, and they should be seen as limiting cases.) When $\theta \to 0$, the index counts all people with at least one deprivation, regardless of their number for each individual: $A_0 = p_{1+} + p_{+1} - p_{11} = q_1 + q_2$. When $\theta = 1$, people with two deprivations are counted twice and A_1 gives the simple mean of the headcount rates in the two dimensions, providing the same result as would be generated with a composite index. As θ goes to infinity, the index tends to coincide with the proportion of people deprived on both dimensions: $A_\infty \to p_{11}$. As the original Atkinson's counting deprivation index, its generalization to more than two dimensions obtained by inserting $\gamma(k) = (k/r)^\theta$ in (3.10) embodies, as limiting cases, both the union criterion (A_0) and the intersection criterion (A_∞). This index characterizes a family of deprivation measures that may be seen as the analog of the poverty measures proposed by Foster et al. (1984), referred to as the *FGT* measures.

The decomposition of the primal and dual measures of deprivation in terms of mean (or transformation of the mean) and dispersion of the deprivation count distributions parallels the mean-inequality decomposition of the social welfare functions derived from the expected and rank-dependent utility-like theories (see Atkinson, 1970; Yaari, 1988). Unlike the income inequality analysis, the structure of the decomposition of the deprivation measures depends on whether social preferences are associated with the union or the intersection criterion, however. In the former case, the deprivation measures fall and social welfare rises when the dispersion of deprivation across the population goes up, meaning that more people are affected by few or no deprivations. Even though they allow for the decomposition in terms of mean dispersion of deprivation, the primal and dual summary measures are silent about the role played by each dimension. Thus, the information provided by these summary measures should be complemented with estimates of the proportions of people who suffer from deprivation in each of the dimensions. This information reveals whether deprivation is concentrated on few or many dimensions.

Table 3.3 shows the estimates for some deprivation indices for the five European countries considered earlier. (Some indices are discussed in the next sections.) As regards dual measures, we consider the class of indices associated with the Lorenz family of inequality measures,

$$D_\tau^{\mathrm{GG}} = r - \sum_{k=0}^{r-1} \left(\sum_{j=0}^{k} q_j \right)^\tau$$

for various values of the parameters τ. For $\tau = 2$, the previous expression gives the convex version of the Gini-type measure of deprivation, and the concave version is given by:

$$D_2^{G,\,\mathrm{concave}} = 2\mu - r + \sum_{k=0}^{r-1} \left(\sum_{j=0}^{k} q_j \right)^2 = 2\mu - D_2^{\mathrm{GG}} = 2\mu - D_2^{G,\,\mathrm{convex}}.$$

Table 3.3 Indices of material deprivations in selected European countries in 2012

Index		Germany	France	Italy	United Kingdom	Norway	Germany versus France (1)	United Kingdom versus Italy (1)

In regard to primal measures, we consider the generalized Atkinson-type class of indices

$$d_\theta^{\mathrm{GA}} = r^{-\theta}\sum_{k=1}^{r} k^\theta q_k$$

for various values of the parameters θ. For $\theta=1$, the previous expression gives the mean headcount ratio, which equals the ratio μ/r. For $\theta=2$, it coincides with the convex version of the variance-type measure of deprivation $d_2^{V,\mathrm{convex}}$ multiplied by r^{-2}, and the concave version ($\gamma(k)=2rk-k^2$) is given by:

$$d_2^{V,\mathrm{concave}} = 2r\mu - \sum_{k=1}^{r} k^2 q_k = 2r\mu - r^2 d_2^{\mathrm{GA}} = 2r\mu - d_2^{V,\mathrm{convex}}.$$

Norway shows the lowest mean number of deprivations followed by Germany and France, which are rather close each other, the United Kingdom, and finally Italy. The mean headcount ratio ranges from 3.6% in Norway to 16.3% in Italy. With a concave index, we always find that deprivation is lower in Germany than in France and lower in the United Kingdom than in Italy, which is not surprising in light of the results on second-degree upward dominance reported in Section 3.3.2.1. On the other hand, the lack of second-degree downward dominance in these same comparisons is noticeable in the fact that the rankings reverse as the functions become more convex. For instance, the generalized Atkinson-type deprivation index turns out to be lower in France than in Germany for values of θ higher than 4. The French overall deprivation is below the German level whenever we favor the intersection criterion and weight somebody suffering from $2h$ deprivations at least 16 ($=2^4$) times somebody suffering from h deprivations (as the index d_4^{GA} assigns each person with h deprivations a weight equal to h^4). Because the United Kingdom fares much better than Italy, except in the occurrence of very severe deprivation (6 or more items), the ranking between the two countries only changes for high values of θ or τ, which correspond to an extreme aversion to the worst conditions of deprivation. Finally, note that the generalized Atkinson-type deprivation index approaches the proportion of people experiencing at least one deprivation (union criterion) as θ tends to 0, and the proportion of people suffering from the maximum number of deprivations (intersection criterion) as θ goes to infinity; as nobody lacks all nine items, in the latter case, the index converges to zero in all countries.

3.3.2.5 Association Rearrangements

In many respects, the discussion so far has proceeded as in the case of a single variable, whereas the key feature of the multivariate case is the pattern of association across dimensions. It is then natural to ask how social welfare responds to a change in the

distribution of deprivations across the population, although the total number of deprivations remains the same. The standard approach is to consider how social welfare varies after a "marginal-free change" in the association between two variables, which is a change that does not affect the marginal distributions. As in the statistical literature on the measurement of association in multidimensional contingency tables (formed by two or several binary variables), we distinguish association rearrangements for distributions characterized by either positive or negative associations. Illustrations of marginal-free association rearrangements are provided by Tables 3.4 and 3.5. Each panel of Table 3.4 is obtained from the opposite panel by a marginal-free positive association-increasing (decreasing) rearrangement, whereas each panel of Table 3.5 can be obtained from the opposite panel by a negative association-increasing (decreasing) rearrangement.

Marginal-free rearrangements have been widely used as a basis for evaluating multidimensional measures of poverty and inequality.[25] Bourguignon and Chakravarty (1999, 2003, 2009) and Atkinson (2003) use the principle of marginal-free correlation-increasing shifts as a basis for making a normative judgement of poverty measures derived

[25] For definitions of association-increasing rearrangements based on the correlation coefficient, we refer to Epstein and Tanny (1980), Atkinson and Bourguignon (1982), Boland and Proschan (1988), Dardanoni (1995), Tsui (1995, 1999, 2002), Bourguignon and Chakravarty (2003), and Duclos et al. (2006a). See also Tchen (1980) who deals with positive association (or concordance) between bivariate probability measures.

from continuous variables (attributes) rather than from deprivation scores. They distinguish whether the poverty measure increases or decreases because of a correlation-increasing shift, and they consider the associated attributes to be substitutes (one attribute can compensate for the lack of the other) in the former case and to be complements in the latter.

Considering marginal-free changes is a neat way to highlight the fact that the multidimensional analysis of poverty and inequality implies making assumptions regarding the degree to which the different attributes can be substituted one for the other. In the real world, the condition of marginal-free changes may be too restrictive because policies may reduce deprivation in one dimension at the cost of increasing deprivation in another. We hence adopt a more general approach, and we require that only the mean number of deprivations but not the marginal distributions be kept fixed. (The latter implies the former, but not vice versa.) It follows that we need a measure of association that is invariant with regard to changes in the marginal distributions, unlike the correlation coefficient. This is the case of the cross-product κ introduced by Yule (1900). In the 2×2 distribution of Table 3.1, Yule's measure is defined by

$$\kappa = \frac{p_{00} p_{11}}{p_{01} p_{10}}, \tag{3.13}$$

which is invariant to the transformation $p_{ij} \to a_i b_j p_{ij}$. This association measure, together with the marginal distributions (p_{0+}, p_{1+}) and (p_{+0}, p_{+1}), provides complete information on the distribution and does not change if the marginal distributions change.[26] Note that $\kappa \in [0, \infty\rangle$, $\kappa = 1$ if X_1 and X_2 are independent, $\kappa = 0$ if there is perfect negative association ($p_{00} = 0$ and/or $p_{11} = 0$), and $\kappa \to \infty$ if there is perfect positive association ($p_{01} = 0$ and/or $p_{10} = 0$).

Following Aaberge and Peluso (2011) and Aaberge and Brandolini (2014), we relax the marginal-free condition by introducing an association-increasing/decreasing rearrangement principle that relies on the condition of a fixed overall mean number of deprivations rather than on the condition of fixed proportions of people suffering from each deprivation. As illustrated by Tables 3.4 and 3.5, marginal-free arrangements are special cases of this alternative rearrangement principle.[27]

[26] Yule's measure of association is related to the copula-based measures of association for continuous variables introduced by Spearman and Kendall; see Nelsen (1998). Decancq (2014) introduces a copula-based generalization of the rearrangement principles for continuous variables and provides an analysis of their links with stochastic dominance. If X_1 and X_2 represent the two social class categories to which an individual can belong at times 1 and 2, the Yule's measure of association also coincides with the odds ratio used in mobility studies. See, for instance, Erikson and Goldthorpe (1993, p. 55) and Chapter 10.

[27] Note that the multinomial distribution defined by the parameters p_{00}, p_{10}, p_{01} and $p_{11} (= 1 - p_{00} - p_{10} - p_{01})$ can alternatively be described by the marginal distributions $(p_{0+}, p_{1+} = 1 - p_{0+})$ and $(p_{+0}, p_{+1} = 1 - p_{+0})$, and the cross-product κ.

Definition 3.3

Consider a 2×2 *table with parameters* $(p_{00}, p_{01}, p_{10}, p_{11})$ *where* $\sum_i \sum_j p_{ij} = 1$. *The change* $(p_{00} + \varepsilon, p_{01}, p_{10} - 2\varepsilon, p_{11} + \varepsilon)$ *is said to provide a mean-preserving positive association-increasing (decreasing) rearrangement if* $\varepsilon > 0$ $(\varepsilon < 0)$ *and* $\kappa > 1$, *and a mean-preserving negative association-increasing (decreasing) rearrangement if* $\varepsilon < 0$ $(\varepsilon > 0)$ *and* $\kappa < 1$.

It follows from Definition 3.3 that a mean-preserving rearrangement reduces the number of people deprived according to indicator X_1 at the cost of increasing the number of people deprived according to indicator X_2 when $\varepsilon > 0$ and vice versa when $\varepsilon < 0$. This is illustrated in Table 3.6, which shows two distributions where the association is negative $(\kappa < 1)$ and the mean is equal to 1. Each panel can be obtained from the opposite panel by a mean-preserving negative association-decreasing (increasing) rearrangement where $\varepsilon = 0.01$.

Aaberge and Peluso (2011) show how to extend Definition 3.3 to r dimensions. As is the standard, subscript notation becomes cumbersome for more than two dimensions, so they simplify the notation to p_{ijm}, where i and j represent two arbitrary chosen deprivation dimensions and m represents the remaining $r-2$ dimensions. The Yule's measure κ_{ijm} is defined by

$$\kappa_{ijm} = \frac{p_{iim} p_{jjm}}{p_{ijm} p_{jim}} \tag{3.14}$$

where m is an $(r-2)$-dimensional vector of any combination of zeroes and ones. In this case, the association is defined by $r(r-1)/2$ cross-products. Aaberge and Peluso (2011) introduce the following generalization of Definition 3.3:

Definition 3.4A

Consider a $2 \times 2 \times \ldots \times 2$ *table formed by s dichotomous variables with parameters* $(p_{iim}, p_{ijm}, p_{jim}, p_{jjm})$ *where* $\sum_i \sum_j \sum_m p_{ijm} = 1$ *and* $\kappa_{ijm} > 1$. *The following change* $(p_{iim} + \varepsilon, p_{ijm}, p_{jim} - 2\varepsilon, p_{jjm} + \varepsilon)$ *is said to provide a mean-preserving positive association-increasing (decreasing) rearrangement if* $\varepsilon > 0$ $(\varepsilon < 0)$.

Definition 3.4B

Consider a $2 \times 2 \times \ldots \times 2$ *table formed by s dichotomous variables with parameters* $(p_{iim}, p_{ijm}, p_{jim}, p_{jjm})$ *where* $\sum_i \sum_j \sum_m p_{ijm} = 1$ *and* $\kappa_{ijm} < 1$. *The following change* $(p_{iim} + \varepsilon, p_{ijm}, p_{jim} - 2\varepsilon,$

Table 3.6 Illustration of a mean-preserving negative association-decreasing rearrangement

	$X_2 = 0$	$X_2 = 1$	
$X_1 = 0$	0.20	0.30	0.50
$X_1 = 1$	0.30	0.20	0.50

$p_{jjm}+\varepsilon$) is said to provide a mean-preserving negative association-increasing (decreasing) rearrangement if $\varepsilon<0$ ($\varepsilon>0$).

Theorem 3.1A demonstrates that social preferences favoring second-degree downward dominance imply that overall deprivation rises after a mean-preserving positive association-increasing rearrangement, as well as a mean-preserving negative association-decreasing rearrangement, irrespective of whether preferences are consistent with the primal or the dual approach. By contrast, Theorem 3.1B proves that preferences favoring upward second-degree dominance consider such rearrangement as a reduction in the overall deprivation. Moreover, it follows directly from the decompositions (3.6) and (3.10) that the principles of mean-preserving association-increasing/decreasing rearrangement are equivalent to the mean-preserving spread/contraction defined by:

Definition 3.5
Let F_1 and F_2 be members of the family $\boldsymbol{F}$ of count distributions based on r deprivations and assume that they have equal means. Then F_2 is said to differ from F_1 by a mean-preserving spread (contraction) if $\Delta_\Gamma(F_2)>\Delta_\Gamma(F_1)$ for all convex Γ or $\delta_\gamma(F_2)>\delta_\gamma(F_1)$ for all convex γ ($\Delta_\Gamma(F_2)<\Delta_\Gamma(F_1)$ for all concave Γ or $\delta_\gamma(F_2)<\delta_\gamma(F_1)$ for all concave γ).

Note that Definition 3.5 is equivalent to a sequence of the mean-preserving spread introduced by Rothschild and Stiglitz (1970).

Let Ω_1 and Ω_2 be subsets of the Γ-family defined by

$$\Omega_1=\{\Gamma:\Gamma'(t)>0,\Gamma''(t)>0\ \text{ for all } t\in\langle 0,1],\ \text{ and } \Gamma'(0)=0\}$$

and

$$\Omega_2=\{\Gamma:\Gamma'(t)>0,\Gamma''(t)<0\ \text{ for } t\in\langle 0,1\rangle,\ \text{ and } \Gamma'(1)=0\},$$

and let ω_1 and ω_2 be subsets of the γ-family defined by

$$\omega_1=\{\gamma:\gamma'(k)>0,\gamma''(k)>0\ \text{ for all } k>0,\ \text{ and } \gamma'(0)=0\}$$

and

$$\omega_2=\{\gamma:\gamma'(k)>0,\gamma''(k)<0\ \text{ for } k>0,\ \text{ and } \gamma'(r)=0\}.$$

All members of the sets Ω_1 and ω_1 are increasing convex functions, and all members of Ω_2 and ω_2 are increasing concave functions.

Theorem 3.1A
Let F_1 and F_2 be members of the family $\boldsymbol{F}$ of count distributions based on r deprivations and assume that they have equal means. Then the following statements are equivalent:

(i) *F_1 second-degree downward dominates F_2;*
(ii) *$D_\Gamma(F_1) < D_\Gamma(F_2)$ for all $\Gamma \in \Omega_1$;*
(iii) *$d_\gamma(F_1) < d_\gamma(F_2)$ for all $\gamma \in \omega_1$;*
(iv) *F_2 can be obtained from F_1 by a sequence of mean-preserving positive association-increasing rearrangements when $\kappa > 1$ for both F_1 and F_2, a sequence of mean-preserving negative association-decreasing rearrangements when $\kappa < 1$ for both F_1 and F_2, and a combination of mean-preserving positive association-increasing and negative association-decreasing rearrangements when $\kappa > 1$ for eitherF_1 or F_2;*
(v) *F_2 can be obtained from F_1 by a mean-preserving spread.*

Theorem 3.1B

Let F_1 and F_2 be members of the family $\boldsymbol{F}$ of count distributions based on r deprivations and assume that they have equal means. Then the following statements are equivalent:
(i) *F_1 second-degree upward dominates F_2;*
(ii) *$D_\Gamma(F_1) < D_\Gamma(F_2)$ for all $\Gamma \in \Omega_2$;*
(iii) *$d_\gamma(F_1) < d_\gamma(F_2)$ for all $\gamma \in \omega_2$;*
(iv) *F_2 can be obtained from F_1 by a sequence of mean-preserving positive association-decreasing rearrangements when $\kappa > 1$ for both F_1 and F_2, a sequence of mean-preserving negative association-increasing rearrangements when $\kappa < 1$ for both F_1 and F_2, and a combination of mean-preserving positive association-decreasing and negative association-increasing rearrangements when $\kappa > 1$ for either F_1 or F_2;*
(v) *F_2 can be obtained from F_1 by a mean-preserving contraction.*

See Aaberge and Peluso (2011) for a proof of the equivalence between (i), (ii), and (iv) of Theorems 3.1A and 3.1B, and Aaberge and Brandolini (2014) for a proof of the equivalence between (i) and (iii). The equivalence between (v) and (ii) and (iii) follows directly from the second terms of Equations (3.6) and (3.10).

Following the distinction made by Bourguignon and Chakravarty (2003, 2009) and Atkinson (2003), the results of Theorem 3.1A (3.1B) justify the use of D_Γ and d_γ for convex Γ and convex γ (concave Γ and concave γ) when the attributes associated with the deprivation indicators can be considered as substitutes (complements). Theorems 3.1A and 3.1B show that D_Γ and d_γ satisfy the mean-preserving association-rearrangement principles, when a distinction has been made between whether an association rearrangement comes from a distribution characterized by a positive or negative association. Consider the specific subfamily of two-dimensional deprivation measures discussed by Atkinson (2003) and defined by (3.12), and assume that there is positive association between the two deprivations ($\kappa > 1$). The d_γ-function associated with the family A_θ is concave for $\theta < 1$ and convex for $\theta > 1$, and it approaches the union condition when $\theta \to 0$ and the intersection condition when $\theta \to \infty$. Theorem 3.1B states that a sequence of mean-preserving positive association-decreasing rearrangements raises the overall deprivation A_θ if $\theta < 1$. Is it reasonable to suppose that the overall deprivation rises as we observe a reduction in the positive association between deprivations in the two attributes? After all, the share of people suffering from deprivation for both attributes falls, while the total number of deprivations does not vary. The answer is positive if we regard the two attributes as complements, which means that we rule out any trade-off between them, and we dislike the fact that more people are deprived more than the fact that fewer people are hit more.

Until now, we have not considered the cases of unequal weighting of the dimensions. However, all results summarized by Theorems 3.1A and 3.1B remain valid for the distribution of weighted deprivation counts. For the dual approach, Aaberge and Peluso (2011) account for different weights by considering the weighted deprivation counts $X = \sum_{i=1}^{r} w_i X_i$ and the associated distribution F, for which $w_1 \leq w_2 \leq \cdots \leq w_r$. For the primal approach, we could apply the procedure suggested by Alkire and Foster (2011a,b) to replace the deprivation count for each person with the sum of the associated weights.

3.3.2.6 Counting Deprivations versus Measuring Poverty

So far, we have been concerned with the distribution of deprivation counts, irrespective of how many people are regarded as poor when deprivation and poverty are considered as distinct concepts. In terms of the classical distinction made by Sen (1976), we have focused only on the aggregation of the characteristics of deprivation into an overall measure of deprivation, ignoring the first step concerning the identification of the poor. The contrast between the union and the intersection criteria emphasized in the previous sections suggests, however, that there is some leeway in defining who is poor. For instance, Brandolini and D'Alessio (1998), Bourguignon and Chakravarty (1999, 2003), Tsui (2002), and Bossert et al. (2013) adopt the more extensive union criterion and define people as (multidimensional) poor if they suffer from at least one deprivation. In this case, deprivation and poverty come to coincide. On the other hand, the European Union regards as multiply materially deprived all persons who cannot afford at least four out of nine amenities, moving midway between the union and the (strict) intersection views. Alkire and Foster (2011a,b) formalize what they label the "dual cut-off" identification system, in which the dimension-specific thresholds are integrated with a further threshold that identifies the minimum number of deprivations required for an individual to be classified as poor. If a person is poor when he or she is deprived in at least c, $1 \leq c \leq r$, dimensions, the headcount ratio is uniquely determined by the count distribution F and is defined by

$$\widetilde{H}(c) = 1 - F(c-1) = \sum_{k=c}^{r} q_k. \tag{3.15}$$

In the case of the European indicator of severe material deprivation, c equals 4. As the choice of a specific cut-off c is arbitrary, it is useful to check the sensitivity of the ranking of distributions to c by treating $\widetilde{H}(c)$ as a function of c, henceforth labeled the headcount curve. As is evident from (3.15), the condition of first-degree dominance of headcount curves is equivalent to first-degree dominance of the associated count distributions. If $c>1$, first-degree dominance for headcount curves is a less demanding condition than that for the overall count distribution, because it ignores what happens to those who suffer from deprivation in fewer than c dimensions. Moreover, the second-degree dominance results of Theorems 3.1A and 3.1B are also valid for the headcount curve, which means that $\widetilde{H}(c)$ satisfies the principle of association-increasing/decreasing rearrangements when this principle is restricted to be applied among the poor.

To complement the information provided by the headcount ratio when only ordinal data are available, we may employ the measures defined by (3.6) and (3.10) as overall measures of poverty for the conditional count distribution $\widetilde{F}$ defined by

$$\widetilde{F}(k;c) = \Pr(X \leq k | X \geq c) = \frac{F(k) - F(c-1)}{1 - F(c-1)} = \frac{\sum_{j=c}^{k} q_j}{\sum_{j=c}^{r} q_j}, \quad k = c, c+1, \ldots, r, \tag{3.16}$$

with mean given by

$$\widetilde{\mu}(c) = \frac{\sum_{j=c}^{r} j q_j}{\sum_{j=c}^{r} q_j}. \tag{3.17}$$

Expressions (3.6) and (3.10) show that the overall measures of poverty for $\widetilde{F}$ admit a decomposition into the mean (or a function of the mean) and a measure of dispersion. An analog to the *FGT* family of poverty measures is obtained by inserting $\gamma(k) = k^{\theta}$ in expression (3.10).

As an alternative, Alkire and Foster (2011a) propose combining the headcount ratio $\widetilde{H}(c)$ and the conditional mean $\widetilde{\mu}(c)$, and they introduce the adjusted headcount ratio defined by

$$\widetilde{M}_1(c) = \frac{\widetilde{H}(c)\widetilde{\mu}(c)}{r} = \frac{1}{r}\sum_{j=c}^{r} j q_j, \tag{3.18}$$

which is the ratio of the total number of deprivations experienced by the poor to the maximum number of deprivations that could be experienced by the entire population. For $c=1$, the index $\widetilde{M}_1(c)$ coincides with the Atkinson-type primal measure of deprivation d_1^{GA}. Expression (3.18) can account for unequal weights for the various deprivations by simply replacing the deprivation count for each person by the sum of the associated weights. Alkire and Foster (2011a, p. 482) underline that both the identification of the poor and the adjusted headcount ratio are invariant to monotonic transformations applied to the deprivation variables and the respective thresholds. Moreover, the index $\widetilde{M}_1(c)$ increases if a poor person becomes deprived in an additional dimension (dimensional monotonicity), and it is decomposable by population subgroups. Therefore, the index can be broken down by indicator because it is the (weighted) average of the deprivations headcount ratios for each dimension computed considering only the poor at the numerator (so-called "censored headcount ratios"). On the other hand, this index is indifferent to changes in the way deprivations are distributed across the poor.[28]

A general family of adjusted poverty measures that take into account not only the average deprivation experienced by the poor, $\widetilde{\mu}(c)$, but also the distribution of deprivations across the poor can be derived from the d-measure defined by (3.10)

$$\widetilde{M}_\gamma(c) = \frac{\widetilde{H}(c)\widetilde{d}_\gamma(c)}{r}, \tag{3.19}$$

where $\widetilde{d}_\gamma(c)$ denotes the d-index for $\widetilde{F}$. Such a measure may weight poor persons differently according to the number of deprivations from which they suffer. Inserting $\gamma(k) = k^\theta$ in $\widetilde{d}_\gamma(c)$ in (3.19) yields the general family of adjusted FGT measures for count data

$$\widetilde{M}_\theta(c) = \frac{1}{r}\sum_{j=c}^{r} j^\theta q_j, \quad \theta > 0, \tag{3.20}$$

which encompasses (3.18) for $\theta = 1$. When $\theta \to 0$, the adjusted FGT measure reaches its minimum value $\widetilde{H}(c)/r$, which ignores altogether any cumulative effect of multiple deprivations. As θ rises, greater weight is placed on those who suffer from deprivation in several dimensions.

Figure 3.3 compares how poverty headcount ratios change as we vary the poverty cut-off using the deprivation indicators in the five European countries considered earlier. The proportion of poor people, shown in the top-left panel, falls by three-fourths in Italy and around nine-tenths in the other countries as the poverty cut-off is raised from one deprivation (union criterion) to four deprivations (the European criterion). Censoring at four deprivations implies excluding from measured poverty a substantial fraction of the population suffering from one, two, or three deprivations: 15% in Norway and 46% in Italy, accounting for 76% and 57% of all deprivations, respectively. However, the ranking

[28] For comments and critiques of the class of multidimensional indices proposed by Alkire and Foster (2011a,b), see, among others, Birdsall (2011), Rippin (2010), Ferreira (2011), Ravallion (2011a, 2012a), Silber (2011), Thorbecke (2011), Ferreira and Lugo (2013), Duclos and Tiberti (forthcoming), and the reply by Alkire et al. (2011).

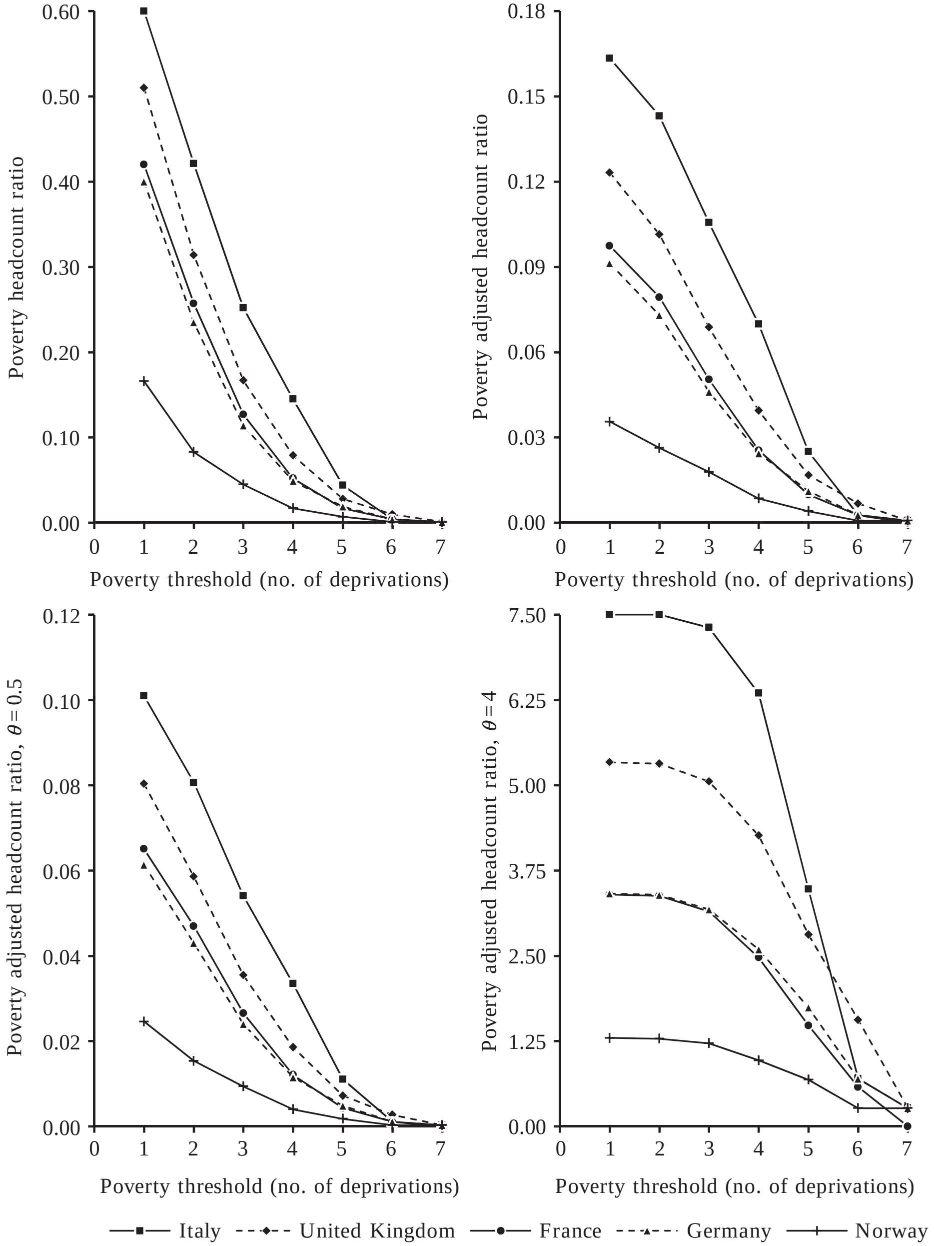

Figure 3.3 Poverty headcount and adjusted headcount ratios for different poverty cut-offs in selected European countries in 2012. *Source: authors' elaboration on data from Eurostat (2014).*

of countries does not change. It changes when the cut-off is set at five deprivations, however, when Germany and France reverse their order, and again at six deprivations, when the United Kingdom becomes the country with the highest share of poor people. In the top-right panel, the ranking is the same for the adjusted headcount ratio $\widetilde{M}_1(c)$, except for a better position granted to France by its lower average intensity of deprivation $(\widetilde{\mu}(c)/r)$ when the cut-off is set at six deprivations. The bottom panels show results for the adjusted *FGT* measure $\widetilde{M}_\theta(c)$: lowering the weights of multiple deprivations ($\theta = 0.5$; left panel) does not modify the sorting produced by the adjusted headcount ratio, whereas significantly raising them ($\theta = 4$; right panel) steadily switches the positions of Germany and France, as seen in Section 3.3.2.4. This comparison reveals that varying the poverty cut-off has a considerable impact on measured poverty, whereas adjusting the headcount ratio for the deprivations experienced by the poor seems to have minor effects, unless their distribution is taken into account.

The adjusted headcount ratio $\widetilde{M}_1(c)$ proposed by Alkire and Foster (2011a,b) provides the theoretical basis for the Multidimensional Poverty Index (*MPI*) developed by Alkire and Santos (2010, 2013, 2014).[29] The *MPI* has replaced the *HPI* in the reports of the United Nations Development Program since 2010 in order to capture "how many people experience overlapping deprivations and how many deprivations they face on average" (UNDP, 2010, p. 95). The *MPI* considers 10 dichotomous indicators for three dimensions: health, education, and living standards. Dimensions and indicators within each dimension are equally weighted, and the cut-off c for the number of (weighted) deprivations is set at three out of a maximum of ten. Applied research estimating Alkire and Foster's class of indices and the *MPI* is rapidly growing.[30]

3.3.3 Poverty Measurement Based on Continuous Variables

The counting approach focuses on the distribution of deprivation scores that summarize binary variables, defined as having or not having goods or performing or not performing activities that are seen as social necessities. When we have cardinal (continuous or categorical) variables, we can use measures of multidimensional poverty that fully exploit

[29] Alkire and Foster's method is utilized by Peichl and Pestel (2013a,b) to derive an adjusted headcount ratio for multidimensional richness. This index accounts for the number of individuals who are affluent in a minimum number of dimensions, as well as for their average achievements in these dimensions.

[30] See for instance, Roelen et al. (2010) for Vietnam, Khan et al. (2011) for Pakistan, Batana (2013) for Sub-Saharan African countries, Battiston et al. (2013) for Latin American countries, Roche (2013) for Bangladesh, Santos (2013) or Buthan, Trani, and Cannings (2013) for Western Darfur, Trani et al. (2013) for Afghanistan, Yu (2013) for China, and Cavapozzi et al. (2013) and Whelan et al. (2014) for European countries. See also Mohanty (2011) for a related study on deprivation scores in India. Bennett and Mitra (2013) develop multiple statistical tests for Alkire and Foster's family of poverty measures.

the informational richness of the available data.[31] As in the counting approach, we may aggregate attributes first across dimensions and then across individuals. This procedure corresponds to representing each individual's vector of attributes with an interpersonally comparable utility-like function and then evaluating the distribution of individual well-being using the same tools as in a univariate space. Consumer theory (Slesnick, 1993) or information theory (Maasoumi and Lugo, 2008) can provide the analytical framework to derive the utility-like function. This function is then used to aggregate the attribute-specific cut-offs to define an aggregate poverty threshold.[32]

Alternatively, we may employ an axiomatic simultaneous aggregation approach for measuring multidimensional poverty. Chakravarty et al. (1998), Bourguignon and Chakravarty (1999, 2003), and Tsui (2002) consider persons to be poor if they suffer from at least one deprivation (the union approach), whereas Alkire and Foster (2011a) take all those who are deprived in at least c dimensions, with c between 1 and r. All these papers then aggregate the individual shortfalls relative to dimension-specific cut-offs into a multidimensional poverty measure. The actual functional forms of the poverty indices are determined by the combination of chosen axioms, many of which parallel those considered in the univariate analysis (e.g., Zheng, 1997). In the next section, we selectively review these indices and illustrate some of their properties. We refer to Chakravarty et al. (1998), Bourguignon and Chakravarty (1999, 2003), Tsui (2002), and Chakravarty and Silber (2008) for proofs and further discussion of the axioms.

3.3.3.1 Measures of Multidimensional Poverty

Let $\mathbf{y}_i, i = 1, 2, \ldots, n$ denote the vector of the attributes of individual i, where $y_{ij} \geq 0$ is the achievement in dimension j, and let $\mathbf{z}$ be a vector of attribute-specific poverty thresholds. Bourguignon and Chakravarty (1999, 2003) introduce the following multidimensional analog of the FGT family of poverty indices

$$P_\theta(y; z) = \frac{1}{nr} \sum_{i=1}^{n} \sum_{j=1}^{r} a_{ij} \left(1 - \frac{y_{ij}}{z_j}\right)^{\theta_j}, \quad \theta_j > 1, \tag{3.21}$$

[31] Bosmans et al. (2013b) introduce an approach that deals with the joint aggregation of cardinal and ordinal variables. Yalonetzky (2013) derives stochastic dominance conditions for ordinal variables.

[32] Merz and Rathjen (2014a,b) apply Maasoumi's utility-like approach, estimating a CES function, to study poverty in the bidimensional space of equivalent income and leisure time. Maasoumi and Lugo (2008) show that the information-theoretic approach can embody attribute-specific thresholds if the utility-like function is replaced by a relative deprivation function the argument for which is the relative shortfall of the attribute relative to its threshold. In this case, the aggregation across individuals has to be restricted to those who are deprived in at least one dimension.

where a_{ij} is equal to the weight w_j assigned to attribute j if $y_{ij} < z_j$ and to 0 otherwise; both a_{ij} and θ_j determine the weight assigned to attribute j in the poverty index.[33]

In addition to displaying *monotonicity*, *continuity*, and *scale invariance*, the members of the family $P_\theta(y;z)$ satisfy three axioms worthy of some comments. *Subgroup decomposability* requires that overall poverty can be expressed as a weighted sum of the poverty ratios of the subgroups and implies that the poverty index is separable across individuals. Thanks to this property, the poverty index identifies an individual poverty function. The *one-dimensional Pigou–Dalton transfer principle* demands that poverty does not increase in the case of a progressive transfer of one unit of attribute j from one poor person to a poorer person. This axiom determines the additivity of (3.21) across attributes. This *factor decomposability* may be a useful feature because it allows identifying the contribution of each attribute to the overall poverty level.

The *focus* axiom highlights the greater complexity of multidimensional analysis. In the univariate income case, it simply entails that the poverty index is independent of the distribution of income among the nonpoor. In the multivariate case, it may require the poverty measure to be invariant with respect to increases in y_{ij} if $y_{ij} > z_j$ for all i, poor and nonpoor alike (*strong focus*), or only with respect to changes in the distribution of attributes among the nonpoor (*weak focus*). The stronger version of the axiom implies that a better achievement in a dimension in which an individual is not deprived cannot compensate for a below-threshold achievement in another dimension. The possibility of trading off one attribute for the other is ruled out. This is the case of (3.21), as a_{ij} equals 0 if $y_{ij} > z_j$.[34]

The family of poverty measures $P_\theta(y;z)$ is a particular specification of the more general class characterized by Chakravarty et al. (1998) and Bourguignon and Chakravarty (1999, 2003) in which the power function is replaced by a continuous nonincreasing convex function. Assuming that all attributes are positive and specifying such a function to be the negative of the logarithm, Chakravarty and Silber (2008) and Chakravarty et al. (2008) obtain the multidimensional version of the poverty index proposed by Watts (1968) and formalized by Zheng (1993):

$$P_W(y;z) = \frac{1}{nr}\sum_{i=1}^{n}\sum_{j=1}^{r} a_{ij} \ln\left(\frac{z_j}{y_{ij}}\right), \tag{3.22}$$

As indicated by Bourguignon and Chakravarty (2003) and Pattanaik et al. (2011), the measures defined by (3.21) are not sensitive to association-rearrangement interventions.

[33] See Lasso de la Vega and Urrutia (2011) for an axiomatic characterization of a generalized version of $P_\theta(y;z)$.

[34] Permanyer (2014) shows how to modify most of the multidimensional poverty indices commonly considered so that they satisfy the *weak* rather than the *strong focus* axiom. Esposito and Chiappero Martinetti (2010) examine poverty indices that embody a hierarchical ordering of well-being dimensions.

This is due to the fact that $P_\theta(y;z)$ is uniquely determined by the marginal distributions of the r attributes and the associated attribute-specific poverty thresholds. By imposing an additional condition, called the *poverty focus* axiom, Alkire and Foster (2011a) provide a justification for the intermediate poverty measure analog to $P_\theta(y;z)$,

$$P_\theta(y;z,c)=\frac{1}{nr}\sum_{i=1}^{n}a_i(c)\sum_{j=1}^{r}a_{ij}\left(1-\frac{y_{ij}}{z_j}\right)^\theta,\quad \theta\geq 0, \tag{3.23}$$

where $a_i(c)=1$ if $\{j: y_{ij}<z_j\}\geq c$ and 0 otherwise. In other words, the role of $a_i(c)$ is to select only the poor individuals: these are now all people who suffer from deprivation in at least c dimensions, which, for $c>1$, is a subgroup of those deprived in any dimension considered with the union criterion. Thus, $P_\theta(y;z,1)=P_\theta(y;z)$. When one or several attributes are dichotomous variables, then $P_\theta(y;z,c)$ is only valid for $\theta=0$. In such a case, we can only use

$$P_0(y;z,c)=\frac{1}{nr}\sum_{i=1}^{n}a_i(c)\sum_{j=1}^{r}a_{ij}, \tag{3.24}$$

which is equal to the average number of deprivations (normalized by the maximum number r) experienced by the poor, or the normalized average among those individuals who suffer from at least c deprivations. Note that $P_0(y;z,c)$ is equal to $\widetilde{M}_1(c)$, defined by (3.18), when $w_j=1$ for all j. For $c=1$, $P_0(y;z,1)$ becomes equal to the average number of deprivations (relative to r) for those who suffer from at least one deprivation. As demonstrated by Alkire and Foster (2011a), $P_\theta(y;z,c)$ for $\theta\geq 1$ satisfies a multidimensional transfer principle based on a bistochastic transformation when it is only applied among the poor. Moreover, the measures defined by (3.24) satisfy the association-rearrangement principle discussed by Alkire and Foster (2011a), even though these measures are decomposable by subgroups. However, this is only true when $c>1$, and it is due to the multidimensional information captured by the counting term $a_j(c)$ of (3.23).[35] By contrast, to account for the correlation between attributes when $c=1$, Bourguignon and Chakravarty (1999, 2003) introduce a family of nonadditive poverty measures, but they limit their discussion to the two-dimensional case.[36] This subfamily of $P_\theta(y;z)$ is defined by

[35] As before, the introduction of the threshold can be criticized because it implies ignoring the condition of those who suffer from deprivation in less than c dimensions as well as because of the arbitrariness of the choice of c.

[36] For alternative families of multidimensional poverty measures and their characterizations, we refer to Kolm (1977), Chakravarty et al. (1998), Tsui (2002), Deutsch and Silber (2005), Duclos et al. (2006a, 2007, 2008), Chakravarty and Silber (2008), and Lasso de la Vega and Urrutia (2011). Diez et al. (2008) and Chakravarty and D'Ambrosio (2013) derive subgroup-decomposable multidimensional poverty indices that are unit-consistent; that is, they provide poverty rankings that are unaffected by a change in the measurement units of dimensions.

$$P^*_{\alpha,\beta}(y;z) = \frac{1}{nr}\sum_{i=1}^{n}\left(\sum_{j=1}^{2} a_{ij}\left(1-\frac{y_{ij}}{z_j}\right)^{\beta}\right)^{\alpha/\beta}, \tag{3.25}$$

where α and β are nonnegative parameters, and it is used by Bourguignon and Chakravarty (1999, 2003) and Atkinson (2003) as a basis for demonstrating that the effect of an increasing association (correlation) rearrangement depends on whether the attributes are substitutes or complements, and that this corresponds to choosing $\alpha > \beta$ or $\alpha < \beta$.[37] Moreover, Atkinson (2003) demonstrates that the family of counting measures A_θ defined by (3.12) can be seen as a limiting case of (3.25) when α and β tend to zero with $\theta = \alpha/\beta$ and $w_1 = w_2 = 1$.

3.3.3.2 Partial Orderings

Most empirical studies consider few measures of poverty when ranking multidimensional distribution functions. A natural concern is that the conclusions reached in these studies are sensitive to the choice of the specific measures.[38] By drawing on Atkinson and Bourguignon (1982), Bourguignon and Chakravarty (2009) investigate what restrictions two alternative stochastic dominance conditions of the first-degree impose on the general family of two-dimensional poverty measures defined by

$$\Pi_p(H;z) = \int_0^{z_2}\int_0^{z_1} p(x_1,x_2;z_1,z_2)\mathrm{d}H(x_1,x_2), \tag{3.26}$$

where H is the bivariate distribution of the two attributes in question and $p(x_1, x_2; z_1, z_2)$ is the level of poverty associated with attribute levels (x_1, x_2) and poverty thresholds (z_1, z_2).[39] Let p_i' denote the derivative of p with respect to x_i and let p_{12}'' denote the second derivative of p with respect to x_1 and x_2. The following alternative presentation of a result from Bourguignon and Chakravarty (2009) provides three equivalent statements:

Theorem 3.2A

Let H and H^* be members of the family $\mathbf{H}$ of the bivariate distributions of the attributes (X_1, X_2) and let H_1 and H_1^* and H_2 and H_2^* be the associated marginal distributions of X_1 and X_2. Then the following statements are equivalent

[37] Brandolini (2009) and Madden (2011) use this index to study income and health poverty in selected European countries, and they analyze the sensitivity of results to different values of the parameters α and β. See also Bibi and El Lahga (2008).

[38] For similar concerns in the single-dimensional case, see Atkinson (1987), Zheng (1999), Spencer and Fisher (1992), Jenkins and Lambert (1997), and Aaberge and Atkinson (2013) who introduce poverty dominance criteria as a basis for obtaining more robust results.

[39] Poverty orderings of bivariate distributions are studied by Gravel and Moyes (2012), under the hypothesis that one attribute is cardinal and transferable between individuals, but the other is ordinal and non-transferable, and by Garcia-Diaz (2013), under the hypothesis of asymmetric treatment of the attributes proposed by Muller and Trannoy (2012).

(i) $H_i(x_i) \le H_i^*(x_i)$ for all $x_i < z_i, i = 1, 2$ *and* $H(x_1, x_2) \le H^*(x_1, x_2)$ for all $x_1 < z_1$ and $x_2 < z_2$

(ii) $\Pi_p(H; z) < \Pi_p(H^*; z)$ for all p where $p_i'(x_1, x_2) \le 0$ for $x_i < z_i, i = 1, 2$ *and* $p_{12}''(x_1, x_2) \ge 0$, for $x_1 < z_1$ and $x_2 < z_2$

(iii) *H^* can be obtained from H by sequences of Pigou–Dalton regressive transfers and/or a sequence of marginal-free (marginal distribution-preserving) correlation-increasing rearrangements.*

The equivalence between (i) and (ii) is proved by Bourguignon and Chakravarty (2009), and the equivalence between (ii) and (iii) is proved by Atkinson and Bourguignon (1982).

Theorem 3.2A shows that poverty measures Π_p that satisfy condition (ii) rank bivariate distributions according to first-degree stochastic dominance for attribute values below the poverty threshold in each dimension and first-degree two-dimensional stochastic dominance below both poverty thresholds. As indicated by Bourguignon and Chakravarty (2003, 2009), and demonstrated by Theorem 3.2A, the principle of correlation-increasing rearrangement (conditional on fixed marginal distributions) is associated with the intersection $H(x_1, x_2)$. Moreover, Theorem 3.2A shows that Π_p increases as a result of correlation-increasing rearrangement if the cross-derivative of p with respect to x_1 and x_2 is nonnegative. This is the reason why Bourguignon and Chakravarty, in this case, refer to the attributes as substitutes. The case in which the cross-derivative is negative corresponds to complements that are associated with nonincreasing poverty under a correlation-increasing rearrangement. An alternative presentation of this result is given by the following theorem:

Theorem 3.2B

Let H and H^* be members of the family $\boldsymbol{H}$ of the bivariate distributions of the attributes (X_1, X_2) and let H_1 and H_1^* and H_2 and H_2^* be the associated marginal distributions of X_1 and X_2. Then the following statements are equivalent

(i) $H_1(x_1) + H_2(x_2) - H(x_1, x_2) \le H_1^*(x_1) + H_2^*(x_2) - H^*(x_1, x_2)$ *for all* $x_1 < z_1$ *and/or* $x_2 < z_2$

(ii) $\Pi_p(H; z) < \Pi_p(H^*; z)$ *for all p where* $p_i'(x_1, x_2) \le 0$ for $x_i < z_i, i = 1, 2$ *and* $p_{12}''(x_1, x_2) \le 0$ for $x_1 < z_1$ and $x_2 < z_2$

(iii) *H^* can be obtained from H by sequences of Pigou–Dalton regressive transfers and/or a sequence of marginal-free (marginal distribution-preserving) correlation-decreasing rearrangements.*

For the proof of Theorem 3.2B, we refer to Atkinson and Bourguignon (1982) and Bourguignon and Chakravarty (2009). Note that Theorems 3.2A and 3.2B are, strictly speaking, only valid in cases for which the association (correlation) between X_1 and X_2 is positive. However, as demonstrated for the counting approach (see Theorems 3.1A and 3.1B), it is straightforward to extend Theorems 3.2A and 3.2B to cover the case in which the association (correlation) is negative.

In practice, multivariate distributions might often cross. This is shown, for instance, by Arndt et al. (2012) and Nanivazo (2014) in their multidimensional analyses of first order dominance for child poverty in Vietnam and Mozambique and in the Democratic Republic of Congo, respectively. Thus, it is helpful to introduce weaker criteria than first-degree dominance. Duclos et al. (2006a, 2007, 2008) consider second-degree and higher-degree dominance conditions when attributes are regarded as substitutes. A good example is when we consider poverty in relation to both income and wealth, which are perfect or very close substitutes. (Imperfect substitutability may derive from the lower degree of liquidity of an asset.) In these exercises, the asset poverty line is often defined with reference to the income poverty line, because it is taken to be the amount of wealth necessary to maintain the socially defined minimum standard for a certain period for someone who has no other economic sources (e.g., Brandolini et al., 2010; Haveman and Wolff, 2004). Bourguignon and Chakravarty (2009) remark that this approach gets close to the unidimensional approach because the poverty line of one attribute is assumed to be a function of the poverty line of the other attribute.

3.4. MULTIDIMENSIONAL INEQUALITY MEASUREMENT

The surge of research on the measurement of inequality in multiple dimensions is fairly recent, but the central question is far from new. In *Income Distribution, Value Judgments, and Welfare*, Fisher was not interested in money income, a "scalar," but in "real" income, that is, "a vector whose components are amounts of commodities" (Fisher, 1956, p. 382). His analysis was carried out by aggregating commodities either by using constant prices—to which he assigned "no particular significance . . . as market valuations of the commodities. Any arbitrary set of weights would do as well" (Fisher, 1956, p. 383, fn. 6)—or by means of individual utility functions. Social welfare was thus seen as an aggregation of individual preferences, in the tradition of what Sen (1977) has labeled "welfarism." The modern approach to measuring inequality in multiple dimensions generally departs from this identification by interpreting the individual utility function as "the observer's evaluation of the individual's welfare" (Kolm, 1977, p. 3), so that "the social criterion makes no use of information on individual *i*'s relative valuation of the different elements of [the vector of goods received by person *i*]" (Atkinson and Bourguignon, 1982, p. 184).

As in the study of a single variable pioneered by Kolm (1969) and Atkinson (1970), the analysis proceeds by investigating the conclusions that can be reached on the ranking of multivariate distributions by making alternative assumptions on the order of aggregation and the shape of the social welfare function, or on the desired properties of inequality indices. We first consider the extension of the Pigou–Dalton transfers principle. We then move to partial orderings and sequential dominance criteria, and lastly to inequality indices.[40]

[40] See Bradburd and Ross (1988) and Fluckiger and Silber (1994) for early proposals of multidimensional inequality indices.

3.4.1 Multidimensional Extensions of the Pigou–Dalton Transfers Principle

Some of the requirements typically specified in the univariate case can be directly transferred to the multivariate context. For instance, the requirement that the social evaluation pays no attention to any other individual characteristics than those included in the vector of attributes—the "anonymity principle"—does not pose any problem, and it may in fact be even less restrictive with multiple dimensions. On the other hand, the multidimensional extension of the Pigou–Dalton transfers principle is less straightforward. In its original formulation, it states that inequality should fall as income is transferred from a richer to a poorer person, without modifying their relative ranks. (The last condition is unnecessary if the anonymity principle is assumed.) There is no unique way to reformulate the principle when there are two or more dimensions (Kolm, 1977).[41]

A first possible generalisation is suggested by Fisher's approach discussed above. Suppose that there are r attributes and n individuals. The distribution is represented by the $n \times r$ matrix $\mathbf{X} = [x_{ij}]$, $i = 1, 2, \ldots, n$ and $j = 1, 2, \ldots, r$, where x_{ij} is the quantity of attribute j enjoyed by individual i, and $x_i = (x_{i1}, x_{i2}, \ldots, x_{ir})$ is the vector of the attributes of individual i. If attributes are aggregated for each individual by a vector of weights (prices) $\mathbf{p}$, the comparison of two alternative distributions $\mathbf{X}$ and $\mathbf{Y}$ can be reduced to that of the two resulting univariate distributions $\mathbf{Xp}$ and $\mathbf{Yp}$: if $\mathbf{Yp}$ Lorenz-dominates $\mathbf{Xp}$ for any possible $\mathbf{p}$, then $\mathbf{Y}$ is socially preferable to $\mathbf{X}$. This dominance criterion is known as "price majorization," "budget majorization," or "directional majorization." The degree of appropriateness of market prices for attributes such as the health status represents a problem for this dominance criterion, and other reasons may lead one to question its ethical foundations (Trannoy, 2006).

A second possibility is then to conceive a Pigou–Dalton experiment in the multivariate context as a transfer simultaneously and identically involving all attributes. Suppose that there are two attributes and three individuals. A (strict) Pigou–Dalton (PD) transfer between individuals 1 and 2 can be defined as the transfer to the poorer individual of the fraction λ of the extra quantity of attribute j held by the richer individual, or $\lambda|x_{2j} - x_{1j}|$ with $0 < \lambda < 1$. Thus, the PD-transfer yields the new vectors $\mathbf{x}_1' = (1-\lambda)\mathbf{x}_1 + \lambda\mathbf{x}_2$ and $\mathbf{x}_2' = \lambda\mathbf{x}_1 + (1-\lambda)\mathbf{x}_2$, while $\mathbf{x}_3$ is unchanged. An example is shown in the left-top panel of Figure 3.4, where the empty diamonds correspond to the new distribution. This distribution is socially preferable to the original one, indicated by full diamonds, as it is obtained by a PD-transfer between 1 and 2 (there is no change for individual 3). More generally, a PD-transfer may be described by $\mathbf{Y} = \mathbf{TX}$ where $\mathbf{T}$ is the $n \times n$ matrix

[41] See also Das Gupta and Bhandari (1989), Dardanoni (1995), Fleurbaey and Trannoy (2003), Mosler (2004), Fleurbaey (2006), Savaglio (2006a,b), Diez et al. (2007), Nakamura (2012), and Banerjee (2014a,b).

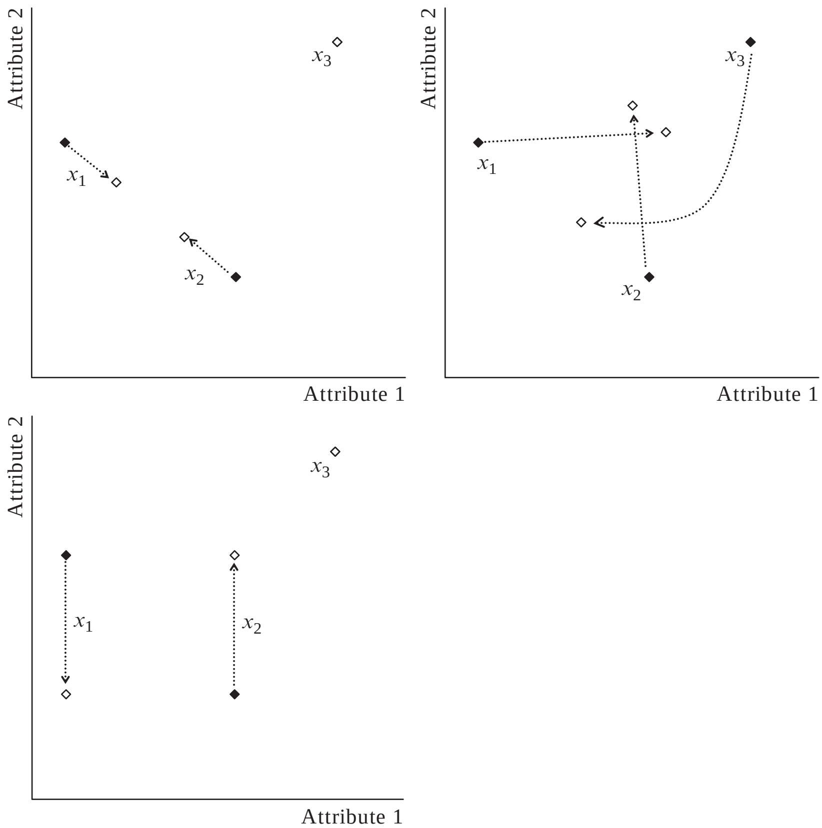

Figure 3.4 Examples of majorization criteria.

$\mathbf{T} = \lambda\mathbf{I} + (1-\lambda)\mathbf{\Pi}_{h,k}$ with $\mathbf{I}$ being the $n \times n$ identity matrix and $\mathbf{\Pi}_{h,k}$ being the $n \times n$ permutation matrix interchanging h and k (e.g., Weymark, 2006, p. 307). A distribution $\mathbf{Y}$ that is obtained from $\mathbf{X}$ by a sequence of PD-transfers is socially preferable to $\mathbf{X}$. This dominance criterion is known as "uniform Pigou-Dalton majorization", or "chain majorization" in Marshall and Olkin's (1979) terminology.

A sequence of PD-transfer matrices $\mathbf{T}$ yields a bistochastic matrix that is a nonnegative square matrix for which each row and each column sum up to 1. Though not all bistochastic matrices can be obtained by a sequence of PD-transfers, the multiplication of $\mathbf{X}$ by a bistochastic matrix is a form of averaging that makes the distribution less spread out. An alternative formulation of the dominance criterion is then to require that $\mathbf{Y}$ is socially preferable to $\mathbf{X}$ if there is a bistochastic $n \times n$ matrix $\mathbf{B}$ such that $\mathbf{Y} = \mathbf{BX}$ ("uniform majorization"). An example of a redistribution of this type, which cannot be obtained by a sequence of (strict) PD-transfers, is given in the right-top panel of Figure 3.4. It is clear, via visual examination, that the three individuals are closer each other after the averaging out performed by the **B** matrix; the deterioration suffered by individual 3 is socially acceptable by virtue of the anonymity principle.

There are two possible objections to these criteria. The first is that a change in one attribute does not affect the contribution to well-being of other attributes. We could however suppose that the correlation of attributes matter. Tsui (1999) introduces the concept of correlation-increasing transfer, which is an exchange of all attributes between two individuals after which one individual is left with the lowest endowment and the other with the maximum endowment of each attribute. By concentrating attributes, this type of transfer leads to a distribution that is less socially preferable than the original one. An example of "correlation-increasing majorization" is shown in the bottom-left panel of Figure 3.4. Figure 3.5 summarizes the majorization criteria.

The second objection is that, unlike income, many constituents of human welfare are not transferable. In general, it does not make much sense to talk of "transferring health" from a healthier individual to a sick one, with the possible exception of organ transplants (e.g. kidney and bone marrow). This has led Bosmans et al. (2009) to study the implications of formulating a version of the Pigou–Dalton principle that applies only to transferable attributes, and it has led Muller and Trannoy (2012) to examine dominance conditions under which attributes are asymmetric in the sense that one attribute (typically income) can be used to compensate for lower levels of other attributes (e.g., needs, health, etc.).

3.4.2 Partial Orderings and Sequential Dominance Criteria

As in the univariate case, conclusions based on summary measures of multidimensional inequality might be questioned. Thus, it is helpful to investigate their robustness by using partial orderings such as stochastic dominance criteria. The first-degree dominance criterion considered by Atkinson and Bourguignon (1982) was briefly discussed in Section 3.3.3.2. For a discussion of second-order multidimensional stochastic dominance and the conditions that this criterion imposes on the expected utility type of social welfare functions and associated measures of inequality, we refer to Atkinson and Bourguignon

Uniform Pigou–Dalton Majorization (UPD): $\mathbf{Y} \succ_{UPD} \mathbf{X}$ if and only if $\mathbf{Y} = \mathbf{TX}$ for some matrix $\mathbf{T}$ that is a finite product of PD transfer matrices and is not a permutation matrix.
Uniform Majorization (UM): $\mathbf{Y} \succ_{UM} \mathbf{X}$ whenever $\mathbf{Y} = \mathbf{BX}$, where $\mathbf{B}$ is a bistochastic matrix and $\mathbf{Y}$ cannot be derived by permuting the columns of $\mathbf{X}$.
Directional Majorization (DM): $\mathbf{Y} \succ_{DM} \mathbf{X}$ if and only if $\mathbf{Yp}$ strictly Lorenz-dominates $\mathbf{Xp}$ for any $\mathbf{p} \in R^m$.
Positive Directional Majorization (PDM): $\mathbf{Y} \succ_{PDM} \mathbf{X}$ if and only if $\mathbf{Yp}$ strictly Lorenz dominates $\mathbf{Xp}$ for any $\mathbf{p} \in R^m_{++}$.
Correlation-Increasing Majorization (CIM): $\mathbf{Y} \succ_{CIM} \mathbf{X}$ whenever $\mathbf{X}$ may be derived from $\mathbf{Y}$ by a permutation of columns and a finite sequence of correlation-increasing transfers at least one of which is strict.

Figure 3.5 Majorization criteria. *Source: adapted from Tsui (1999, pp. 149–152).*

(1982). Trannoy (2006) and Duclos et al. (2011) propose extensions of the results provided by Atkinson and Bourguignon (1982). Koshevoy (1995, 1998) and Koshevoy and Mosler (1996, 1997, 2007) introduce an alternative approach based on a multidimensional generalization of the Lorenz curve. Note that the equivalence between second-degree stochastic dominance and first-degree Lorenz dominance for fixed means does not hold in the multidimensional case.

The elaboration of sequential dominance criteria for the bivariate asymmetric space of income and household composition has been an early topic of the research on partial orderings in a multidimensional framework. Following Atkinson and Bourguignon (1987), many authors have seen the advantage of this approach over the standard income equivalization procedure in the fact that it only requires ranking family types in terms of needs, without specifying how much needier one family type is than another. Bourguignon (1989), Atkinson (1992), Jenkins and Lambert (1993), Moyes (2012), Chambaz and Maurin (1998), Ok and Lambert (1999), Ebert (2000), Lambert and Ramos (2002), Duclos and Makdissi (2005), Decoster and Ooghe (2006), and Zoli and Lambert (2012) belong to this branch of research, with a focus either on poverty or on inequality. Sequential dominance analysis can be applied to other bivariate distributions. Brandolini and D'Alessio (1998) present an early application to the joint distribution of equivalent income and health in Italy, whereas Duclos and Échevin (2011) and Madden (2014) carry out a similar exercise to compare Canada and the United States. Duclos et al. (2006b) study the joint distributions of household expenditure and children's heights in Ghana, Madagascar, and Uganda. Bérenger and Bresson (2012) use sequential dominance to test whether growth is "pro-poor" when poverty is measured by income and another discrete well-being attribute. Sequential dominance criteria for more than two attributes are presented by Gravel et al. (2009), Gravel and Mukhopadhyay (2010), and Muller and Trannoy (2011). McCaig and Yatchew (2007) and Batana and Duclos (2011) have developed statistical inference techniques to test dominance.

3.4.3 Measures of Multidimensional Inequality

As for the measurement of multidimensional deprivation and poverty, the informational basis defined by the order of aggregation plays a crucial role in measurement of multidimensional inequality as well. Thus, it is helpful to make a distinction between measures of multidimensional measures of inequality for which the order of aggregation either begins with aggregating across individuals for each single attribute or across attributes for each individual. In the former case, we obtain measures of overall inequality that aggregate inequality over each of the attributes. If we invert the order of aggregation, we derive an overall measure of inequality that aggregates synthetic functions of the attributes across individuals. The latter approach embeds the association between the achievements in the various dimensions into an overall indicator of individual achievements.

3.4.3.1 Two-Stage Approaches: First Aggregating Across Individuals

Two-stage approaches either aggregate individuals' achievements on each dimension and then the resulting attribute-specific indicators over the r dimensions, or they aggregate the single attributes into individual-specific well-being indicators, before aggregating these individual indicators into a summary measure of multidimensional inequality. The former approach forms the basis of the Inequality-adjusted Human Development Index (*IHDI*; e.g., UNDP, 2013), which belongs to the class of distribution-sensitive composite indices proposed by Foster et al. (2005), as well as of the following family of multidimensional generalized-Gini coefficients proposed by Gajdos and Weymark (2005):

$$J_{\tau w}(F) = 1 - \frac{W_{\tau w}(F)}{W_{\tau w}\left(F_{\text{equal}}\right)}, \tag{3.27}$$

where $W_{\tau w}(F)$ and $W_{\tau w}(F_{\text{equal}})$ are defined by

$$W_{\tau w}(F) = \begin{cases} \left[\sum_{j=1}^{r} \tau_j \left(\sum_{i=1}^{n} w_{ij} x_{ij}\right)^{\alpha}\right]^{1/\alpha} & \text{when}\, \alpha \neq 0 \\ \prod_{j=1}^{r} \left(\sum_{i=1}^{n} w_{ij} x_{ij}\right)^{\tau_j} & \text{when}\, \alpha = 0, \end{cases} \tag{3.28}$$

and

$$W_{\tau w}\left(F_{\text{equal}}\right) = \begin{cases} \left[\sum_{j=1}^{r} \tau_j \mu_j^{\alpha}\right]^{1/\alpha} & \text{when}\, \alpha \neq 0 \\ \prod_{j=1}^{r} \mu_j^{\tau_j} & \text{when}\, \alpha = 0, \end{cases} \tag{3.29}$$

where μ_j is the mean of attribute j.

Gajdos and Weymark (2005) demonstrate that the family of social evaluation functions $W_{\tau w}(F)$ is characterized by the following set of distributional associated axioms: *uniform Pigou–Dalton majorization principle* (*UPD*), *strong attribute separability* (*SAS*), *weak comonotonic additivity* (*WCA*), and *homotheticity* (*HOM*), as well as the conventional non-distributional axioms *ordering*, *continuity*, and *monotonicity*. *UPD* is a multidimensional Pigou–Dalton transfer principle. *SAS* requires that any subset of the attributes is independent of the other attributes. *WCA* is a multidimensional extension of the weak independence of income source axiom imposed by Weymark (1981) on the ordering of univariate income distributions, which is equivalent to the *dual independence* axiom discussed in Section 3.3. *HOM* is an extension of the scale invariance axiom for unidimensional inequality measures and requires that a common proportional change in the measurement units of the attributes should not affect the social evaluation ordering.[42]

By specifying $\alpha = 1$ and $\tau_j = 1/r$ in (3.28) and (3.29), $J_{\tau w}(F)$ becomes a weighted average of the attribute-specific generalized-Gini coefficients introduced by Donaldson and Weymark (1980). Alternatively, by choosing $\tau_j = 1/\mu_j$, $J_{\tau w}(F)$ becomes equal to the arithmetic mean of the attribute-specific generalized-Gini coefficients, previously proposed by Koshevoy and Mosler (1997).[43] Replacing *WCA* with a multidimensional extension of the *independence* axiom gives a normative justification of a multidimensional Atkinson family similar to the generalized-Gini family (3.27).

These types of multidimensional inequality measures ignore the impact of the association between attributes on overall inequality, and therefore, they do not exploit all information when individual-level data on multiple attributes are available.

3.4.3.2 Two-Stage Approaches: First Aggregating Across Attributes

Measures that capture the association between attributes can be derived either from a two-stage aggregation approach or from a direct one-stage approach. The two-stage approach originally proposed by Maasoumi (1986, 1989, 1999) uses a (common) utility-like function (measure of well-being) to aggregate the attributes for each individual in the first stage and a univariate inequality measure to aggregate the utility-like values across individuals in the second stage. Seth (2013) and Bosmans et al. (2013a) give the two-stage approach a normative justification. Let the social evaluation (or welfare) function W associated with the two-stage approach be defined by

$$W(F) = v(u(x_1), u(x_2), \ldots, u(x_n)), \tag{3.30}$$

where $x_i = (x_{i1}, x_{i2}, \ldots, x_{ir})$ is the attribute bundle of individual i, $i = 1, 2, \ldots, n$; F is the multidimensional distribution of the r attributes; and u is the common utility-like function. Bosmans et al. (2013a) demonstrate that $W(F)$ is characterized by the following axioms:[44] *monotonicity*, *continuity*, *normalization* (provides a cardinalization of the social evaluation function), *anonymity* (makes the utility function common to all individuals), *homotheticity* ($W(F)$ is invariant to a common proportional change in each attribute), *weak uniform majorization* (progressive transfers uniformly applied to each attribute do not

[42] See Gajdos and Weymark (2005) for a discussion of strengthening the scale invariance axiom to allow for independent proportional changes in the measurement units of the attributes, which is required when one considers both monetary and nonmonetary attributes.

[43] Okamoto (2009) provides a decomposition of this class of multivariate Gini indices which satisfies the *completely identical distribution* condition, whereby the between-group inequality is equal to zero if the distribution is the same within all population subgroups.

[44] Seth (2013) provides an axiomatic characterization of a two-stage approach in which generalized means form the basis of the aggregation in each stage. See also Lasso de la Vega et al. (2010) who consider the two-stage generalized mean approach for analyzing multidimensional deprivation distributions.

decrease $W(F)$), and *individualism* (social evaluation is made in two steps: the first step aggregates across attributes for each individual and the second step aggregates the aggregated attributes across individuals).

Thus, several of the proposed families of multidimensional inequality measures can be ethically justified by drawing on the characterization results of Bosmans et al. (2013a). For example, the common utility-like function can be specified as

$$u(x_i) = \sum_j w_j x_{ij}, \tag{3.31}$$

where w_j is the weight associated with attribute j, equal across individuals, and weights are normalized to sum to unity. The hypothesis of additive separability used in (3.31) rules out attributes that are not perfect substitutes. As suggested by Maasoumi (1986), a straightforward generalization of (3.31) is offered by the class of utility functions showing constant elasticity of substitution (CES)

$$u(x_i) = \begin{cases} \left[\sum_j w_j x_{ij}^{-\beta}\right]^{1/\beta} & \beta \neq 0 \\ \prod_j x_{ij}^{w_j} & \beta = 0, \end{cases} \tag{3.32}$$

where β is a parameter governing the degree of substitution between the attributes. As β goes to infinity, the attributes are perfect complements, whereas they are perfect substitutes for $\beta = -1$. To aggregate the distribution of $u(x_i)$'s, Maasoumi (1986) proposes using either the entropy family or the Atkinson family of inequality measures.[45] Alternatively, in the second aggregation stage, we can rely on the family of rank-dependent measures, which includes the generalized-Gini family. List (1999), Banerjee (2010), and Decancq and Lugo (2012) characterize multidimensional Gini indices that aggregate first across attributes and then across individuals.

Tsui (1995, 1999) follows the direct one-stage approach. Tsui (1995) generalizes to the multivariate context Kolm's (1969) and Atkinson's (1970) analysis in which inequality is identified with the social welfare loss (see Sen, 1978, 1992, for a critique of ethical inequality indices). After restricting the class of social evaluation functions to be continuous, strictly increasing, anonymous, strictly quasi-concave, separable, and scale-invariant, Tsui (1995) derives the two following multidimensional (relative) inequality indices:[46]

[45] For instance, in their applications of Maasoumi's approach, Nilsson (2010), Justino (2012) and Rohde and Guest (2013) use the Theil indices.

[46] Abul Naga and Geoffard (2006), Brambilla and Peluso (2010), and Croci Angelini and Michelangeli (2012) provide decompositions of this class of indices into the univariate inequality indices of the attributes and a residual term capturing their joint distributions. See also Kobus (2012) for a stronger definition of decomposition by attributes. Diez et al. (2008) derive unit-consistent multidimensional inequality indices. Gigliarano and Mosler (2009) construct multidimensional indices of polarization. Abul Naga (2010) derives the large sample distribution of a class of multidimensional inequality indices including the Tsui index.

$$I_1 = 1 - \left[\frac{1}{n}\sum_i \prod_j \left(\frac{x_{ij}}{\mu_j}\right)^{r_j}\right]^{1/\sum_k r_k} \tag{3.33a}$$

$$I_2 = 1 - \prod_i \left[\prod_j \left(\frac{x_{ij}}{\mu_j}\right)^{r_j/\sum_k r_k}\right]^{1/n}, \tag{3.33b}$$

where μ_j is the mean of attribute j over all persons and parameters r_j's must satisfy certain restrictions. The separability condition implies that the attributes can be aggregated for every person i into an indicator of well-being $u(x_i) = \Pi_j x_{ij}{}^{w_j}$, where $w_j = r_j/\Sigma_k r_k$ can be seen as a normalized weight on attribute j. By replacing ε for $\Sigma_k r_k$, (3.33a) and (3.33b) can be rewritten as

$$I = \begin{cases} 1 - \left[\frac{1}{n}\sum_i \left(\frac{u(x_i)}{u(\mu)}\right)^{1-\varepsilon}\right]^{1/1-\varepsilon} & \varepsilon \neq 1 \\ 1 - \prod_i \left(\frac{u(x_i)}{u(\mu)}\right)^{1/n} & \varepsilon = 1 \end{cases}, \tag{3.34}$$

where $u(\mu) = \Pi_j \mu_j^{w_j}$ is the "representative" well-being of the society, or, in other words, the well-being of a person showing the mean achievement for each attribute. The restrictions on r_j transfer to w_j and ε; in the bivariate case, it is sufficient that $\varepsilon > 0$ and $0 < w_1 = 1 - w_2 < 1$.

This reformulation has four advantages. Firs, it demonstrates that the family defined by (3.33a) and (3.33b) could also be justified by the two-stage approach. Second, it shows the close link of the Tsui multidimensional inequality measure with the Atkinson univariate index applied to the $u(x)_i$'s, from which it differs only for the replacement of *mean* well-being with *representative* well-being. This is indeed the appropriate normalization because "maximizing social welfare under the constraint of fixed total resources of attributes ... requires to give each individual the average available quantity of attributes" (Bourguignon, 1999, p. 478). This observation exposes a conceptual diversity between the direct one-stage approach and the two-stage approach: the first normalizes by the representative well-being $u(\mu) = \Pi_j \mu_j^{w_j}$, but the latter uses the mean well-being $(1/n)\Sigma_i \Pi_j x_{ij}^{w_j}$. (Of course, the two indices coincide in the univariate case.) Third, (3.34) brings out the role of ε, or $\Sigma_k r_k$ in the original formulation, as the parameter that governs the degree of concavity, and hence inequality aversion, of the social evaluation function. In the univariate income space, the range of economically sensible values for ε can be restricted on the basis of considerations on the preference for redistribution. A similar analysis has not been conducted in the multivariate space of well-being, but "there is not necessarily any reason to change our views about the value of [ε] simply because we have moved to a higher dimensionality" (Atkinson, 2003, p. 59).[47] Fourth, (3.34) shows that the Tsui index allows for different weightings of the attributes (through the w_j's), but it makes no allowance for a variation in the degree of substitution between the attributes: the Cobb–Douglas functional form of the underlying well-being indicator implies that the elasticity of substitution between two attributes is uniformly equal to unity. In the bivariate case, a straightforward generalization is represented by the index derived by Bourguignon (1999) by assuming a CES functional form for the indicator of well-being, which has the Tsui index as a special case (see Lugo, 2007). Tsui (1999) examines alternative axioms that lead to characterizing a class of multidimensional generalized entropy measures.

3.4.3.3 Indices for Binary Variables

If information is restricted to marginal distributions of zero/one variables, an overall measure of inequality is a function of the proportions of people with attribute values above each of the attribute-specific thresholds, which means that they do not suffer from deprivation in these dimensions.

By contrast, when multiple attributes are observed for the same individuals, let p_j be the proportion of people with j attributes that take values above the attribute-specific threshold levels, and $G(k) = \sum_{j=0}^{k} p_j$ can be the cumulative proportion of people with k or fewer attributes that take values above the attribute-specific threshold levels. Then, similar to the discussion for the distribution of deprivation counts in Section 3.3.1, the social evaluation function

$$W_{\Psi}(G) = r - \sum_{k=0}^{r-1} \Psi\left(\sum_{j=0}^{k} p_j\right) \tag{3.35}$$

yields the following measures of dual multidimensional inequality:

$$I_{\Psi}(G) = 1 - \frac{W_{\Psi}(G)}{\nu} = 1 - \frac{r - \sum_{k=0}^{r-1} \Psi\left(\sum_{j=0}^{k} p_j\right)}{\nu}, \tag{3.36}$$

where ν is the average number of individual achievements above the attribute thresholds, and Ψ, with $\Psi(0) = 0$ and $\Psi(1) = 1$, is a nonnegative and nondecreasing concave function capturing the preferences of a social evaluator who supports axioms similar to those underlining the rank-dependent utility theory of Yaari (1987).

[47] In the analysis of income inequality, Atkinson and Brandolini (2010) suggest that plausible values for ε are between 0.3 and 3. This range includes the values used by Lugo (2007) and Brandolini (2009) in their empirical analyses. In a cross-national comparison of multidimensional inequality, Aristei and Perugini (2010) use country-specific values of ε, ranging from 1.04 to 1.77, estimated from national tax structures.

Note that $G(k) = 1 - F(r - k - 1)$, where F and μ are the count distribution of deprivations and the mean number of deprivations discussed in Section 3.3.1, which means that $\nu + \mu = r$. In other words, the sum of the mean number of deprivations and the mean number of achievements is necessarily equal to the number of attributes. By specifying $\Psi(t) = 1 - \Gamma(1 - t)$ it can be demonstrated that this adding-up condition is also satisfied by the sum of the deprivation measure D and social evaluation function W,

$$\begin{aligned} W_{\Psi}(G) &= W_{1-\Gamma}(1 - F(r - k - 1)) \\ &= r - \sum_{k=0}^{r-1}\left(1 - \Gamma\left(1 - \sum_{j=0}^{r-k-1} p_j\right)\right) = \sum_{k=0}^{r-1}\left(\Gamma\left(\sum_{j=0}^{k} q_j\right)\right) = r - D_{\Gamma}(F). \end{aligned}$$

Thus, inequality in the count distribution of achievements, rather than deprivations, can be given the following alternative expression:

$$I_{\Psi}(G) = 1 - \frac{r - D_{\Gamma}(F)}{r - \mu} = \frac{D_{\Gamma}(F) - \mu}{r - \mu} = \frac{\Delta_{\Gamma}(F)}{r - \mu}, \tag{3.37}$$

where Γ is a nondecreasing convex function. Inequality in the distribution of achievements is equivalent to the relative spread of deprivations (divided by the difference between the mean number of deprivations and achievements). Note that the notion of inequality is closely associated with the intersection approach discussed in Section 3.3, whereas the union approach is in conflict with the notion of inequality.

The primal analogs to $W_{\psi}(G)$ and $I_{\Psi}(G)$, and the counterpart of $d_{\gamma}(F)$ defined by (3.10), are given by

$$w_{\xi}(G) = \sum_{k=0}^{r} \xi(k) p_k \tag{3.38}$$

and

$$J_{\xi}(G) = 1 - \frac{w_{\xi}(G)}{\xi(\nu)} = 1 - \frac{\sum_{k=0}^{r} \xi(k) p_k}{\xi(\nu)}, \tag{3.39}$$

where ξ is a nonnegative and nondecreasing concave function capturing the preferences of a social evaluator who supports the *independence* axiom for orderings defined on the set of G-distributions. By specifying $\xi(k) = \gamma(r) - \gamma(r - k)$ and inserting for $p_k = q_{r-k}$, we get

$$w_{\xi}(G) = \sum_{k=0}^{r} \xi(k) p_k = \sum_{k=0}^{r} \xi(k) q_{r-k} = \sum_{k=0}^{r} \xi(r-k) q_k = \sum_{k=0}^{r} (\gamma(r) \; - \gamma(k)) q_k \; = \gamma(r) - d_{\gamma}(F)$$

and $\xi(\nu) = \gamma(r) - \gamma(\mu)$, which yield the following alternative expression for J_{ξ}

$$J_\xi(G) = 1 - \frac{\gamma(r) - d_\gamma(F)}{\xi(\nu)} = \frac{d_\gamma(F) - \gamma(\mu)}{\gamma(r) - \gamma(\mu)} = \frac{\delta_\gamma(F)}{\gamma(r) - \gamma(\mu)}, \tag{3.40}$$

where $\delta_\gamma(F)$ is defined by (3.11) and γ is a nondecreasing convex function such that $\gamma(\mu) \leq d_\gamma(F) \leq \gamma(r)$.

3.5. SUMMARY AND CONCLUSIONS

Since the 1990s, the measurement of multidimensional inequality and poverty has turned into a thriving research area. Novel analytical results have accompanied a massive production of applied research. The increasing availability of new and rich databases has fueled the growth, but this process would have not been possible without the spreading of new conceptualizations of well-being, prominently the capability approach, and of a policy orientation more inclined to consider the nuances of human well-being. The progress has not always been coherent: applied researchers have sometimes moved from available data, unaware of analytical developments, and theoretical researchers have sometimes ignored the applicability of their results to real data. This is common when development is rapid, and it can contribute to explaining why we have enriched our toolbox with so many new instruments, but we still disagree on whether and how to use them. Our aim in this chapter has been to provide a manual to this toolbox, drawing connections between different strands of the literature, clarifying some ambiguities, and exposing the strict link between analytical tools and the characteristics of the data available for the analysis.

The informational basis of the analysis is indeed crucial: tools intended for cardinal or categorical variables need not be appropriate for dichotomous variables, which often represent the bulk of the available information. This is one reason why we have paid special attention to the counting approach. Another one is expository convenience: the role of marginal distributions and the association between the attributes are particularly transparent for dichotomous variables, especially in the two-dimensional case, although the descriptive and normative issues are similar to those of continuous variables. However, the main motivation for this choice has been the attempt to bridge the gap between a copious empirical literature and a still relatively underdeveloped analytical elaboration. We have derived dominance criteria and measures of deprivation by exploiting the fact that counting deprivations brings us back to a univariate space. Thus, the social evaluation of distributions of deprivation counts is in many respects analogous to the social evaluation of income distributions, although it implicitly accounts for the association among the deprivation indicators. Of course, concave preferences in the income space correspond to convex preferences in the space of deprivations counts, which represent "bads" (loss in welfare) rather than "goods" (gains in welfare). However, although convex preferences are ruled out in the analysis of income distributions because they would yield a social evaluation function violating the Pigou–Dalton principle of transfers, concave preferences are perfectly legitimate in the analysis of deprivation counts. This happens when we lean toward the union criterion, while convex preferences are associated with the intersection criterion. This example illustrates how the multidimensional case brings in new aspects that are unknown to the univariate case, but it also neatly exposes the strict connection between value judgements—where we draw the boundaries of poverty when there are multiple deprivations—and analytical tools—the degree of concavity/convexity of social preferences. There is clearly a need for further work on the analytical foundations of the social evaluation of distributions of deprivation scores.

The opposite situation characterizes the axiomatic treatment of poverty and inequality for continuous and categorical variables: a fairly rich theoretical apparatus does not appear to have yet made an impact on empirical investigations, except in sporadic applications. This may be due to the scarcity of suitable variables and databases, but it may also reflect the difficulty of discriminating among many equally sensible alternative tools. In addition to further developing and refining theoretical analysis, in this case, empirical work may play an important role in screening the most effective tools. Whatever the approach adopted, the quality and reliability of databases and the elaboration of inference tools, two aspects that we have virtually ignored in this chapter, are essential to supporting the validity of empirical analyses, especially when they are used to inform policy.

Yet, is it really worth devoting so much intellectual effort to develop the multidimensional analysis of poverty and inequality? It is an odd question at the end of such a long chapter, but as discussed in the introduction, the widely shared view that well-being, and hence poverty, is multidimensional does not necessarily imply that the social evaluation must itself be multidimensional. It may be for philosophical reasons or, more practically, because too much is lost in the process of aggregation. Once Sen (1987, p. 33) remarked that "the passion for aggregation makes good sense in many contexts, but it can be futile or pointless in others. . . . When we hear of variety, we need not invariably reach for our aggregator." On the other hand, the "eye-catching property" of the Human Development Index was praised by Streeten (1994, p. 235) as a powerful feature for its affirmation in the public debate, in spite of the theoretical weaknesses pointed out by its critics.[48] Three points may help us to find an answer to the question.

First, there is a pervasive demand by media commentators and policy-makers for multidimensional analyses. This demand must be met, not the least in order to avoid that such analyses are left to practitioners that conceive them as a bunching together of living standard indicators through some simple averaging or multivariate technique easily available in statistical and econometric packages. Empirical research confirms that broadening the evaluative space to include variables other than income can modify the picture drawn on

[48] For a recent example, see the exchange between Klugman et al. (2011a,b) and Ravallion (2011b, 2012a,b). See also Chakravarty (2011).

the basis of income alone. There is distinct informative value in adopting a multidimensional perspective. The theoretical work surveyed in this chapter facilitates the interpretation of empirical findings by bringing to the fore the implicit measurement assumptions and their economic meaning. If we estimate a lower deprivation index in the United Kingdom than in Italy using concave social preferences, as in Section 3.3.2.4, it is because we favor the union criterion, and hence, we tend to be relatively more worried by the spreading of a given number of deprivations across many people than by their concentration on fewer people who are hit more. If, on the contrary, we have convex preferences and are particularly concerned about those suffering from severe deprivations, we cannot unequivocally rank one country ahead of the other.

Second, the difficulties of multidimensional measurement should not be overstated. The choice of the degree of poverty or inequality aversion and the proper definition of indicators less familiar to us than income also arise in the univariate context. The problems that are new to the multivariate case are the weighting structure of the attributes and their degree of substitutability. Both these aspects are not technical hitches but rather the expression of implicit value judgements. Far from being a weakness of multidimensional approaches, the investigation of alternative assumptions is necessary to allow for the different views in the society. This is a sufficient reason for not devolving the resolution of these measurement problems to some statistical algorithm.

Third, the battery of instruments in our toolbox is ample. If we are reluctant to use a summary poverty or inequality index, we may fruitfully use sequential dominance analysis: it may yield a partial ordering, but it may sometimes be sufficient to evaluate, say, the impact on the distribution of well-being of alternative policies. The variety of our toolbox means that there is a middle ground between multidimensional summary indices and the dashboard approach, as stressed by Ferreira and Lugo (2013).

These are all good arguments in favor of multidimensional social evaluation. Are they also compelling enough to push us as far as to accept summary indices? Probably not, but two further comments are in order. The first is a pragmatic suggestion drawn from Bourguignon (1999, p. 483): when their building assumptions are properly understood, these indices can provide valuable insights if used "more as a dominance instrument than a strictly cardinal rule of comparison." The second is a somewhat deeper point. In a sense, the uneasiness with such a summary index in sectors of the economics profession may stem from the reluctance of those economists to abandon a utility-based conception of well-being. Only individuals are able to assess the trade-offs between the different constituents of well-being, and prices are the best available way to reveal such trade-offs, because they derive from the interactions of individuals in a market economy. If externalities, distortions, and missing markets prevent us from relying on prices as the aggregator of well-being dimensions, then the dashboard approach may be preferable, because no arbitrary weighting is imposed. The most developed conceptualization of multidimensional well-being to date, the capability approach, originates exactly from the rejection of a utility-based conception: "*valuing* a life and measuring the *happiness* generated in that life are two different exercises" (Sen, 1985, p. 12). If this is the founding aspect of multidimensional analysis, then the weighting of the different dimensions is an integral part of the evaluation exercise, and the reference to market prices loses much of its appeal. Social evaluation may attach more weight to work effort than that revealed by the wage, because jobs are characterized by other attributes that might contribute to reinforcing social integration. From this perspective, the practical solutions given to the selection of weights, which often boil down to equal weighting, may miss a decisive part of the evaluation. If this conjecture is correct, there is little chance that we will ever settle the controversy between the dashboard approach and summary indices.

ACKNOWLEDGMENTS

We are very grateful to Tony Atkinson and François Bourguignon for their inspiring discussions, insightful comments, and generous patience. We would also like to thank Sabina Alkire, Conchita D'Ambrosio, Jean-Yves Duclos, Stephen Jenkins, Eugenio Peluso, Luigi Federico Signorini, Henrik Sigstad and Claudio Zoli for their helpful comments. The views expressed here are solely ours; in particular, they do not necessarily reflect those of the Bank of Italy and Statistics Norway.

Abstract

The modern formulation of equality of opportunity emerges from discussions in political philosophy from the second half of the twentieth century beginning with Rawls (1971) and Dworkin (1981a,b). Equality of opportunity exists when policies compensate individuals with disadvantageous circumstances so that outcomes experienced by a population depend only on factors for which persons can be considered

to be responsible. Importantly, inequality of opportunity for income exists when individuals' incomes are in some important part determined by the educational achievement and income of the families that raised them. We review the philosophical debates referred to, commenting upon them from an economist's viewpoint. We propose several ways of modeling equality (or inequality) of opportunity, pointing out that an equal-opportunity ethic implies a non-welfarist way of ranking social outcomes. We propose that economic development should be conceived of as the equalization of opportunities for income in a country. We consider equalization of opportunity from a dynamic viewpoint, and we review popular attitudes with regard to distributive justice, showing that there is substantial popular support for an equal-opportunity ethic. We discuss the empirical issues that emerge in measuring inequality of opportunity and provide a review of the empirical literature that measures degrees of inequality of opportunity for the achievement of various objectives, in various countries.

4.1. INTRODUCTION

In the welfarist tradition of social-choice theory, egalitarianism means equality of welfare or utility.[1] Conservative critics of egalitarianism rightly protest that it is highly questionable that this kind of equality is ethically desirable, as it fails to hold persons responsible for their choices, or for their preferences, or for the way they process outcomes into some interpersonally comparable currency that one can speak of equalizing. In political philosophy, beginning with Rawls (1958, 1971), this critique was taken seriously, and a new approach to egalitarianism transpired, which inserted personal responsibility as an important qualifier of the degree of equality that is ethically desirable. Thus, the development of egalitarian theory, since Rawls, may be characterized as an effort to replace equality of outcomes with equality of opportunities, where opportunities are interpreted in various ways. Metaphors associated with this view are "leveling the playing-field," and "starting gate equality." The main philosophical contributions to the discussion were, following Rawls, from Sen (1980), Dworkin (1981a,b), Arneson (1989), and Cohen (1989).[2] The debate is said to be about "equality of what," and the philosophical view is sometimes called "luck egalitarianism," a term coined by Anderson (1999).

[1] Welfarism is the view that social welfare (or the social objective function) should be predicated only on the utility levels of individuals; that is, that the only information required to compare social alternatives is that summarized in the utility-possibilities sets those alternatives generate. It is a special case of consequentialism. See Chapter 2 for further discussion.

[2] The philosophical literature generated by these pioneers is too large to list here. Book-length treatments that should be mentioned are Rakowski (1993), Van Parijs (1997), and Hurley (2003).

Economists (besides Sen) have been involved in this discussion from 1985 onward. Roemer (1993, 1998) proposed an algorithm for calculating policies that would equalize opportunities for achievement of a given objective in a population. Marc Fleurbaey and François Maniquet contributed economic proposals beginning in the 1990s, and recently summarized in Fleurbaey (2008). Other authors who have contributed to the theory include Van de gaer (1993), Bossert (1995, 1997), and Peragine (2004). An empirical literature is rapidly developing, calculating the extent to which opportunities for the acquisition of various objectives are unequal in various countries, and whether people hold views of justice consonant with equality of opportunity (EOp).

There are various ways of summarizing the significance of these developments for the economics of inequality. Prior to the philosophical contributions that ignited the economic literature that is our focus in this chapter, there was an earlier skirmish around the practical import of equalizing opportunities. Just prior to the publication of Rawls's magnum opus (1971), contributions by Jensen (1969) and Herrnstein (1971) proposed that inequality was in the main due to differential intelligence (IQ), and so generating a more equal income distribution by equalizing opportunities (for instance, through compensatory education of under-privileged children) was a chimera. Economists Bowles (1973) and Conlisk (1974) disagreed; Bowles argued that inequality of income was almost all due to unequal opportunities, not to the heritability of IQ. Despite this important debate on the degree to which economic inequality is immutable, prior to Rawls, economists' discussions of inequality were in the main statistical, focusing on the best ways of measuring inequality.

The post-Rawls–Dworkin inequality literature changed the focus by pointing out that only some *kinds* of inequality are ethically objectionable, and to the extent that economists ignore this distinction, they may be measuring something that is not ethically salient. This distinction between morally acceptable and unacceptable inequality is perhaps the most important contribution of philosophical egalitarian thought of the last 40 years. From the perspective of social-choice theory, equal-opportunity theory has sharply challenged the welfarist assumption that is classically ubiquitous, maintaining that more information than final outcomes in terms of welfare is needed to render social judgment about the ranking of alternative policies—in particular, one must know the extent to which individuals are responsible for the outcomes they enjoy—whether those outcomes were determined by social (and perhaps genetic) factors beyond their control, or not—and this is non-welfare information.

One must mention that another major non-welfarist theory of justice, but a nonegalitarian one, was proposed by Nozick (1974) who argued that justice could not be assessed by knowing only final outcomes; one had to know the process by which these outcomes were produced. His neo-Lockean view, which proposed a theory of the moral legitimacy of private property, can evaluate the justness of final outcomes only by knowing whether the history that produced them was unpolluted by extortion, robbery, slavery, and so on.

Simply knowing the distribution of final outcomes (in terms of income, welfare, or whatever) does not suffice to pass judgment on the distribution's moral pedigree. So the period since 1970 has been one in which, in political philosophy, non-welfarist theories flourished, on both the right and left ends of the political spectrum.

In this chapter, we begin by summarizing the philosophical debate concerning equality since Rawls (Section 4.2), presenting economic algorithms for computing policies which equalize opportunities—or, more generally, ways of ordering social policies with respect to their efficacy in opportunity equalization (Sections 4.3, 4.4, and 4.5), application of the approach to the conceptualization of economic development (Section 4.6), discussion of dynamic issues (Section 4.7), a preamble to a discussion of empirical work (Section 4.8), evidence of population views from surveys and experiments concerning conceptions of equality (Section 4.9), a discussion of measurement issues, and summary of the empirical literature on inequality of opportunity to date (Section 4.11). We conclude by mentioning some critiques of the equal-opportunity approach, and some predictions (Section 4.12).

4.2. EGALITARIAN POLITICAL PHILOSOPHY SINCE RAWLS

Rawls (1958) first published his ideas about equality over 50 years ago, although his magnum opus did not appear until 1971. His goal was to unseat utilitarianism as the ruling theory of distributive justice, and to replace it with a type of egalitarianism. He argued that justice requires, after guaranteeing a system which maximizes civil liberties, a set of institutions that maximize the level of "primary goods" allocated to those who are among the worse off in society, in the sense of receiving the least amount of these goods. Economists call this principle maximin primary goods; Rawls often called it the difference principle. Moreover, he attempted to provide an argument for the recommendation based on construction of a "veil of ignorance" or "original position," which shielded decision makers from knowledge of information about their situations that was "morally arbitrary," so that the decision they came to regarding just allocation would be impartial. Thus, Rawls's (1971) project was to derive principles of justice from rationality and impartiality.

Rawls did not advocate maximining utility (even assuming interpersonal utility comparisons were available), but rather maximining (some index of) primary goods. This was, in part, his attempt to embed personal responsibility into the theory. For Rawls, welfare was best measured as the extent to which a person is fulfilling his or her plan of life: but he viewed the choice of life plan as something up to the individual, upon which social institutions had no business passing judgment. Primary goods were deemed to be those inputs that were required for the success of any life plan, and so equalizing primary goods bundles across persons (or passing to a maximin allocation that would dominate component-wise an equal allocation) was a way of holding persons responsible for their life-plan choice. The question of how to aggregate the various primary goods into an index that would allow comparison of bundles was never successfully solved by Rawls (and some skeptical economists said that the subjective utility function was the obvious way to aggregate primary goods).

Rawls defended the difference principle by arguing that it would be chosen by decision makers who were rational but were deprived of knowledge about their own situations in the world, to the extent that this knowledge included information about their physical, social, and biological endowments, which were a matter of luck, and therefore whose distribution Rawls described as morally arbitrary. He named the venue in which these souls would cogitate about justice the "original position." In the original position, souls were assumed to know the laws of economics and to be self-interested. They were, moreover, to be concerned with the allocation of primary goods, because they did not know their life plans, or even the *distribution* of life plans in the actual society. Nor were they to know the *distribution* of physical and biological endowments in society.

Here, we believe Rawls made a major conceptual error. If the veil of ignorance is intended to shield decision makers from knowledge of aspects of their situations that are morally arbitrary, and only of those aspects, they *should* know their plans of life, which, by hypothesis, are not morally arbitrary, because Rawls deems that persons are responsible for their life plans. Second, although a person's *particular* endowment of resources, natural and physical, might well be morally arbitrary (to the extent that these were determined by the luck of the birth lottery), the *distribution* of these resources is a fact of nature and society, and should be known by the denizens in the original position, just as they are assumed to know the laws of economics. Therefore, Rawls constructed his veil too thickly, on two counts, given his philosophical views.

Given the paucity of information available to the decision makers in the original position, it is not possible to use classical decision theory to solve the problem of the desirable allocation of primary goods. Indeed, the only precise arguments that Rawls gives for the conclusion that the difference principle would be chosen in the original position occur at Rawls, 1999[1971], p. 134), and they essentially state that decision makers are extremely risk averse. For example:

> *The second feature that suggests the maximin rule is the following: the person choosing has a conception of the good such that he cares very little, if anything, for what he might gain about the minimum stipend that he can, in fact, be sure of by following the maximin rule. It is not worthwhile for him to take a chance for the sake of further advantage, especially when it may turn out that he loses much that is important to him. The last provision brings in the third feature, namely, that the rejected alternatives have outcomes one can hardly accept. The situation involves grave risks.*

But extreme risk aversion, which Rawls here depends on for his justification of maximin, is certainly not an aspect of rationality.

Thus, despite its enormous influence in political philosophy, Rawls's argument for maximin is marred in two ways: first, its reliance on deducing the principle of justice from the original position was crucially flawed in depriving the denizens of that position of knowledge of features of themselves (life plans) and of the world (the distributions of various kinds of resources, including genetic ones, and ones possessed by families into which a person is born) which were *not* morally arbitrary,[3] and second, for its assumption (despite claims to the contrary by Rawls and others) that decision makers were extremely risk averse. The value of Rawls's contribution is in stating a radical egalitarian position about the injustice of receiving resources through luck—and, in particular, the luck of the birth lottery—and that it shifted the equalisandum from utility to a kind of resource, primary goods. In our view, however, the project of deducing equality or maximin from rationality and impartiality alone was a failure. Indeed, Moreno-Ternero and Roemer (2008) argue that some solidaristic postulate is necessary to deduce maximin or, more generally, to deduce some kind of egalitarianism as the ordering principle for social choice. Although egalitarians might wish to deduce their view from postulates that can garner universal approval (like rationality and impartiality), this is not possible. Therefore, an egalitarian theory of justice cannot have *universal* appeal, if the solidaristic postulate, which we believe necessary, is contentious.

Although Rawls is usually viewed as the most important egalitarian political philosopher of the twentieth century, one may challenge the claim that his view is egalitarian: to wit, the just income distribution, for Rawls, allows incentive payments to the highly skilled in order to elicit their productive activity, even though this produces inequality. The main philosopher who challenges Rawls's acceptance of incentive-based income inequality is Cohen, whom we discuss below.

In 1981, Ronald Dworkin published two articles that essentially addressed the problems in the Rawlsian argument that we have summarized, although he did not use the Rawlsian language (original position, primary goods). His project was to define a conception of equality that was ethically sound. In the first of these articles, he argued that "equality of welfare" was not a sound view, primarily because equality of welfare does not hold persons responsible for their preferences. In particular, Dworkin argued that if a person has expensive tastes, and he identifies with those tastes, society does not owe him an additional complement of resources to satisfy them. (The only case of expensive tastes, says Dworkin, that justifies additional resources are those tastes that are addictions or compulsions, tastes with which the person does not "identify," and would prefer he

[3] We reiterate it is the distribution of traits that is a fact of nature, and hence not morally arbitrary, whereas the endowment of a given individual may well be morally arbitrary, in the sense of its being due to luck.

did not have.) In the second article, Dworkin argues for "equality of resources," where resources include (as for Rawls) aspects of a person's physical and biological environment for which he should not be held responsible (such as those acquired through birth).

But how can one "equalize resources," when these comprise both transferable goods, such as money, and inalienable resources, including talent, families into which persons are born, and even genes? Dworkin proposed an ingenious device, an insurance market carried out behind a veil of ignorance, where the "souls" participating represent actual persons and know the preferences of those whom they represent, but do not know the resources with which their persons are actually endowed in the world. In this insurance market, each participant would hold an equal amount of some currency and would be able to purchase insurance with that currency against bad luck in the birth lottery, that is, the lottery in which nature assigns souls to persons in the world (or resource endowments to souls). Dworkin argues that the allocation of goods that would be implemented after the birth lottery occurred, the state of the world was revealed, and insurance policies taken behind the Dworkinian veil were settled, was an allocation that "equalized resources." It held persons responsible for their preferences—in particular, their risk preferences—and was egalitarian because all souls were endowed, behind the veil, with the same allotment of currency with which to purchase insurance. Impartiality with respect to the morally arbitrary distribution of resources was accomplished by shielding the souls from knowledge of their endowments in the actual world associated with the birth lottery (genetic and physical). Thus, Dworkin retained Rawls's radical egalitarian view about the moral arbitrariness of the distribution of talents, handicaps, and inherited wealth, but implemented a mechanism that held persons responsible for their tastes that was much cleaner than discarding preferences and relying on primary goods, as Rawls had done.

Despite the cleverness of Dworkin's construction, it can lead to results that many egalitarians would consider perverse. To illustrate the problem, consider the following example. Suppose there are two individuals in the world, Andrea and Bob. Andrea is lucky: she has a fine constitution and can transform resources (wealth) into welfare at a high rate. Bob is handicapped; his constitution transforms wealth into welfare at exactly one-half of Andrea's rate. We assume, in particular, that Andrea and Bob have interpersonally comparable welfare. The internal resource that Andrea possesses and Bob lacks is a fine biological constitution (say, a healthy supply of endorphins).

We assume that Bob and Andrea have the same risk preferences over wealth: They are each risk averse and have the von Neumann–Morgenstern utility function over wealth $u(W) = \sqrt{W}$. Suppose that the distribution of (material) wealth in the world to (Andrea, Bob) would be (W^A, W^B), with no further intervention. Thus each individual is endowed with an internal constitution and some external resource.

We construct Dworkin's hypothetical insurance market as follows.[4] Behind the veil of ignorance, there is a soul, Alpha, who represents Andrea, and a soul, Beta, who represents Bob. These souls know the risk preferences of their principals and the constitutions of Andrea and Bob, but they do not know which person they will become in the birth lottery. Thus, from their viewpoints, there are two possible states of the world, summarized in the table:

State 1	Alpha becomes Andrea	Beta becomes Bob
State 2	Alpha becomes Bob	Beta becomes Andrea

Each state occurs with probability one-half. *We* know that state 1 will indeed occur, but the souls face a birth lottery with even chances, in which they can take out insurance against bad luck (that is, of becoming Bob).

There are two commodities in the insurance market: a commodity x_1, a unit of which pays the owner \$1 if state 1 occurs, and a commodity x_2, a unit of which pays \$1 if state 2 occurs. Each soul can either purchase or sell these commodities: selling one unit of the first commodity entails a promise to deliver \$1 if state 1 occurs. Each soul possesses, initially, zero income (behind the veil) with which to purchase these commodities. In particular, they have *equal wealth endowments* behind the veil in the currency that is recognized in that venue. Thus, the insurance market acts to redistribute tangible wealth in the actual world to compensate persons for their natural endowments, which cannot be altered, in that way which the souls, who represent persons, would desire, had they been able to insure against the luck of the birth lottery. It is an institution that transforms what Dworkin calls "brute luck" into "option luck." The former is luck that is not insurable; the latter is luck whose outcome is protected by insurance, or the outcome of a gamble one has chosen to take.

An equilibrium in this insurance market consists of prices $(1,p)$ for commodities (x_1,x_2), demands $(x_1^\alpha,x_2^\alpha),(x_1^\beta,x_2^\beta)$ by souls Alpha and Beta for the two contingent commodities, such that

(1) $\left(x_1^\alpha, x_2^\alpha\right)$ maximizes $\frac{1}{2}\sqrt{W^{\mathrm{A}}+x_1^\alpha}+\frac{1}{2}\sqrt{\frac{W^{\mathrm{B}}+x_2^\alpha}{2}}$
subj. to $x_1^\alpha + px_2^\alpha = 0$

(2) $\left(x_1^\beta, x_2^\beta\right)$ maximizes $\frac{1}{2}\sqrt{W^{\mathrm{B}}+x_1^\beta}+\frac{1}{2}\sqrt{2\left(W^{\mathrm{A}}+x_2^\beta\right)}$
subj. to $x_1^\beta + px_2^\beta = 0$

(3) $x_s^\alpha + x_s^\beta = 0 \quad \text{for } s=1,2$

[4] Dworkin did not propose a formal model but relied on intuition. The model here is a version of an Arrovian market for contingent claims.

Let us explain these conditions. Condition (1) says that Alpha chooses her demand for contingent commodities optimally, subject to her budget constraint—that is, she maximizes her expected utility. Her utility if she becomes Andrea (state 1), will be $\sqrt{W_1^{\mathrm{A}} + x_1^{\alpha}}$. Now if Alpha becomes Bob (state 2), her wealth will be $W^{\mathrm{B}} + x_2^{\alpha}$; however, from the viewpoint of her principal, Andrea, that will generate only half as much welfare, so she evaluates this wealth as being worth, in utility terms, $\sqrt{\frac{W^{\mathrm{B}} + x_2^{\alpha}}{2}}$. Condition (2) has a similar derivation, but this time, soul Beta takes the benchmark situation as becoming Bob. Condition (3) says that both markets clear.

The equilibrium is given by

$$p = 1, \quad \left(x_1^{\alpha}, x_2^{\alpha}\right) = \left(\frac{2W^{\mathrm{B}} - W^{\mathrm{A}}}{3}, \frac{W^{\mathrm{A}} - 2W^{\mathrm{B}}}{3}\right),$$

$$\left(x_1^{\beta}, x_2^{\beta}\right) = \left(\frac{-2W^{\mathrm{B}} + W^{\mathrm{A}}}{3}, \frac{-W^{\mathrm{A}} + 2W^{\mathrm{B}}}{3}\right).$$

Now state 1 occurs. Therefore Andrea, after the insurance contracts are settled, ends up with wealth $W^{\mathrm{A}} + x_1^{\alpha} = \frac{2}{3}(W^{\mathrm{A}} + W^{\mathrm{B}})$—two-thirds of the total wealth—and Bob ends up with one-third of the total wealth. The result is perverse because *Bob is the one with the low resource endowment*, that is, with a low ability to transform money into welfare. It is Bob, putatively, whom an equal-resource principle should compensate, but it is Andrea who ends up the winner.[5] Even should state 2 have occurred, the outcome would have been the same—two-thirds of the wealth would end up being Andrea's.

Why does this happen? Because, even though both souls are risk averse, they are not sufficiently risk averse to induce them to shift wealth into the bad state (of being born Bob); it is more worthwhile (in terms of expected utility) to use wealth in the state when it can produce a lot of welfare (when a soul turns out to be Andrea). If the agents were *sufficiently* risk averse, this would not occur. (If the utility function were $u(W) = W^c/c$, and $c < 0$, then, post-insurance, Bob would end up with more wealth than Andrea. If the utility function is $u(W) = \log W$, then the agents split the wealth equally.) But the example shows that in general the hypothetical insurance market does not implement the kind of compensation that Dworkin desires: for Bob is the one who suffers from a deficit in an internal resource—from morally arbitrary bad luck. For Dworkin's insurance market to avoid this kind of perversity, individuals would have to be sufficiently risk averse, and this

[5] This perversity of the Dworkin insurance mechanism was first pointed out by Roemer (1985). Dworkin never proposed a model of the insurance market but conjectured that it would reallocate wealth in a way to compensate those with a paucity of nontransferable resources. He continued to use the insurance-market thought experiment to justify social policies (e.g., in the case of national health insurance for the United States), even though his thought experiment did not necessarily produce the compensatory redistributions that he thought it would implement.

it is inappropriate to assume, for the theory should surely produce the desired result (of compensating those with a paucity of internal resources) in the special case that all agents have the same risk preferences.[6]

In the model just presented of the hypothetical insurance market, note that it was necessary to make interpersonal welfare comparisons. Alpha, Andrea's soul, has to contemplate how she would feel if she were to be born as Bob, and with a given amount of wealth. She does this by transforming Bob's wealth into a *welfare-equivalent wealth* for Andrea. And soul Beta has to make a similar interpersonal comparison. We maintain that it is impossible to construct a veil-of-ignorance thought experiment without making such comparisons. The point is simple: if a soul has to compare how it would feel when being incarnated as different persons, it must be able to make interpersonal welfare comparisons. Without the ability to compare the lives of different persons in different circumstances, an investment in insurance would have no basis.[7]

Despite the problem we have exhibited with Dworkin's proposal, it was revolutionary, in the words of Cohen, in transporting into egalitarian theory the most powerful tool of the anti-egalitarian Right, the importance of personal responsibility. One might argue, after seeing the above demonstration, that Dworkin's insurance market is an appealing thought experiment, and therefore one should give up on the egalitarian impulse of compensating persons for features of their situations for which they are not responsible; that is, instead of rejecting Dworkin's model as inadequate, one should reject his egalitarian desideratum. Moreno-Ternero and Roemer (2008) consider this and argue instead that the veil of ignorance is an inappropriate thought experiment for ascertaining what justice requires. Although their arguments for this are new, the position is not: It was also advocated earlier by Barry (1991).

In the example we have given, there is, for egalitarians, a moral requirement to transfer tangible wealth from Andrea to Bob, because Bob lacks an inalienable resource that Andrea possesses, the ability effectively to transform goods into welfare, a lack that is beyond his control, and due entirely to luck. Dworkin also focused upon a different possible cause of unequal welfares, that some persons have expensive tastes, while others have cheap ones. His view was that persons with expensive tastes do *not* merit additional

[6] When Dworkin was confronted with this example at a conference in Halifax in 1985, he responded that he would not use the insurance device in cases where it produced the "pathological" result. This is, however, probably an unworkable position, for how does one characterize a priori the set of admissible economic environments?

This is not the first time that insufficient concavity of preferences causes problems for economic analysis. See, for example, the discussion of money-metric utility in Chapter 1.

[7] Readers may recall that Harsanyi (1955) claimed to construct a veil-of-ignorance argument for utilitarianism without making interpersonal comparisons. But his argument fails—not as a formal mathematical statement, but in the claim that utilitarianism is what has been justified. (See, for an early discussion, Weymark, 1991; and for a more recent one, Moreno-Ternero and Roemer, 2008.)

wealth in order to satisfy them, as long as those persons were satisfied with their tastes, or, as he said, identified with them. There is no injustice in a world where wealth is equal, but those with champagne tastes suffer compared to those with beer tastes, due to the relative consumptions of champagne and beer that that equal wealth permits. So the "pathology" that we have illustrated with the Andrea and Bob example depends on the source of Bob's relative inefficiency in converting wealth into welfare being a handicap, rather than an expensive taste.

Slightly before Dworkin's articles were published, Sen (1980) gave a lecture in which he argued that Rawls's focus on primary goods was misplaced. Sen argued that Rawls was "fetishist" in focusing on goods, and should instead have focused on what the goods provide for people, which he called "functionings"—being able to move about, to become employed, to be healthy, and so on. Sen defined a person's *capability* as the set of vectors of functionings that were available to him, and he called for equality of capabilities.[8] Thus, although a rich man on a hunger strike might have the same (low) functioning as a poor man starving, their capabilities are very different. While not going so far as to say utilities should be equalized, Sen defined a new concept between goods and welfare—functionings—which Cohan (1993) later described as providing a state of being that he called "midfare." For Sen, the opportunity component of the theory was expressed in an evaluation not of a person's actual functioning level, but of what functionings were *available* to him, his "capability."

Sen's contribution led to both theoretical and practical developments. On the theoretical level, it inspired a literature on comparing opportunity (or feasible) sets: If one desires to "equalize" capabilities, it helps to have an ordering on sets of sets. See Foster's (2011) summary of this literature. On the practical side, it led to the human development index, published annually by the UNDP. For development of Sen's capability approach, see Chapter 2.

Later in the decade, further reactions to Dworkin came from philosophers, notably Arneson (1989) and Cohen (1989). Arneson argued that Dworkin's expensive-taste argument against equality-of-welfare was correct, but his alternative of seeking equality of resources was not the only option: Instead, one should seek to equalize *opportunities for welfare*. This, he argued, would take care of the expensive-tastes problem. Rather than relying on the insurance mechanism to define what resource egalitarianism means, Arneson proposed to distribute resources so that all persons had equal opportunity for welfare achievement, although actual welfares achieved would differ because people would make different choices. There are problems with formalizing Arneson's proposal (see Roemer, 1996), but it is notable for not relying on any kind of veil of ignorance, in contrast to the proposals of Rawls and Dworkin.

[8] Sen has not proposed an ordering of sets that would enable one to compare capabilities.

Cohen (1989) criticized Dworkin for making the wrong "cut" between resources and preferences. The issue, he said, was what people should or should not be held responsible for. Clearly, a person should not be held responsible for his innate talents and inherited resources, but it is not true that a person should be fully responsible for his preferences either, because preferences are to some (perhaps large) degree formed in circumstances (in particular, those of one's childhood), which are massively influenced by resource availability. Indeed, if a person has an expensive taste for champagne due to a genetic abnormality, he would merit compensation under an egalitarian ethic.[9] Cohen's view was that inequality is justified if and only if it is attributable to choices that are ones for which persons can sensibly he held responsible—so if a person who grows up poor, develops a "taste" against education, induced by the difficulty of succeeding in school due to lack of adequate resources—a taste with which he even comes to "identify"—then Cohen would not hold him responsible for the low income due to his consequently low wage, while Dworkin presumably would hold him responsible. Cohen does not propose a mechanism or algorithm for finding the just distribution of resources, but provides a number of revealing examples (see, for example, Cohen, 1989, 2004). He calls his approach "equal access to advantage."

Besides criticizing Dworkin for his partition of the space of attributes and actions into ones for which compensation is, or is not, due, Cohen (1997), importantly, critiqued Rawls's difference principle, as insufficiently egalitarian. The argument is based on Rawls's restriction of the ambit of justice to the design of social institutions—in particular, that ambit does not include personal behavior. Thus, the Rawlsian tax system should attempt to maximize the welfare of the least-well-off group in society, under the assumption that individuals choose their labor supplies to maximize their personal utility. Suppose the highly skilled claim that if their taxes are raised from 30% to 50%, they will reduce their labor supply so much that the worst-off group would be less well off than it is at the 30% tax rate. If 30% is the tax rate that maximizes the welfare (or income) of the least well off, given this self-interested behavior of the highly skilled, then it is the Rawlsian-just rate. But Cohen responds that, as long as the highly skilled are at least as well off as the worst off at the 50% tax rate, then justice requires the 50% tax rate. This difference of viewpoint between Rawls and Cohen occurs because Cohen requires individuals to act, in their personal choices, according to the commands of the difference principle (that is, to take those actions that render those who are worst off to be as well off as possible), and Rawls does not. Indeed, Rawls stipulates that one requirement of a just society is that its members endorse the conception of justice. It is peculiar, Cohen remarks, that that conception should apply only to the design of social institutions, and not to personal behavior.

[9] This is not a crazy example. There is a medically recognized syndrome in which people who sustain a certain kind of brain injury come to crave expensive foods (see Otsuka (2011, p. 81).

A question that arises from the discussion of responsibility is its relationship to freedom of the will. If responsibility has become central in the conceptualization of just equality, does one have to solve the problem of free will before enunciating a theory of distributive justice? Different answers are on offer. We believe the most practical answer, which should suffice for practicing economists, is to view the degree of responsibility of persons as a parameter in a theory of equality. Once we assign a value to this parameter, then we have a particular theory of EOp, because we then know for what to hold persons responsible. The missing parameter is supplied by each society, which has a concept of what its citizens should be held responsible for; hence, there is a specific theory of EOp for each society, that is, a theory that will deliver policy recommendations consonant with the theory of responsibility that that society endorses. This is a political approach, rather than a metaphysical one.

Another answer to the free will challenge is to make a distinction prevalent among philosophers. "Compatibilists" are those philosophers who believe that it is consistent both to endorse determinism (in the sense of a belief in the physical causation of all behavior) *and* the possibility of responsibility; incompatibilists are those who believe that determinism precludes responsibility. Most philosophers (who think about the problem) are probably, at present, compatibilists. For instance, Scanlon (1986) believes that the determinist causal view is true, but also that persons can be held responsible for their behavior, as long as they have contemplated their actions, weighed alternatives, and so on. (The issue of sufficient contemplation is independent of the issue of the cause of expensive tastes, raised above.) From a practical viewpoint, the problem of free will therefore does not pose a problem for designing policies motivated by the idea that persons should not be held accountable for aspects of their condition that are due to circumstances beyond their control.

The philosophical literature on "responsibility-sensitive egalitarianism" continues beyond the point of this quick review, but enough summary has been provided to proceed to a discussion of economic models.

4.3. A MODEL AND ALGORITHM FOR EQUAL-OPPORTUNITY POLICY

Consider a population whose members are partitioned into a finite set of *types*. A type comprises the set of individuals with the same circumstances, where *circumstances* are those aspects of one's environment (including, perhaps, one's biological characteristics) which are beyond one's control, and influence outcomes of interest. Denote the types $t = 1, \ldots. T$. Let the population fraction of type t in the population be f^t. There is an *objective* for which a planner wishes to equalize opportunities. The degree to which an individual will achieve the objective is a function of her circumstances, her *effort*, and the social policy: We write the value of the objective as $u^t(e, \varphi)$, where e is a measure of effort and $\varphi \in \Phi$ the set of social policies. Indeed, $u^t(e, \varphi)$ should be considered to be the average achievement of the objective among those of type t expending effort e when the policy is φ. Here, we will take effort to be a nonnegative real number. Later, we will introduce luck into the problem.

u^t is not, in general, a subjective utility function: Indeed u^t is assumed to be monotone *increasing* in effort, whereas subjective utility is commonly assumed to be decreasing in standard conceptions of effort. Thus, u might be the adult wage, circumstances could include several aspects of childhood and family environment, and e could be years of schooling. Effort is assumed to be a choice variable for the individual, although that choice may be severely constrained by circumstances, a point to which we will attend below. The final data for the problem consist of the distributions of effort within types as a function of policy: For the policy φ, denote the distribution function of effort in type t as $G_\varphi^t(\cdot)$. We would normally say that effort is chosen by the individual by maximizing a preference order, but preferences are not the fundamentals of this theory: Rather, the data are $\{T, G_\varphi^t, f^t, u, \Phi\}$, where we use T to denote, also, the set of types.

Defining the set of types and the conception of effort assumes that the society in question has a conception of the partition between responsible actions and circumstances, with respect to which it wishes to compute a consonant approach to equalizing opportunities. We describe the approach of Roemer (1993, 1998). The verbal statement of the goal is to find that policy which nullifies, to the greatest extent possible, the effect of circumstances on outcomes, but allows outcomes to be sensitive to effort. Effort comprises those choices that are thought to be the person's responsibility. But note that the *distribution* of effort in a type at a policy, G_φ^t, is not due to the actions of any person (assume here a continuum of agents), but is a characteristic of the type. If we are to indemnify individuals against their circumstances, we must not hold them responsible for being members of a type with a poor distribution of effort.

We require a measure of *accountable* effort, which, because effort is influenced by circumstances, cannot be the raw effort e. (Think of years of education—raw effort—which is surely influenced in a major way by social circumstances.) Roemer proposed to measure accountable effort as the rank of an individual on the effort distribution of her type: thus, if for an individual expending effort e, $G_\varphi^t(e) = \pi$, we say the individual expended the *degree* of effort π, as opposed to the *level* of effort e. The rank provides a way of making inter-type comparisons of the efforts expended by individuals. A person is judged accountable, that is to say, by comparing her behavior only to others with her circumstances. In comparing the degrees of effort of individuals across types, we use the rank measure, which sterilizes the distribution of raw effort of the influence of circumstances upon it.[10]

[10] Some authors (Ramos and Van de gaer, 2012) have called this move—of identifying the degree of effort with the rank of the individual on the objective distribution of his type—the Roemer identification axiom (RIA). Although the name is lofty, the idea is simple: Persons should not be held responsible for characteristics of the distribution of effort in their type, for that distribution is a circumstance.

Because the functions u^t are assumed to be strictly monotone increasing in e, it follows that an individual will have the same rank on the distribution of the objective, within his type, as he does within the distribution of effort of his type.[11] Define:

$$v^t(\pi,\varphi) = u^t(e^t(\pi),\varphi)$$

where $e^t(\pi)$ is the level of effort at the πth quantile of the distribution G^t_φ, that is, $G^t_\varphi(e^t(\pi)) := \pi$. Then the functions $v^t(\cdot,\varphi)$ are the inverse functions of the distribution functions of the objective, by type, under the policy φ. (In this sense, v^t is like Pen's parade, which is also the inverse of a distribution function.) Inequality of opportunity holds when these *functions* are not identical. In particular, because we are viewing persons at a given rank π as being equally accountable with respect to the choice of effort, the vertical difference between the functions $\{v^t(\cdot,\varphi)\}$ is a measure of the extent of inequality of opportunity (or, equivalently, the horizontal distance between the cumulative distribution functions).

What policy is the optimal one, given this conception? We do not simply want to render the functions v^t identical at a low level, so we need to adopt some conception of "maxi-minning" these functions. We want to choose that policy which pushes up the lowest v^t function as much as possible—and as in Rawlsian maximin, the "lowest" function may itself be a function of what the policy is. A natural approach is therefore to maximize the area below the lowest function v^t, or more precisely, to find that policy which maximizes the area under the *lower envelope* of the functions $\{v^t\}$. The formal statement is to:

$$\max_{\varphi\in\Phi}\int_0^1 \min_t v^t(\pi,\varphi)\mathrm{d}\pi. \tag{4.1}$$

We call the solution to this program the opportunity-equalizing policy, φ^{EOp}. (Computing (4.1) is equivalent to maximizing the area to the left of the left-hand envelope of the type distributions of the objective, and bounded above by the horizontal line of height one.)

In the case in which the lower envelope of the functions $\{v^t\}$ is the function of a single type (the unambiguously most disadvantaged type), what we have done is simply to maximize the average value of the objective for the most disadvantaged type, since $\int_0^1 v^t(\pi,\varphi)\mathrm{d}\pi$ is simply the mean value of the objective for type t at policy φ.

Thus, the approach implements the view that differences between individuals caused by their circumstances are ethically unacceptable, but differences due to differential effort are all right. Full EOp is achieved not when the value of the objective is equal for all, but when members of each type face the *same chances*, as measured by the distribution functions of the objective that they face.

[11] If actual effort is a vector, then a unidimensional measure e would be constructed, for example, by regressing the objective values against the dimensions, thus computing weights on the dimensions of raw effort.

One virtue of the approach taken here is that it is easy to illustrate graphically. In Figure 4.1, we present two graphs, to illustrate inequality of opportunity in Hungary and Denmark. In each graph, there are three cumulative income distributions, corresponding to male workers of three types: those whose more educated parent had no more than lower secondary education, those whose more educated parent just completed

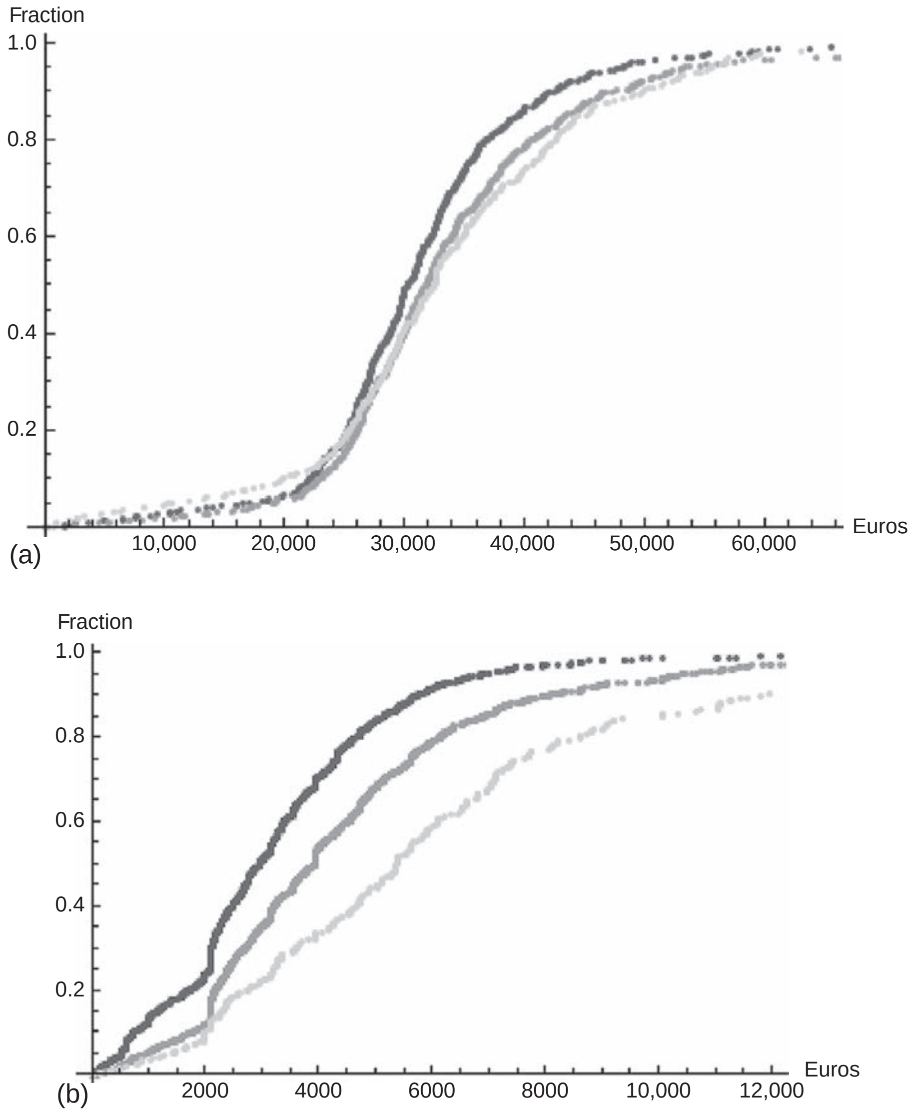

Figure 4.1 (a) Three income distribution functions for Danish male workers, according the circumstance of parental education. (The curve with darkest hue is the income distribution of sons of the least-educated parents; the lightest hue is the income distribution of sons of the most-educated parents.) (b) As in (a), but for Hungary.

secondary education, and those whose more educated parent had at least some tertiary education. (The data are from EU-SILC-2005.) The inverses of these distribution functions are the functions $v^t(\cdot, \varphi)$ defined above. The policy is the status-quo policy. It seems clear that, with respect to this one circumstance (parental education), opportunities for income have been more effectively equalized in Denmark than in Hungary.[12] The graphs are taken from Roemer (2013).

The approach inherent in (4.1) is one that treats all causes of inequality not accounted for by a person's type as being due to effort. For example, with respect to Figure 4.1, there are many circumstances that influence outcomes not accounted for in the definition of type, and so the inequality of opportunity illustrated in that figure should be considered to be a lower bound on the true inequality of opportunity. Nevertheless, it is often the case that delineating only a few circumstances will suffice to illustrate obvious inequality of opportunity, and one can say that social policy should attempt to mitigate at least that inequality.

Let us note that the equal-opportunity approach is *non-welfarist* or more precisely *non-consequentialist*. A welfarist procedure for ordering social policies uses information only in the objective possibilities sets of the population associated with those procedures. In the income example, it would use only the data of the income distribution of the population and ignore the data of what individuals were of what types. Circumstances are non-welfare (or nonobjective) information. More informally, consequentialism only considers the final results of policies (incomes), and not the causes of those consequences. Here, we say there are two kinds of cause of outcomes with different moral status: circumstances and effort. We must distinguish between these causes and social policy should attempt to mitigate the inequality effects of one of them, but not necessarily of the other.

At this point, we return briefly to consider a philosophical critique of this approach—and indeed of the general evolution of responsibility-sensitive egalitarianism, as it was reviewed in Section 4.1 above—offered by Hurley (2002), who writes that "Roemer's account does not show how the aim to neutralize luck could provide a basis for egalitarianism." Hurley says that, absent luck, many possible distributions of the objective could have occurred, and one cannot claim that "neutralizing" luck means to render outcomes sensitive only to degrees of effort. Moreover, she writes that it is not an *argument* for EOp that it neutralizes the effects of luck.

The moral premise of the EOp view is that rewards should be sensitive only to the autonomous efforts of individuals. This is a special case of rewards according to deserts. People deserve, in the EOp view, to acquire the objective in proportion to how hard they try. Thus, strictly speaking, the EOp view is not one whose fundamental primitive is equality: deservingness is fundamental, together with the normative thesis that justified inequality tracks deservingness. Inequalities that are not due to unequal efforts are *defined*

[12] We say "seems" clear, because the horizontal-axis euro scale is different in the two figures.

as being due to luck; that is, luck is so-called because it is a cause of reward that is illegitimate from the EOp view. The statement that "EOp intends to neutralize the effects of luck on outcomes" is therefore equivalent to the statement "EOp intends to render outcomes sensitive only to effort."

So, for example, suppose a child, A, does well in life because his parents were rich, not because he exerted great effort, while another child, B, from a poor family, does well by virtue of exerting great effort. Some might argue that it may be no less a matter of luck that B was the kind of person who works hard than that A had rich parents, but that approach, whatever its merits, is not the sense in which responsibility-concerned egalitarians use the word "luck." Luck, for us, *means* the source of noneffort-caused advantage. To be sure, it is not an *argument* for EOp that it neutralizes luck; it is rather *definitional* of the EOp view that it does so. The *argument* for EOp must be that it is *right* to render outcomes sensitive only to effort.[13]

The next example, which is hypothetical, is given to illustrate the difference between the equal-opportunity approach and the approach that is conventional in many areas of social policy, utilitarianism. A *utilitarian* policy maximizes the average value of the objective in a population. Utilitarianism is a special case of welfarism, although there are many welfarist preference orderings of policies.

We consider a population partitioned into T types, where the frequency of type t is f^t. The population suffers from I diseases, with the generic disease denoted i. The types might be defined by socioeconomic characteristics,[14] and the Health Ministry is interested in mitigating the effect of socioeconomic characteristics on health. There is available in the health sector an amount of resource (money), $\overline{R}$ per capita. We do not address how much of a society's product should be dedicated to health, but only how to spend the amount that has been so dedicated. Effort is here conceived of as lifestyle quality (exercise, smoking behavior, etc.). We choose the policy space to be allocations of the resource to treating various diseases; that is vectors $R=(R^1, \ldots, R^I)$, which will be constrained by a budget condition, where R^i is the amount that will be spent to treat each case of disease i, regardless of the characteristics of the person who has contracted the disease. Thus, *by definition*, we restrict ourselves to policies that are *horizontally equitable*: Any person suffering from disease i, regardless of her type and lifestyle quality, will receive the same treatment, because treatment expenditure is not a function of these variables. A more highly articulated policy space could allocate medical resources predicated also on the type of the patient and the lifestyle that patient had led. But in the health sector, doing so would set the stage for antagonistic patient-provider relations, and interfere with

[13] This point is due to Cohen (2006).

[14] Of course, persons are surely in part responsible for their socioeconomic circumstances. But the Health Ministry's mandate might be to eliminate health inequalities due to those circumstances, and so formally, it would consider socioeconomic aspects of households as circumstances.

other values we hold, and so we choose to respect horizontal equity. We will return to this point below.

For any given vector, $R=(R^1,\ldots,R^I)$ there will ensue a distribution of lifestyle quality in each type t, and a consequent distribution of disease occurrences in each type. Lifestyle quality may not be responsive to the policy, but we allow for the general case in which it is. Let us denote the fraction of individuals in type t who contract disease i when the policy is R by $p^{it}(R)$. Then the policy is *feasible* when:

$$\sum_{i,t} f^t p^{it}(R)x^i \leq \overline{R}$$

and it exhausts the budget precisely when:

$$\sum_{i,t} f^t p^{it}(R)x^i = \overline{R} \tag{4.2}$$

The set of *admissible policies* comprises all those for which (4.2) holds: This is the set Φ.

We next suppose that we know the *health production functions* for each type; these are functions that give the probability that a person of type t will contract disease i if she lives a lifestyle of quality q. Let $i=0$ represent the case of "no disease" being contracted. We denote these functions $s^{it}(\cdot)$; thus $s^{it}(q)$ is the probability that a t-type will contract disease i if she lives lifestyle quality q. We presume it is the case that $\{s^{it}\}$ are monotone decreasing functions for $i>0$; that is, raising lifestyle quality reduces the probability of disease.

We also have as data of the problem the mapping from the policy space Φ to the space of cumulative distribution functions on the nonnegative real numbers. Denote that class of distribution functions by Γ. The map

$$F^t : \Phi \rightarrow \Gamma$$

gives us the distribution of lifestyle qualities that will occur in type t, at any policy R in Φ. We write $F_R^t = F^t(R)$. Thus, an individual with lifestyle quality q in type t lies at rank π of the effort distribution of her type, when the policy is R, if $F_R^t(q)=\pi$. We denote this value of q by $q_R^t(\pi)$.

Finally, we need to postulate the relationship between treatment of disease and health outcome. Let us take the outcome to be life expectancy. We therefore suppose that we know the life expectancy for those in type t who have contracted disease i and who are treated with the resource expenditure specified by R. Denote this life expectancy by $\lambda^{it}(R)$. (Denote by λ^{0t} the life expectancy of a person of type t who contracts no disease.) We could further complexify, here, by assuming that life expectancy is a function, in addition, of the lifestyle quality of the individual, but choose not to do so.

Consider, now, a policy $R=(x^1,\ldots,x^I)$, which induces a distribution of lifestyle quality in each type. Consider a type t and all those at rank π of t's lifestyle quality distribution. Assume there is a large number of people in each type, so that the fraction of people in a type who contract a disease is equal to the probability that people in that type will contract the disease. Then,[15] the average life expectancy of all such people—the (t,π) cohort—will be

$$s^{0t}\left(q_R^t(\pi)\right)\lambda^{0t}+\sum_{i=1}^{I}s^{it}\left(q_R^t(\pi)\right)\lambda^{it}(R)\equiv L^t(\pi,R)$$

We can now define the EOp policy, which is:

$$R^{\mathrm{EOp}}=\arg\max_R\int_0^1\min_t\ L^t(\pi,R)\mathrm{d}\pi \tag{4.3}$$

Although we need a lot of data to compute the EOp policy, it is only the Ministry of Health who must have these data: once the policy is computed, a hospital need only diagnose a patient to know what treatment is appropriate (i.e., how much to spend on the case). No patient need ever be asked her type or her lifestyle characteristics. There is, that is to say, no incursion of privacy necessitated by applying the policy—apart from the initial incursion in the research survey on a population sample that assembles the data set to compute the health production functions. The policy is horizontally equitable. This is an important point, because some philosophers have falsely concluded that applying the equal-opportunity approach will necessitate incursions into privacy, and making distinctions among individuals in resource-allocation questions that are either difficult or socially objectionable in some way (see Anderson, 1999). But this is incorrect: The planner can choose the policy space in a way that makes such distinctions irrelevant for implementing the policy. In other words, not only is the delineation of circumstances a political/social decision that may vary across societies, but so must the specification of the policy space take into consideration social views concerning privacy and fairness.

Let us make this example numerical. We posit a society with two types, the rich and the poor. The poor have lifestyles whose qualities q are uniformly distributed on the interval [0,1], while the rich have lifestyle qualities that are uniformly distributed on the interval [0.5, 1.5]. The probability of contracting cancer, as a function of lifestyle quality (q) is the same for both types, and given by:

$$s^{\mathrm{CP}}(q)=s^{\mathrm{CR}}(q)=1-\frac{2q}{3}.$$

Only the poor are at a risk of tuberculosis; their probability of contracting TB is:

$$s^{\mathrm{TB}}(q)=1-\tfrac{q}{3}.$$

[15] In the formula that follows, we have assumed for the sake of simplicity that an individual contracts either no or one disease. Of course, the formula can be generalized to the case where we drop this assumption, as we do in the numerical example that follows.

Suppose that life expectancy for a rich individual is given by:

70, if cancer is not contracted, and

$60 + 10\dfrac{x_C - 1}{x_C + 1}$, if cancer is contracted, and x_C is spent on its treatment.

Thus, if the disease is contracted, life expectancy will lie between 50 and 70, depending on how much is spent on treatment (from zero to an infinite amount). This is a simple way of modeling the fact that nobody dies of cancer before age 50.

Suppose that life expectancy for a poor individual is:

70 if neither disease is contracted,

$60 + 10\dfrac{x_C - 1}{x_C + 1}$ if cancer is contracted and x_C is spent on its treatment, and

$50 + 20\dfrac{0.1x_{TB} - 1}{0.1x_{TB} + 1}$ if tuberculosis is contracted and x_{TB} is spent on its treatment.

Thus, the poor can die at age 30 if they contract TB and it is not treated. With large expenditures, a person who contracts TB can live to age 70. Furthermore, it is expensive to raise life expectancy above 30 if TB is contracted. We further assume that if a poor person contracts both cancer and TB then her life expectancy will be the minimum of the above two numbers.

Finally, assume that 25% of the population is poor and 75% is rich, and that the national health budget is $\overline{R} = \$3000$ per capita.

With these data, one can compute that 33% of the rich will contract cancer, 9.3% of the poor will contract only cancer, 26% of the poor will contract only TB, and 56% of the poor will contract both TB and cancer. (Here, we do not exclude the possibility that a person could contract both diseases.)

Our policy is $R = (x_C, x_{TB})$, the schedule of how much will be spent on treating an occurrence of each disease. The objective is to equalize opportunities, for the rich and the poor, for life expectancy.

The life expectancy of a rich person is given by:

$$L^R(\pi, x_C) = \frac{2}{3}(\pi + 0.5)70 + \left(1 - \frac{2}{3}(\pi + 0.5)\right)\left(60 + 10\frac{x_C - 1}{x_C + 1}\right)$$

and of a poor person by:

$$\begin{aligned} L^P(\pi, x_C, x_T) \;=\; & \frac{\pi}{3}\frac{2\pi}{3}70 + \frac{\pi}{3}\left(1 - \frac{2\pi}{3}\right)\left(60 + 10\frac{x_C - 1}{x_C + 1}\right) \\ & + \left(1 - \frac{\pi}{3}\right)\frac{2\pi}{3}\left(50 + 20\frac{0.1x_{TB} - 1}{0.1x_{TB} + 1}\right) \\ & + \left(1 - \frac{\pi}{3}\right)\left(1 - \frac{2\pi}{3}\right)\min\left[\left(50 + 20\frac{0.1x_{TB} - 1}{0.1x_{TB} + 1}\right), \left(60 + 10\frac{x_C - 1}{x_C + 1}\right)\right]. \end{aligned}$$

The solution of the program that maximizes the minimum life expectancy of the two types, subject to the budget constraint, is $x_C = \$686$, $x_{TB} = \$13{,}027$. In Figure 4.2, we present the life expectancies of the rich and the poor, as a function of the rank at which they sit on the effort (lifestyle) distribution of their type, at this solution. The higher curve is that of the rich. We see that, at the EOp solution, the rich still have greater life expectancy than the poor—despite the large amounts being spent on treating tuberculosis.[16] The difference, however, is much less than 1 year. Moreover, life expectancy increases with lifestyle quality—this inequality of outcome is an aspect that EOp does *not* attempt to eliminate.

Let us compare this solution to the *utilitarian* solution, the expenditure schedule at which *life expectancy in the population as a whole* is maximized. The solution turns out to be $x_C = \$1915$, $x_{TB} = \$10,571$. Three times as much is spent on cancer as in the EOp solution. Figure 4.3 graphs the life expectancy of the two types in the utilitarian solution (dashed lines) as well as the EOp solution (solid lines).

We see that the utilitarian solution narrows the life expectancy differential between the types less than the EOp solution does (although, in absolute terms, the differences are not great in this example). The EOp solution is more egalitarian, across the types, than the

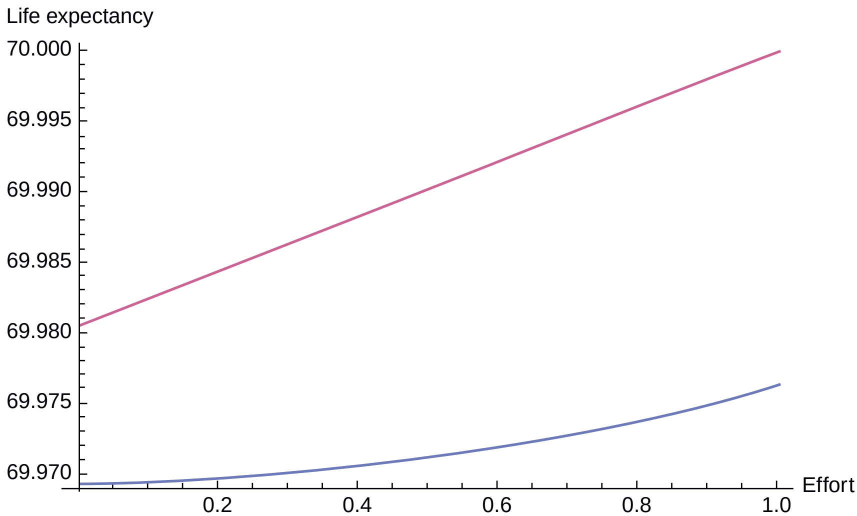

Figure 4.2 EOp policy: Life expectancy as a function of effort in two types, rich and poor.

[16] We could further reduce the difference in the life expectancies of the two types if we were willing to predicate the expenditure policy on a person's type, as well on her disease. But we have opted for a policy space that respects the social norm of horizontal equity and does not distinguish between types in the treatment of illness.

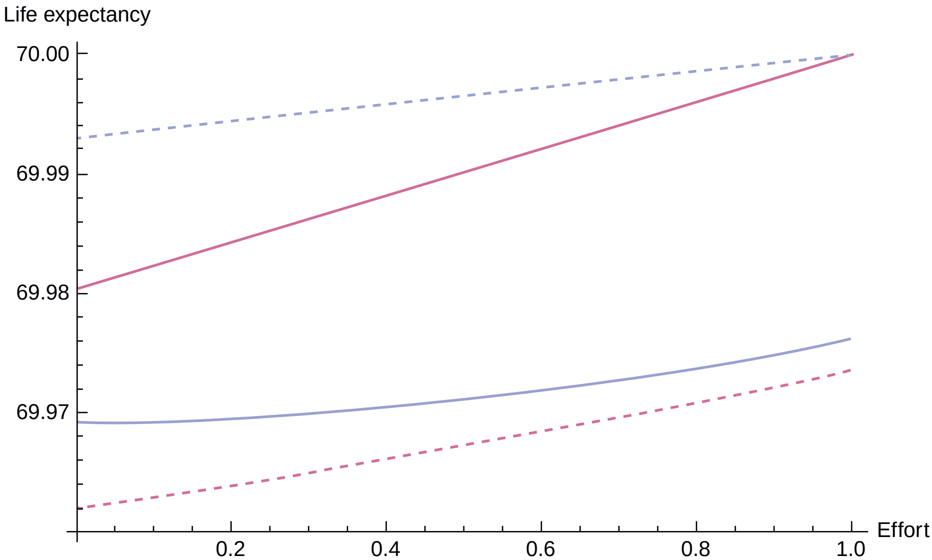

Figure 4.3 Life expectancies of rich and poor, utilitarian (dashed) and EOp (solid) policies.

utilitarian solution—the utilitarian cares only about average life expectancy in aggregate, not on the distribution of life expectancy across types.

It is obvious that different objective functions will engender different optimal solutions. The unfortunate habit that is almost ubiquitous in policy circles is to identify the utilitarian solution with the *efficient* solution. Critics of the EOp solution will say that it is *inefficient* because it delivers a lower life expectancy *on average* for the population than the utilitarian solution. But this is a confusion. Both solutions are Pareto efficient, in the sense that it is impossible, for either of them, to find a policy that weakly increases the life expectancies of everyone. Identifying the utilitarian social objective with efficiency is an unfortunate practice, rooted in the deep hold that utilitarianism has in economics. *Social* efficiency is defined with respect to whatever the social objective is, and there are many possible choices for that objective besides the social average. We discuss this point with respect to measuring economic development below in Section 4.5.

4.4. A MORE GENERAL APPROACH

Formula (4.1) gives an ordering on policies, with regard to the degree to which they equalize opportunities, after the set of circumstances has been delineated. It implements the view that inequalities due to differential circumstances for those who expend the same degree of effort are unacceptable. There is, however, a conceptual asymmetry: while the instruction to eliminate inequalities due to differential circumstances is clear, the permission to allow differential outcomes due to differential effort is imprecise. How much reward does effort merit? There is no obvious answer. To provide a social-welfare function (or a preference order over policies) that question must be answered, at least implicitly. In formula (4.1), the preference order is delineated by stating that, if there is a society with just one type, then policies will be ordered according to how large the average outcome is for that society. Fleurbaey (2008) therefore calls formula (4.1) a "utilitarian approach" to EOp.

What are the alternatives? At a policy $\varphi \in \Phi$, the *lower envelope* of the objective functions $v^t(\cdot, \varphi)$ is defined as:

$$\theta(\pi, \varphi) = \min_t v^t(\pi, \varphi). \tag{4.4}$$

We wish to render the function θ as "large" as possible: formula (4.4) measures the "size" of θ by taking its integral on [0,1]. More generally, let the set of nonnegative, weakly increasing functions on [0,1] be denoted Θ; we desire an ordering $\succeq$ on Θ which is increasing, in the sense that if $\theta(\cdot) \geq \theta^*(\cdot)$, then $\theta \succeq \theta^*$, with strict preference if $\theta(\cdot) > \theta^*(\cdot)$ on a set of positive measure. The integral of $\theta\, \mathrm{d}\pi$, as in (4.4), provides such an ordering. But many other choices are possible. For instance, consider the mapping $\Theta \to \mathbb{R}$ given by:

$$\Gamma(\theta; \varphi)\left(\int_0^1 \theta(\pi, \varphi)^p \mathrm{d}\pi\right)^{1/p} \quad \text{for } -\infty < p \leq 1. \tag{4.5}$$

Each of these provides an increasing order on Θ. As p becomes smaller, we implement more aversion to inequalities that are due to effort. As p approaches negative infinity, the order becomes the maximin order, where no reward to effort is acceptable.

We do not have a clear view about what the proper rewards to effort consist in, and hence remain agnostic on the choice of ways to order the lower envelopes $\theta(\cdot, \varphi)$. The problem of rewards to effort goes back to Aristotle, who advocated "proportionality," a view that is incoherent, as it depends on the units in which effort and outcomes are measured. Because we possess no theory of the proper rewards to effort, this is an open aspect of the theory. We believe that considerations outside the realm of EOp must be brought to bear to decide upon how much inequality with respect to differential effort is allowable. For instance, Cohen (2009) has suggested that the inequalities allowed by an equal-opportunity theory should, if they are large, be reduced by appealing to the value of social unity (what he calls "community"), which will be strained if outcome inequalities are too large.

Our agnostic view concerning the degree of reward that effort deserves contrasts with that of Fleurbaey (2008), who advocates an axiom of "natural reward" to calibrate the rewards to effort, as will be discussed in Section 4.5.

We can provide somewhat stronger foundations for the view that *an equal-opportunity ordering of policies must maximize some increasing preference order on* Θ. The first step is to note the importance of the lower-envelope function θ: for the persons who are most unfairly treated at a given policy are those, at each effort level, who experience the lowest outcomes, across types. (Hence, they are the ones represented on the lower envelope.) This is because the EOp view says outcomes that are different, due to circumstances, for those who expend the same effort, are unfair. The second step is to state an axiom which encapsulates a requirement of an EOp ordering $\succeq$ of Θ, which is:

Axiom DOM

A. *For any two policies $\varphi, \hat{\varphi} \in \Phi$, such that $\varphi \succeq \hat{\varphi}$, there exists a set of positive measure S such that $\pi \in S \Rightarrow \theta(\pi, \varphi) > \theta(\pi, \hat{\varphi})$.*

B. *For any $\varphi, \hat{\varphi} \in \Phi$ such that $\varphi \sim \hat{\varphi}$, either $\theta(\cdot, \varphi) = \theta(\cdot, \hat{\varphi})$ or there is a set of positive measure Y such that $\gamma \in Y \Rightarrow \theta(\gamma, \varphi) > \theta(\gamma, \hat{\varphi})$ and a set of positive Y' measure such that $\gamma \in Y' \Rightarrow \theta(\gamma, \varphi) < \theta(\gamma, \hat{\varphi})$.*

Part A of Axiom DOM states that if one policy is preferred to another, it must make *some* people who are among the most unfairly treated are better off than the other policy, and Part B has a similar justification. Thus, DOM is a special case of what is sometimes called the *person-respecting principle* (see Temkin, 1993): that one social alternative is better than another only if some people are better off in the first than in the second.

It is not hard to show that (see Roemer, 2012):

Proposition

Let $\succeq$ be an order on Θ satisfying DOM. Then $\succeq$ is represented by an increasing operator Γ on Θ. Furthermore, if $\succeq$ is a continuous order, then Γ can be chosen to be a continuous increasing operator.

Thus, with any continuous order on the lower-envelope functions Θ, we may write the associated EOp program as:

$$\begin{aligned} &\max \Gamma(\theta) \\ &\text{s.t.} \\ &\theta(\pi, \varphi) \equiv \min_t v^t(\pi, \varphi) \\ &\varphi \in \Phi \end{aligned} \qquad \text{(GEOp)}$$

for some increasing operator $\Gamma : \Theta \to \mathbb{R}$. The acronym GEOp stands for "generalized equality of opportunity."

We reiterate the main point of this section. Because we possess no theory of what comprise the just rewards to effort, we should not be dogmatic on the exact way to order policies. We have argued that an ordering of policies must come from an increasing order on the set of lower-envelope functions Θ, where the lower-envelope function induced by a policy φ is given by (4.5). This ambiguity in the theory results in program (GEOp), where the degree of freedom is the choice of the operator Γ. Considerations outside of the theory of equal opportunity might put constraints on the degree of overall inequality that is desirable or admissible in a society, and this can guide the choice of Γ.

We have thus argued that the theory of equal opportunity is not intended as a complete theory of distributive justice, for two reasons. First, we have emphasized its pragmatic nature. We do not have a complete theory for what people are, indeed, responsible, and have advocated the present approach as one that should be viewed as providing policy recommendations for societies that are consonant with the society's conception of responsibility. Thus, the choice of the set of types, and even of the policy space, will be dictated by social norms (we have illustrated the policy-space point with the health-expenditure example). Second, the theory does not include a view on what the proper rewards to effort consist in, and this is reflected in the openness inherent in program (GEOp).

Because we view the approach as most useful when the objective in question is something measurable like income, life expectancy, or wage-earning capacity, we shy away from taking an all-encompassing objective of "utility." We view the usefulness of the approach as one for policy makers, in particular ministries, who are concerned with narrower objectives than overall utility: the health ministry has an objective of life expectancy or infant survival, the education ministry has an objective of the secondary-school graduation rate, the labor ministry is concerned with opportunities for the formation of wage-earning capacity, or for employment, and so on. All these objectives are cardinally measurable, and it makes sense to use any of the operators defined in Equation (4.5) to generate an ordering on policies.

Nevertheless, we wish to remark that it is possible to apply the theory where the objective is "utility," if utility is cardinally measurable. (Actually, to use the operators in Equation (4.5) we require what is called cardinal measurability and ratio-scale comparability.) Because, when thinking about utility, we often conceive of effort as implying a disutility, we now show why this is not a problem for the application. Suppose utility functions over consumption and labor expended are given by $u(x, L; w)$, where $w \in W$ is the individual's wage rate. The distribution function of w in type t is given by F^t. Let us suppose we are considering the space of linear tax policies, where after-tax income is given by $(1-\varphi)wL+b$, where b is a lump-sum demogrant and $\varphi \in [0,1]$ is the tax rate. (It is implicitly assumed, since wage rates are fixed, that production is constant-returns-to-scale.) Then, the utility-maximizing individual chooses his labor supply optimally, denoted by $L(\varphi, w)$, and of course, budget-balance requires $b=\varphi \int wL(\varphi, w)\mathrm{d}F(w)$, where F is the population distribution of w. Define $w^t(\pi)$ by $F^t(w^t(\pi))=\pi$. Then the outcome functions are just the indirect utility functions:

$$v^t(\pi, \varphi) = u((1-\varphi)w^t(\pi)L(w^t(\pi), \varphi) + b, L(w^t(\pi), \varphi)),$$

and we are ready to calculate the EOp policy. Here, "effort" is interpreted not as one's labor supply, but rather as those actions the person took that gave rise to his wage-earning capacity. There are different distributions of wages in different types, reflecting the differential circumstances that impinge upon wage-formation, but within each type, there is a variation of the wage due to autonomous factors that we view as effort and worthy of reward.

4.5. THE FLEURBAEY–MANIQUET APPROACH

Marc Fleurbaey and Francois Maniquet have, in a series of writings, made a number of proposals for ordering policies with respect to the degree to which they equalize opportunities, which are similar in spirit to those discussed above, but different in detail. Their work is summarized in Fleurbaey (2008); the general inspiration of the theory is the idea of envy-freeness, pioneered in the works of Foley (1967), Kolm (1972), and Varian (1975). Here, we present one of their main proposals, which falls in the family of egalitarian-equivalent proposals, and as such, descends from the work of Pazner and Schmeidler (1978). The approach is substantially different from the one outlined in Section 4.3, because it does not take the viewpoint that equalizing opportunities involves maximizing the lower-envelope function θ defined in Equation (4.4).

Suppose that a population is characterized by an outcome function $u(c, r, \varphi)$, where c is a vector of circumstances (characteristics of the individual or his environment for which he is deemed not responsible), r is a vector of characteristics for which he is deemed responsible, and φ is a policy. We will specialize to the case where φ is the distribution of some resource to the population: say, an allocation of money. Let us suppose, further, that there is some type (i.e., vector of circumstances c^*) that characterizes the most disadvantaged type. We desire to place an ordering on policies φ that reflects the view that persons should not be held responsible for their circumstances, but should be held responsible for the choice of r.

Fleurbaey (2008) represents the idea that persons should not be held responsible for their circumstances by various "principles of compensation." An example would be "equal well-being for equal responsibility," meaning that if two individuals have the same values of r, their outcomes should be the same (i.e., independent of their circumstances). Thus, the ordering of policies should reflect this desideratum. He, Bossert (1995) and Maniquet also advocate various "principles of reward." For instance, if all individuals have identical circumstances, then the resource should be divided equally among them, called the "liberal reward principle." That is, if everyone is of the same type, there is no justification for any compensatory policy. It is clear from simple examples that it is, in general, impossible to respect the liberal reward principle and the "equal well-being for equal responsibility" principle simultaneously as long as the environment is sufficiently rich, and so Fleurbaey (2008) is a study of social-policy orderings that satisfy weaker versions of postulates inspired by these principles.

We summarize a prominent example of such an ordering. Let φ be given, and construct another allocation of the resource, $\hat{\varphi}$—which need not be feasible, given the budget—defined by:

$$u(c_i.r_i,\varphi_i) = u(c^*, r_i, \hat{\varphi}_i),$$

where i indicates the individual and c^* is a reference set of circumstances—say, those of the most disadvantaged type. Thus, under $\hat{\varphi}_i$ each individual receives an amount of resource that makes her as well off as she is in the φ allocation, but assuming, counterfactually, that she had been a member of the reference type, and had maintained the same values of the responsible factors. In the counterfactual world in which $\hat{\varphi}$ lives, everybody is of the same type (c^*) and so, *no special compensation* should be made to individuals from the opportunity-equalizing viewpoint, according to the liberal reward principle. Hence, the ideal policy φ is one in which the associated $\hat{\varphi}$ is an *equal distribution* of the resource. This tells us how to order actual policies φ: we say that $\varphi \succeq \varphi'$ if the counterfactual distribution $\hat{\varphi}$ is "more equal" than $\hat{\varphi}'$; to be precise

$$\varphi \succeq \hat{\varphi}' \Leftrightarrow \hat{\varphi} \succeq_{\text{lex}} \hat{\varphi}'$$

where $\succeq_{\text{lex}}$ is the leximin ordering.

This particular version of the egalitarian-equivalent approach to responsibility is what the authors call zero egalitarian equivalence (ZEE), because the standardization takes place by counterfactually making everyone a member of the worst-off type. Of course, standardizing with some other set of circumstances would do as well, although each choice of how to standardize will (generally) produce a different ordering over policies. One virtue of this approach is that an ordinal outcome function u is all that is required, as we only need to compare the outcome for individuals to variants of themselves (where they have different circumstances), which contrasts with the approaches discussed in Section 4.3, that require cardinality and even ratio-scale comparability.

Of course, the ZEE approach will in general give a different ordering of policies than the GEOp approach; Roemer (2012) calculates some examples. Both approaches are incomplete: GEOp, as has been discussed, does not dictate a choice of the operator Γ and ZEE does not dictate a choice of the way to standardize circumstances.

An essential feature of the egalitarian-equivalent approach is the liberal reward principle, that if everyone were of the same type, then no redistribution is called for. To be specific, in the EOp approach, Roemer closes the model by saying that if everyone is of the same type, then policies are preferred if they produce higher *average* outcomes, whereas Fleurbaey and Maniquet say that policies are better in this case the closer they are to *equal-resources*. But, as we have argued in Section 4.4, we remain agnostic on the right way of closing the model, because we do not think the concept of EOp contains a theory of just rewards to effort. In particular, the liberal reward principle, described above, will sometimes or often use market institutions to close the model. Consider a problem where all persons have the same circumstances, but preferences differ, due to voluntary choices. The principle of liberal reward might be interpreted as saying that the allocation of goods should be that associated with the competitive equilibrium following from an equal division of wealth. But this means that the welfare of individuals is determined by a particular set of institutions (markets with private property). Our objection, then, to the liberal reward principle is that in some cases there is no obvious benchmark that can be considered "natural" to define distribution in the case where there is a unique set of circumstances. This point harkens back to the legal realists, who argued that there is no conception of laissez-faire that is free of ethical bias (see Fried, 1998)—or, to put it more starkly, the usual conception of laissez-faire is a misnomer, as it presupposes property rights enforced by state power.

One disadvantage of the egalitarian-equivalent approach is that the notation does not force the practitioner to come to grips with the fact that choices people make are themselves influenced by circumstances. Recall that in the EOp approach, it was the *degree* of effort rather than the *level* of effort that was taken as reflecting responsibility, and this distinction was made because the *distribution* of levels of effort is infected with circumstances. Now one can model the same idea in the ZEE approach, but the notation does not invite doing so: There may be a tendency of practitioners to take r as *observed* levels of effort and choices of various kinds, and this would fail to take account of the fact that the distribution of choices r in a type is itself a characteristic of the type, and something that calls for compensation. So a literal application of the ZEE model, which is insensitive to this fact, will ascribe to persons responsibility for choices that are perhaps heavily influence by circumstances, and should therefore call for compensation.

One of the innovative applications of the egalitarian-equivalent approach by the authors is to tax policy. From among feasible tax policies, the policy that should be chosen is most preferred according to the ZEE preference order. As noted, this approach provides a theory of optimal taxation that does not rely on any cardinalization of the utility function. Therefore, Fleurbaey and Maniquet have produced a theory of optimal taxation liberated from cardinal measurement of utility (that is, from maximizing the integral of some social-welfare function). See Fleurbaey and Maniquet (2006) and Fleurbaey and Maniquet (2011, Chapter 11).

Fleurbaey and Maniquet also propose a kind of dual to ZEE: namely, imagine a counterfactual where all individuals expend the same reference level of effort but maintain their actual circumstances. In this case, that allocation is most preferred which most closely equalizes outcomes (that is, each person should be indifferent to how she would feel if she had the circumstances of any other person). The basis of this view is that if persons all expend the same value of the responsible factors r, then there is no ethical basis for their having different outcomes. Again, this gives a preference order on policies that can be defined without using cardinal utility functions, but using egalitarian equivalence. The authors name this approach "conditional equality."

One way to compare the approaches of Roemer and Fleurbaey–Maniquet is to ask, Can the Fleurbaey–Maniquet preference orders be rationalized as instances of program (GEOp), for some choice of Γ? It turns out that the ZEE approach can be, but the conditional-equality approach cannot be. See Roemer (2012) and Fleurbaey (2012).

Fleurbaey and Maniquet, in their work reported in Fleurbaey (2008), take an axiomatic approach, proposing a number of axioms modeling the ideas that persons should be held responsible for their autonomous actions but not for their circumstances. Strong versions of these axioms produce impossibility results, as we noted. (This is immediately clear if one thinks of the EOp model discussed in Section 4.3. There will almost never exist a policy that uses all the budget available and equalizes *for all* π, the outcomes across all types. This would be the *summum bonum*, from the viewpoint of EOp, but it cannot be achieved in a problem of any complexity. So some compromise is called for.) Their approach is to sequentially weaken axioms until they find possible preference orders over policies. A significant part of their analysis therefore consists in providing axiomatizations of different preference orders over policies, each of which has some purchase as reflecting the equal-opportunity view. The egalitarian-equivalent and conditional-equality families turn out to be the important ones.

Before concluding this section, we mention another preference ordering of policies similar in spirit to the EOp ordering, first proposed by Van de gaer (1993): order policies according to the value of

$$\min_t \int_0^1 v^t(\pi,\varphi)\mathrm{d}\pi. \tag{4.6}$$

In other words, maximize the average outcome value of the most disadvantaged type. Formally, this proposal simply commutes the integral and "min" operators compared to Roemer's approach in (4.1). Its virtue is that it is sometimes easier to compute than (4.1). If there is an unambiguously worst-off type (that is a type t such that for all policies φ and for all types t', and all $\pi \in [0,1]$ we have $v^t(\pi,\varphi) \leq v^{t'}(\pi,\varphi)$), then (4.1) and (4.6) are equivalent. Unfortunately, (4.6) is not a special case of (GEOp); it does not necessarily maximize the size of the lower-envelope function θ, for any conception of how to measure size (i.e., Γ). See Roemer (2012). Ooghe et al. (2007) compare the orderings over social policies induced by (4.6) and (4.1) by introducing a number of axioms that distinguish between the two. They argue that Roemer's approach (4.1) is a "compensating outcomes" approach, while Van de gaer's (4.3) is an "equalizing opportunity sets" approach, in the sense that the integral $\int_0^1 v^t(\pi,\varphi)\mathrm{d}\pi$ can be viewed as a measure of the degree of opportunity available to type t. Therefore, these authors link their approach to the large literature on equalizing opportunity sets (e.g., Bossert, 1997; Foster, 2011) which derived its inspiration from Sen's capability approach.

Our final topic of this section is the attempt to incorporate luck into the theory of equal opportunity. Of course, luck has already to some extent been incorporated, as circumstances are aspects of luck—for example, the luck of birth lottery assigns genes, families, and social environments. Besides the luck inherent in circumstances, however, there are two other kinds of luck that are important: first, what might be called episodic luck, which is randomly distributed across individuals, and is often unobservable to third parties (being in the right place at the right time), and the luck due to the outcome of gambles. Dworkin's view was that no compensation is due to anyone who suffers a bad outcome owing to a voluntarily taken gamble—such "option luck" is due to an exercise of preferences for which the person is held responsible. Fleurbaey (2008), however, contests this view. He splits gambles into two parts: the decision to take the gamble, which is the person's responsibility, and the outcome of the gamble, which is an aspect of luck. Let us view the risk-taking preference of the individual as a responsibility characteristic, and the outcome of the gamble as a circumstance—something over which the individual has no control. Fleurbaey proposes giving all persons with a given risk-taking propensity (i.e., responsibility characteristic) the average value of all gambles that such persons take. Thus, everyone with the same responsibility characteristic receives the same outcome. Of course, the informational requirements for implementing such a plan are severe. Moreover, this proposal seems to countervene the purpose of gambling. If gamblers wanted to protect themselves from bad outcomes, they would insure to receive the expected value of the gamble. If, however, gamblers are risk-loving, then they would only insure to receive something more than the gamble's expected value, and such insurance is not fiscally feasible. So in offering gamblers the expected value of all gambles taken by their risk type, their welfare is being reduced from actual gambling, assuming that they are true risk lovers.[17] This solution, first advocated by Le Grand (1991), has other weaknesses. The different lotteries offered to the individual decision makers can be ranked unambiguously from the most profitable to the least if Fleurbaey's solution is implemented. Indeed, the lotteries would only differ in terms of the average outcome since all risk is eliminated. All rational decision makers (who prefer more than less) will choose the same lottery. Full equality will be then observed *ex post*.

Lefranc et al. (2009) believe that the project of separating influences into circumstances and effort is too binary. They call "residual luck" a third influence, and recommend something weaker than compensation for residual luck, namely, that the correlation between such luck and circumstances be eliminated. Consider the following examples: Some people gain by the chance meeting of another person; popular views do maintain that persons with rare productive talent be specially compensated; the winnings

[17] Fleurbaey (2008, p. 162) distinguishes between risk lovers and super risk lovers. If they lose, the former regret gambling *ex post* whereas the latter do not. Following the distinction introduced by Kahneman et al. (1997) between decision utility and experience utility, preferences that might be respected are "experience' preferences, in the present case, the preferences of the super risk lover. Fleurbaey does not propose a compensation scheme for them.

of national lotteries (Belgium, France, United Kingdom) are often not taxed. The luck inherent in these examples (especially the first two) is often considered to be part of life, something that policy should not eliminate. The first example could be brute luck or due to special effort; the second example is brute luck; the third is option luck. These authors maintain that these kinds of luck should be equally distributed across types, at any given level of effort.

Suppose the income-generating process is given by:

$$y = g(c, e, l)$$

where c, e, and l are circumstances, effort, and residual luck, respectively. The distribution of income, conditional upon c and e is defined as:

$$H(y|c,e) = F_{c,e}\left(g^{-1}(y, c, e)\right)$$

where $F_{c,e}$ is the distribution of luck in the element of the population characterized by (c, e). The above-described principle says that

$$\text{for any } (c, c')H(\cdot|c,e) = H(\cdot|c',e) = K(\cdot|e).$$

This allows the distribution of virtual luck to depend on effort but not on circumstances. If all luck factors are named as circumstances, then the distribution K is simply a point mass. More generally, the support of this distribution can be as small as the decision maker wishes. It depends on her inequality aversion. The authors propose further refinements using stochastic-dominance arguments.

4.6. ECONOMIC DEVELOPMENT

The standard measure of economic development, GDP per capita, is inspired by the utilitarian ethic. If we identify utility with income, then average utilitarianism calls for maximizing average income. Hence, this conception of economic development is a corollary to an ethical view. As utilitarianism was ubiquitous in economic thinking until Rawls (1971), and continues to be extremely influential in economics after Rawls, especially in growth theory and policy analysis, it is unsurprising that our central measure of economic development has a basis in utilitarian thought.

There are various ways we might alter our measurement of economic development, based on other ethical views. Indeed, some alterations can be made within utilitarianism. By recognizing that some needs are more urgent than others, we could apply a concave transformation to income, say the logarithm, and measure economic development by $\sum \log x_i$, where x_i is income, which is ordinally equivalent to maximizing $\prod x_i$. Of course, this would place much more policy focus upon avoiding poverty, as a single very small income is socially catastrophic. Another approach, still within utilitarianism, is to include other arguments besides income in the utility function—education, health, etc.—but to take the average of an index of these goods over the nation. This is the approach of the UNDP's human development index. But if equalizing opportunities is an attractive ethic, then we should construct measures of economic development that are consonant with it. This section begins that discussion.

As a preliminary consideration, we must clear the deck of an opposing position which argues that economic development is a technical concept, not one related to social welfare. This cannot be correct. Economics is not engineering: Its goal is to maximize *social* welfare, however that may be conceived. Even for those who abjure the possibility of interpersonal comparisons, Pareto efficiency is a conception of social welfare. An economy consisting of slaves who produce, for a very small elite, huge wealth, should not be considered highly developed, no matter how refined the technology. Economic development must mean the development of human beings (some would include other sentient beings), and how to conceive of it must be corollary to a theory of the good life and good society.

If EOp is to replace utilitarianism as the ethical view of choice, then we must replace GDP per capita with some measure of opportunity equality as a measure of economic development. We will propose, here, a two-dimensional index of economic development, based upon the EOp approach. The first component of the index is the value of (4.1), and the second is a measure of the extent to which inequality in the society is due to inequality of *opportunity* (as opposed to differential effort).[18]

There are various methods for defining the second component; here is one. Suppose H is the distribution of income in the society, let H^t be the income distribution in type t, and let f^t be the frequency of type t. Then $H = \sum f^t H^t$. Let μ(resp., μ_t) be the mean of H(resp., H^t). Define the square of the coefficient of variation of H by:

$$C(H) = \frac{\mathrm{var} H}{\mu^2}.$$

Define the distribution:

$$\Phi^T(x) = \sum_{t=0}^{k} f^t \text{on the interval}\, \mu_k \le x \le \mu_{k+1}, \tag{4.7}$$

where $k = 0, \ldots, n$ and $\mu_0 = 0$ and $\mu_n = \infty$ and $f^0 \equiv 0$. Clearly the mean of Φ^T is μ. If Φ^T were the actual distribution of the objective in society, then everybody in a given type would have exactly the same value of income, equal to the mean income of that type. (The distribution function Φ^T is a step function with the same mean as H.) Were this

[18] For instance, take income as the objective, and define a typology by parental education levels.

the case, then the contribution of effort to inequality would be nil, as no variation of the objective would exist within any type. Now it is well known that we can decompose $C(H)$ as follows:

$$C(H) = C\left(\Phi^T\right) + \sum f^t (\rho^t)^2 C(H^t), \tag{4.8}$$

where $\rho^t = \frac{\mu_t}{\mu}$. Since both addends in this decomposition are positive, it is natural to interpret $C(\Phi^T)$ as a lower bound on the amount of inequality due to circumstances, and $\sum f^t (\rho^t)^2 C(H^t)$ as an upper bound on the amount of inequality due to effort. We therefore propose, as a measure of an upper bound on the *degree* of inequality due to effort the index:

$$\eta = 1 - \frac{C(\Phi^T)}{C(H)}. \tag{4.9}$$

The reason that the measure η is only an upper bound on the fraction of inequality due to effort is that circumstances continue to influence the second term in the decomposition (4.8). See Shorrocks (1980) for a characterization of all inequality indices that can be decomposed in the sense of (4.8).

Our proposal is to measure economic development by the ordered pair $d = (W^{\mathrm{EO}}, \eta)$. W^{EO} replaces GDP per capita: It is the average income of those who belong to the most disadvantaged type.[19] Thus, d presents both a level of welfare and a degree of inequality.[20]

The proposal to measure the degree of EOp using the decomposition (4.8) is not original with us. It is a special case of the inequality of opportunity ratio (IOR), defined in Ferreira and Gignoux (2011). Ferreira and Gignoux's preferred measure of inequality is not the square of the coefficient of variation but the mean logarithmic deviation (MLD). The same idea for measuring the degree of inequality due to circumstances is proposed in Checchi and Peragine (2010) as well.

In Figure 4.4, we present a graph plotting the points d for a set of European countries, where the data are taken from EU-SILC (2005) and the population of male workers is partitioned into three types, depending on the level of education of the more educated parent. (Type 1: parent completed only lower secondary; type 2: parent completed upper secondary; type 3: parent had some tertiary education.)

[19] Or, more generally, as we explained above, it is the average value of the objective of those in the population who comprise the left-hand envelope of the type distributions of the objective. Frequently, the left-hand envelope of the type-income-cdfs is the cdf of a single type.

[20] Atkinson suggests to us a simple normalized measure of the degree of equality of opportunity. Letting $\theta(\pi) = \min_t v^t(\pi)$, as in equation (4.1), define the degree of opportunity equality as $\int_0^1 \theta(\pi)\mathrm{d}\pi/\mu$, where μ is the mean value of the objective—that is, divide our measure of EOp, which is $\int_0^1 \theta(\pi)\mathrm{d}\pi$ by the mean. The advantage of the normalization is that it always gives a number between 0 and 1. If F is the population distribution function of the objective, then $\theta(\pi) \le F^{-1}(\pi)$ and so $\int_0^1 \theta(\pi)d\pi \le \int_0^1 F^{-1}(\pi)\mathrm{d}\pi = \mu$.

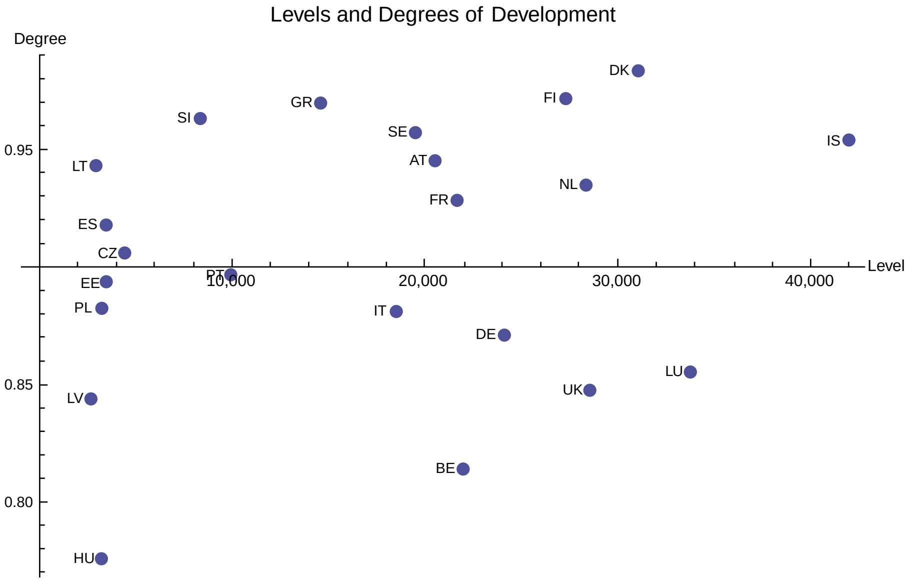

Figure 4.4 The points $d = (W^{EO}, \eta)$ for a set of European countries.

Several remarks are in order. (1) Generally, over 80% of the inequality in income is due to "effort," but recall our typology is very coarse: There is only one circumstance, parental education, partitioned into three levels. A finer decomposition of the population into more types would lower the degree of inequality due to effort. (2) Iceland's (IS) strong position on the first component, it must be remembered, is from data before the bank crisis. (3) No country dominates all others on both components of d. But Denmark (DK) dominates all other countries except Luxemburg (LU) and Iceland. (4) Greece's high component η is due to the fact that the great majority of individuals in the sample were of the least advantaged type (their parents had not completed high school). (5) The Eastern European countries (Lithuania, Lativa, Estonia, Poland, Czech Republic, and Hungary) perform relatively poorly. Finally, recall that we are looking at highly developed countries; were we to calculate the point d for developing countries, there would be a much larger spread. (For further details on this calculation, see Roemer, 2013.)

Ferreira and Gignoux (2011) calculate their version of the measure η for six Latin American countries as well. Their calculation differs from the one presented here using the EU-SILC data in two ways: They have a different set of circumstances, and they use a different measure of inequality. There is, as one might expect, a lower degree of opportunity equalization in the Latin American countries than in the European ones.

There is one study, of Sweden, in which the population of male workers was decomposed into 1152 types, based on the observation of seven circumstances (Björklund et al., 2012). These authors use a Shapley-value method to assign the degree of income inequality due to the various circumstances and to effort. For the coefficient-of-variation-squared measure, the fraction of long-run income inequality due to effort is calculated to be between 59% and 80%, considerably lower than the 96% shown in Figure 4.4. It is a testament to the degree of EOp in Sweden that, with such a fine decomposition of the working population into types, (only) between 20% and 40% of income inequality is due to circumstances.

One disadvantage of reporting the level of economic development as a two-dimensional statistic is complexity; in particular, this generates only a partial ordering of countries with respect to the degree of development. One could create a single index by aggregating as follows:

$$\hat{d}_\alpha = \left(W^{\mathrm{EO}}\right)^\alpha \eta^{1-\alpha} \tag{4.10}$$

for some $\alpha \in (0,1)$. The advantage of the Cobb-Douglas aggregation is that the ordering it imposes on countries is independent of the units in which W and η are measured, so it does not matter that W is a large number and η is a small one. For the European countries in Figure 4.4, most values of α in (0,1) render a country-ordering that is very highly correlated with the ordering of the first component. We conjecture that this would not occur with a larger set of countries, in which the variation of η would be more substantial.

The World Bank has been an important innovator in bringing considerations of equal opportunity into economic development. Its two important publications to date have been the 2006 World Development Report, *Equity and Development*, and a monograph, *Measuring Inequality of Opportunities in Latin America and the Caribbean* (Paes de Barros et al., 2009). The more recent publication contains a wealth of information on the effects of social circumstances on various measures of achievement and output.

Paes de Barros et al. (2009) propose a measure of EOp. Consider a particular kind of opportunity, such as attaining the sixth grade in elementary school. Let the total sixth-grade attendance in a country be H, and the total number of children of sixth-grade age be N, and define $\overline{p} = \frac{H}{N}$ to be the *access* on average of children to the opportunity of a sixth-grade education. $\overline{p}$ measures the level of this opportunity in the country, but not the extent to which access is unequal for different children, based on their social circumstances. Now using a logit model, they estimate the probability that each child, j, in the country has of attending the sixth grade, where that probability is a function of a vector of circumstances; denote this estimated probability by $\hat{p}_j$. Define $D = \frac{1}{2\overline{p}N}\sum\left|\hat{p}_j - \overline{p}\right|$. D measures the variation in access to the opportunity in question across children in the country. The normalization guarantees that $0 \le D \le 1$. Now define the *human opportunity index* as

$$O = \overline{p}(1 - D);$$

note that $0 \le O \le \overline{p}$.

The human opportunity index is a nonconsequentialist measure of development, because the probabilities $\hat{p}_j$ can only be computed knowing the circumstances of the children. The measure combines a concern with the level of provision of opportunities and the inequality of the distribution of them. This is to be contrasted with the ordered pair $\left(\hat{W}^{\mathrm{EO}}, \eta\right)$, which separates these two concerns into two measures. Obviously, some information is lost in using a single measure rather than two measures.

The concern of the 2009 report is in large part with children. In our view, where children are concerned, all inequality should be counted as due to circumstances, and none to effort, and so the fact that the human opportunity index does not explicitly make the distinction between effort and circumstances is unobjectionable.[21] However, if the measure is used for addressing inequality of opportunity for adults, this may be a defect.

To study this, let us take an opportunity for adults—the capacity to earn an income above M. Suppose there are three types of worker, according to the level of education of their more educated parent. Denote the distribution of income in type t as F^t; let the fraction of type t be f^t and let F be the distribution of income in the society as a whole. Then $\overline{p} = 1 - F(M)$ is the average access to the opportunity in question in the country. Now for all members j of a given type, t, compute that $\hat{p}_j = 1 - F^t(M)$: This is because the probabilities $\hat{p}_j$ are computed by taking the independent variables in the logit regression as the circumstances. Hence, the human opportunity measure is:

$$\begin{aligned} O &= \overline{p}\left(1 - \frac{1}{2\overline{p}}\sum f^t |1 - F^t(M) - (1 - F(M))|\right) \\ &= (1 - F(M)) - \frac{1}{2}\sum f^t |F(M) - F^t(M)|. \end{aligned} \tag{4.11}$$

Despite the fact that effort is not explicitly mentioned in defining the index, effort is reflected in the measure, because the distributions F^t appear in the calculation. Indeed, the first term $1 - F(M)$ measures the level of opportunity in the country, while the second term is a penalty for the degree to which this opportunity is mal-distributed with respect to circumstances (e.g., if there was no inequality of opportunity, then $F^t(M) = F(M)$ for all t, and the penalty is zero).

In expression (4.11), the first term on the right-hand side, $1 - F(M)$, plays the role that $\hat{W}^{\mathrm{EO}}$ plays in the ordered-pair measure we introduced above: It measures the level of

[21] Children should only become responsible for their actions after an "age of consent" is reached, which may vary across societies. Both the effects of nature and nurture should be considered circumstances for the child.

development. But while $\hat{W}^{\mathrm{EO}}$ focuses upon how well off the most disadvantaged type is doing, $1 - F(M)$ is a level for the society at large. The second component of our measure, η, is explicitly derived to show the degree to which inequality is due to circumstances, whereas the second term on the right-hand side of (4.11) is a form of a variance. Certainly, these two measures are getting at the same phenomenon. We have a slight preference for our proposal, as it is more carefully justified as measuring what we are concerned with. But these are minor differences; certainly, the measure O is in the spirit of thinking of economic development as opportunity equalization.

We finally consider a confusion (from our viewpoint) that infects discussions of "equity versus development," similar to the one we mentioned when we presented the health-expenditure example. It is often said that equity and efficiency are competing goals, and that equity is purchased at the expense of efficiency. There are two senses in which this phrase is uttered. The first is that redistributive taxation may be purchased only at the cost of *Pareto* inefficiency, due to workers and firms facing different effective wages. This is true. The second sense is that redistribution may lower total output. These two claims are in principle independent. There may be policies that reallocate income in a more equitable manner and lower total output, but are not Pareto inefficient. (Think, for example, of reallocating educational funds from tertiary education to secondary education in a poor country. This might have a purely redistributive effect, without significant consequences for Pareto efficiency.)

We wish to criticize the second usage of the phrase. Saying that there may be a trade-off between equity and efficiency *where efficiency is measured as total output* is equivalent to saying there is a trade-off between equity and the *utilitarian* measure of development, which (in its simplest form) is given by output per person. Consider the following quotations from the otherwise fine World Development Report 2006, issued by the World Bank, entitled *Equity and Development*. In these quotations, equity and development are counter-posed:

> *Greater equity is thus doubly good for poverty reduction: through potential beneficial effects on aggregate long-run development and through greater opportunities for poorer groups within any society (p. 2)*

> *If the opportunities faced by children like N. are so much more limited than those faced by children like P. or S., and if this hurts development progress in the aggregate, then public action has a legitimate role in seeking to broaden opportunities. (p. 3)*

> *Third, the dichotomy between policies for growth and policies specifically aimed at equity is false. (p. 10)*

In the first quotation, saying that equity is "doubly good," in that it is good for the poor and also good for long-run development, only makes sense if one assumes that equity and long-run development are *different goals*. In our view, long-run development *means* approaching equity—that is, EOp. We believe that the authors of this sentence had in mind GDP per capita as the measure of long-run development, and so what is being said is that equalizing opportunities will increase GDP per capita. This is peculiar in a report that is devoted to advocating the view that economic development requires the achievement of equal opportunity.[22] In the second quotation, the assumption is that redressing the inequality of opportunity among the children is justifiable because that inequality *hurts development*; but in our view, it is that inequality which *comprises* underdevelopment, and so the sentence is tautological. Here, the authors have in mind a utilitarian concept as the measure of economic development. Finally, the third quotation would likewise be a tautology for us; but in the context, the authors are saying that policies that increase *EOp also lead to an increase in total income*. (That is, the third quotation is offered as an empirical claim, while for us, it is a tautology.) Again, there is an ambivalence in the conceptualization of economic development: Does it mean equalizing opportunities or increasing per capita output?

It will often be the case that policies that redress inequality of opportunity will also increase total output, because improving opportunities for the disadvantaged releases talents that were, before, unused. But this need not be the case, and we maintain that our justification for redressing inequality of opportunity should not depend on its being the case. There may be groups in society that are so disadvantaged that it is very costly to compensate them: The return in output per funds invested may be small. Equity may be advanced only by shifting investment from uses where it generates high output to ones where it generates lower output. (This may be so, particularly in the short run.) But if this is the case, it does not mean that the policy in question should not be undertaken, nor does it mean that development is thereby reduced if it is.

The ambivalence in *Equity and Development* is a reflection of the competing conceptions of justice represented by utilitarianism and opportunity equalization. Utilitarianism, as we said, has a strong hold on economists. This is a holdover from an earlier period when utilitarianism was the only game in town—let us say, until John Rawls's work (Rawls, 1958, 1971). Economists and mathematicians developed optimization techniques (e.g., the Bellman equation), which are suited to solving problems where utilities are added up across persons, but not to solving problems where the minimum is maximized. And so it is often comfortable to work with utilitarian formulations. We submit, however, that this is a bad habit we should not continue to practice.

If our view of economic development is adopted, there may be a significant change in policy evaluation. One would not have to justify investment in very disadvantaged social groups by showing that such investment increases total output. As we indicated, in the long run, such a conflict might not exist, but often, policy makers are under political pressure to evaluate the consequences of their policy choices in the short run. If a country is

[22] To say that development "requires" equalizing opportunities is weaker than saying that it is synonymous with equalizing opportunities: We have been advocating the latter position in this section.

evaluated on the basis of its ordered-pair statistic $d = (W^{\mathrm{EO}}, \eta)$ rather than on GDP per capita, policies could be quite different.

4.7. DYNAMICS

EOp invites a dynamic approach. If we apply an EOp policy today, what effect will it have on the distribution of types in the next generation? One hopes that sequential application of EOp policies would create a society in which most of the effect on inequality from circumstances has been eliminated. A natural way to study this question is to analyze stationary states; that is, policies which have the property that the society they produce at date $\tau + 1$ is a replica of the society that existed at date τ.

We know of only one paper on this topic, by Roemer and Ünveren (2012), which presents an extended example. In the society postulated, there are two economic classes, rich (R) and poor (P), whose pretax (inelasticallly produced) incomes are w_R and w_P, $w_R > w_P$. Both the family and state invest in children. Let private investment in its child by a type J family be i_J and state investment in a J child be s_J, for $J \in (P, R)$. At a point in time, the fraction of $R(P)$ households is $f_R (f_P = 1 - f_R)$. Mean income at this time is $\mu = f_R w_R + f_P w_P$. The state investments are funded by a linear income tax at some rate t; thus

$$t\mu = f_R s_R + (1 - f_R) s_P. \tag{4.12}$$

Let $z_J = i_J + s_J$ be the total monetary investment in a J child, $J \in (P, R)$. The probability of the child's being successful, in the sense of becoming an R adult, is a function of his background. For a child growing up in an R household, it is

$$\pi_R(z_R, z_P) = \frac{e^{z_R}}{e^{z_R} + e^{z_P}}, \tag{4.13a}$$

while the probability of transition to the R class for a child from a P background is:

$$\pi_P(z_R, z_P) = \frac{a e^{z_P}}{e^{z_R} + e^{z_P}}, \quad 0 < a < 1. \tag{4.13b}$$

The fact that $a < 1$ models the idea that the cultural effects of growing up in a P household (and neighborhood) reduce the chances of becoming an R adult. The formulation of the transition probabilities is a reduced-form representation of a process of competition for the "good" jobs among young workers.

The *standard of living* of a J adult is his after-tax income, which is $y_J = (1 - t) w_J - i_J$. The *utility* of an adult is a function of his income and the expected income of his child when she becomes an adult. We may write the utility of a J adult at date τ as:

$$U_J^\tau = y_J + \varphi\left(\pi_J^\tau y_R^{\tau+1} + \left(1 - \pi_J^\tau\right) y_P^{\tau+1}\right). \tag{4.14}$$

A *stationary state* is a stable set of policies and decisions. It comprises a policy (t^*, s_P^*, s_R^*), optimal private-investment choices by households, (i_R^*, i_P^*), and a stable fraction of rich households f_R^*, such that the following hold:

(1) $t^*\mu^* = t^*\left(f_R^* w_R + \left(1 - f_R^*\right) w_P\right) = f_R^* s_R^* + \left(1 - f_R^*\right) s_P^*,$

(2) i_R^* maximizes (over i)

$$\left.\begin{array}{l}(1-t^*)w_R - i + \\ \varphi\left(\pi_R\left(s_R^* + i, z_P^*\right)\left((1-t^*)w_R - i_R^*\right) + \left(1 - \pi_R\left(s_R^* + i, z_P^*\right)\right)\left((1-t^*)w_P - i_P^*\right)\right)\end{array}\right\} \text{Program } P_R$$

(3) i_P^* maximizes (over i)

$$\left.\begin{array}{l}(1-t^*)w_P - i + \\ \varphi\left(\pi_P\left(z_R^*, s_P^* + i\right)\left((1-t^*)w_R - i_R^*\right) + \left(1 - \pi_P\left(z_R^*, s_P^* + i\right)\right)\left((1-t^*)w_P - i^*\right)\right)\end{array}\right\} \text{Program } P_P$$

(4) $f_R^* \pi_R\left(z_R^*, z_P^*\right) + \left(1 - f_R^*\right)\pi_P\left(z_R^*, z_P^*\right) = f_R^*$

Condition (1) is the budget constraint, and condition (4) says that the fraction of R households is stable; condition (2) defines the optimal investment choice of an R parent, knowing that the next period will look exactly like the present period from the viewpoint of his child. Condition (3) defines the optimal investment choice of a P parent in the stationary state.

Write

$$I_J = \left\{i_J \geq 0 : i_J \text{ solves Program } P_J\right\}, J = R, P.$$

An *environment* is summarized by the data (w_R, w_P, a, φ) with the intergenerational transmission functions (π_R, π_P). For this environment, there will exist a set of stationary states. We are interested in the stationary state that is best from the equal-opportunity viewpoint. We define this as follows. In a stationary state, the expected standard of living of a J child is:

$$E_J = \pi_J((1-t)w_R - i_R) + \left(1 - \pi_J\right)((1-t)w_P - i_P)$$

The equality-of-opportunity ethic maintains we should maximize the expected standard of living of the worse-off type of child. Thus, if ξ and ξ^* denote two stationary states, then EOp weakly prefers ξ to ξ^* if:

$$\min_{J=P,R} E_J(\xi) \geq \min_{J=P,R} E_J(\xi^*). \tag{4.15}$$

Obviously, the ordering on stationary states defined by (4.15) induces an ordering on policies. We wish to compute the most desirable state policy according to the preference order (4.15).

Solving for the optimal stationary state is complicated, because the optimization program is nonconvex due to the incentive-compatibility constraints. The authors compute optimal policies for a randomly generated set of economies by analysis and simulation.

The striking result is that, in 76% of the economies randomly generated, the optimal stationary state from the EOp viewpoint is *laissez-faire*; that is, the state should neither tax nor invest in children. The reason is that if the state invests in poor children, rich families compensate by investing more in their children.

Admittedly, this is just an example. The authors then consider a second type of policy: investment in parents. Formally, this is modeled by devoting state investment to raise the coefficient a (see Equation (4.13b)), which reduces the handicap that poor children face due to their background. Now, in the simulations, in 80% of the cases, the state invests in parents (that is, in increasing a), but not in children.

These results are mindful of the work of Heckman (2011), who has been championing the importance of early childhood education. It appears that much of the disadvantage of being poor has already occurred by the age of three or four. We suggest, based on these results, that investment in poor families may be more productive, in the long run, than investing directly in children.

Finally, a more radical solution to the disappointing result that rich parents will often undermine, through private investments, the effort of the state to equalize opportunities for children through educational investment, is to ban private education. This is essentially what has been done in the Nordic countries, and it is perhaps no coincidence that these countries perform among the best in the world in terms of social mobility and equalization of opportunities.

A second approach to incentive issues in EOp is the work of Calsamiglia (2009), who points out that if there are several ministries attempting to equalize opportunities for different objectives, each taking a "local" approach, the consequence may be to not equalize opportunities globally. Her paper characterizes the types of local EOp policies that will induce global EOp.

Suppose that Paul and Richard have identical preferences and skills; both want to play professional basketball and to attend college. They face the same basketball resources in their two neighborhoods, but Richard's (rich) neighborhood has better schools. So Richard is advantaged with respect to the probability of college admission due to a fortunate circumstance. Their probabilities of being admitted to college and a professional basketball team will depend on their efforts in school and in basketball, respectively, and on the resources in their neighborhoods.[23] Suppose initially that both pro-basketball and college recruiters adopt a "market" policy: they admit candidates based only on their scores on relevant tests, which are functions of effort and circumstances in the relevant arena. Facing these policies, Paul and Richard choose basketball and school effort (e_B, e_S) to maximize the total probability of admission to the basketball league and college, minus some convex cost in total effort. Since school effort is relatively less effective for

[23] We ignore American colleges' propensity to admit star basketball players, regardless of their academic accomplishment.

Paul, he devotes less effort to school than Richard and more effort to basketball. It turns out that Richard has a higher utility, although the two boys have identical preferences and skills.

Now the basketball league and college alter their policies in an attempt to equalize opportunities. Suppose that the league's policy is to admit players based only on their efforts pertaining to basketball. Then if Paul and Richard expend the same basketball effort, e_B, they will enjoy the same probability of recruitment by the league, which is locally fair, because they have the same basketball circumstances. Suppose that the college admissions officer decides to give extra points on his college-admission score to Paul as compensation for Richard's advantaged circumstances: he simply adds a lumpsum to Paul's SAT score. This is also a local EOp policy. Given these two policies, Paul and Richard will not alter their efforts, because of the lump-sum nature of the compensation to Paul, and hence Paul and Richard will have the same probability of college admission (locally EOp), but Paul has a higher probability of getting into the basketball league, as he expended more basketball effort. Although the policies are each *locally* EOp, the global result is not opportunity equalizing.

The problem lies with the lump-sum nature of the EOp policy in the college sector. Calsamiglia proves that, under assumptions that the environment is sufficiently rich, the necessary and sufficient condition for local EOp policies to aggregate to a global policy that is opportunity-equalizing is that the *marginal* returns to effort must be identical for all candidates in each sector. Because Paul's effort in school is less remunerative than Richard's, due to his inferior school, the proper policy is to augment the *returns per unit of school effort* for Paul in terms of the desired outcome (probability of college admission).

Certainly, many affirmative action policies are of the wrong, lump-sum type. For example, universities often given extra points to students from disadvantaged backgrounds, in considering admissions. The empirical implications of Calsamiglia's result have yet to be examined.

4.8. PREPARING THE GROUND FOR EMPIRICAL ANALYSIS

The literature on distributive justice is divided into two strands, a large normative one and a small descriptive one. The previous sections have considered the normative foundations of EOp. This section and the next review the empirical evidence showing that in many societies, ordinary people distinguish between two causes of inequality: those for which individuals should not be held responsible, and those for which they should be. If people do make this distinction when discussing inequality, then implementing opportunity-equalizing policies may be politically more feasible than otherwise. The issue of social acceptance of the principle is even more important if one follows Roemer's (1993) view according to which the cut between circumstances and effort should be a social and cultural decision, rather than a metaphysical one. Each society should determine the precise set of variables that describe the circumstances and the effort variables according to the views of its population. Intercultural differences in social preferences will obtain in this pragmatic view of EOp. Empirical work on intercultural differences in the attribution of the responsibility is then relevant. The state of our knowledge on these matters is still weak. Below, we list the most obvious candidates for an empirical assessment.

The first issue concerns the so-called responsibility cut. In the philosophical literature, there is a debate between those who advocate that people should be responsible for their preferences (for example, Dworkin, 1981a,b; Fleurbaey, 2008) and those who argue that the responsibility variables should be those under the control of the individual (prominently, Arneson, 1989; Cohen, 1989).

The second issue concerns the correlation between effort and circumstances. Lifestyle choices (patterns of alcohol use, exercise, smoking, diet, and so on) are examples of variables under proximate personal control. These choices are, however, influenced by family and social background. As we have said, for the measure of effort to be appropriate for the theory, it must be sterilized of the impact of circumstances upon it. "If we could somehow disembody individuals from their circumstances, then the distribution of the propensity to exert effort would be the same in every type" wrote Roemer (1998). As we wrote earlier, Roemer's technique for sterilizing effort of the effect of circumstances upon it is to measure the degree of a person's effort by her rank on the distribution of effort of those in her type. The same issue arises with preferences: If a large number of persons in a given type have preferences which, let us say, degrade the value of education, one must recognize that educational choices of such persons are influenced by their circumstances, and are not autonomous in the appropriate sense. Dworkin's (1981b) opposition to this move is to claim that *not* holding persons responsible for their preferences is to disrespect them. Another philosopher who opposes sterilizing the effort distribution of its circumstantial causes was Brian Barry, who believed that persons should be rewarded for hard work, even if that was induced by familial culture and pressure.

The responsibility cut must also to be drawn among the different kinds of luck.[24] As we wrote, Dworkin (1981b) distinguished between brute and option luck. A typical example of option luck is the outcome of a deliberate gamble. As we wrote, Fleurbaey (2008) does not advocate holding individuals responsible for the entire consequences of option luck. He attempts to disentangle the risk-taking aspect from the purely random aspect of a gamble, considering the latter to be a circumstance. Various compensation schemes respecting this distinction are proposed.

Implementing EOp may be viewed as weakening the traditional role of the family. Roemer (2004) has proposed that parents affect the opportunities of their children

[24] Alesina and Angeletos (2005) argue that societies are divided on the importance played by luck in shaping outcomes.

through four channels: (C1) the provision of resources and social connections, (C2) the formation of beliefs and skills in children through family culture and investment, (C3) genetic transmission of ability, and (C4) the formation of preferences and aspirations in children. He views the first three as circumstances, deficits in which should be compensated by an equal-opportunity policy. Preferences and aspirations are more complicated. If a coal miner loves coal-mining culture and instills in his child the desire to become a miner, this is a legitimate influence that does not call for compensation. What better conception of immortality is there than transferring one's values to one's children? If, however, the parent instills that desire because he views no other career as being available to the child, that transfer of preference is not legitimate—that is to say, preferences which are themselves induced by resource deficits comprise grounds for compensation. We know of no study that attempts to disentangle the kinds of preferences parents pass on to their children in this way.

One consequence of viewing (at least some) preference transmission to children from parents as morally legitimate is to recognize that even a perfect regime of equal opportunity should not aim at equalizing the rows of the intergenerational mobility matrix. Parents may legitimately induce differential preferences in their children, *leading to differential incomes*, even if the effects of all other circumstances were miraculously compensated for. If one does not admit this, then it is difficult to justify why we do not advocate raising children collectively. At some point, when the unacceptable differential effects of socioeconomic circumstances have been largely eliminated it will become important to address the distinction discussed with respect to channel (C4).

Finally, the importance of the *nature of the objective* must be taken into account. Three important objectives appear frequently in the empirical discussion. First, education, which takes place mainly during childhood and adolescence; second, income, which is closely related to conditions in the labor market; and third, health, which matters for a lifetime. Education is peculiar because a good part of it occurs before the "age of consent," that is, the age at which people should be held at least partially responsible for the various choices they make. Health, by many, is viewed as a right, in which matters of choice should not count. Thus, the *scope* of equal-opportunity policy may differ substantially depending upon the nature of the objective.[25]

4.9. DO PEOPLE ADVOCATE EOp? LESSONS FROM QUESTIONNAIRES AND EXPERIMENTS

The information reviewed here is derived both from the answers of respondents on questionnaires and from the actions chosen by players in laboratory or field experiments.

[25] For an early survey experiment, which shows that norms of justice differ quite radically depending upon what the *distribuendum* is, see the seminal paper of Yaari and Bar-Hillel (1984).

Questionnaires are sometimes regarded with skepticism by economists, whereas they are used extensively by psychologists and political scientists (see Chapter 13 for more methodological issues). Gaertner and Schokkaert (2012) made a plea for the use of questionnaires in the field of social choice and justice and here we build upon their reasoning. What we desire is a procedure or protocol that helps subjects to reveal their norms of distributive justice. We recognize that respondents can lie; Gaertner and Schokkaert (2012) ask why respondents would do so. In the absence of self-interest, they assert, respondents will choose to reveal their true norms. (We often assume that when an agent is indifferent between cheating and telling the truth, he will tell the truth.) The main risk with questionnaires is that respondents answer at random when the question is too complex, a difficulty of which social psychologists are well aware.

4.9.1 Questionnaire on the Empirical Validity of EOp

A first source of information is provided by value surveys conducted by polling companies or scientific associations like the World Values Survey. In our opinion, these are not fully satisfactory, because the questions remain quite vague and are not related to specific normative theories. Rather, they address the beliefs of respondents concerning the determinants of success in a given country.

Since Schokkaert and Lagrou's (1983) early work, many surveys have been conducted, most of which propose vignettes about different aspects of life in order to inquire whether individuals' opinions about justice coincide with the theoretical propositions put forward by social scientists (for references and overviews, see Gaertner and Schokkaert, 2012; Konow, 2003; Schokkaert, 1999). The literature related to our topic can be divided in two subsets. The first tests the raw idea of responsibility. The second is rooted in the theories of EOp proposed by Roemer and Fleurbaey. Konow's (1996, 2001) studies, although not anchored in a theory, introduced the distinction between discretionary and exogenous variables, which is very close to the responsibility cut as viewed by Cohen (1989), although Konow was apparently unaware of Cohen's work. A discretionary variable affects output and can be controlled or influenced by the person, while an exogenous variable can have an influence on the amount or quality of output but cannot, under normal circumstances, be influenced by personal choice. His findings (telephone interviews with a general adult population of Los Angeles and written questionnaires completed by college students) support the view that for income acquisition, variables that are deemed to be controlled by the individual are viewed as legitimate influences upon income, whereas exogenous variables are not.

Perhaps the most thorough empirical study related to the philosophical project of EOp is that of Schokkaert and Devooght (2003) (see also Schokkaert and Capeau, 1991; Schokkaert and Overlaet, 1989). First, the authors test the two principles of "full compensation" and "natural reward," which are at the heart of Fleurbaey's approach (Bossert and Fleurbaey, 1996; Fleurbaey, 1995). The principle of full compensation states that two individuals who exert the same effort should enjoy the same outcome; thus, the effect of differential circumstances is fully compensated. The principle of natural reward states that, if individuals have the same circumstances, there is no reason to transfer income between them (thus, full responsibility for effort). Second, there is an intercultural dimension in their study, as they distributed the questionnaire to first-year university students in three very different countries: Belgium (April 1996), Burkina Faso (May 1996), and Indonesia (August 1997). (See also Gaertner and Schwettmann, 2007). Finally, this study highlights whether views of responsibility are sensitive to what we have defined as the objective (or the opportunity equalidandum), as the questionnaire addresses views of responsibility with respect to income acquisition and health.

Four situations are contrasted in a two-person society. The two persons differ in only one characteristic. Possibilities of redistribution between the persons are then offered, and students are asked to choose what they think is the fair *ex post* tax income distribution.

The first vignette describes a difference in preferences in income-leisure space. No explanation is offered to explain this difference in tastes, whereas the second vignette stipulates that this difference comes from different backgrounds. That vignette tests the disagreement between Roemer and Barry about sterilizing the distribution of effort of the influence of circumstances. It is important here to notice that the issue raised is not the transmission of wealth, or social networks, but the transmission of values and preferences across different generations. People convinced by Roemer's reasoning should be more inclined to redistribute from hard-working Elizabeth to easy-going Catherine in the second situation than in the first. The third and fourth vignettes concern differences in productivity. In the third vignette, the difference originates in a difference of effort in the past. The fourth vignette describes a difference in innate talent.

The results are instructive and we will present them in terms of how the majority voted. The Belgian sample made the most clear-cut choice: A majority vote for no compensation at all (no redistribution) in case of Vignettes 1, 2, and 3, and for full compensation for the situation described in Vignette 4. Thus, the Belgians endorse the view that preference for leisure is a responsibility variable—they agree with Brian Barry not to take the causal relationship with parents' preferences into account. Innate talent, however, is considered as a circumstance. Were that vote representative of Belgian choices as a citizenry, this society would possess the basic ingredients to implement an equal-opportunity policy.

The authors find that the intercultural differences are much less pronounced than one might have thought. Still, they cannot be completely ignored, since, according to the majority vote criterion, the Burkina Faso sample is indecisive for all four vignettes. The Indonesian vote is closer to the Belgian one. Indonesians share the same views on the three first vignettes, but no majority is found on the last issue, although full compensation for talent has a plurality of votes.

At this stage, it is useful to ask whether the objective matters. Schokkaert and Devooght (2003) attempted to adapt their questionnaire to health care situations. From the start, two differences with income scenarios must be noticed that render the comparison less than clear-cut. In the income case, the stakes belong to the domain of gains, whereas they belong to the domain of losses in the health care case: the health vignettes describe illness and how to cope with health care expenditures. Since the work of Tversky and Kahneman (1991), we know a person's tendency strongly to prefer avoiding losses to acquiring gains. This may explain a stronger inequality aversion in the health vignettes. In addition, if questions are asked about how to allocate a budget between two sick persons, an efficiency issue is raised, which makes it difficult to deduce views about fairness. All studies about fairness in health care (Dolan and Tsuchiya, 2009; Ubel et al., 1999, and the above-cited paper) have chosen to formulate the vignettes in a scarcity context. Of course, scarcity of resources is an important issue in the health domain (as in others), but a sequential approach with two steps might better elicit preferences about the responsibility cut.

As an example consider two of the four vignettes proposed by Schokkaert and Devooght (2003), concerning Luke and Mark who are both suffering from lung cancer. They have the same wealth at their disposal and earn the same income. Luke and Mark have to be admitted to a hospital for treatment. It is supposed that all treatments are effective. The two vignettes raise the relevance of factors that are under the control (smoking) or beyond the control (genetic) of the individual for covering lung cancer expenditure. The respondents have the choice between different divisions of the amount of public resources: equal split between the two patients, all resources for the extra cost of treating Mark, and intermediate solutions between these two.

It is noteworthy that in all three societies, equal-split garners a majority of votes in Vignette 1. A majority favor an intermediate solution when genetics calls for extra cost. The social policy that this study suggests is clear-cut: smokers should purchase private insurance for coverage of smoking-related illness. This conclusion holds as long as the society is able to attribute the cause of the extra cost to lifestyle. These results suggest that the reason that the welfare state in many countries does not appear to be inspired by responsibility-sensitive egalitarianism is not due to popular ethics, but to the difficulty of identifying an indisputable causal link in health matters. Off-piste skiing is "the exception which proves the rule," where the cost of an accident is generally borne by the individual. One salient issue remains unsettled: we know of no questionnaire focusing on the link between lifestyle and family background. The difference of opinion between Roemer and Barry has not been reflected in the empirical literature on fairness in health.

Education is another domain where we can conjecture a different attitude with respect to responsibility. Primary and secondary education take place when the person is still, arguably, below the age of consent. Richard Arneson (1990, p. 179) has appealed to this fact in egalitarian debates. Lu et al. (2013) have investigated whether primary education elicits different responses from income acquisition in the degree to which persons are held responsible for outcomes. They contrast the results obtained with two vignettes.

In the sales vignette, there are salespersons whose sales compensation is composed of two parts: a salary and a bonus. The issue concerns the fairness of the bonus. Sales depend on characteristics which are described as follows. The salesperson's circumstances are identified with his parents' network of acquaintances. Effort is described as the salesperson's hard work, and talent is described as the salesperson's skill. A salesperson's brute luck is defined by the territory to which she is randomly assigned. Finally, option luck is described as the risks the salesperson takes: he has to choose between selling an old product that has been on the market for a long time and is familiar to customers, or a more recent product with unknown customer reaction. If a bonus is to be paid to the successful salesperson, respondents are asked how fair it is to judge the salesperson by her circumstances, effort, talent, brute luck, or option luck. The respondent has to choose exactly one answer among very unfair, rather unfair, quite fair, or absolutely fair for each of these choices.

In the school vignette, pupils face difficulties at school. Remedial tuition is supposed to help schoolwork. Five factors are related to school difficulties. Circumstances are determined by parents' ability to help children with their homework. Effort is identified as the zeal with which the child does his or her homework. Talent is defined as cognitive ability, which is precisely described as an ability to concentrate. Brute luck occurs when the child missed part of the previous school year because of illness. Finally, option luck is risk taking. The child wants to be in the advanced class, with friends, but cannot keep up with the class. Respondents were asked to judge the fairness of remedial tuition, if it were necessary because of circumstances, effort, talent, brute luck, or option luck.

Figure 4.5 presents the differences in the answers to both vignettes (432 respondents in Marseilles). In the sales vignette, we interpret the answers "quite fair" or "absolutely fair" as indicating that the respondent holds the salesperson responsible for the factor. In the school vignette, we interpret the answers "very unfair" or "rather unfair" as revealing that the pupil was deemed responsible for the factor by the respondent. A chi-square test for goodness of fit is used to test whether subjects treated each factor similarly in the two vignettes. Respondents evaluated moral responsibility with respect to all causal factors except circumstances differently in the two vignettes. More specifically, salespersons were held responsible for talent, while almost no subjects held pupils responsible for talent. Only a small minority deem students responsible for risk taking, while almost everyone deem the opposite for salespersons. The difference for effort is less impressive, since a small majority of respondents still agree to hold schoolchildren responsible for their effort in doing homework. Our results are preliminary as they are perhaps influenced by framing. Nevertheless, they cast doubt on holding children responsible for educational outcomes, at least at the primary level. If that decision is implemented, then primary-school

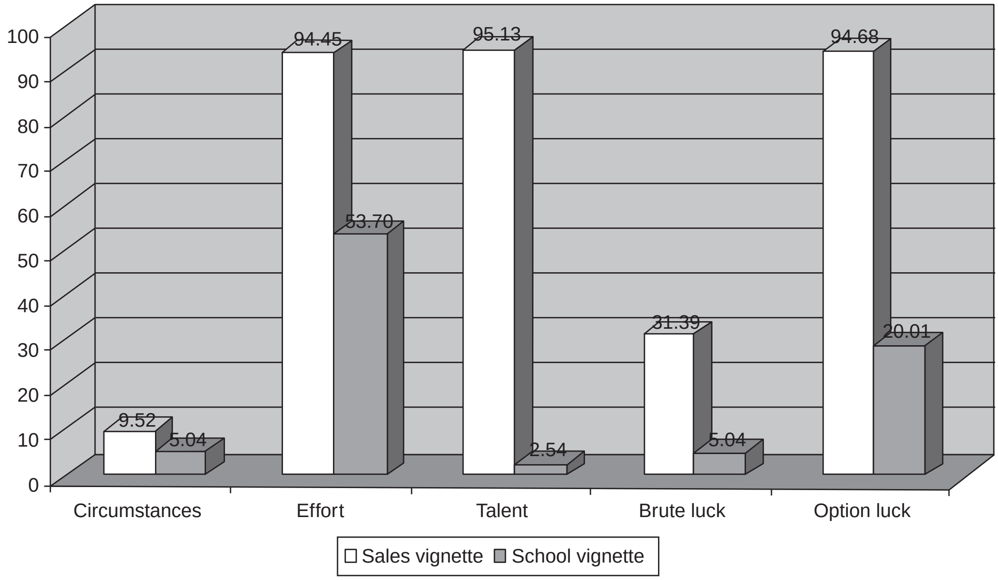

Figure 4.5 The fraction of subjects holding the agent responsible for each factor. *Source: Lu et al. (2013).*

achievements should be treated as a circumstance in studying opportunity equalization of outcomes in later life.

4.9.2 Experiments

Fairness attitudes in sharing a cake have been studied in laboratory experiments with the ultimatum game and the dictator game (Camerer, 2003), which provide a neat elicitation of preferences. These experiments reproduce exchange or distribution economies where resources are manna from heaven. Various authors (Almås et al., 2010; Cappelen et al., 2007, 2010, 2013; Frohlich et al., 1987, 2004; Konow, 2000; Rutström and Williams, 2000) have conducted experiments to study explicitly what happens to people's distributive preferences by introducing an earned-money or production stage prior to a distribution phase consisting of a dictator game. The most recent articles test the prevalence of responsibility egalitarianism among distributive justice theories. More explicitly, they investigate the control view of responsibility advocated by Cohen, summarized by the principle that "only inequalities that arise from factors under individual control should be accepted."[26]

Cappelen et al. (2007) study a situation in which individuals differ with respect both to their investments and to the rates of return that they enjoy. The agent chooses the

[26] Cappelen et al. (2007), p. 818.

amount to be invested, while the rate of return is assigned randomly. The former factor is clearly an effort variable, while the rate of return is brute luck, like talent. They assume that an individual endorses either strict equality of earnings, laissez-faire, libertarianism (each keeps his income), or responsibility egalitarianism, in which case total income is shared in proportion to investments. The distribution phase is a two-person setting in a one-shot dictator game. A parametric utility function is a weighted sum of a purely selfish element, and an altruistic quadratic loss term, which is larger, the more the distribution differs from the ideal distribution according to the individual's ethical view. The econometric analysis attempts to retrieve the parameters of the utility function, the marginal utility of money, and the preferred distributive ethic view of the subject. The authors deduce that 43.5% of subjects are strict egalitarians, 38.1% are responsibility egalitarians, and 18.4% are libertarians. The subject pool consisted of approximately one hundred students at the Norwegian School of Economics and Business Administration (NHH), a sample that cannot be viewed as representative of the Norwegian society. In addition, the results may depend on the specific form of the utility function, which balances self-interest and fairness. Nevertheless, their results confirm that responsibility-sensitive egalitarianism is endorsed by a fraction of the population and competes with libertarianism and outcome egalitarianism. But we do not learn much about the responsibility cut.

In a companion paper, Cappelen et al. (2010) use the same methodology and pool of students to enlarge the set of proposed fairness views. Individuals now differ with respect to three characteristics: working time, productivity, and the market price of their product. Subjects choose their working time (effort), market price is set randomly (brute luck), and productivity (talent) is determined through a test in the experiment (the number of correctly typed words in a short period). The authors consider four competing distributional views expressed by the list of responsibility factors. An empty list corresponds to outcome egalitarianism. If effort is the only factor belonging to this list, the view is control-responsibility egalitarianism. When this list comprises effort and talent, the view is named meritocratic[27] by the authors. (In other words, people may rightfully benefit from their inborn talent.) Finally when this list comprises effort, talent, and brute luck, it is said that the participant endorses the libertarian view. The subject pool includes students from all undergraduate years and some alumni. The differences in preferred distributive views, as estimated by the econometric model, are not pronounced among students, but alumni have quite different ethical preferences. Whatever the age group, the meritocratic view is the most popular view among students whereas the libertarian view is slightly more popular among alumni. The striking fact is that the control view of EOp is only supported by a tiny fraction of the pool: 6% among students and 2% among alumni. At this stage, it is premature to declare that these results are biased by a selection

[27] See Arrow et al. (2000) for a discussion of meritocratic ideas.

effect: however, let us remark that business-school students and alumni are very likely among the least egalitarian people in society.

In a less sophisticated way but using the same framework, Almås et al. (2010) investigate how the views about distributive justice evolve as pupils mature between the 5th and 13th grades. At the beginning of this span, schoolboys favor outcome egalitarianism (two-thirds) and libertarianism (one-third). As the children get older, they become increasingly sensitive to equality-of-opportunity arguments and by the end of the grade span, meritocracy[28] becomes the plurality view, even if it does not garner a majority of votes. Indeed it is striking that the distribution of views in this study for the 13th grade is almost the same as that obtained for the first year of college obtained by Cappelen et al. (2010).

If we assemble the lessons of these two instructive studies, they lead to the following conjecture for the development of distributive ideals over the life cycle. Starting with the stark and simple views of outcome egalitarianism and libertarianism in childhood, the development of cognitive skills induces understanding of more complex and less clear-cut views, like EOp. Views appear not to change significantly between the end of the high school and the end of the university.

Those successful in the labor market tend more toward laissez-faire opinions. Were that true in the real world, we should observe a self-serving bias (Messick and Sentis, 1983) on a large scale, in the sense that individuals, given their degree of success, would (tend to) endorse the fairness ideal that most benefits themselves. In that sense, experiments are superior to surveys and vignettes in that they enable one to measure the extent of this self-serving bias. This phenomenon should be at its minimum when subjects are students. At this stage of development, subjects are able to understand all theories of justice but they are still shielded by a veil of ignorance regarding their degree of success (in the United States, where 50% of a generation enrolls in tertiary education). The prediction would be that the difference between surveys and experiments would be minimal for this adult group.

We turn now to testing popular views about option luck. Buchanan (1986) identifies four factors that determine the distribution of income and wealth: luck, choice, effort, and birth. He considers the acceptability of rewarding effort the least controversial, and believes that the only inequalities that conflict with common views of justice are ones caused by birth (pp. 129–30). The difficulty with option luck comes from the fact that it is a mix of two more fundamental factors, one for which we want to hold people responsible, choice, and the other that is exogenous, luck. A similar difficulty prevails for talent which is a mix of birth, an exogenous factor, and past effort, which is a responsibility variable. (Buchanan does not observe the semantic convention that talent is an inborn factor, and skill results from the application of effort to talent.)

[28] This study does not make the distinction between control-responsibility egalitarianism and meritocracy.

Two papers, Cappelen et al. (2013) and Chanel et al. (2013), investigate the views of people about option luck and risk taking vis-à-vis the responsibility cut. The first article endeavors to shed light on the relative popularity of three views about option luck. The first view is Dworkin's, according to which no redistribution of gains or losses from risk taking is ethically required. Dworkin argues in favor of a laissez-faire stance, because risky lifestyles or risk taking are expressions of preferences. The second view considers it fair to eliminate all inequalities resulting from risk taking. The third view is intermediate between the first two: It would approve *ex post* redistribution between lucky and unlucky gamblers but not between gamblers and nongamblers. This view is reminiscent of a position first defended by Le Grand (1991) and refined by Fleurbaey (2008), who considers that people should be fully insured and only bear the consequences of their decisions over the expected value of the lottery. Gamblers will then receive the expected gain corresponding to their class of risk. The experiment consists of a risk-taking phase followed by a distribution phase. In the risk-taking phase, subjects face a sequence of choices between a risky and a safe alternative, where the value of the safe alternative varies. Estimates of the choice model reveal that subjects (students at the Norwegian School of Business in Bergen) have diverse opinions and split quite evenly into three groups. Roughly speaking, two-thirds of the subject pool think that people should be deemed responsible for their choice of risk taking. The same proportion but not the same individuals think that people should not bear the consequences of luck. If we interpret the econometric results as a vote, Le Grand–Fleurbaey's view is the Condorcet winner among the three alternatives offered to participants. This interesting result needs to be confirmed by other studies.

Chanel et al. (2013) are less precise in studying option luck but their aim is to deduce the relative importance of option luck in the set of factors for which individuals should be held responsible. They conduct an experiment on a large scale whose purpose is to reveal the preferences of agents when four factors matter for earnings: circumstances, effort, brute luck, and option luck. Three experimental sessions were organized involving a treatment of about 100 subjects each, who are told that they form a small society. Each treatment involves an earned-money phase followed up by a redistribution phase, where the allocation rule is determined by majority vote. In the first phase, participants can earn money through four different channels, each of which reflects a specific factor: the place of one's birth represents a circumstance and success at a visual-spatial attention task requires effort. Brute luck and option luck are easily contrasted by a random draw and taking a bet, respectively. Votes are then organized on whether or not to redistribute the gains from each step, which corresponds to a given factor. A self-serving vote is found to be prevalent (about one-third of the sample who succeeded in earning money vote not to redistribute) and nonparametric econometrics are mobilized to retrieve the true ethical preferences beneath the votes. The distribution of ethical preferences among the subject pool is described in Figure 4.6.

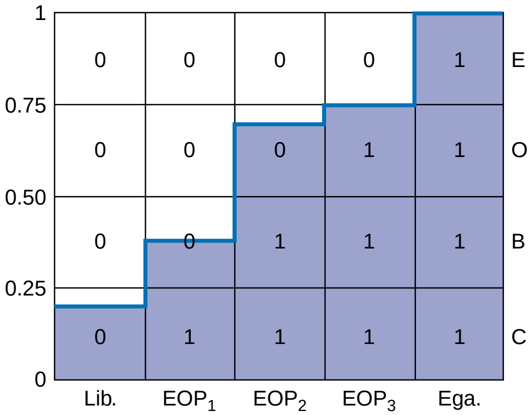

Figure 4.6 Distribution of ethical preferences about the responsibility cut. On the left vertical axis, the figures are proportions. On the right vertical axis, E stands for effort, O for option luck, B for Brute luck, C for circumstances. In each square, 0 (respectively 1) means no compensation (resp. compensation). For example, egalitarians think redistribution is mandated regardless of the cause of earnings. *Source: Chanel et al. (2013)*.

Five ethical positions are represented here.[29] At the two extremes, we find the libertarian and outcome-egalitarian stances. Three intermediate positions are allowed: in EOP1, only differential circumstances merit compensation; in EOP2 brute luck in addition merits compensation. Option luck joins the compensation set with EOP3. The two extreme positions attract almost a quarter of the views. This means that 60% of the sample endorse some version of EOp. There remains a large diversity of opinion regarding the locus of the responsibility cut. In the aggregate, the result of this experiment supports Dworkin's view according to which we should draw a distinction between option luck and brute luck, option luck being on the responsibility side along with effort, and brute luck being on the compensation side with circumstances. Nevertheless, we need to be more careful before a more definitive conclusion is reached, for many areas of uncertainty must addressed. More specifically, the design of the experiment tests Le Grand–Fleurbay's position against that of Dworkin. Redistributing gains from bettors to nonbettors has not been proposed to voters.

4.9.3 A Progress Report

In agreement with Roemer's suggestion (1993), we have developed the view that theory and empirical work are more complements than substitutes. As stated by Gaertner and Schokkaert (2012), "The theory of EOp offers a general and consistent framework which

[29] Fewer than 10% of the subjects convey an ethical preference that is not captured by one of these.

can be applied for any cut between effort and circumstances, while empirical work supplies the necessary information about where the boundary is drawn in different societies."

If we take again the four "primary factors" identified by Buchanan—birth, luck, choice, and effort[30]—it seems indisputable that subjects make a clear distinction between the first two and the last two. In questionnaire-experiments, the assumption that choice and effort are under the control of the individuals and that participants are well-informed about the consequences of the acts cannot be disputed, since the protocols of the experiments are clear. Even if more research is welcome, the conclusion reached by Konow (2001) 10 years ago appears to stand: "To summarize, the evidence from experiments and surveys generally indicates that someone whose contribution is more highly valued is more deserving if that person bears responsibility for the contribution but not if it is due to factors outside his or her control." Does this mean that from an empirical perspective, the control view of Arneson and Cohen prevails over the preference view of Dworkin and Fleurbaey–Maniquet? Not exactly, for the proper test has not been conducted. Except for Schokkaert and Devooght (2003), we know of no study testing both theories in a competitive way through questionnaire-experiments. The control theory has been repeatedly tested by psychologists and economists but not against the preference theory. We observe choices, not preferences. Economists are keen on promoting the concept of preference among social scientists; the main weakness of the concept is that preferences are not easily revealed to experts, let alone laypersons. It is asking a lot to make preferences pivotal in a theory of distributive justice that will garner mass agreement, when, at best, only some experts can argue that they have been able to deduce what preferences people hold.

EOp involves an *equalizing* aspect and a *disequalizing* one.[31] Equalization, or compensation, takes place with respect to those factors deemed circumstances; inequality is non-compensable, however, if it is due, tautologically, to factors for which individuals are held responsible. The difficulties arise when some causes of success or failure, with respect to a desirable objective, involve mixtures of these two kinds of element. Skill is a mixture of talent, due to birth, and past effort; option luck is a mixture of choice and luck. Self-protection as defined by Ehrlich and Becker (1972) is an expenditure that reduces the probability of a loss, which can be generalized to any effort that transforms the probability distribution of states in a good way for the agent. We do not know whether the

[30] One wonders why it is important to distinguish between effort and choice. An answer is suggested by Cohen, who distinguishes difficulty from costliness. It is difficult to lift a weight, but not costly; it is costly to sign a large check, but not difficult. Effort is difficult. Choice is often costly (as in taking a bet) but not difficult in the natural sense of the word. Barry's view that effort deserves remuneration even if not due to the person's choice can be explained if one believes that difficult actions deserve reward, regardless of the intent of the actor.

[31] No empirical study has tested whether people support the liberal or the utilitarian approach to reward (as far as we know).

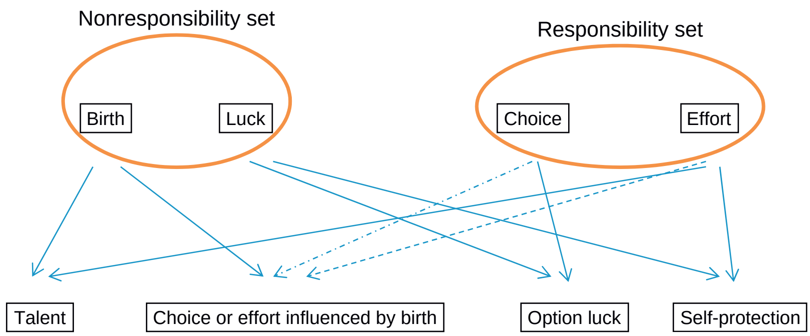

Figure 4.7 Binary combination of primary factors.

differences in views that people hold about distributive justice are due to the ambiguities introduced by the mixtures of these two kinds of factor in real life, or to fundamentally different ethical principles. See Figure 4.7.

4.10. INEQUALITY OF OPPORTUNITY: MEASUREMENT ISSUES AND EMPIRICAL RESULTS

This section will focus on methodological issues and applications of the theory. An excellent survey of the material covered in this section is provided in Ramos and Van de gaer (2012).[32]

4.10.1 Methodological Issues: General Remarks

We begin with some general remarks for the reader who is familiar with the literature on the measurement of inequality of outcomes. Measuring inequality of opportunity may mean different things. At the most basic level, we may want to encapsulate the inequality of opportunity with an index, as has been done for inequality of outcomes with the Gini, Atkinson, Theil, and others indices. We may be more modest in just wanting to rank distributions, and be content with incomplete but robust rankings provided by instruments of a dominance analysis, such as the Lorenz curve. Circumstances, effort, and luck are just sources of outcome inequality, and we may wish to trace their contribution to overall inequality. Decomposition exercises among sources are just as appropriate in EOp empirics as in inequality-of-outcome analysis. Quantifying, ranking, and decomposing are three familiar operations which we may apply to equal-opportunity analysis, and the tools are mainly borrowed from the measurement of inequality literature.

[32] See also Pignataro (2012).

4.10.1.1 EOp Measurement as a Multidimensional Problem

Nevertheless, it seems fair to say that the level of complexity of the analysis is greater because EOp is multidimensional. Equality-of-opportunity analysis may use the conceptual framework developed by Atkinson and Bourguignon (1987) in the field of multidimensional inequality. These authors focus on how to measure income inequality when each income unit belongs to a specific needs group. The information is two-dimensional—income and needs for each household—and the aim of the analysis is to rank income distributions taking into account the information provided by the vector of needs. In EOp analysis, we would rank outcome distributions (income, health, education) which are unidimensional, taking into account the information provided by the vector of circumstances, the vector of efforts and perhaps the vector of residuals. EOp measurement then belongs to the family of problems of multidimensional inequality when *margins* are fixed, where margins comprise the non-outcome information that matters in EOp assessment (circumstances, effort and perhaps the residual). The inequality in the objective must be assessed conditional on the types and efforts of the population.

A direct application of the sequential Lorenz quasi-ordering to this setting is not appropriate and it is interesting to see why. Of course, effort can be seen as analytically similar to needs; that is, at the margin, the more effort one expends, the more one deserves. Reciprocally, circumstances can be seen as negative needs: the better one's circumstances are the less one deserves. But these two statements have limitations. We may wish not to reward effort excessively, for reasons discussed in Section 4.4. And regarding circumstances, there is an asymmetry: we desire to compensate for disadvantageous circumstances, but do not regard advantaged circumstances as an evil. Furthermore it is the interplay between circumstances and effort that makes the evaluation of the ensuing inequality problematic. We need to know how additional effort should be rewarded across the circumstance dimension; as we discussed, there is no clear answer to this question within the theory. For further discussion, see Bossert (1995), Fleurbaey (1995), and Fleurbaey and Peragine (2013).

4.10.1.2 EOp as a Process

What also distinguishes EOp empirical analysis from inequality-of-outcome analysis is its two-stage nature: one generally requires an econometric-estimation stage, preceding the inequality-measurement stage. It is not so much the difference in circumstances *per se* that matters, but the difference in the impact of circumstances. Socioeconomic advantage has to be estimated through parametric and nonparametric estimation techniques, captured by the coefficient of the circumstance variable in a linear model regressing the outcome on a set of circumstances and effort variables. An evaluation of inequality must be concerned with the process that generates it. This leads Fleurbaey and Schokkaert (2009) to state, provocatively, that any EOp empirical analysis must be preceded by an estimation phase to discover the best structural model leading to the results. Only in the second step should we be interested in measuring inequality of opportunity as such.

In principle, we agree. This is, however, more easily said than done. Two observations are in order. The two main obstacles to any causal inquiry are reverse causality and endogeneity due to omitted variables. The good news is that, regarding circumstances, reverse causality can often be dismissed since circumstances are frequently characteristics of states that existed in the past (e.g., one's parents' education). However, endogeneity cannot be discarded in that way since EOp measurement is plagued with informational problems. Omitted variables are widespread; a good example is provided by genetic variables which have been found paramount in income attainment by Björklund et al. (2012). Omitted variables in empirical EOp analysis cause skepticism in claims of causality we may wish to assert. The situation is even worse when the objective is earnings, since according to Bourguignon et al. (2007), "an instrumental variable strategy is unlikely to succeed, since it is difficult to conceive of correlates of the circumstance variables that would not themselves have any direct influence on earnings." Experiments and quasi-experiments enable one to make causal statements, but experiments can usually only study problems which are much more circumscribed than those which interest researchers in this field. We are trying to understand the whole process by which someone reaches an income level, a health status, or an educational attainment. The processes are dynamic and cover part of the life span of an individual, and understanding them fully in a causal way seems out of reach at present.

Should we worry about this lack of causal interpretation? Of course, if we want to give advice to policy makers about the true effect of level-the-playing-field policies, impact evaluation needs to be causal. However, if one merely wants to measure the degree of inequality of opportunity—that is inequality due to circumstances—a correlation (with variables which occurred in the past) is already something that is relevant.

The challenge is even greater if we use the preference view for responsibility variables advocated by Dworkin and Fleurbaey. Retrieving the true parameter of the preferences is perhaps the most difficult issue in econometrics in terms of identification conditions. See, however, Fleurbaey et al. (2013) for an attempt to estimate the individual's trade-off between health and income and Bargain et al. (2013) for the estimation of cross-country preference heterogeneity in the consumption-leisure trade-off.

4.10.1.3 Lack of Relevant Information

It should be clear from this discussion that we need a much richer database to perform EOp empirical analysis than a pure inequality-of-outcome analysis. We should have variables describing the situation of the family and social background and variables pertaining to effort. It is quite common that some important background variables are missing and then we have an incomplete description of the circumstances. More importantly, effort variables are generally missing for the very reason that effort is private information, as is emphasized in economic theory. We must use proxies, which are problematical.

The measurement of effort depends on our view of responsibility. On the one hand, there is the view that effort takes into account what set of actions a person can *access*, where access is a question not simply of physical constraints, but of psychological ones, which may be determined by one's circumstances. On the other hand, there is the view that a person should be held responsible for his preferences, and hence a person is responsible for taking those actions that flow from his preferences. Roemer's measurement of effort as the rank of a person's effort in the distribution of effort of her type represents the access (or control) view: one judges the accessibility of actions to members of a type by what people in that type actually do. (This view is also reflected in Cohen's, 1989 phrase "access to advantage," which he desires to equalize.) Dworkin and Fleurbaey represent the preference view, in which a person is held responsible for his choices, if they flow from preferences with which he identifies. Because almost all empirical studies (except Fleurbaey et al., 2013; García-Gómez et al., 2012) seem implicitly guided by the control view, the authors should explain in what sense the chosen variables are under the control of the individual. Jusot et al. (2013) have argued that lifestyles in health (diet, exercise) are examples of variables under the control of the individual, and inequality of opportunity for achieving health status should be measured with this in mind.[33]

Several points that should be made about two variables that appear repeatedly in empirical analysis when trying to measure EOp in income attainment: the number of hours of work and years of education. The number of hours of work is a good effort variable, under the control view, for self-employed occupations, but is clearly less satisfactory for wage earners. It is true that hours of work correspond to a quantum of effort: The issue is whether they correspond to the *desired* amount of hours. Part-time jobs may be involuntary; overtime work may depend on the orders of the firm, and obviously unemployment may be just bad luck. To a large extent, using hours of work in a given period as an effort variable is therefore problematical for wage earners. We can be more confident that the number of hours of work over the life span is under the control of the individual because one can compensate for the impact of bad luck and low hours of work during a given period by working more in luckier periods. Using the full data for the life span is, however, quite rare (See Aaberge et al., 2011 or Björklund et al., 2012 for examples.) For snapshot distributions, the question arises of how to purge hours of work of bad luck, which, by assumption is not under control of the individual. Detecting chosen part-time from involuntary part-time is a difficult econometric issue. At best, we would

[33] See Rosa-Dias and Jones (2007), Rosa-Dias (2009, 2010), García-Gómez et al. (2012), and Van de gaer et al. (2012) for papers measuring inequality of opportunity in health.

estimate a probability that the person works voluntarily part-time, which makes the effort variable a number in the interval [0, 1]. Any empirical study that fails to do so will not respect Fleurbaey and Schokkaert's methodological dictum to do the best to estimate the most thorough structural model before any attempt is made to measure inequality of opportunity.

Years of education is also a popular effort variable in empirical studies. It is controversial to consider it as a variable under individual control, because primary and secondary education take place when the person is a child and adolescent, largely prior to the relevant age of consent. If a child is lazy in school, there might be factors not under his control that explain his laziness. Only tertiary education and lifelong learning are immune from this criticism. The problem with tertiary education comes from its path-dependency: One's probability of being accepted to university depends on one's grades in secondary education, which, in turn, depend on achievements in primary school. The above-mentioned problem for the two early stages of education then contaminates higher education attainment.

A good starting point is to attempt to account for achievements in early education by circumstances of the family. Socioeconomic circumstances may be available in data sets, but parental pressure to achieve is also an important determinant of educational outcomes, and is usually not measured. We cannot, therefore, usually give a complete account of educational achievement. However, if one views all actions of the child as due to either nature or nurture, both of which are beyond his or her control, by hypothesis, before the age of consent, then one should simply take the child's educational accomplishments at the age of consent as a circumstance with respect to determining outcomes in later life. Family circumstances may still be important in explaining choices after the age of consent: for example, a young adult might not attend college both because his achievements in secondary school were mediocre (which, according to the view just expressed would be a circumstance) and also because his parents put little value on tertiary education (also a circumstance). Facing these two circumstances, if a low-achieving 18-year-old nevertheless succeeds in going to college, through taking compensatory courses, that would be ascribed to exceptional effort, ceteris paribus.

In both the hours of work and education examples, then, we will often not have an accurate measure of effort. It will be measured with error and bias. Broadly speaking, the authors do not pay sufficient attention to these problems and overlook their practical implications. Since effort measurement does not have the same robustness as circumstance measurement, choosing effort as the conditioning variable as in the tranche approach (see for instance, Peragine, 2004; Peragine and Serlenga, 2008) seems risky. True, circumstances may be only partially described, but generally they are not noisy. Since tranche and type approaches seem incompatible (see below), conditioning on type seems a better choice than conditioning on tranches for a measurement error problem.

4.10.1.4 Age and Sex

The issue of availability of information cannot be raised about age and sex. The problem is how to treat these variables. Under the control view, age and sex are circumstances. Under the preference view, because age and sex are important determinants of preference, they will implicitly enter as factors of effort. Because, under this view, preferences should be respected whatever they are unless they are not well-informed, they are put on the responsibility side of the cut.[34] Of course, as Fleurbaey and Schokkaert (2009) pointed out, we are free, once the true impact of age and sex has been identified econometrically, to test whether it matters to put age and sex on one side or on the other (see García-Gómez et al., 2012 for an application). When we are explaining health, it does not come as a surprise to learn that 45% of the explained variance in health comes from these two demographic variables (see Jusot et al., 2013). This is not the thorniest issue in EOp measurement, but the reader should be aware that the extent of inequality of opportunity may depend on whether or not one includes these variables in the responsibility set. For instance, Almås et al. (2011) put age among the responsibility variables, on the ground that our concern should be with inequality of lifetime earnings. Another solution would be to exit the dual world of the model and to admit that there are variables that are neither under the control of the individual nor for which compensation is due. An example is provided in the health sphere where it is admitted, by most, that health policies cannot erase the impact of demographics. (We should not consider males disadvantaged with respect to females if, due to innate biological factors, their life expectancy is shorter.) For earnings achievement, this stance cannot be easily argued, because differences in returns, linked to gender and perhaps age, may be related to discrimination, which would obviously be a violation of EOp.

As in other domains of econometrics, there is a large issue of what to do with poor data. The mistake to avoid is pretending that a poor data set is rich. Innovative methods exist to deal with missing variables. An important methodological issue that has been raised and partially solved is to deduce what can be said about inequality of opportunity when we know that the observables are far from recovering the process through which the objective has been attained. We should adapt our empirical strategy to the richness of the informational structure of the database. Basically, we can contrast situations from the richest informational setting to the poorest one. In the first situation, we have a good description of the world, that is, a quite comprehensive set of circumstances and some candidates for effort variables. In the second situation, no effort variables are available and individuals can be ranked in broad type categories. We will contrast the methods accordingly.

[34] Of course, if age determines both the outcome directly and indirectly through preferences, it is ad hoc to allocate the impact of age entirely to either circumstances or effort.

4.10.2 The Estimation Phase

4.10.2.1 The Case of a Rich Data Set

The first choice is to decide between parametric and nonparametric estimation. Because, by assumption, there are many observable variables, a parametric estimation will fit the data better (see, Pistolesi, 2009 for a semiparametric estimation). Bourguignon et al. (2007) took the lead regarding the econometric strategy in this case. We should estimate a system of simultaneous equations. The first equation will describe the process of attainment of the outcome. In the income context, it can be called a return equation, the coefficient of each determinant giving the marginal return (in a linear model) of each determinant whether it is a circumstance, effort, or demographic variable. The other equations (one for every effort variable) will relate the effort variable to circumstances and other control variables. In the control view of responsibility variables, we should understand how variables that are outside the control of the individual influence her effort variables. In these "reaction equations" circumstances must be introduced, including market conditions (prices, any market disequilibrium such as the local rate of unemployment for job decisions), and demographics. One supposes that the reaction of individuals to their environments (market and background conditions) may vary across individuals. We should let the coefficients vary according to demographics. The difference in the value of these coefficients, if any, would be interpreted in a different way according to the control versus the preference view. According to the latter, they are preference shifters, whereas according to the former they are driven by circumstances, and belong to the nonresponsibility side of the cut.

We introduce some notation. Let y_i be the outcome of individual i (the original outcome variable or some function of it), C_i the vector of circumstances, $E_i = (e_{i1}, \ldots, e_{ij}, \ldots, e_{ik})$ the vector of effort of dimension k, D_i the vector of demographics, M_i the market conditions prevailing for i, ε_i, the mean-zero residual of the return equation, and o_{ij} the mean-zero residual of the reaction equation of effort j. The other letters employed are for coefficients of both regressions. In the simplest linear model the following equations have to be estimated:

$$y_i = \mu_{y1} + \alpha_c C_i + \alpha_d D_i + \alpha_e E_{i,} + \varepsilon_i, \tag{4.16}$$

$$e_{ij} = \mu_{e_j} + \beta_c C_i + \beta_d D_i + \beta_m M_{i,} + \gamma_{cd} C_i D_i + \gamma_{cm} M_i D_i + o_{ij}, \text{ for each effort variable } j = 1, \ldots, k \tag{4.17}$$

Equation (4.16) is written in a compact way: Coefficients β describe the average reaction of adjusting effort to external conditions, whereas coefficients γ are the "preference shifters" which allow individuals to adjust in a different way according to their age and sex group.

It is plausible that market conditions do not always explain the outcome (for instance, the price of fruit and vegetables may impact the diet, while having no impact on mortality rate). If this is the case, we may have exclusion restrictions that will be helpful to identify the system.

The omitted variables (perhaps IQ or any measure of innate talent) may impact the residuals of all equations. The structure of residuals may follow some common pattern that can be captured by a correlation between disturbance terms. (See table 1 in García-Gómez et al., 2012 for an implementation for mortality outcome.) If the correlation is significant, it may reveal an omitted covariate that matters for the estimation of the full system. However, we cannot tell if the revealed omitted variables are on the circumstances or effort side.

Many authors (e.g., Bourguignon et al., 2007; Trannoy et al., 2010) have argued that the estimation of the full system is not necessary if we are only interested in determining the full impact of circumstances. Estimating the reduced form (4.18) suffices if we want to measure the impact of observable circumstances:

$$y_i = \mu_{y_3} + \delta_c C_i + \delta_d D_i + v_i. \tag{4.18}$$

This statement, however, requires some qualification. Neglecting the shift parameter, it is true that in a linear model $\delta_c = \alpha_c + \alpha_e \beta_c$, due to the Frisch-Waugh theorem, α_c captures the direct effect of circumstances and $\alpha_e \beta_c$ captures the indirect effect of circumstances through effort. (The same goes for demographics.) However, the relation is lost for a nonlinear model, such as a logit or probit specification, even if Jusot et al. (2013) found that the difference between δ_c and $\alpha_c + \alpha_e \beta_c$ is quite small. More importantly, the reduced form (4.18), which has been repeatedly estimated in empirical studies, does not allow the effect of circumstances on outcomes to be mediated by demographics. The information provided by the preference shifters γ introduced in the reaction equations (4.17) is lost. It will be split into the reduced coefficient of circumstances, the reduced coefficient of demographics and perhaps the residual. A solution would be to introduce a cross effect of circumstances and demographics in the reduced equation but, to some extent, the effect of demographics as shifters of preferences will go beyond the cross effect in the structural model. The basic message here is that, with a reduced form, we cannot isolate the effect of demographics as circumstances from the effect of demographics as shifters of preferences, and therefore responsibility variables: to do so, we would need to estimate the full structural model. We recall the claim of Fleurbaey and Schokkaert (2009) that failing to estimate a structural model is costly in terms of the limitations that are thereby imposed in the measurement phase.

We now comment on the impact of omitted variables on the estimation. The coefficients will be biased and cannot be interpreted as causal. An example from health is the presence of lead in a child's home, which could entail health problems for both children and parents. If this variable is missing in the data set, a correlation between the health status of children and parents will be observed, whereas there is no causal link. It would then be unwise to base policy recommendations on the estimates of the structural model

(4.16) and (4.17) or the reduced model (4.18). Other empirical strategies have to be implemented if we want to use the estimates in this way. Regarding the reduced form, it must be clear that the estimate $\hat{\delta}_c$[35] conveys the impact of any unobserved variable correlated with observable circumstances. If these variables are circumstances, this is fine from a correlation viewpoint. We can claim that $\hat{\delta}_c C_i$ gives a fair account of the contribution of all factors linked to observable circumstances to the income of individual i.

The interpretation becomes trickier if all the unobservables correlated with circumstances are not interpreted as circumstances. Let us take the example of innate talent and suppose that an accurate measure is IQ. We have advocated treating IQ, measured before the age of consent, as a circumstance. However, as is clear from surveys and questionnaires (see Section 4.8), opinions are quite diverse on this question. If we follow the self-ownership view, it should be a responsibility variable (i.e., persons would deserve to benefit from their high IQs). Ferreira and Gignoux (2011) have argued that the reduced form will lead (through the computation of $\hat{\delta}_c C_i$) to a lower bound estimate of circumstances. If the missing variables in the reduced form are classified as efforts and are positively correlated to observable circumstances such as IQ, it is the other way round. Instead of having a downward bias, the impact of circumstances would be biased upward. The remedy is not trivial because any other simple solution fails to solve the problem. Estimating a reduced form with only observable effort would convey the impact of circumstances correlated with effort, which conflicts with the message of EOp. Now the estimates given by the structural model will be even more at odds with the ethics of EOp. The impact of unobservable IQ will be split into the various coefficients estimated in the return equation (4.16) plus the residual, meaning that some part of innate talent would be assimilated with responsibility characteristics and some part would be nonresponsibility characteristics. At this stage, we should recognize that since innate talent is a form of luck, the parametric estimation is too restricted to cope with luck (see below).

One of the virtues of the structural model is that it enables one to decompose the impact of the circumstances into a direct and an indirect term (through effort). Bourguignon et al. (2007) and Ferreira and Gignoux (2011) acknowledge that subdecompositions into direct or indirect effects, or into the effects of individual circumstances, would be strongly affected by the presence of omitted variables. Bourguignon et al. (2013) show that it is no so much the magnitude of inequality of opportunity, but rather its decomposition between direct and indirect effects, that will be affected by biased estimates of coefficients of circumstances in both the return and the reaction equations.

We conclude with the interpretation of the residuals of the various equations. We first emphasize that they are not orthogonal to the regressors with omitted variables, which is worrying. That said, the residuals of the reaction equation are close in spirit to the

[35] A circumflexed variable denotes an estimate.

Roemerian effort. They are effort sterilized of the impact of circumstances and external conditions. This leads Jusot et al. (2013) to estimate an equation where we substitute Roemerian effort for effort in equation (4.16), namely:

$$y_i = \mu_{y_4} + \delta_c C_i + \delta_d D_i + \alpha_e O_i + \tau_i, \tag{4.19}$$

where O denotes the vector of residuals of equations (4.17). Due to the Frisch-Waugh theorem, the coefficient of Roemerian effort will be the same as the coefficient of true effort, whereas the coefficients of circumstances and demographics will be augmented by their indirect influence through effort and then equal to the coefficients estimated in the reduced equation (4.18).[36] This enables these authors to offer a decomposition of the inequality into responsibility, nonresponsibility, and demographic parts, in the spirit of Roemer. They contrast the results with the estimates obtained with equation (4.16) where the impact of circumstances is only direct and thus follows Brian Barry's recommendation (individuals should be rewarded for their absolute, not relative, effort).

It should be clear from the previous discussion that the residual of the return equation (4.16) is a mixed bag of error terms and omitted variables, which may be circumstances, effort, or luck variables. Generally, the error term represents a large part of the variance, more than 70% in Björklund et al. (2012) for the residual of the reduced form (4.18). It is quite normal that the explained part remains small on cross-sectional estimation: 30% is already an achievement. Should we assign the residual to the effort or circumstance side? Several views clash here. Roemer and his coauthors over the years put the residual of the reduced equation on the effort side, while Devooght (2008) and Almås et al. (2010) put the residual of the structural return equation on the circumstance side.[37] Lefranc et al. (2009) and Jusot et al. (2013) argue that these solutions are ad hoc. They prefer to maintain the position that we cannot tell what the residual represents. Furthermore, when it represents 50% of the variance or more, putting it on one side or the other will determine the relative magnitude of inequality of opportunity. Consequently, they prefer to discard it in any decomposition analysis and move on with the explained part of the outcome, from (4.16):

$$\hat{y}_i = \hat{\mu}_{y1} + \hat{\alpha}_c C_i + \hat{\alpha}_d D_i + \hat{\alpha}_e E_i \tag{4.20}$$

Parametric methods try to estimate the conditional expectation $\boldsymbol{E}(y|C,E)$.[38] Nonparametric methods are more ambitious because they try to estimate the conditional distribution $F(y|C,E)$. O'Neill et al. (2000) were the first to use a kernel density estimator to

[36] In fact, this is not quite correct if market conditions and shift parameters are introduced as in (4.17). The statement is valid for a simple form of (4.17).

[37] They also present robustness results where the residual belongs to the responsibility set. Almås (2008) considers both alternatives.

[38] **E** denotes the expectation operator.

estimate the distribution of income conditional on parental income. It is not by accident that the authors chose a continuous variable (parental income) to perform a nonparametric analysis. The parametric estimation already offers some flexibility for discrete variables. Pistolesi (2009) borrows a semiparametric estimation technique from Donald et al. (2000). In a nutshell, since the hazard rate is defined as

$$H(y) = \frac{f(y)}{1-F(y)} = \frac{f(y)}{S(y|C,E)},$$

with $S(.|.)$ the conditional survivor function, one can write:

$$f(y|C,E) = H(y|C,E)(S(y|C,E)).$$

The trick is then to estimate a hazard-function-based estimator and introduce covariates using a proportional-hazards model. In a second step, the necessary transformations using the above equation are made to obtain an estimate of the associated conditional density function. It is known that the estimation of duration models is more flexible than of linear models. In substance, Pistolesi estimates the conditional distributions corresponding to Equations (4.16) and (4.17) with this estimation technique.

4.10.2.2 The Case of a Poor Data Set

The distinctive feature of a poor data set is that no effort variable is available, but we may still have a rich set of circumstances and a large sample. We can construct types but we cannot a priori build tranches. The approach here comes from Roemer (1993, 1996, 1998) with his identification axiom. It is the only assumption that enables us to say something about inequality of opportunity in the poor-information case. It is nonparametric in essence, since effort is deduced from the distribution of outcome for a type, $F(y|C)$. Two individuals located at the same quantile of their type-conditional distribution are defined as having exerted the same effort, which will be denoted e_{RO}. Formally, starting from the income-generating process given by

$$y = g(C, E),$$

the Roemer identification axiom (RIA) reads:

$$F_y(g(C,E)|\,C) = F_y(g(C',E')|\,C') \Rightarrow e_{RO} = e'_{RO}$$

By construction, this effort is distributed uniformly over [0, 1] for all types. This way of identifying effort has been used by O'Neill et al. (2000) in a nonparametric setting to depict the opportunity set of an heir defined as the income range that she can reach for all levels of Roemerian efforts belonging to [0, 1]. The opportunity sets are contrasted according to the level of advantage given by the decile of parental income.

This way of identifying effort has also been used by Peragine (2004) to build a tranche approach to EOp where the multivariate distribution is described by a matrix whose typical element is the income for a given type and percentile of the type-conditional income distribution. However, this approach is not immune to the omitted variable problem that was discussed above. As was rightly pointed out by Ramos and Van de gaer (2012), omitted circumstances induce wrong identification of the Roemerian effort unless the unobserved circumstances, after conditioning on observed circumstances, no longer affect income (see their Proposition 6). This is a strong condition that will be rarely be satisfied in empirical work.

The identification axiom may be questionable from an analytical point of view (see Fleurbaey, 1998), because it is not clear how multidimensional effort can be aggregated into one indicator, and luck factors can interact with effort in a complex way. The view that the *distribution* of effort specific to a type is a circumstance makes sense in the control view but not in the preference view. Let us coin this axiom as the *type-independent effort distribution*: the relevant normative effort distribution should be independent of type. This axiom is clearly weaker than Roemer's identification axiom. It has inspired fruitful empirical strategies, both in a parametric and nonparametric setting. In the former case, Björklund et al. (2012) estimated a reduced form as in (4.18) with v_i a Gaussian white noise. They assimilate the distribution of the residual to the distribution of effort. However, the distribution of the residual can vary across types and this variation is a nonresponsibility characteristic. They have corrected for variation in the second moment by adding and subtracting to the regression equation a residual term that has the overall variance. Hence, the relevant effort in each type is renormalized to have the same variance.

In a nonparametric setting, Lefranc et al. (2009) retain this independence view of effort, which is postulated in the Roemer identification axiom, without assuming that we can identify effort with the quantile of the type-conditional income distribution. Let the distribution of effort conditional on type (supposed to be unidimensional) be given by $G(e|C)$. The authors follow Roemer's proposition (see Section 4.3) according to which the accountable effort π is given by the quantile within the effort distribution of an individual's type:

$$\pi = G(e|C). \tag{4.21}$$

Equipped with this conception of effort, they are able to link what we can check (in a poor setting) with what we would want to check if we had all the information about effort. What we can check is obviously the equality of the distribution of income conditional on the observables, here, only the vector of circumstances:

$$\text{For any } (C, C'),\quad F(\cdot|C) = F(\cdot|C') \quad \text{(conditional-distribution equality)} \tag{4.22}$$

We have already stated (see Section 4.5) that we would like luck to be even-handed in a world where all circumstances and effort are observed.

$$\text{For any } (C, C', e)\quad F(\cdot|C,e) = F(\cdot|C',e) = K(\cdot|e) \quad \text{(equal-luck opportunity)} \tag{4.23}$$

This allows the distribution of episodic luck to depend on effort but not on circumstances. Their main result, mathematically obvious but of practical importance, is that a necessary condition for equal-luck opportunity to be satisfied is conditional-distribution equality, if we use relative effort. Mathematically, if we replace e by e_r, in (4.23), then (4.23) implies (4.22). Lefranc et al. (2009) prove that this is still the case if some circumstances are not observed. Checking the conditional-distribution equality on the set of observed circumstances is still necessary for the global EOp condition to be satisfied. These results pave the way for using stochastic-dominance tools[39] to measure the unfairness of the distribution, which we discuss below.

4.10.3 The Measurement Phase

Once a model has been estimated, the question of how to proceed to use the estimates obtained in the econometric phase remains open. Various choices have been proposed concerning three issues: the types versus tranches approach, the direct unfairness (DU) versus the fairness gap (FG), and the inequality index. We will deal with these three approaches in turn.

4.10.3.1 Types Versus Tranches

A way to organize the information in a discrete setting is to construct a matrix in which rows are types and columns effort. An element m_{ij} of the matrix is the outcome for type i and effort level j:

$$\begin{array}{cc} & \textit{Effort } j \\ \text{Type } i & \begin{pmatrix} \square & \cdots & \square \\ \vdots & m_{ij} & \vdots \\ \square & \cdots & \square \end{pmatrix} \end{array}$$

It is important to emphasize that this way of proceeding is correct if and only if the knowledge of circumstances and effort is sufficient to determine the outcome level. It means that, with respect to the decomposition of the process allowed by the regression, the residual is assigned to either effort or circumstances, unless the outcome is replaced by the predicted outcome. In this setting, two principles of compensation can be stated. First, we define a *tranche* as the set of individuals who expend the same degree of effort.

The *tranche-compensation principle* states that the closer each column is to a constant vector, the better. If for some effort (column), the inequality of outcome across types is reduced, and everything else remains unchanged, EOp has been improved.

The *type-compensation principle* states that it is good to transfer from an advantaged type to a disadvantaged type, provided that the ranking of types is respected. Suppose that

[39] It is possible to go beyond stochastic dominance to define the relative advantage of a type (see Herrero et al., 2012, for a proposal involving an eigenvalue of a matrix).

between two types, one is unambiguously better off than the other, that is, the outcomes can be ranked unambiguously according to first-order stochastic dominance. Then a transfer from the dominant type to the dominated type for some effort level, ceteris paribus, is EOp enhancing. This principle can be extended further to a second-order stochastic-dominance test (Lefranc et al., 2009). Indeed if two types have the same average outcome but the first one has a larger variance, any risk-averse decision maker would prefer to belong to the second type and consequently one cannot declare that the two types have the same opportunities in terms of risk prospects. The need to take into account the risk dimension echoes the treatment of heteroscedasticity of the residuals in the parametric case by Björklund et al. (2012). This extension leads to a weak criterion of EOp, which corresponds to a situation of absence of second-order stochastic dominance across types.[40]

Fleurbaey and Peragine (2013) show by the means of an example that the two principles clash. There is no complete ordering of the full domain of (positive) matrices, which respects both principles. If we connect this to the results obtained by Lefranc et al. (2009), it is as if we said that *equal-luck opportunity* conflicts with *conditional-distribution equality*.[41] They claim that a choice should be made between the two principles. Logically this is correct. Empirically, it seems to us, that the conflict is not that deep because the principles are useful in different informational contexts. Either one trusts the information about effort and the tranche-compensation principle is appropriate, or one lacks the information about effort, or believes it is insufficiently reliable because of the omitted-variable problem, and then the type-compensation principle remains available.

Fleurbaey and Peragine (2013) also point out that the tranche-compensation principle clashes with two principles of reward, the principle of natural reward and the principle of utilitarian reward. Ramos and Van de gaer (2012) showed that this incompatibility extends to another principle of reward inspired by a criticism of Roemer against the principle of natural reward. The *principle of inequality adverse reward* requires that a within-type Pigou–Dalton transfer be socially desirable.[42] It seems to us that this kind of conflict should not be overemphasized if we agree to prioritize the principles. If we annihilate the inequality due to circumstances according to the tranche-compensation principle, then in each column, each element is equal to its tranche average before the redistribution took place. Hence, this redistribution according to the tranche-compensation principle respects a simple *natural arithmetic average reward* principle: The arithmetic average income

[40] These two principles have been dubbed *ex ante* (type) and *ex post* (tranche) approaches by Fleurbaey and Peragine (2013). The terms are misleading because *ex post* and *ex ante* usually refer to a situation with uncertainty which is not explicit here.

[41] The comparison is not artificial because to some extent, both principles can be viewed as a ranking adaptation of (4.22) and (4.23).

[42] This principle is incompatible with the tranche-compensation principle but not the type-compensation principle.

difference due to differences in effort should remain invariant to redistribution. At this stage, this principle of reward reduces to the principle of natural reward and no more redistribution is required to comply with the requirements of EOp.

We conclude with an insight borrowed from Ramos and Van de gaer (2012), who remark that if we retain the Roemerian effort, annihilating inequality within the columns of the matrix implies equalizing the prospects for each type, since by construction the distribution of Roemerian effort is the same for every type.

4.10.3.2 DU Versus FG

Almost the same idea appears in the papers of Fleurbaey and Schokkaert (2009) and Pistolesi (2009) concerning how to measure inequality due to circumstances. We will here retain the nomenclature of the former authors, while we are closer to the latter in terms of the definitions. These authors propose two approaches.

DU is computed as the inequality of the counterfactual distribution when one has removed the effect of effort variables, either by suppressing them, or by imputing to each individual a reference value of effort such as the average value. Following are some examples of possible computations of DU, where I denotes some inequality index.

For the reduced form (4.18), a natural choice for DU is to compute the inequality of the conditional expectation of outcomes across types (a solution first proposed by Van de gaer, 1993). Since the regression decomposes the conditional expectation, we get

$$I(\mathbf{E}(y|C_i, D_i)) = I\left(\hat{\mu}_{y3} + \hat{\delta}_c C_i + \hat{\delta}_d D_i\right) \tag{4.24}$$

which is a neat solution chosen by Ferreira and Gignoux (2011). The residual is set to 0, its mean value.

For the more structural model (4.16) or (4.19), where an estimation of the impact of the effort variable has been obtained, it is possible to set the effort variable to 0 or to consider some reference value such as the average effort. The inequality of the conditional expectation of outcome for an average effort level is given by

$$I(\mathbf{E}(y|C_i, D_i, \overline{E})) = I\left(\hat{\mu}_{y1} + \hat{\alpha}_c C_i + \hat{\alpha}_d D_i + \hat{\alpha}_e \overline{E}_i\right), \tag{4.25}$$

where an overbar on a variable denotes a mean. A potential problem for both the above calculations is that the distribution of estimated residuals across types may be type dependent. If so, then the difference in the mean of estimated residuals across types should be taken into account.

The FG measures the gap between the inequality of the actual distribution and the inequality of a counterfactual distribution in which all the effects of circumstantial variables have been removed, either by suppressing them, or by imputing to each individual a reference value of circumstances such as the average one. We give some examples below. If we had estimated a reduced form with only effort variables (something that has not been done in the literature so far), we could have the analog of formula (4.24) with an estimation of the inequality of the expected outcomes across tranches when circumstances are in the residual and have been removed. Computing directly from the data the average outcome of those sharing the same effort, as done by Checchi and Peragine (2010), is a nonparametric way of doing this. The FG is then given by[43]

$$I(y) - I(\mathbf{E}(y|E_i)). \tag{4.26}$$

For the more structural model (4.16) or (4.19), where both effort and circumstances variables are introduced as regressors, we can do better and estimate the FG for a counterfactual distribution where the set of circumstances has been set to a reference value, for example, the average one. Then, one obtains for the FG

$$I(y) - I\left(\mathbf{E}\left(y|\overline{C}_i, \overline{D}_i, E_i\right) = I(y) - I\left(\hat{\mu}_{y1} + \hat{\alpha}_c\overline{C}_i + \hat{\alpha}_d\overline{D}_i + \hat{\alpha}_e E_i\right)\right). \tag{4.27}$$

Bourguignon et al. (2007) propose a similar measure. The problem is, again, how to assign the residual. According to (4.27), the residual has been removed and is considered as measuring a circumstance. The above authors implicitly consider the residual as measuring effort. Another solution is to replace the overall inequality by the explained inequality, that is, remembering that $\hat{y}_i$ is the explained outcome (see Equation (4.20)), to compute:

$$I(\hat{y}_i) - I\left(\hat{\mu}_{y1} + \hat{\alpha}_c\overline{C}_i + \hat{\alpha}_d\overline{D}_i + \hat{\alpha}_e E_i\right), \tag{4.28}$$

a solution chosen by Jusot et al. (2013).

The reference values in (4.26) and (4.27) are somewhat arbitrary and we can compute the formula for different values and then take the arithmetic mean. DU and FG as defined above are defined in absolute value. They can of course be defined in relative terms and be divided by the overall inequality. Several recent empirical studies (e.g., Aaberge et al., 2011; Checchi and Peragine, 2010) perform both estimations of the inequality of opportunity as robustness checks.

The measurement of unjust inequality using DU is linked to the *tranche-compensation principle* as follows: if DU computed according to formula (4.25)[44] for some matrix M is lower than for some other matrix M' for all inequality indices, then M is preferred to M' according to the tranche-compensation principle where the considered transfers are of the Pigou-Dalton sort. Similarly, there is a link between the *type-compensation principle* and the FG. Indeed, if M is preferred to M' according to the type-compensation principle,

[43] Fleurbaey and Schokkaert (2009) are the only who propose to apply the inequality index to the gap. The other authors compute the gap between total inequality and the inequality of the counterfactual distribution.

[44] In a parametric or nonparametric way.

then the FG is lower for M than for M', computed according to (4.27), for all inequality indices when the reference type is different from the two types involved in the Pigou-Dalton transfer. The statement is not as general for FG as for DU since we cannot extend the above statement whatever the reference type, the choice of which is ad hoc. This leads some authors to consider instead a weighted average of the FG. In that case it can be proved that, if M is preferred to M' according to the type-compensation principle, then the weighted[45] sum of the FGs is lower for M than for M', computed according to (4.27), for all inequality indices belonging to the entropy class.[46]

We conclude the discussion of DU and the FG by observing that the concepts in substance are not new as methods of decomposing inequality among its sources. When Shorrocks (1980) advocated the use of the variance, he observed in his conclusion that when one thinks about the contribution of one source to inequality, one can wonder either about how much inequality is left when the impact of this inequality factor is neutralized, or about how much inequality remains when the other sources are equalized. This is exactly the choice available in the literature on EOp measurement. Shorrocks (1980) also observed that when there are two sources (here, the set of circumstances and the set of effort variables) the natural decomposition of the variance given by the covariance of the source with outcome has a nice interpretation: the covariance of a source is just equal to the arithmetic mean of the above two computations. In the context of EOp, this means that the covariance of circumstances with outcome is the arithmetic mean of the DU and FG when the other source is removed in the computations (not put at a reference level). This point was made by Jusot et al. (2013) and by Ferreira and Gignoux (2011) (see their appendix).

4.10.3.3 The Choice of an Index

The entire spectrum of inequality indices has been used by researchers in EOp, perhaps with the exception of Atkinson's indices. One can speculate that the absence of the Atkinson indices is due to EOp's not being a welfarist theory. Lefranc et al. (2008) and Almås et al. (2011) have used the Gini index, and Aaberge et al. (2011) have used the Gini and other rank-dependent measures. Elements of the entropy family have been used by Bourguignon et al. (2007), who picked the Theil index, and Checchi and Peragine (2010), Ferreira and Gignoux (2011), Lefranc et al. (2007, 2012) use the MLD. Pistolesi (2009) and Björklund et al. (2012) are eclectic and use a range of measures. These examples are when the objective is income attainment, and they are relative measures. When the objective is health status (self-assessed health or mortality), it makes

[45] For the statement to be true, the weights cannot be chosen arbitrarily. The weight of a type is given by the weight of this type in the between-type term.

[46] For further results regarding the link between the tranche/type approaches and the DU/FG measures, see Brunori and Peragine (2011).

sense to use an absolute measure such as the variance, a choice made by Jusot et al. (2013) and Bricard et al. (2013), which possesses the decomposition property mentioned above. However, the variance is not such a good choice for income attainment since it is not relative. Returning to the income case, there is no first-best choice. The connection with stochastic dominance, which is the advantage of rank-dependent measures (among them the Gini index), is counterbalanced by the decomposability properties of the entropy family. The relevant decomposition is among sources of inequality, and not so much among subpopulations, and the Shapley decomposition (Chantreuil and Trannoy, 2013; Shorrocks, 2013) can be applied to any inequality index.

The property of path independence of the MLD pointed out by Foster and Shneyerov (2000) has recently been emphasized by Ferreira and Gignoux (2011) to single out this index. Indeed, path independence is interesting in the context of EOp because it can be interpreted as saying that the inequality measured by the DU criterion be equal to the inequality measured by the FG. This proposition has to be qualified. DU is computed as the inequality of the average outcome across types. The FG is obtained by rescaling the distribution of the outcome due to effort by the ratio of average income to average income in a type. This is one among many possibilities for nullifying the impact of circumstantial factors. Thus, if we find this way of neutralizing the impact of circumstantial inequalities appealing for the FG, then we do not have to worry about computing two measures of EOp because they are equivalent (under path independence). We conclude by saying that in the health realm, variance may be a better choice, whereas MLD is prominent for income achievement.

4.11. RESULTS

It is beyond our scope to present a unified treatment of all empirical results. As argued earlier, the estimates of inequality of opportunity are likely a lower bound of the true figure in all cases and the magnitude of the underestimation is inversely related to the richness of the data set. Consequently, the importance of the empirical results has to be gauged by considering the number of types that can be defined with the data set. Intriguing issues that may arouse the curiosity of the readers can be easily identified. First, what is the extent of EOp with respect to overall inequality? What is the contribution of effort to inequality, is it larger than that of circumstances? Is the indirect contribution of circumstances through its impact on effort sizeable? Does it make much difference to follow Roemer's viewpoint in measuring effort, or will using absolute measures of effort give similar results? Among circumstances, what are the most significant? Is there a common pattern among inequalities of opportunity with respect to the objectives of health, education and income? Is there a difference of magnitude in inequality of opportunity between the developed countries and the developing countries? Does the ranking of countries differ when we look at inequality of opportunities versus inequality of outcomes? Do taxes and benefits or other instruments make a large difference when measuring EOp? (i.e., inequality of opportunity for pre-fisc versus post-fisc income.)

Starting from a very coarse definition of types (three levels for father's education, five levels for income), Lefranc et al. (2008) found that Sweden and Norway almost achieve EOp for income, while at the other extreme in the range of Western countries are Italy and the United States, with other European countries in the middle. The qualitative results are similar to those of Roemer et al. (2003). We will take a closer look at the Nordic countries before reporting the results obtained for Italy and the United States. We will then contrast these results with those obtained for Latin America, Africa, and Turkey.

Three thorough empirical studies have studied EOp for income in Scandinavia: Aaberge et al. (2011) and Almås et al. (2011) for Norway, and Björklund et al. (2012) for Sweden. Starting with the latter, the authors claim that they have a fine-grained typology (1152 types), which partitions the sample into types based on parental-income quartile group (four groups), parental education group (three groups), family structure/type (two groups), number of siblings (three groups), IQ quartile (four groups), and body mass index (BMI) quartile at age 18 (four groups).[47] The random sample consists of 35% of Swedish men born between 1955 and 1967 and the outcome is an average of pre-fisc income over 7 years (age group: 32–38). Looking at the graphs of stochastic dominance reveals something that was already present in Lefranc et al. (2008). The income CDFs of the different educational or parental-income types are quite close. The differences are more pronounced for IQ-types. Parametric results reveal that the three most important contributors to inequality of opportunity are parental income, IQ, and the type heterogeneity of the disturbance (which may be due to effort, luck, or unobserved type heterogeneity, because the parental-income and education groups are still large). Looking at the Gini coefficient (the results are a bit sensitive to the measure, as usual), putting IQ aside, the other "social" circumstances account for between 15.3% and 18.7% of the overall Gini. That means that in the counterfactual situation where the only factors of inequality would be these social circumstances, the Gini coefficient would attain a modest value of 0.043 for the oldest cohort. The contribution of IQ represents about 12% of the overall Gini. So far, these results are very impressive and confirm that Sweden is close to reaching a situation of equal opportunity. Still, it remains to be seen if introducing parental income in a continuous way and perhaps education of both mother and father, thus refining the typology, would alter the results significantly.

The results for Norway obtained by Aaberge et al. (2011) are built on a coarser typology (three educational parental levels, to grow up in a large family or not, to be born in a

[47] BMI is measured at a young age. It would be far more controversial to put BMI on the circumstance side for older people. Of course, there are genetic roots of obesity among some subjects, but the main determinant is lifestyle (see the discussion in Bricard et al., 2013).

main city or not, and birth cohort). Tranches are defined by relying upon the Roemer identification axiom. The data come from a rich longitudinal set containing records for every Norwegian from 1967 to 2006, enabling one to build up a permanent income measure. The Gini coefficient of permanent income is as low as 0.17, and the authors graph Pen's parade (the inverses of the permanent income CDFs) for the three educational groups. These inverse CDFs are quite close. The Gini coefficient corresponding to inequality of opportunity is about 0.05 suggesting that opportunity inequality accounts for about 28% of income inequality when the analysis is based on permanent income. Since the typology is coarser than in Björklund et al. (2012) for Sweden, the results so far are compatible with a higher inequality of opportunity and likely a higher contribution of inequality of opportunity to overall inequality. Almås et al. (2010) use a different methodology and the results cannot be easily compared. Nevertheless, we can observe an upper bound for the impact of effort. If we consider the usual candidates for effort variables such as years of education, hours of work (for those who work), working in the public sector, county of residence, and choice of university major, then effort's raw contribution to the Gini in Norway in 1986 is about 25.5% in pretax income when we do not sterilize effort variables of the impact of circumstances. However, the impact of parental background on effort variables is quite small. It represents one Gini point over a Gini of 0.26. It is generally observed that the unexplained part (by circumstances or effort) remains quite large and even dominant in all empirical studies of inequality of opportunity.

Next, we will review results on the "poor achievers" of the EOp class among developed countries, the United States and Italy. Pistolesi (2009) uses panel data, the PSID from 1968 to 2001, and he considers age, race, education of both parents, the region of birth and the occupation of the father as circumstances. The two responsibility variables are the years of education and the hours of work. Their conditional distributions are estimated nonparametrically against the vector of circumstances. Pistolesi then predicts two counterfactual distributions for both educational and working-duration distributions. In the first, the effect of unequal circumstances is removed, whereas each individual is assumed to have exerted the same effort in the second. The circumstances have a weaker impact on hours of work than on education, a finding quite common across empirical studies, and which makes sense. A presentation of the results with the Gini to allow comparisons with previous studies shows that the share of inequality due to circumstances in the DU sense is about 35% for a 5-year average earnings at the mean point of the distribution. It is indisputably higher than in Sweden, but it follows a quite remarkable decreasing trend over the period. If the results were confirmed, it would mean that the increase in inequality that has occurred in the United States is not due to an increase in inequality of opportunity. Checchi and Peragine (2010) study the inequality of opportunity in Italy. There are three circumstances: parents' education (five types), sex, and regions (North, South). What is striking is that with such a coarse typology, they find that inequality of opportunity accounts for about 20% of overall income inequality in Italy—that is, higher than the 16% in Sweden with a much finer typology.

Perhaps the sharpest indication of inequality of opportunity for income and wealth is a high elasticity of the income (or wealth) of fathers and sons.[48] Corak (2013) provides an excellent review of the facts for highly developed countries. The Great Gatsby Curve is a strongly positive relationship between the Gini coefficient of income and intergenerational income elasticity. For a set of OECD countries, the United States, United Kingdom, and Italy have both the highest Gini of disposable household income (about 0.35) and of intergenerational income elasticity (about 0.5); Norway, Finland, and Denmark have the lowest of both measures (about 0.23 for the Gini, and less than 0.2 for the elasticity). According to Corak (2013), the main determinants of the high elasticities are the behavior of mobility at the top and bottom of the distribution. In the United States, more than half of sons of fathers in the top decile are placed, as adults, in the top three deciles; similarly, about one-half of sons of fathers in the bottom decile are placed, as adults, in the bottom three deciles. In the United States, high-income families pour private resources into their children; Corak (2013) reports that these "enrichment expenditures" (books, computers, summer camps, high-quality day care, and private schooling) total about $8,900 per annum per child for families in the top-income quintile, while families in the bottom quintile spend $1,300 per annum per child (2006 figures). An equal-opportunity policy should compensate low-income children with similar resources, publicly financed. We recall that private schools hardly exist in the Nordic countries, which surely contributes to the lower intergenerational income elasticities there.

Next, we will turn to less-developed countries. The Latin American study by Ferreira and Gignoux (2011) provides results that can be compared with previous studies. Circumstances are defined as ethnicity, father's and mother's occupations, and birth region, for Brazil, Ecuador, Guatemala, Panama, Colombia, and Peru. The number of types is more than one hundred for the first four countries and about 50 for the last two countries. The contribution of circumstances to inequality is quite high and it varies quite a lot across the six countries. If we look at income, Guatemala and Brazil have in common a high value of the share explained by observed circumstances, about one-third, followed by Panama (30%) and Ecuador (26%). The contribution of inequality of opportunity to total inequality is about 28% in Peru and only 23% in Colombia. However, these two countries have fewer types, which biases the estimates downward with respect to the other countries. The authors also provide estimates of the contribution of nonresponsibility characteristics to consumption inequality per capita, which may be more similar to permanent income. The degree to which inequality of opportunity explains inequality is even higher for some countries, over 50% for Guatemala. Ferreira et al. (2011) study the

[48] For an empirical study of the correlation between income inequality, inequality of opportunity, and intergenerational mobility at the international level, see Brunori et al. (2013).

case of Turkey, which has roughly the same level of development as Brazil, and find that on a sample of ever-married women aged 30–49, inequality of opportunity accounts for at least 26% of overall inequality in imputed consumption, which is by and large a lower value that those found for Latin American countries, except for Colombia. For African countries we will refer to the study of Cogneau and Mesplé-Somps (2008). The surveys that are selected are the only large sample nationally representative surveys in Africa that provide information on parental background for adult respondents. They cover two countries under Britain's former colonial rule, Ghana and Uganda, and three countries under France's former colonial rule, Ivory Coast, Guinea, and Madagascar. The types are defined by a small number of occupational, educational and geographical circumstances. For the two most developed countries, Ivory Coast and Ghana, the Gini inequality of opportunity index is about 0.15 (the triple of what is found in Sweden) and it represents about one-third of overall inequality (0.45). The information is poorer for other countries but, given the results one has on a comparative basis, one can guess that the share of inequality of opportunity is even higher there.

All in all, it seems that the inequality of opportunity for income is highly correlated with inequality of income. This observation is confirmed by the high correlation (0.67) between these two kinds of inequality, measured by the Gini coefficient for western countries (Lefranc et al., 2008). Moreover, this strong correlation seems a general pattern that does not depend on the outcome chosen. Indeed, working on the Retrospective Survey of SHARELIFE, which focuses on life histories of Europeans aged 50 and over, Bricard et al. (2013) observe a positive correlation of about 0.39 between inequality of opportunity in health and health inequality. Furthermore, since lifestyles are documented in this data set, the authors are able to show that inequalities of opportunity for health status in Europe represent on average half of the health inequalities due to both circumstances and effort (lifestyles). There are, however, large variations across countries. The health indicator in this study is SAH (self-assessed health) but using mortality indicators as in García-Gómez et al. (2012), the importance of lifestyles also comes out as a distinctive feature. These authors use a rich data set for the Netherlands (1998–2007), linking information about mortality, health events, and lifestyles. They estimate a full structural model that reveals strong educational gradients in healthy lifestyles which, in turn, have the expected effect on mortality.

From a dynamic viewpoint, intergenerational mobility is clearly an important measure of EOp. Almost all studies of intergenerational mobility define the classes between which mobility is measured as income classes; see Chapter 9 for a thorough discussion of the literature. We mention only one study here. Lefranc et al. (2007) show that under a loglinear relationship between parent and child earnings, whose slope β is the intergenerational earnings elasticity, and choosing the MLD as inequality index, then the following relation holds:

$$I_t^f = -\alpha_t + \beta_t I_t^p,$$

The MLD among descendants, I_t^f, can be written as an affine function of the mean MLD among the fathers' incomes at date t, I_t^p, which is a circumstance for children. The constant $-\alpha_t$ can be interpreted as residual inequality were there to be no inequality of parental income. We may interpret $\beta_t I_t^p$ as the inequality of opportunity due to the circumstance of parental earnings. Reduction of inequality of opportunity can derive from either a drop in the intergenerational transmission of advantages (β), or from mitigating income inequality in the parental generation. In the case of France, the authors found that the reduction of inequality of opportunity was a consequence only of a decrease of inequality in fathers' incomes without any clear contribution of the intergenerational link.

We are at the very beginning of solid empirical analyses of inequality of opportunity. Analysis has been hampered so far by limitation of data sets and the intricacy of the issue. For each recent paper beginning with Bourguignon et al. (2007), the same ritual sentence appears in the introduction, to the effect that "this set of circumstance and effort variables is richer than those used so far in the existing empirical literature on inequality of opportunity." If this trend continues, we can be optimistic that, in the coming years, data sets will improve, as the stakes become clearer.

4.12. CONCLUSION

The main contribution of the equality-of-opportunity literature to the vast literature on inequality is to point out that the *source* of inequality matters from an ethical viewpoint. Most would agree that effects of circumstances on persons' well-being that are beyond the control of individuals should be rectified, while at least some differential outcomes due to choice are not compensable at the bar of justice. Thus, measures of inequality *as such* are not terribly useful—unless one is a simple outcome-egalitarian, who views all inequality as unjust. To the extent that economists ignore this ethical principle—and popular view—their measurements of inequality will not persuade people to rectify it.

As we said, the theory of equal opportunity involves both an equalizing aspect and a disequalizing one. Some philosophers focus—we believe excessively—on the disequalizing aspect, which induces criticisms of the approach from the left. We mention the work of Scheffler (2003) and Anderson (1999), both of whom criticize what they call "luck egalitarianism" as too focused on individual choice: to this they oppose a view of "democratic equality," which involves treating all persons with equal dignity and respect. Indeed, one would surely be sympathetic to their complaint, if the entirety of the equal-opportunity approach were limited to cases of expensive tastes, whether or not society should pay for the hospitalization of the motor cyclist who crashes having chosen not to wear a helmet, or even with the more socially important issue of the responsibility for smoking-related disease. These examples focus upon the disequalizing aspect of the equal-opportunity view—that the effects of imprudent choices are not compensable in the strict interpretation of the view. However, we believe that the main focus of the EOp view is upon its mandate for *equalization* of outcomes that are due to differential circumstances: Most urgently, at this juncture in history, for eliminating differences in income, health, and educational achievement which are due to the vastly different socioeconomic backgrounds in which children are raised, due in large part to the institutions of our capitalist societies. The bourgeois revolutions, which eliminated feudalism and inequality of opportunity due to arbitrary social status, although not complete (think of caste in India), marked a huge advance in the equalization of opportunities: but they replaced feudal inequality of opportunity with inequality of opportunity due to differential wealth. Of course, ancient forms of inequality of opportunity, due to gender, ethnicity, and race still remain as well. The Nordic social democracies have done most at eliminating inequality of opportunity due to income and wealth.[49]

We have characterized economic development earlier as an elimination of inequality of opportunity due to parental socioeconomic status. Assuming development continues globally, according to this measure, we will eventually replace the most important circumstance with—we conjecture—inequality due to natural talent. Many people in the experiments we reported support the meritocratic view, that returns to natural talent are just. Perhaps, as we succeed gradually in eliminating inequalities of important objectives that are due to differential wealth, the focus will then turn to inequalities due to differential natural talent. This would not necessarily require that untalented people be compensated for not having access to the pleasure which talented people enjoy from exercising their talents, but it may well require that no income advantage accrue to the talented. (The taxman will not bill you because you get great pleasure from singing in the shower.) Think of the communist slogan, "From each according to his ability, to each according to his need." That slogan does not begrudge the psychological pleasure and social respect that talent garners, but advocates a complete separation of *income* from talent.

Skeptics will say that markets will always be necessary in large and complex societies, and markets cannot operate efficiently if earnings are too sharply divorced from productive contribution. But this view accepts without question the assumption that individuals always maximize selfishly against the tax regime, or other redistributive policy, which they face. In other words, the incentive problem, so central to economic theory today, takes that problem as a fact of nature, like Newton's laws of gravitation. It is, however, not a fact of that kind, but rather a corollary to a particular human psychology, that has

[49] One should also query, of those who advocate "democratic equality" over the kind of equality of opportunity discussed here, whether democratic equality of the kind they envisage can possibly exist before the invidious inequalities due to circumstances are eliminated. How can people treat each other as equals when massive material inequalities among them, due to luck, continue to exist?

developed in a particular historical epoch, when material scarcity is still prevalent globally, and capitalist economic relations are virtually ubiquitous.[50] It is quite possible (and we believe it to be so) that human material needs are limited, and an historical period will arrive, perhaps relatively soon, when they are more or less universally satisfied. Keynes (1930) in fact argued that such an epoch was virtually upon us, at least in what he called the progressive countries, and that attitudes toward material acquisition would change radically over the next century. If and when this occurs, it seems to us quite reasonable to conjecture that societies will attempt to eliminate differential rewards to talent, having by then done away with inequalities due to feudal status, and capitalist wealth. The question of how an economic mechanism can accomplish this efficiently may well be the central problem for economists of that era.

Abstract

This chapter reviews the basic conceptual foundations for the measurement of polarization, the origins of those foundations, how polarization is distinct from inequality and other ways of considering distances and differences across individuals, and how polarization can be measured in an economic, a social, and a hybrid socioeconomic perspective. The chapter focuses largely on concepts and measurement, with only cursory overviews both of the empirical polarization literature and of the theoretical polarization/conflict literature. The chapter distinguishes five types of polarization: income polarization (where the polarizing variable of interest is any one-dimensional cardinal variable), income bipolarization (the extent to which a population is polarized across two separate groups lying on either side of an income median), social polarization (for cases in which variables of interest are qualitative or have no particular cardinal content), socioeconomic polarization (where some income groups split along social characteristics), and multidimensional polarization (where identity and distances/alienation are measured by several variables of interest).

Keywords

Polarization, Bipolarization, Inequality, Middle class, Alienation, Identification, Social conflict

5.1. INTRODUCTION

This chapter reviews the basic conceptual foundations for the measurement of polarization, the origins of those foundations, how polarization is distinct from inequality and other ways of considering distances and differences across individuals, and how polarization can be measured in an economic, a social, and in a hybrid socioeconomic perspective. The chapter focuses largely on concepts and measurement, with only cursory overviews of both the empirical polarization literature and the theoretical polarization/conflict literature.

It is useful to stress at the outset that the term *polarization* means different things to different people. First, some people view polarization as important for ethical reasons and others consider polarization as instrumental toward generating tensions and conflicts. Second, there are different "types" of polarization. This chapter distinguishes five such types: income polarization, income bipolarization, social polarization, socioeconomic polarization, and multidimensional polarization. They are listed in Table 5.1, along with their main distinguishing features—how they form groups and how they measure distances. Some of the relevant indices are also listed.

Table 5.1 A categorization of polarization indices

Types of polarization	Identification	Distance	Indices
Income (clustering of cardinal variable around local means)	Discrete/ continuous	Discrete/ continuous	Esteban and Ray (1994), Duclos et al. (2004), and Esteban et al. (2007)
Bipolarization (clustering of cardinal variable across two groups)	Discrete/ continuous	Discrete/ continuous	Thurow (1984), Levy (1987), Leckie (1988), Foster and Wolfson (2010/1992), Blackburn and Bloom (1995), Apouey (2007), Duclos and Échevin (2005), and Chakravarty and Maharaj (2013)
Social (polarization over noncardinal variables)	Qualitative	0/1	Reynal-Querol (2002), Duclos et al. (2004), and Chakravarty and Maharaj (2011b, 2012)
Socioeconomic (social variables define groups; economic variables yield distances)	Qualitative	Discrete/ continuous	Zhang and Kanbur (2001), Gradín (2000), Duclos et al. (2004), Permanyer (2010), Gigliarano and Mosler (2009), and Permanyer and D'Ambrosio (2013)
Multidimensional (multidimensional generalization of income and socioeconomic polarization)	Discrete/ continuous	Discrete/ continuous	Anderson (2010, 2011) and Gigliarano and Mosler (2009)

5.1.1 Income Polarization

The chapter first discusses income polarization, understood as polarization over the univariate distribution of a cardinal variable of interest. This regards polarization as a clustering of that variable around an arbitrary number of local means. Variables of interest in that context usually measure welfare; income polarization is then polarization over the distribution of a measure of welfare. This measure of welfare is often income, which explains why the term "income polarization" is chosen to denote this class of polarization measures. The variable of interest can also be unrelated to welfare. One can think, for instance, of income polarization over a distribution of political attitudes or over a distribution of geographical locations. As long as these variables have cardinal value, polarization over them will be referred to as income polarization.

The formalization of income polarization has mostly relied in the literature on an identification/alienation framework. Members of the same group identify with each other; members of different groups feel alienation with respect to one another. Income polarization is assumed to be increasing in both aspects: the greater the level of group identification or the greater the level of alienation, the greater the level of polarization.

5.1.2 Bipolarization

An alternative notion of polarization across a cardinal variable of interest is bipolarization. Bipolarization captures distances across two groups. These two groups have usually been defined as lying on either side of a median, thus taken as the middle of a distribution; for this reason, the bipolarization literature is closely linked to the literature on the size of the middle class. But one can also think of bipolarization as being concerned with the distance between two other separate income groups, such as the poor and the nonpoor or the bourgeois and the proletarians. (Those two groups cannot, however, be defined by a variable other than the variable interest; using a variable other than the variable of interest to define groups would generate a measure of socioeconomic polarization—see later discussion.)

Two notions are intrinsic to the nature of bipolarization: the notion of *changes in spreads* from the middle and the notion of *variations in "bipolarity."* An increase in the spreads of incomes from a middle position increases bipolarization. An increase in bipolarity—smaller income distances either among those below or among those above the middle—raises bipolarization. Equivalently, a reduction in the income gaps between any two incomes, both above or below the median, increases bipolarization.

The discussion until now already makes clear that the measurement of polarization generally involves both inequality- and equality-like constituents. The equality-like constituent is the basis of the fundamental conceptual difference between inequality and polarization. Polarization differs from inequality in that the importance of pole (or group) homogeneity carries weight in addition to the importance of heterogeneity across individuals. Increased distances across individuals of different groups increase both inequality and polarization; increased bunching (for income polarization) or increased equality (for bipolarization) across individuals of the same group decreases inequality but raises polarization.

Much of the debate on the differences between inequality and polarization—and on the possible relevance of each in explaining conflict—effectively rests on the nature of the effects of Pigou–Dalton transfers on each of these measures of the income distribution. A regressive Pigou–Dalton transfer increases bipolarization if the transfer takes place across the median; however, such a transfer increases inequality but decreases bipolarization if it occurs entirely on one side of the median.[1] Whether either (or both) of these transfers increases conflict is a matter of debate;

[1] Note that there is also evidence in the welfare economics literature that, when asked about inequality, a majority of respondents in various surveys believe that such same-side-of-the-median regressive transfers should also reduce inequality; see Amiel and Cowell (1992).

the polarization literature generally supports the view that a regressive same-side-of-the-median transfer actually reduces conflict.[2]

5.1.3 Social Polarization

The chapter then turns to social polarization. Social polarization is concerned with polarization over variables that are qualitative or have no particular cardinal content. Social polarization does not use information on distances between individuals or groups; it only takes into account the size of the groups and sets distances between them to a constant. This is not to say that social polarization cannot measure tensions or distances across groups; it does this by focusing on the distribution of group sizes.

What matters for social polarization is not only how many groups there are, but also how salient their sizes are. The social polarization literature argues that, ceteris paribus, the larger the size of another group, the greater the threat felt by a given group (proportionally to the size of the other group). This introduces a fundamental distinction between inequality of 0/1 group membership (also called group fractionalization) and social polarization. Fractionalization increases when two identical groups split into two because there is then greater group membership inequality; social polarization falls following such a change.

5.1.4 Socioeconomic and Multidimensional Polarization

Social polarization bases group identity on social characteristics; it sets distances to a binary 0/1 variable and thus does not make use of cardinal distance information. But a richer analysis of differences across members of different social groups can also sometimes be performed jointly on social and economic indicators. Some income groups may be split along some social characteristics; social groups can exhibit heterogeneity in welfare. The introduction of these joint dimensions leads to two generalizations, socioeconomic polarization and multidimensional polarization.

Socioeconomic polarization makes an asymmetric use of these dimensions. One set of social variables is used for group identification; a second set of economic variables fixes distances.[3] Because of this, the usual properties of the income polarization and income bipolarization settings do not apply. In particular, bipolarization properties of increasing spread and of increasing bipolarity do not hold in a socioeconomic polarization context.

Multidimensional polarization measures can also be designed.[4] Group membership can be based on the entire set of social and economic characteristics; so can the

[2] For an exception to this, see Esteban and Ray (2011a), where an increase in within-group inequality increases conflict: increased inequality raises the likelihood that demonstrators within a group may be compensated for the cost of mobilization by other demonstrators within the same group.

[3] This is reminiscent of issues involved in the measurement of equality of opportunity—see Chapter 4 of this Handbook.

[4] See Chapter 3 of this Handbook for broader techniques for comparing dispersions of multivariate distributions.

measurement of distances across individuals. When this is done, a multidimensional analogue of unidimensional income polarization is obtained. Multidimensional polarization can also be of a socioeconomic type; this is achieved by defining social membership by social characteristics (as is usual) and by measuring distances on the basis of a multivariate distribution of welfare indicators.

5.2. MOTIVATION

As for inequality, part of the motivation for studying polarization is ethical. Unlike inequality, however, the ethical motivation comes from the view that distances and differences across groups—as opposed to across individuals for inequality—are normatively undesirable. The hollowing out of the earnings distribution and the disappearance of the middle class may, for instance, create a more segregated and an intrinsically less good society.

Much of the motivation for the study of polarization also owes to the view that it is closely linked to the "generation of tensions, to the possibilities of articulated rebellion and revolt, and to the existence of social unrest in general" (Esteban and Ray, 1994, p. 820). Linking group formation and the eruption of social unrest has a long history. Aristotle wrote (2350 years ago) that "it is manifest that the best political community is formed by citizens of the middle class, and that those states are likely to be well-administered, in which the middle class is large . . . where the middle class is large, there are least likely to be factions and dissension" (Aristotle-350).

To take just another prominent historical example, the Marxist critique of Hegel's philosophy (see, for instance, O'Malley and Blunden, 1970) has forcefully argued that the emergence of two distinct social classes, the bourgeoisie and the proletariat, leads progressively to class struggles as societies industrialize. More generally, humanity's history is often described as a series of group struggles, those groups being typically fairly well defined according to socioeconomic characteristics, interests, and statuses.

The modern formal conceptualization of economic polarization along such antagonistic lines owes much to Esteban and Ray (1994)—ER. Polarization is defined as the grouping of the population into significantly sized clusters such that each cluster has members with similar attributes, and different clusters have members with dissimilar ones. Views differ, however, on how to measure the importance and the relevance of such grouping and on how and whether, in particular, it is social or economic differences that matter in defining polarization. They also differ as to which of these differences is more likely to generate conflict.[5]

[5] See, for instance, the 2008 special issue of the *Journal of Peace Research* on the linkages between polarization and conflict.

Consider first the case of social polarization. Ethnicity (broadly interpreted to include religious, racial, and linguistic identities) is commonly perceived as an important source of it; ethnic groups are seen as firmly bounded, inclined toward ethnocentrism, hostile to outsiders, and as exhibiting a belief that one's ethnic group is centrally important. This can position ethnicity at the center of politics and development in many societies—it is indeed frequent to observe political parties split along ethnic lines (Horowitz, 1985). A social norm of equality further makes the subjugation of ethnic minorities illegitimate and spurs ethnic groups to compare their standing in society against that of other groups. With various technological and social developments, associated political divisions and resultant conflicts may also be increasingly common (Glaeser and Ward, 2006).

The economic consequences of ethnic identities and of (potential or actual) conflict can be numerous (Montalvo and Reynal-Querol, 2005a). Trust and trade may be restricted to individuals of the same ethnic group; public infrastructure may be ethnically biased; government transfers may disproportionately favor some ethnic groups, and so on.

Underlying the listed social tensions also clearly lies a diversity of economic statuses and interests. It is in fact often argued that sociopolitical markers of tension are just proxies for more fundamental economic determinants of polarization (Creamer, 2007). The evidence in McCarty et al. (2006) suggests, for instance, that the increase in the divergence of economic interests of the major constituencies of the two major American political parties may have led to an increase of polarization in American politics.

Theoretical demonstrations of the role of polarization in politics and governance can take a variety of forms. Rent seeking on the part of the different groups is one of them. Montalvo and Reynal-Querol (2005b) present a simple pure contest game in which agents seek rent by spending resources in favor of a preferred group outcome. The utility distances across the groups are set to a constant, and group sizes are assumed to be equal. The level of resources spent by agents affects the probability of success in the contest; that probability is equal to the share of each group in the total resources allocated to the contest. Because of the interaction between group sizes and group probabilities of contest success, the total resources allocated to the contest are shown to be a function of the social polarization index shown in Equation (5.33).

Polarization can also be modeled to lead to conflict in contexts in which distances across groups matter. A brief formalization of this takes the following form. Individuals in a given group derive greater utility from outcomes preferred by groups that are "closer" to them. The probability of a group implementing its preferred (ideal) outcome at the expense of other groups depends on the resources spent by the group in taking control. The sum of these resources also determines the importance of group conflict.

Outcomes of such a game have been studied in Esteban and Ray (1999). Increases in the utility distance between any pairs of groups lead to increases in social conflict. Conflict is always maximized on the symmetric bimodal distribution of the population. But there are many nonlinearities. For instance, a merger of two groups in a society with at least three social groups can increase or decrease conflict depending on the size of the merged groups as well as on the distribution of the population across the nonmerged groups. A movement away from a symmetric distribution of three equally sized groups to a symmetric two-group distribution initially decreases conflicts before it eventually increases it. Bunching—and not only spreads from a "middle"—emerges as an important determinant of conflicts.

A richer framework for studying both the occurrence and the intensity of conflicts and the effect of polarization and fractionalization in each case is found in Esteban and Ray (2008). In a highly polarized society, conflict is expensive, so that its appearance is rare. But when conflict occurs, it is intense. Less-polarized societies, where conflict is less costly, witness a higher frequency of social unrest but of a more moderate intensity. Frequency and intensity can therefore be negatively correlated; it may be that the overall importance of conflict (frequency times intensity) may be reached at intermediate levels of polarization. The occurrence and the intensity of conflicts also depend crucially on the nature of the political system. For all these reasons, the precise overall relationship between polarization and conflict ends up being complex and nonlinear, even in relatively well-structured theoretical settings.

Group distances and group identity affect differently inequality, social polarization, and income polarization. Group cohesion and group distances can also influence differently the size of group conflict in an environment in which control over resources is partly determined by group action. The most elaborate modeling of the linkages between conflict and features of group distance and identity is found in Esteban and Ray (2011b).

The game consists of fighting over a budget, a fraction of which is used for a public good and the rest of which is used for a private good. Each group has a most-preferred composition of public goods. An exogenous fraction of the budget is used for the public good; the precise allocation of that public good is endogenously determined by the identity of the winning group. A degree of group cohesion captures whether group payoffs, and not individual ones, are maximized. Group cohesion can be interpreted, for instance, as a degree of altruism or as an indicator of group leadership. Both of these features reinforce group cohesion and also provide possible answers to the important question of why individuals would want—or would need—to act in groups.

Group members choose to make contributions to the resources used by their group to increase the group's probability to win the game, seize control over the government's budget, and choose the allocation of the public good. In equilibrium, members of any given group make the same contribution; in equilibrium, the groups might be contributing different per capita levels of effort, but it is shown that this is not expected to affect significantly the value of aggregate conflict intensity. An approximately linear relationship is then established in Esteban and Ray (2011b) between equilibrium conflict intensity, the Gini index, fractionalization, and polarization over differences in public good utilities. Four interesting polar cases emerge.

First, when all goods are private, utility distances across different group choices of public good allocations do not matter. This is because utility distances matter only when the allocation of public goods is important to groups. Only group sizes (and not group distances) drive conflict over the allocation of private goods. Distance-based indicators of divergences such as inequality and polarization do not predict conflict; it is only those indicators that are based solely on group size divergences (namely, fractionalization) that matter.

Second, when all goods are public, distances over preferences become salient, and the distance-influenced measures of polarization and inequality dominate fractionalization (which is invariant to group distances) as determinants of conflict. The degree to which polarization dominates inequality as a determinant of conflict depends on the strength of group cohesion; the greater the degree of group cohesion, the greater the conflict-determining importance of polarization as a measure influenced both by group sizes and by group distances.

Third, the relative importance of polarization and fractionalization depends on the importance of public goods. If public goods dominate the allocation of government spending, then conflict rests entirely on the value of winning the public goods allocation game. The importance of polarization (which takes into account the utility distances across groups) then dominates the importance of fractionalization as a determinant of conflict because it alone takes into account public good utility distances across groups and therefore the value of competing for the precise allocation of that good.

Last, inequality has a negligible role when group cohesion is important and, more important, when population size is large (a large population makes individual action less effective). More generally, conflict arises only if population size is small (in which case inequality across individuals is important because there are few interacting individuals and individual action is thus important) or if there is group cohesion (in which case it is polarization and fractionalization—instead of inequality—that play an important role).

5.3. NOTATION

Before proceeding, it is useful to introduce the common notation that will be used in the different sections of the chapter. We denote income—or any other cardinal measure of welfare or, more generally, any cardinal measure of "locations" along which individuals can be found and that can therefore be used to measure distances across individuals by y. Let $F(y)$ be the cumulative distribution function (*cdf*) of income and $p=F(y)$ the proportion of individuals in the population that enjoy a level of income that is less than or equal to y. We will often suppose the existence of a density function, which is the first-order derivative of a continuous *cdf*, denoted as $f(y)=F'(y)$. For discrete distributions, we will think of $f(y)$ as the relative frequency of an income of a value y.

We will denote quantiles as $Q(p)$. For a strictly increasing continuous $F(y)$, they can be defined as $F(Q(p))=p$, or using the inverse distribution function, as $Q(p)=F^{(-1)}(p)$. For discrete distributions, $Q(p)=\inf\{y : p \le F(y)\}$. Thus, with a discrete distribution of N

incomes y_i, ranked in increasing values of y_i such that $y_1 \leq y_2 \leq y_3 \leq \cdots \leq y_{N-1} \leq y_N$, the quantiles are given by $Q(p) = y_i$, for $(i-1)/N < p \leq i/N$ and for $i = 1, \ldots, N$.

The median $Q(0.5)$ is denoted by m and mean income by μ. The mean-to-median ratio is given by $\widetilde{\mu} = \mu/m$ and is a measure of the skewness of the distribution. Let $\widetilde{Q}(q) = Q(q)/Q(0.5)$ denote quantiles normalized by the median, and let $\widetilde{F}(\cdot)$ be the *cdf* of those median-normalized incomes. The Lorenz curve $L(p)$ for $0 \leq p \leq 1$ gives the share of income received by the poorest p proportion of the population. It is defined by $L(p) = \int_0^p Q(q)\mathrm{d}q/\mu$ for all $p \in [0, 1]$. An example of a Lorenz curve is shown in Figure 5.9, to which we return later for additional details.

We will often need to think of a partitioning of the population into n separate and exclusive socioeconomic groups. We will denote by $\mathbf{F}$ the vector of the nonnormalized *cdf* for these groups, each of them denoted by $F_i(y)$ for group i. By definition, $F(y) = \sum_{i=1}^{n} F_i(y)$. The total population of each of these groups is given by n_i, and the vector of these population sizes is denoted by $\mathbf{n}$. Mean income and the relative population share of group i are given, respectively, by μ_i and $\pi_i = n_i/n$ (these shares sum to 1).

5.4. INCOME POLARIZATION

5.4.1 Discrete Income Polarization

The classic and influential formulation by Esteban and Ray (1994) of an alienation/identification framework also presents the first axiomatic formalization of polarization. Every person has one value of a discrete cardinal (such as a discrete income level) attribute; those with the same value identify with the same group. Different values of the attribute generate alienation between members of different groups. A high degree of homogeneity within each group (also called "internal homogeneity"), a high degree of heterogeneity across groups (external heterogeneity), and a small number of significantly sized groups increase polarization.

More formally, it is assumed that the income distribution can be split into a finite number of income classes $i = 1, \ldots, n$, each with income precisely equal to y_i (another interpretation uses μ_i instead of y_i; see following). Identification felt by individuals is an increasing function $I(n_i)$ of the number n_i of individuals in their income class i. The sense of identification depends only on the number of individuals in a given income cluster. (Extensions of this to account for other characteristics belong to socioeconomic polarization.) The distance of individual i from another individual j is denoted by $\delta(y_i, y_j)$. An individual with income y_i feels alienation $a[\delta(y_i, y_j)]$ toward an individual with income y_j. The effective antagonism felt by i toward j is represented by a continuous function $T(I, a)$, where $a = a[\delta(y, y')]$ and $I = I(n_i)$.

The basic formulation of the Esteban and Ray (1994) polarization index ER is then:

$$\mathrm{ER}(\mathbf{n}, \mathbf{y}) = \sum_{i=1}^{n} \sum_{j=1}^{n} n_i n_j T\{I(n_i), a[\delta(y_i, y_j)]\} \tag{5.1}$$

Hence, polarization within a society depends *only* on the distribution of effective antagonism, $T\{I(n_i), a[\delta(y_i, y_j)]\}$. A justification for the additive formulation of Equation (5.1) may be provided along the lines suggested by Harsanyi (1953): an impartial observer might want to use the expected value of effective antagonism to judge overall polarization.

Esteban and Ray (1994) narrow the preceding general formulation by imposing one condition and three axioms on Equation (5.1). The condition is one of invariance with regard to population size: polarization orderings should not change if population sizes are all multiplied by the same number. This is called condition H (for homotheticity).

Condition H

Consider two discrete income distributions $(\mathbf{n}, \mathbf{y})$ and $(\mathbf{n}', \mathbf{y}')$. If $\mathrm{ER}(\mathbf{n}, \mathbf{y}) > \mathrm{ER}(\mathbf{n}', \mathbf{y}')$, then $\mathrm{ER}(k\mathbf{n}, \mathbf{y}) > \mathrm{ER}(k\mathbf{n}', \mathbf{y}'), \forall k > 0$. This condition leads to a constant elasticity formulation of polarization with respect to population sizes in Equation (5.1). It is a common condition in welfare economics, and it is also commonly found in the polarization literature.

ER's identification/alienation framework then proceeds with three different axioms. The first two axioms deal with the impact of income movements on polarization. These first two axioms help characterize the structure of the dependence of $T(I, a)$ in Equation (5.1) on alienation. The third axiom considers the impact of changes in the size of population groups; that third axiom defines the sensitivity of antagonism to identification.

Axiom ER 1

Consider a population made of three income groups, as shown in Figure 5.1. If the two smaller and closer groups join together at the average of their incomes, polarization increases.

Axiom ER 1 considers the effect of reducing local alienation on total polarization. The average distance between the two groups originally at x and y and the group at 0 does not change. Average alienation does fall, however, because of incomes x and y moving closer. Axiom ER 1 says that the effect of increased identification of the two groups to the

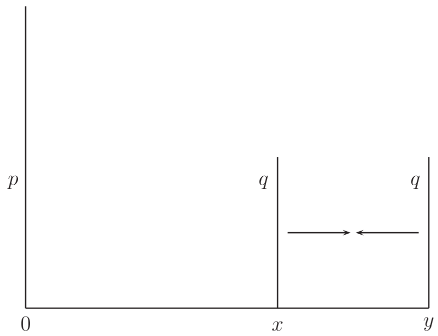

Figure 5.1 Merging two relatively small and close groups at the average of their incomes increases polarization. *Note: There are p individuals at income 0, q individuals at income x, and q individuals at income y. The incomes of the q+q individuals are changed to (x+y)/2.*

right dominates the reduction of alienation. It also implies that the polarization index should be concave in alienation: the effect of the increased alienation between those at incomes 0 and (initial) x dominates the effect of the lower alienation between those at 0 and (initial) y.

Axiom ER 2

Consider a population made of three income groups, as shown in Figure 5.2. If x moves to the right toward y, polarization increases.

Axiom ER 2 involves two changes in alienation. The first one is a fall in alienation between those at x and those at y. The second is an increase in alienation between those at 0 and those at x. Axiom ER 2 says that the greater proximity of x and y should increase polarization. Axiom ER 2 also implies that the index should be convex in alienation. The combinations of Axioms ER 1 and ER 2 imply that the polarization index should be linear in alienation.

Axiom ER 3

Any new distribution formed by shifting population mass from a central mass of size q equally to two lateral masses each of size p and equally distant away from the central mass increases polarization; see Figure 5.3 for an illustration.

Axiom ER 3 says that absorption (or disappearance) of the middle class into richer and poorer classes should increase polarization. It puts a bound on the relative importance of identification in the measurement of polarization: the effect of the fall in identification felt by middle-class individuals located at x in Figure 5.3 should not be too strong in relation to the effect of the increase in identification felt by those individuals on each side of the middle class.

Esteban and Ray (1994) then show that this framework implies a particular form for Equation (5.1):

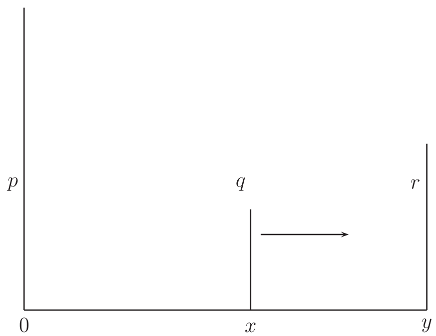

Figure 5.2 Moving x toward y increases polarization. *Note: There are p individuals at income 0, q individuals at income x, and r individuals at income y. Incomes x is moved upward.*

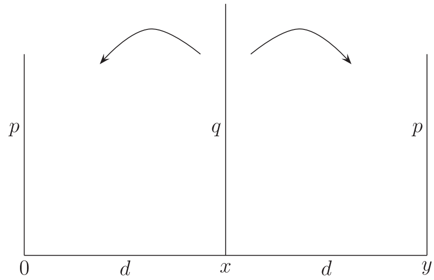

Figure 5.3 Absorption of the middle class into richer and poorer classes increases polarization. *Note: There are p individuals at income 0, q individuals at income x, and p individuals at income y = 2x = 2d. Part of the q individuals at x are shifted equally to 0 and y.*

Theorem 4.1

A class of polarization measure satisfies condition H and the three Axioms ER 1, ER 2, and ER 3 if and only if Equation (5.1) has the form:

$$\mathrm{ER}(\alpha, \mathbf{F}) = K\sum_{i=1}^{n}\sum_{j=1}^{n} n_i^{1+\alpha} n_j |y_i - y_j| \tag{5.2}$$

where $K > 0$ *is a normalization constant and* $\alpha \in (0, 1.6]$, *and if therefore* $T\{I(n_i), a[\delta(y_i, y_j)]\} = n_i^{\alpha}|y_i - y_j|$.

A few remarks may be useful. There are only two degrees of freedom in Equation (5.2), each based on K and α. K is a simple multiplicative constant that has no effect on the ordering of distributions, and α reflects the relative importance of identification and alienation, commonly referred to as a parameter of "polarization aversion." The polarization measure bears resemblance to the Gini coefficient. Aside from the fact that Equation (5.2) uses the logarithm of incomes (see following), it would equal the Gini if α were equal to zero. The fact that α can exceed zero distinguishes income polarization and inequality. The larger the value of α, the greater the departure from inequality measurement because of the greater the departure of Equation (5.2) from the pure consideration of income distances.

In the formulation of Esteban and Ray (1994), y_k in Equation (5.2) is taken to be the log of income (or the log of the relevant cardinal variable). One justification is that individuals may be sensitive to percentage differences in income and not to absolute differences in them. Another justification is that the measure in Equation (5.2) is then invariant to proportional changes in all incomes. The use of income logarithms makes, however, the polarization measure to be noncomparable with the Gini index even when the α parameter is set to zero. Furthermore, $K = \mu^{-1}$ could be used in such a way as to make Equation (5.2) invariant to proportional changes and all incomes, when incomes and not income logarithms are used in the formula.

5.4.2 Continuous Income Polarization

The discrete formula in Equation (5.2) provides an index whose application to indicators of welfare that are commonly continuous (such as income) raises difficulties. First, both the number and the location of income groups are assumed to be (potentially arbitrarily) set/preidentified. Second, a marginal change in the value of y for some individuals may lead to a nonmarginal change in the polarization index (as when a small change in income changes group sizes discretely), a discontinuity that would seem regrettable.

Duclos et al. (2004) (DER) address both of these issues in a framework that is reminiscent of Esteban and Ray (1994) in surface, but with differences at a deeper level. DER postulates that their polarization index should be proportional to the sum of all effective antagonisms in a continuous distribution,

$$\mathrm{DER} = \int\int T[f(x), |x-y|] f(x) f(y) \mathrm{d}x\mathrm{d}y, \tag{5.3}$$

where $f(x)$ is the (unnormalized) density function—capturing identification—and $|x-y| = a$ is the distance between individuals of income x and y—capturing alienation. The antagonism function $T(I, a)$ is increasing in its second argument, and $T(I, 0) = T(0, a) = 0$.

A functional expression for Equation (5.3) is characterized through the formulation of axioms that, though analogous to those of Esteban and Ray (1994), differ in that the income space is continuous. The domains of the axioms are primarily the union of one or more "basic densities." These densities are symmetric, are unimodal, are normalized by population size, and have a compact support. For $0 < r < 1$, a r-squeeze of a density function is defined as a transformation of the form $f^r(x) = (1/r)f[(x-(1-r)\mu)/r]$ such that f^r is a density. The transformation leaves the mean of the distribution unchanged but reduces its standard deviation by a factor $1-r$. The first axiom considers the polarization impact of squeezing basic densities—the first one locally and the second one for two densities, each located on either side of a middle class. These two axioms make it possible to define the role of identification in the antagonism function $T(I, a)$. The third axiom considers the impact of changes in alienation and thus the role of a in $T(I, a)$. The fourth axiom is a population invariance axiom.

Axiom DER 1

A squeeze of a distribution made of only one basic density (as shown in Figure 5.4) does not increase polarization.

Alienation diminishes and identification rises following this squeeze; the impact on polarization of greater identification is nevertheless offset by the impact of a decline in alienation. This effectively limits the parameter α (that will be introduced later, see Equation (5.4), and that is the analogue of the α of the discrete formulation of Equation (5.2)) to be no greater than one because Axiom DER 1 says that polarization should not depart excessively from inequality measurement.

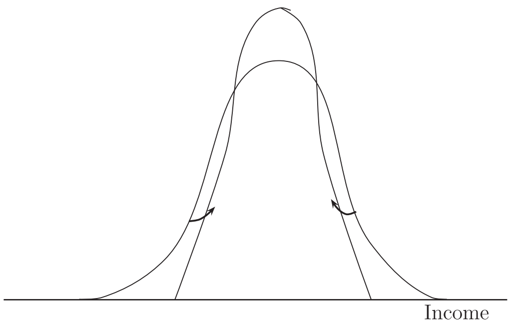

Figure 5.4 A squeeze of a basic density does not increase polarization.

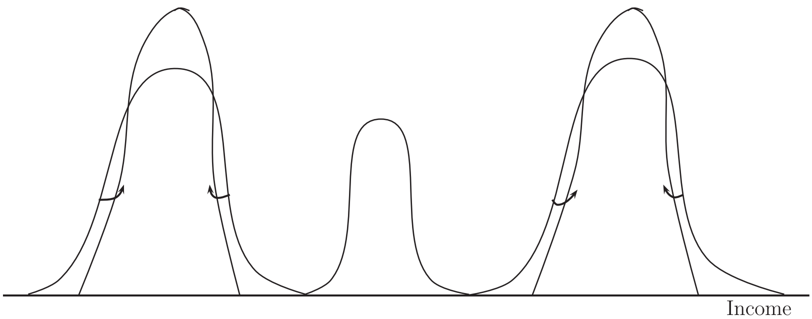

Figure 5.5 A double squeeze cannot reduce polarization.

Axiom DER 2

If the distribution of a symmetric density has three poles (see Figure 5.5), then a squeeze of the outer poles does not decrease polarization.

The decline of intergroup alienation in the outer poles is counterbalanced by the rise of identification. Axiom DER 2 is the "defining" axiom of polarization: It differentiates polarization from inequality. It also puts a lower bound on the parameter α in Equation (5.4): It should not lie below 0.25 for the fall in local alienation (the alienation within each extreme group) to be outweighed by the increase in identification. The axiom also implies that the polarization index should be concave in alienation—for the fall in larger alienation values (the more extreme distances from the middle fall following the squeeze) not to have too large an impact on total polarization.

Axiom DER 3

If a symmetric density has four poles and if each of the two middle poles shifts to the nearer outer pole, as in Figure 5.6, then polarization must go up.

Figure 5.6 shows a fall in local alienation combined with an increase in larger alienation values (an increase in the larger distances between groups). This implies that polarization should be weakly convex is alienation; the effect of a fall in smaller distances should be outweighed by a similarly sized increase in the value of larger distances. Axioms DER 2 and DER 3 imply that polarization should be linear in alienation.

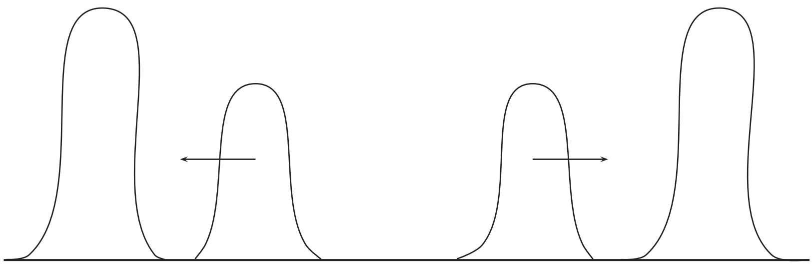

Figure 5.6 A symmetric outward slide must raise polarization.

Axiom DER 4

If the polarization index for one distribution is higher than for another one, then it remains higher when both populations are identically scaled.

This axiom states that polarization orderings should be invariant to population size. It plays a role similar to Condition H given earlier for discrete income polarization. It links identification and polarization through a constant elasticity function in Equation (5.4). DER then shows that:

Theorem 4.2

The index Equation (5.3) satisfies Axioms DER 1, DER 2, DER 3, and DER 4 if and only if it is proportional to:

$$\mathrm{DER}(\alpha) = \int\int f(x)^{1+\alpha} f(y)|x-y|\mathrm{d}x\mathrm{d}y \tag{5.4}$$

for $\alpha \in [0.25\ 1]$, *and if therefore* $T[f(x), |x-y|] = f(x)^{\alpha}|x-y|$.

Making polarization invariant to proportional changes in all incomes can be done by multiplying $\mathrm{DER}(\alpha)$ by $\mu^{\alpha-1}$. For $\alpha=0$, the measure would be equivalent to the Gini coefficient. Note, however, that Theorem 4.2 excludes the Gini index: the Gini index would indeed fall following the squeeze of Figure 5.4, which would violate Axiom DER 2.

The $\mathrm{DER}(\alpha)$ polarization index can be decomposed into identification and alienation components. For a particular value of α, average α-identification can be expressed as

$$\bar{\imath}_{\alpha} \equiv \int f(y)^{\alpha}\mathrm{d}F(y) = \int f(y)^{1+\alpha}\mathrm{d}y. \tag{5.5}$$

The average alienation felt by an individual with income y is given by $a(y) = \int |y-x|\mathrm{d}F(x)$, and the overall average alienation is thus $\bar{a} = \int a(y)\mathrm{d}F(y) = \int\int |y-x|\mathrm{d}F(x)\mathrm{d}F(y)$, which is proportional to the Gini index. Let $\rho_{i,a} = \frac{\mathrm{cov}[f(y)^{\alpha}, a(y)]}{\bar{\imath}_{\alpha}, \bar{a}}$ be the normalized covariance of identification and alienation. Then, $\mathrm{DER}(\alpha) = \bar{\imath}_{\alpha}\bar{a}[1+\rho_{i,a}]$. Ceteris paribus, this means that greater multimodality in the density is likely to translate into greater $\bar{\imath}_\alpha$ and into greater polarization—this effect becoming stronger when α is larger. Greater inequality and thus greater average alienation $\bar{a}$ will also mean greater polarization. Finally, a greater covariance $\rho_{i,a}$ between identification and alienation will raise polarization.

5.4.3 Discrete Income Polarization with Endogenous Grouping

The DER(α) index effectively sets the number of possible income groups to infinity. Each group displays perfect internal homogeneity, being associated with one and only one income level. That removes the need for selecting either the number or the position of income groups.

We might, however, think of measuring income polarization on the basis of a finite and prespecified number of income groups and select their position to maximize internal group homogeneity. Choosing positions to maximize internal homogeneity has the advantage of maximizing local identification and minimizing local alienation—but because individuals in a given group do not all have the same income with discrete income groupings, there will necessarily remain internal heterogeneity, even after such an optimization procedure.

Such an approach is used by Esteban et al. (2007) on the Esteban and Ray (1994) index, using a continuous variable such as income and specifying the number of income groups to be used but not their precise location. Clustering into a finite number of classes introduces errors in the measurement of continuous income polarization. This clustering introduces an approximation error $\varepsilon(\mathbf{F})$. The greater the error, the greater the level of internal heterogeneity, the lower the level of internal identification, the greater the level of local alienation, and the greater the likelihood of a bias in using $\mathrm{ER}(\alpha, \mathbf{F})$ as an index of continuous income polarization. An "extended" polarization index that attempts to correct for such biases is given by:

$$\mathrm{EGR}(\alpha, \sigma, \mathbf{F}) = \mathrm{ER}(\alpha, \mathbf{F}) - \sigma\varepsilon(\mathbf{F}), \tag{5.6}$$

where α is the usual polarization sensitivity parameter and σ is a parameter that weights the measurement error. The approximation error is specified as

$$\varepsilon(\mathbf{F}) = \sum_i \int_x \int_y |x - y| \mathrm{d}F_i(x)\, \mathrm{d}F_i(y) \tag{5.7}$$

and the problem is set to minimize $\varepsilon(\mathbf{F})$ for a given number n of groups. From Equation (5.7), it can be seen that it is equivalent to minimizing the sum of the within-group Gini indices or, alternatively, to minimizing the sum of within-group alienation. The solution is denoted by $\mathbf{F}^*$, with

$$\varepsilon(\mathbf{F}^*) = \mathrm{GB}(\mathbf{F}^*) \tag{5.8}$$

where GB(.) is between-group Gini coefficient of $\mathbf{F}^*$. The Esteban et al. (2007) index is then

$$\mathrm{EGR}(\alpha, \sigma, \mathbf{F}^*) = \mathrm{ER}(\alpha, \mathbf{F}^*) - \sigma \mathrm{GB}(\mathbf{F}^*). \tag{5.9}$$

Note that $\sigma\mathrm{GB}(\mathbf{F}^*)$ is originally meant to capture the effect of one error, the overestimation by $\mathrm{ER}(\alpha, \mathbf{F}^*)$ of income identification in a context in which incomes are artificially grouped. Another error also exists, however, and comes from the underestimation by $\mathrm{ER}(\alpha, \mathbf{F}^*)$ of income alienation in a context in which local alienation is removed through a discrete formation of income groups. The true approximation error of the Esteban and Ray (1994) is therefore quite complicated and should attempt in particular to account both for the identification and the alienation errors of grouping individuals. The formulation of the error should also be consistent with the special form taken by the Esteban and Ray (1994) index; Equation (5.9) takes the awkward shape of a difference between noncomparable functions whenever α is different from zero.

An example of a difficulty created by the form of Equation (5.9) is noted in Lasso de la Vega and Urrutia (2006); the Esteban et al. (2007) measure may fall when groups move farther away from each other because identification errors may increase when this happens, with a resulting fall in Equation (5.9). The alternative index proposed in Lasso de la Vega and Urrutia (2006) is given by

$$\mathrm{CM}(\alpha, \beta, \mathbf{F}) = K \sum_i \sum_j \pi_i \pi_j \pi_i^{\alpha} (1 - G_i)^{\beta} |\ln \mu_i - \ln \mu_j| \tag{5.10}$$

where $\beta \geq 0$ is the degree of sensitivity toward group cohesion, G_i the Gini coefficient of group i, K is a normalization constant, and $1 - G_i$ the Gini *equality* coefficient of group i. The new identification term for each member of group i is thus $\pi_i^{\alpha}(1 - G_i)^{\beta}$, a term that decreases with group Gini. (One could also think of maximizing $\mathrm{CM}(\alpha, \beta, \mathbf{F})$ over a fixed number of groups, in the spirit of the Esteban et al. (2007) index, yielding $\mathrm{CM}(\alpha, \beta, \mathbf{F}^*)$.) As for Equation (5.9), Equation (5.10) does not explicitly account for the dual nature of the identification/alienation approximation error.

5.5. BIPOLARIZATION

5.5.1 Measures of the Size of the Middle Class

Income polarization captures the existence and the importance of an arbitrary number of income poles; bipolarization measures the extent to which a population is divided into two separate groups. An important motivation for developing the concept of bipolarization has been the perception in the 1980s and in the early 1990s—see also Kolm (1969) and Love and Wolfson (1976)—that the size of the "middle class" may be changing over time (and in particular the view that it may be declining). This is because a smaller middle class is presumably associated with greater separateness of the bottom and top halves of the income distribution and with greater (normatively regrettable) distances between groups. Measures of the middle class have, however, relied on definitions that have often been imprecise and heterogeneous.[6]

The size (and the composition) of the middle class is important for a number of economic and social aspects of development. The middle class is a key provider of skilled labor and constitutes an important market for domestic goods and services. The middle class also directly or indirectly provides a large part of a country's tax revenue. A higher share of income for the middle class has been empirically associated with higher incomes and higher growth (Easterly, 2001) as well as with more education, better health care, better infrastructure, better economic policies, less political instability, less civil war and ethnic tension, more social modernization, and more democracy. One reason frequently suggested for this is that a larger-sized middle class is associated with societies with lesser poles at each extreme of the income distribution, thus facilitating political and social harmony and more stable and stronger economic development.

As in the inequality literature, much of the analytical efforts have centered around the construction of indices. The exercise can be made in four different steps: first, specifying the space over which a distribution is split across the middle (population or income wise); second, setting the definition of the middle itself (mean or some middle quantile, such as the median); third, setting the boundaries of the middle class; and, fourth, aggregating the data. An income space is often selected, with income being monthly salary, yearly expenditure, or some other unidimensional indicator of welfare. Though it is common to use the median for the middle, it is also possible to use mean income for that purpose, though the proportion of the population on either side of the mean will typically diverge from 50%, especially if the distribution is not symmetric.[7]

The most influential initial measures of the size of the middle class have then relied on the position of two income cutoff points around the median and on defining the middle class as the share of the population with income within these cutoff points. The middle class is hence defined as the share of the population with incomes between 75% and 125% of the median income by Thurow (1984); Blackburn and Bloom (1995) broaden that middle income range to 60–225% of median income; in Leckie (1988), the middle class is defined on the basis of an income range of 85–115% of median wage. The resulting middle-class indices, denoted as M, is then the share of the population found within these cutoff points. This approach is illustrated graphically using either the density function of

[6] Note that we do not discuss explicitly here the relatively recent literature on the polarization of wages, usually concerned with potentially growing inequality in the top half of the wage distribution and possibly stable or shrinking inequality in the bottom half; see for instance Autor et al. (2008), Acemoglu and Autor (2012), or Mishel et al. (2013).

[7] The middle class can also be defined independent of the "middle." A recent influential example is Kharas (2010), where estimates of the "global" middle class are based on the "ability to lead a comfortable life" and contain those individuals living in households with per capita daily consumption within (PPP) USD 10 and USD 100.

the income distribution (Figure 5.7) or the *cdf* F (Figure 5.8). If the density function is used, the index M is the area situated under its curve and between the lower and the upper bounds of the income range. With the cumulative distributive function, the index M is the vertical distance between the values of the *cdf* evaluated at the two cutoff points.

A people space can also be used. Levy (1987) considers the income share of the middle three-fifths of the population as the size of the middle class. The middle is thus taken to be the 50th percentile, and a range from the 20th to the 80th percentile is identified as the width of the middle class. A middle-class index is then the share of the income earned by that middle class. This can be seen in Figure 5.9 as the difference between two points on the Lorenz curve, $L(0.8) - L(0.2)$. It can also be observed on Figure 5.10 as a quantile function. The measure is the ratio of the hatched area over the total area underneath the quantile curve.

Levy's (1987) index was criticized by Foster and Wolfson (2010/1992) for measuring something other than the size of the middle class or bipolarization. Foster and Wolfson (2010/1992) argued that the index can be considered to be a sound measure of the skewness of the distribution; it should not be viewed, however, as a good index of the size of

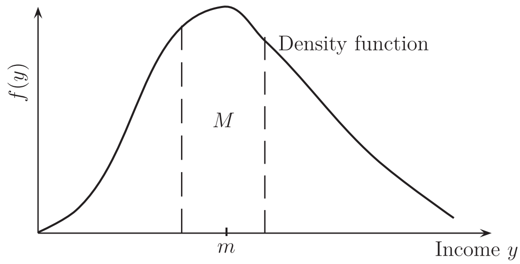

Figure 5.7 Finding the size M of the middle class with a density function.

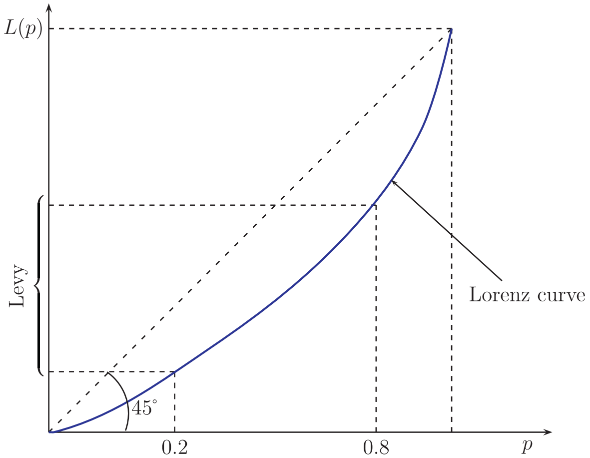

Figure 5.9 Lorenz curve and the Levy (1987) index of the size of the middle class.

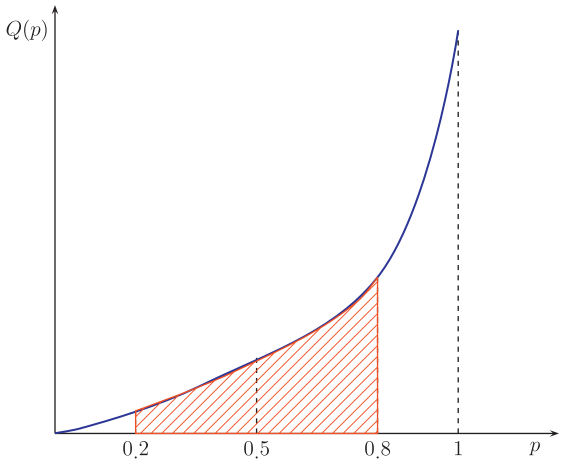

Figure 5.10 Quantile function.

the middle class or of the extent of bipolarization because it fails to measure "spreads" on each side of the middle class. One way to see the problem is to observe that any symmetric distribution will exhibit exactly the same value for the Levy index. For any symmetric distribution, we have indeed that $L(1-p)-L(p)=1-2p$ for all p. For the specific case of $p=0.2$, the index yields a value of 0.6, which is therefore the value of the Levy index for all symmetric distributions, however far incomes may be from the median and however bipolarized these incomes may be.

The fact that Levy-type measures fail to capture spreads on each side of the median can be illustrated in several fashions. For instance, an increase in any quantile

$Q(p)$ for $p \in [0.5, 0.8]$ will increase the Levy measure of the size of the middle class (because $L(0.8)$ will increase and $L(0.2)$ will fall); that, however, will increase the spreads from the median and should therefore conceivably increase bipolarization. Similarly, a fall in $Q(0.1)$ will decrease $L(0.2)$ and increase the Levy measure of the size of the middle class, although that should arguably lead to an increase in the level of bipolarization. Increases in bipolarity that occur entirely within $p \in [0.2, 0.8]$ will not change the Levy measure, although they should reasonably impact bipolarization.

5.5.2 Two Basic Properties of Bipolarization Indices

From the preceding, it is clear that quantifying levels of bipolarization and of the size of the middle class may be treacherous conceptually and thus methodologically. To solve part of the ambiguity, it may be useful to agree on basic properties that the methodological exercise should obey. The two basic properties of bipolarization measurement on which most of the bipolarization literature has insisted are the effects of "increased spread" and "increased bipolarity" (or increased bimodality in Wolfson, 1997).[8]

Consider a discrete population of two income groups, B and D, distributed around median income C and as drawn in Figure 5.11. Now assume that those below and above the median line move away from it; that is, the poorer (at B) become poorer until their income becomes A, and the richer (at D) become richer until their income is at E. Each of these movements away from the middle is called an "increased spread." When this occurs, polarization and inequality are said both to increase. The new distribution is indeed obtained from the old one by a mean preserving regressive transfer across the middle; this increases distances between individuals (and therefore increases inequality), and it

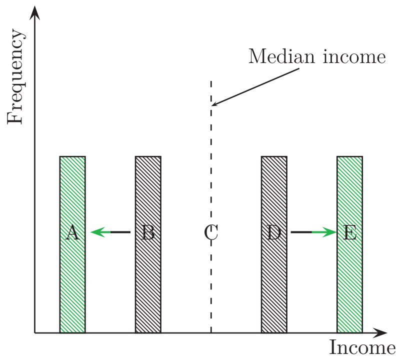

Figure 5.11 Increased spread.

[8] A recent survey of the bipolarization literature can be found in Nissanov et al. (2010).

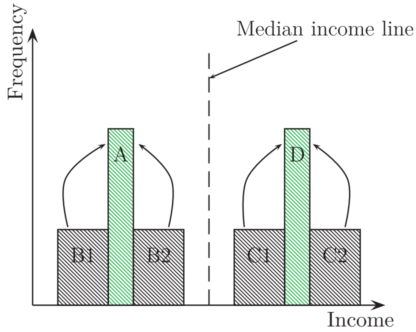

Figure 5.12 Increased bipolarity.

also increases all distances from the middle (and thus raises bipolarization). As in the inequality literature, these movements can be thought to be ethically regrettable.

Figure 5.12 illustrates the property of increased bipolarity. Increased bipolarity is the result of two "spread changes," an "increased spread" and a "decreased spread." Suppose that, below the median, populations with income B1 and B2 cluster at their mean income A and, above the median, populations with income C1 and C2 cluster at their mean income D. Inequality decreases, but polarization can be reasonably said to increase. With increased bipolarity, the average positions of the masses on each side of the median do not change, and the median themselves are not altered, but the distributions on each side of the median are tightened up. During the movement, individuals nearer to the middle move away from it, whereas individuals farther from the median move toward it. The movements of the first group increase the spreads from the median, whereas the movements of the second group of individuals reduce those spreads. Overall, bipolarization increases because the first movements are thought to carry more weight than the second ones.

Increased bipolarity thus distinguishes fundamentally polarization from inequality. Any progressive transfer leads to an unambiguous decrease in inequality, irrespective of the location of the transfer. Bipolarization also falls when the transfer takes place across the middle. Bipolarization is said to increase when the transfer occurs on one side of the middle.[9] A concern about polarization can thus lead us to reject a transfer that would otherwise reduce inequality, where that transfer would take people away from the median.

Much of the literature on bipolarization takes these two properties as given and then proceeds into alternative directions. The first direction leads to the construction of bipolarization indices that are consistent with these two properties. These indices provide complete bipolarization orderings of distributions. The second direction provides dominance curves for making partial bipolarization orderings. The design of these curves draws from the well-known applications of stochastic dominance in the inequality literature.

[9] See Chakravarty (2009, Chap. 4) for a discussion.

It is also on this basis that Foster and Wolfson (2010/1992) (FW) set their influential paper. (The paper was published in 2010 in the *Journal of Economic Inequality* as a "rediscovered classic," having circulated until then as a 1992 working paper.) FW introduce two bipolarization curves as well as a new Gini-like index of bipolarization. The first curve says that bipolarization is greater when the size of the middle class is smaller, viz., when the distances to the median are larger. The second bipolarization curve says that bipolarization is higher when the average distance from the median, on either side of the median, are larger.

The index proposed by FW equals twice the area between the Lorenz curve and the tangent to the Lorenz curve at median income (this area being multiplied by $\widetilde{\mu}$). The index can also be expressed as a function of within- and between-group inequalities: the larger the extent of between-group inequality, the larger is bipolarization, and the larger the level of within-group inequality, the lower is the level of bipolarization. We now examine this in more details.

An income distance between two quantiles at percentiles q^- and q^+ is defined by

$$S(q^-, q^+) = \widetilde{Q}(q^+) - \widetilde{Q}(q^-) \tag{5.11}$$

$S(q^-, q^+)$ is a median-normalized income distance between two quantiles. If $[q^-, q^+]$ overlaps 0.5, it can also be thought of as a measure of the size of the middle class. When S is large, there are fewer individuals near the middle, and consequently the middle class is deemed smaller and there is more bipolarization. FW (see also Wolfson, 1994) define a first-order polarization curve as:

$$S(p) = |S(p, 0.5)| \tag{5.12}$$

for $0 \leq p \leq 1$. For each p, $S(p)$ is the distance that separates median income from the income of the person situated at the pth percentile. This is illustrated in Figure 5.13. Two distances from the median are shown in the upper panel, $S(q^-)$ and $S(q^+)$. The bottom panel of Figure 5.13 mirrors the left-hand side of the upper panel. It draws a first-order bipolarization dominance curve "looking a bit like a lopsided gull" (Wolfson, 1994, p. 355).

FW also define a second-order polarization curve as

$$B(q) = \left| \int_q^{0.5} S(p)\mathrm{d}p \right| \tag{5.13}$$

for $0 \leq q \leq 1$. $B(q)$ is the area under the $S(p)$ curve between points q and 0.5. This is also shown in Figure 5.13 as hatched areas representing $B(q^-)$ and $B(q^+)$. Figure 5.14 shows the shape of a typical $B(p)$ curve, and how its side values $B(0)$ and $B(1)$ can be expressed as functions of the Lorenz point $L(0.5)$. An important point is that $B(q)$ is obtained by integrating "inward" to the median (p from q to 0.5); the usual stochastic dominance curves integrate from 0.

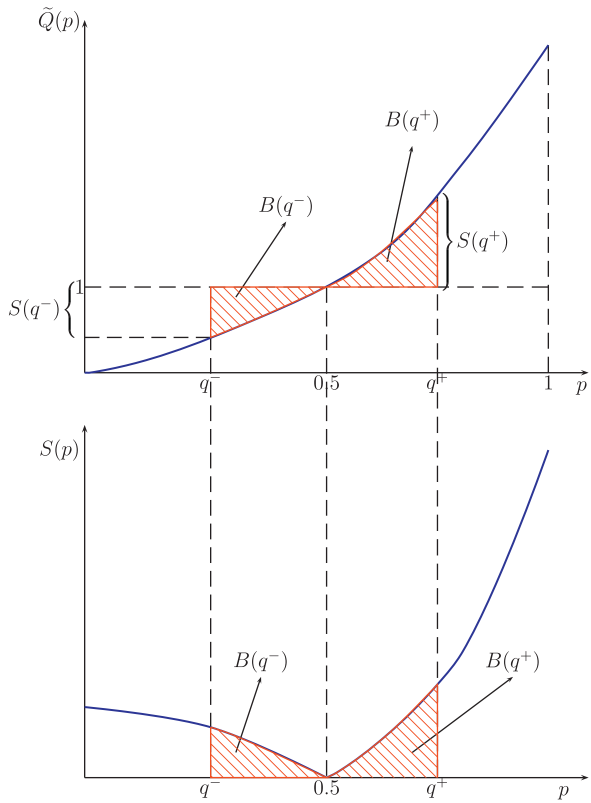

Figure 5.13 First-order bipolarization curves.

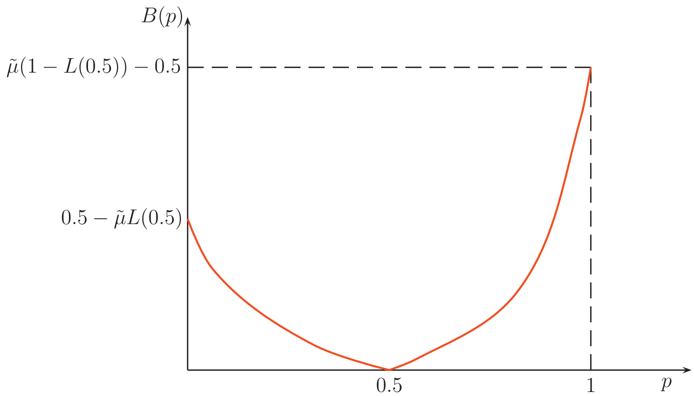

Figure 5.14 Second-order bipolarization curve.

5.5.3 Bipolarization Dominance

The curves just introduced can be used for descriptive as well as for normative purposes. They are called dual curves because they are a function of percentiles p. Analogous dual curves in welfare economics include quantile, Lorenz, generalized Lorenz, poverty gap, and cumulative poverty gap curves—see, for instance, Duclos and Araar (2006) for definitions and a discussion. Primal curves also exist. These primal curves are a function of income levels. These incomes need to be expressed as proportions of the middle (the median, usually) for bipolarization comparisons. A natural first-order primal curve for such comparisons is given by $F(\lambda m) - 0.5$ for $\lambda > 1$, namely, the proportion of the population found between the median itself and λ times the median, or the expression $0.5 - F(\lambda m)$ for $\lambda > 1$, that is, the proportion of the population found between λ times the median and the median. Both of these measures are popular features of the measurement of the size of the middle class—see for instance Morris et al. (1994). They are illustrated in Figure 5.15 (recall that $F(\lambda m) = \widetilde{F}(\lambda)$).

Increases in spreads from the median will decrease each of these two expressions, $F(\lambda m) - 0.5$ and $0.5 - F(\lambda m)$. Increases in bipolarity will increase these expressions at some values of λ and will reduce them at other values of λ.

Let Π^1 then be a class of bipolarization indices P that are functionals of $\widetilde{F}$, population size invariant, monotonically increasing in $\widetilde{Q}(p)$ for $p > 0.5$ and monotonically decreasing in $\widetilde{Q}(p)$ for $p < 0.5$. The following conditions can then be shown to be equivalent:

5.5.3.1 First-Order Bipolarization Dominance

1. $P_B \geq P_A$ for all P in Π^1.
2. $S_A(p) \leq S_B(p)$ for all $0 \leq p \leq 1$.
3. $|\widetilde{Q}_A(p) - 1| \leq |\widetilde{Q}_B(p) - 1|$ for all $0 \leq p \leq 1$.

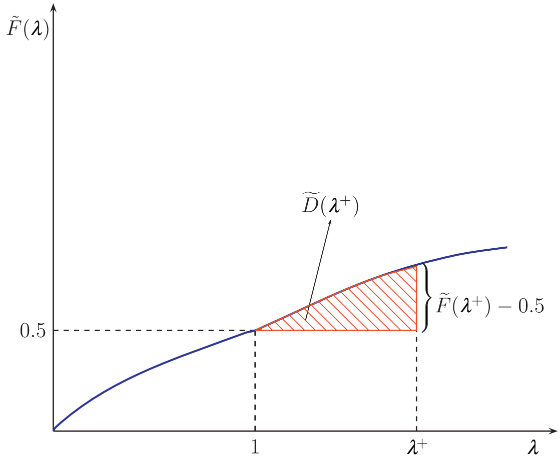

Figure 5.15 Average distance from bipolar extremes.

4. $|\widetilde{F}_A(\lambda) - 0.5| \geq |\widetilde{F}_B(\lambda) - 0.5|$ for all $\lambda > 0$.
5. $|F_A(\lambda m_A) - 0.5| \geq |F_B(\lambda m_B) - 0.5|$ for all $\lambda > 0$.
For $\lambda > 1$, condition 5.4 can be rewritten as $\widetilde{F}_A(\lambda) \leq \widetilde{F}_B(\lambda)$: The proportion of the population with income less than λ times median income (a frequently used relative poverty line) should be lower in A for A to be less bipolarized.

These results can be extended to the case of symmetry of bipolarization indices with respect to distances on each side of the median. Let Π^{S1} be a class of bipolarization indices P that are functionals of $\widetilde{F}(y)$, are population invariant, and are monotonically increasing in $|\widetilde{Q}(p) - 1|$. The following conditions are then equivalent.

5.5.3.2 First-Order Symmetric Bipolarization Dominance

1. $P_B \geq P_A$ for all P in Π^{S1}.
2. $\widetilde{F}_A(\lambda) - \widetilde{F}_A(2-\lambda) \geq \widetilde{F}_B(\lambda) - \widetilde{F}_B(2-\lambda)$ for all $\lambda > 1$.
This is equivalent to comparing the shares of the population within a distance $\lambda - 1$ of the median (Duclos and Échevin, 2005), which is also a frequently used and simple descriptive statistic of the size of the middle class.

The welfare economics literature often stresses the view that some income levels in the income distribution are more important than others, in the sense that changes in these incomes engender greater changes in social evaluation functions (such as social welfare functions or inequality indices). The same view is put forth in the bipolarization literature through the application of the increased bipolarity property, which technically says that indices of bipolarization should be concave in distances from the median and conceptually means that increases in smaller spreads from the median have a greater impact on bipolarization than rises in larger spreads. The curves that are used to establish dominance on the basis of these indices cumulate income distances from the median, in the manner of $B(p)$ for dual curves and in the manner of

$$\widetilde{D}(\lambda) = \begin{cases} \int_{0.5}^{1} \left(\lambda - \widetilde{Q}(p)\right)_{+} \mathrm{d}p & \text{if } \lambda \geq 1 \\ \int_{0}^{0.5} \left(\widetilde{Q}(p) - \lambda\right)_{+} \mathrm{d}p & \text{if } \lambda < 1 \end{cases} \tag{5.14}$$

for primal curves. Figure 5.15 illustrates $\widetilde{D}(\lambda)$ for λ^{+}. It can be seen as the integral of the $F(\lambda m) - 0.5$ (for $\lambda > 1$) and $0.5 - F(\lambda m)$ (for $\lambda < 1$). From Equation (5.14), it can also be seen that $\widetilde{D}(\lambda)$ can be expressed as the sum of the distances between median-normalized incomes $\widetilde{Q}$ and a threshold λ. This is analogous to the aggregation of poverty gaps in the poverty literature: the larger the sum of poverty gaps, the greater is poverty; the larger the sum of the gaps between normalized incomes and a threshold on each side of the median, the greater is bipolarization. $\widetilde{D}(\lambda)$ can also be understood as the average distance from bipolar extremes (λ) on either side of the median.

Let Π^2 be a class of bipolarization indices P that are functionals of $\widetilde{F}$, population invariant, monotonically increasing in $\widetilde{Q}(p)$ for $p > 0.5$, monotonically decreasing in $\widetilde{Q}(p)$ for $p < 0.5$, and concave in $\widetilde{Q}(p)$. The following conditions are then equivalent.

5.5.3.3 Second-Order Bipolarization Dominance

1. $P_B \geq P_A$ for all P in Π^2.
2. $D_A(\lambda) \geq D_B(\lambda)$ for all $\lambda < 0$.
3. $B_A(p) \leq B_B(p)$ for all $0 \leq p \leq 1$.

As discussed earlier, this can be extended to the case of symmetric of bipolarization indices with respect to distances on each side of the median. Let Π^{S2} be a class of bipolarization indices P that are functionals of $\widetilde{F}$, population invariant, and monotonically increasing and concave in $|\widetilde{Q}(p) - 1|$. The following conditions are then equivalent.

5.5.3.4 Second-Order Symmetric Bipolarization Dominance

1. $P_B \geq P_A$ for all P in Π^{S2}.
2. $D_A(\lambda) + D_A(2-\lambda) \geq D_B(\lambda) + D_B(2-\lambda)$ for all $\lambda > 1$.

A natural question is whether these bipolarization partial orderings have power empirically, namely, whether it is possible to rank bipolarization across distributions using them. The comparisons of 29 Luxembourg Income Study (LIS) countries found in Duclos and Échevin (2005) show some evidence of this. The comparisons are made with and without statistical testing of the differences between the curves; it is more difficult to distinguish the curves statistically than numerically.[10] Symmetric and asymmetric bipolarization dominance tests are also performed; symmetric tests have naturally more power. Overall, Duclos and Échevin (2005) found that first-order dominance is found statistically across 32% of the 406 possible pairwise comparisons; that percentage increases to 55% for symmetric first-order dominance testing and to 73% for second-order symmetric dominance.

5.5.4 Bipolarization Indices

Specific numerical indices are frequently used to summarize and compare income distributions and have the advantage of providing complete orderings over distributions. FW propose one such index with two principles in mind:

1. The index should conform to basic underlying notions of the concept being measured; for example, inequality measures should be Lorenz-consistent, the Lorenz curve being the gold standard in comparing inequality robustly and graphically. In the case of bipolarization, FW base their index on the second-order dual bipolarization curve $B(p)$, which is the bipolarization analogue of the Lorenz curve.

[10] See Chapter 6 of this Handbook for a coverage of some of the estimation and inference issues involved in comparing distributions.

2. The index should be easily understandable. For example, the Gini coefficient can be expressed as twice the area between the Lorenz curve and the diagonal of equality. FW follow a similar procedure in proposing their index.

The bipolarization index of Foster and Wolfson (2010/1992) is then defined as

$$\mathrm{FW} = 2\int_0^1 B(p)\mathrm{d}p, \tag{5.15}$$

which is twice the area beneath the second-order bipolarization curve $B(p)$. FW is therefore necessarily consistent with a partial ordering based on comparing $B(q)$. It is also simple to understand.

FW also has quite a few other interesting features. It is, for instance, linked to the Gini index and the line tangent to the Lorenz curve at the median income. Let the average distance between incomes under the median and incomes above the median be given by:

$$T = \left(\mu^{\mathrm{U}} - \mu^{\mathrm{L}}\right)\frac{1}{\mu} = 1 - 2L(0.5), \tag{5.16}$$

where $\mu^{\mathrm{U}} = (1 - L(0.5))\mu$ is the mean income of those above the median and $\mu^{\mathrm{L}} = L(0.5)\mu$ is the mean income of those below the median. FW call T the relative median deviation.[11] $T = 2V$ is twice the share V of total income needed to increase to mean income the incomes of those below the median. Thus, it can be measured as twice the vertical distance from the first diagonal to the Lorenz curve at the level at which the cumulative percentage of the population equals 0.5. This is shown in Figure 5.17.

Another expression for T is given by integrating $S(p)$:

$$T = \widetilde{\mu}^{-1}\int_0^1 S(p)\mathrm{d}p = \widetilde{\mu}^{-1}(B(0) + B(1)), \tag{5.17}$$

so that T is twice the area under the first-order polarization curve normalized by $\widetilde{\mu}$—see Figure 5.13.

T is also twice the area of the quadrilateral 0ABC in Figure 5.17. This has two consequences: first, T is greater than the Gini coefficient G and, second, the area between the Lorenz curve and the tangent line (the light gray area in Figure 5.17) is never zero when G is nonzero.

Foster and Wolfson (2010/1992) then show that

$$\mathrm{FW} = (T - G)\widetilde{\mu} \tag{5.18}$$

The index FW is a scaling up (by the skewness measure (μ/m)) of the light gray area of Figure 5.17. It is thus simple to construct from such basic statistics as mean income, median income, the Gini coefficient, and the relative median deviation.

[11] This is different from the relative mean deviation, which is given by $2(F(\mu) - L(F(\mu)))$.

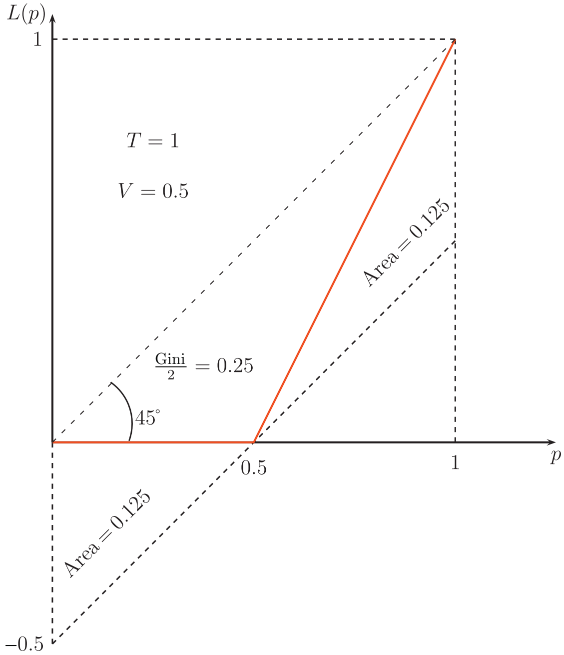

Figure 5.16 Maximum bipolarization.

When a distribution is perfectly bimodal, half of the population has zero income and the other half has income equal to 2μ. This case of perfect bimodality is shown in Figure 5.16. Maximal FW bipolarization is given by twice the area covered by the triangles that lie between the Lorenz curve of the bimodal distribution and the 45° line that touches the horizontal axis at $p=0.5$. Each triangle has an area of 0.125, as shown on the figure. Twice those areas equals 0.5, which is the maximum value attained by FW. FW equals zero in the case of a perfectly equal distribution. Wolfson (1994, 1997) prefer to redefine FW by multiplying it by 2, so that the new index ranges from 0 to 1.

The polarization index FW can also be expressed as a function of components of the Gini coefficient, between-group inequality, and within-group inequality. Divide the population into two groups, one made of individuals with income below the median and the other one made of individuals with income above the median. Give income μ^{L} to individuals below the median and μ^{U} to individuals above the median. GB($\mathbf{F}$) is the between-group Gini coefficient of this new income distribution, which has no within-group inequality. The difference $\mathrm{GW}(\mathbf{F}) = G(\mathbf{F}) - \mathrm{GB}(\mathbf{F})$ is a measure of within-group inequality and is a population-weighted sum of Ginis within the two groups.

An illustration of this decomposition is given in Figure 5.17. The three values of the Lorenz curve at points 0, 0.5, and 1 are joined to form a between-group Lorenz curve, a

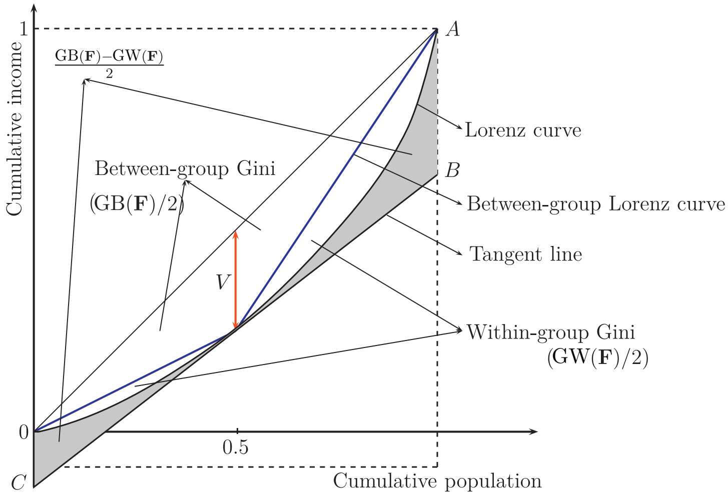

Figure 5.17 Polarization, relative median deviation, and within- and between-group inequality.

piece-wise linear curve. $GW(\mathbf{F})$ is twice the area between the original Lorenz curve and the newly graphed between-group Lorenz curve; $GB(\mathbf{F})$ is twice the area captured by the between-group Lorenz curve, that is, the area between it and the 45° line. The area of the triangle formed by the between-group Lorenz curve and the diagonal equals $[0.5 - L(0.5)]/2$, such that between-group inequality equals $GB(\mathbf{F}) = 0.5 - L(0.5)$ and that $T = 2GB(\mathbf{F})$ is twice the between-group inequality term. Given this, an alternative expression for the FW index is therefore

$$FW = (GB(\mathbf{F}) - GW(\mathbf{F}))\tilde{\mu}. \tag{5.19}$$

Equation (5.19) is a function of between-group inequality minus within-group inequality as measured by the Gini index and with the two groups, respectively, above and below the median. This nicely shows how the bipolarization index FW is influenced both by spreads from the median and by bipolarity. Increases in spreads from the middle raise GW; increases in bipolarity reduce GW. Both effects increase bipolarization. Changes in spreads from the middle have a larger impact on bipolarization when the spreads are initially small: increases in spreads from the middle raise between-group inequality, but within-group inequality indeed falls faster when those closer to the median move away from it.

We use 2004 Canadian data from the LIS to illustrate some of these expressions. The estimates of the Gini for those below and above the median are $G_L = 0.206$ and $G_U = 0.213$, respectively; the data also yield estimates of $\tilde{\mu} = 1.165$ and $L(0.5) = 0.286$. This leads to $T = 0.430$, namely, the relative median deviation and twice the share of total income needed to increase to mean income of those below the median. The between-group Gini index ($GB = 0.5 - L(0.5)$) is found to be 0.215, and the within-group Gini index $(\mathrm{GW} = 0.5L(0.5)G_{\mathrm{L}} + 0.5(1 - L(0.5))G_{\mathrm{U}})$ equals $0.332 - 0.215 = 0.117$. The overall Gini index is therefore $0.215 + 0.117 = 0.332$. By Equation (5.18), this leads to $\mathrm{FW} = 0.114$. The same result is also obtained using Equation (5.19): $\mathrm{FW} = (0.215 - 0.117)\widetilde{\mu} = 0.114$.

As shown in Equation (5.19), inequality and polarization rise together when inequality between the two groups rises; they move in opposite directions when within-group inequality declines. When between-group inequality increases, inequality and polarization rise simultaneously—this corresponds to a greater spread; when within-group inequality ($\mathrm{GW}(\mathbf{F})$) decreases, inequality decreases too, but polarization rises, corresponding to increased bipolarity.

5.5.5 Income Polarization and Bipolarization

Note that increased bipolarity leads to lower inequality on each side of the median, but not necessarily to poles that are necessarily more defined on each of these sides. Consider, for instance, Figure 5.18. The initial distribution (shown by the 45°-hatched rectangles) has four equally sized separate groups, two on each side of the median. Say that the two groups on the right-hand side each split into two smaller groups (leading to the $6 - 45°$-hatched rectangles, two on the left-hand side and four on the right-hand side) following an increase in bipolarity on the right-hand side of the distribution. Within-group inequality has increased, and between-group inequality has been left unchanged. Bipolarization should therefore be judged to have increased, but is this also the case for polarization? It may instead be argued that the poles of the distribution have now become less well defined and that income polarization has fallen.

This important distinction between income polarization and bipolarization can be pushed further. It should be clear that concepts and measurement of income polarization and bipolarization are related and yet different. Conceptually, income polarization is concerned with the existence of multiple groups; bipolarization deals with the existence of

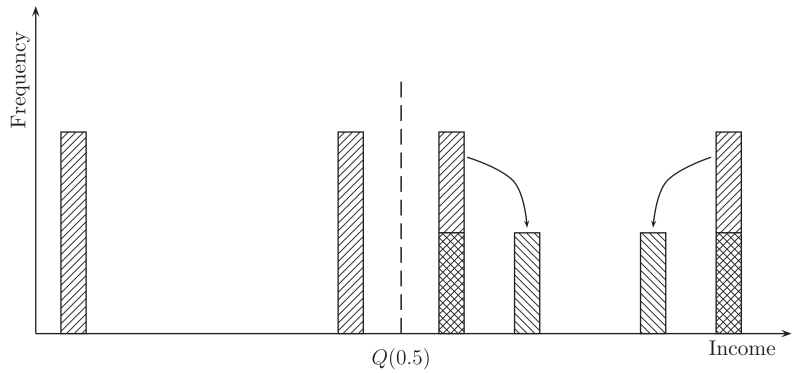

Figure 5.18 Does increasing bipolarity increase polarization?

two bipolar groups. From a measurement perspective, different functional restrictions are also imposed. Income polarization is based on the average antagonism generated by the mixture of identification and alienation. Bipolarization is a function of distances from a middle. It is therefore not surprising that income polarization and bipolarization orderings may clash.

Axiomatically, there are also similarities and differences across the two frameworks. For instance, the properties of bipolarization measurement imply some of the commonly used income polarization axioms. The property of increased spread implies Axioms DER 1 and DER 3; the property of increased bipolarity implies Axiom DER 2. Thus, bipolarization indices such as FW obey Axioms DER 1, DER 2, and DER 3 (and DER 4 as well because of population size invariance). But the converse is not true. The DER axioms do not imply the two fundamental properties of bipolarization measurement. This also suggests that (leaving aside the differences in the initial functional restrictions, see Esteban and Ray, 2012) the income polarization framework is more flexible than the bipolarization one, as intuition also suggests because the income polarization framework is set over an arbitrary number of groupings.

Because of this greater flexibility, the DER indices can fail, however, to obey the increased spread and the increased bipolarity properties (again, see Esteban and Ray, 2012). This is because the movements involved in these properties can decrease identification sufficiently to lead to a fall in average antagonism and thus in income polarization. Again, a demonstration of this is shown in Figure 5.18, where the movements increase bipolarization but may decrease income polarization.

Conversely, bipolarization indices such as FW can fall following squeezes of local distances that increase local identification. For instance, a squeeze of each of three equally sized and equally spaced symmetric basic densities will always decrease FW, but will also always increase DER. (This is in fact true for squeezes of any odd number of such symmetric groups.) Again, the source of the clash comes from the conceptual distinction between distances across well-identified groups and distances of those groups from a middle.

5.5.6 Extensions

Various extensions of the FW index have been proposed. Most of them rely on intuitive alternative applications of the spread/bipolarity framework. One fruitful general approach is to think of distances from the median as the variable of normative interest and to use well-known aggregation techniques from welfare economics to aggregate these distances in a manner that ensures that desirable properties are fulfilled. Note that, for the measurement of polarization, those properties then apply to distances from the median: in welfare economics, the same properties normally apply to distances from the mean or from other incomes—see, for instance, Chapter 4 in Duclos and Araar (2006).

Wang and Tsui (2000) proposed two types of extensions, both of which are axiomatically characterized. In both cases, income distances from the median are aggregated. The first type of aggregation uses rank weighting to aggregate the distances in a manner analogous to Donaldson and Weymark (1980) and Yitzhaki (1983). The measure is defined as

$$\mathrm{WT_A} = \int w(p)S(p)\mathrm{d}p \tag{5.20}$$

where $w(p)$ is positive and increasing for $p \leq 0.5$ and positive and decreasing for $p > 0.5$. Positivity of p is needed for the increasing spread property to hold: Any increase in $S(p)$ must raise $\mathrm{WT_A}$. Increasingness of $w(p)$ for $p \leq 0.5$ and decreasingness of $w(p)$ for $p \geq 0.5$ are needed for the increasing bipolarity property to hold as well. Makdissi and Mussard (2010) used classes of such indices to assess the impact of tax reforms.

Wang and Tsui (2000) also considered polarization measures defined as transformation of distances from the median and normalized in such a way that there is no polarization when income is equally distributed across all individuals. A class of such indices is given by

$$\mathrm{WT_B} = \int_0^1 \psi(S(p))\mathrm{d}p, \tag{5.21}$$

where $\psi(u)$ is a continuous function. The class of polarization indices $\mathrm{WT_B}$ satisfies the axioms of increasing spread and of bipolarity if and only if $\psi(u)$ is strictly increasing, strictly concave, and with $\psi(0)=0$. A constant elasticity formulation for ψ emerges if rankings of nonnormalized distances must always be the same as those for normalized distances from the median. This yields the polarization class of indices

$$\mathrm{WT_C} = \int S(p)^r\mathrm{d}p \tag{5.22}$$

where $r \in (0,1)$. The larger the value of r, the more sensitive are the polarization indices to the deviations of richer persons' incomes from the median.

Inspiration from the inequality literature can also be used to generalize the aggregation of distances from the median that Foster and Wolfson (2010/1992) and much of the subsequent bipolarization literature have adopted. An example of this is Chakravarty and Majumder (2001)'s exploration of the use of the Atkinson (1970), Kolm (1969), and Sen (1973) inequality indices for the measurement of bipolarization—see also Chakravarty (2009, section 4.3). By constructing, inter alia, "equally distributed equivalent incomes" on the separate distributions of incomes lower and greater than the median, it is possible to take into account inequality on each side of the median to assess by how far the two groups are from the middle of the entire distribution. When the welfare evaluation function is of the Gini type, such procedures simplify to the Foster and Wolfson (2010/1992) measure of bipolarization.

Rodríguez and Salas (2003) follow in FW's footpath by applying a sensitivity parameter to weight the subgroup decomposition of the Gini coefficient into between and within-group inequality. Using the Donaldson and Weymark (1980) and Yitzhaki (1983) single parameter/extended Gini coefficients, they propose a bipolarization index of the form

$$\mathrm{RS}(\nu, \mathbf{F}) = \mathrm{GB}(\nu, \mathbf{F}) - \mathrm{GW}(\nu, \mathbf{F}). \tag{5.23}$$

where ν is an inequality aversion parameter—see Duclos and Araar (2006) for a discussion. A progressive median-preserving transfer within (between) the two groups on each side of the median increases (reduces) polarization.

5.5.7 Absolute and Relative Bipolarization Indices

The literature on inequality offers both absolute and relative inequality indices. Absolute inequality indices are invariant to translations of every income by the same constant. Relative inequality indices are invariant to changes in the scaling of all incomes; they are homogeneous of degree zero in all incomes.

Similar distinctions can be (and have been) made in the bipolarization literature. Chakravarty et al. (2007) discuss how the second-order bipolarization curve of Foster and Wolfson (2010/1992) can be made absolute, in the sense of being invariant to translations of every income by the same amount. Integrating the area under this absolute curve leads to an absolute version of the relative bipolarization index of Foster and Wolfson (2010/1992). The absolute inequality indices of the Kolm (1969) and Donaldson and Weymark (1980) types can also be used to weight the sums of absolute distances from the median.

Chakravarty and D'Ambrosio (2010) furthered these distinctions by defining intermediate bipolarization indices, namely, bipolarization indices that generate as special cases absolute and relative bipolarization indices. More precisely, we may want a distribution of income y and a distribution $y + c[\gamma y + (1-\gamma)]$ to exhibit the same level of bipolarization, where $c > 0$ is a scalar. This implies that it is the distances $S(p)m/(\gamma m + (1-\gamma))$ that must be aggregated in the measurement of bipolarization. The bipolarization curves of Equations (5.12) and (5.13) then become intermediate polarization curves and are given by

$$\mathrm{IS}(p, \gamma) = \frac{S(p)}{\gamma + (1-\gamma)/m} \tag{5.24}$$

and

$$\mathrm{IB}(p, \gamma) = \frac{B(p)}{\gamma + (1-\gamma)/m}. \tag{5.25}$$

When $\gamma = 0$, an absolute polarization curve is obtained; $\gamma = 1$ yields a relative polarization curve. These curves can be used to derive an intermediate polarization index analogous to that of Foster and Wolfson (2010/1992), given by the area below the intermediate bipolarization curve. This yields:

$$\mathrm{IFW} = \frac{\mathrm{FW}}{\gamma + (1-\gamma)/m}. \tag{5.26}$$

The intermediate polarization index IFW becomes an absolute index if $\gamma = 0$ and a relative one if $\gamma = 1$.

We may also wish distributional rankings to remain invariant to the choice of measurement units. This invariance property (known as unit consistency) does not require indices to be invariant to changes in monetary units (such as cents or dollars); it only requires the distributional orderings not to be affected by such changes. The implications of such a property for the measurement of bipolarization are explored in Lasso de la Vega et al. (2010), following Zheng (2007) for the measurement of inequality. The results make use of Krtscha-type (Krstcha, 1994) intermediate polarization indices, indices that rank polarization identically across distributions A and B if and only if

$$\frac{Q_{\mathrm{A}}(p) - m_{\mathrm{A}}}{m_{\mathrm{A}}^{\gamma}} = \frac{Q_{\mathrm{B}}(p) - m_{\mathrm{B}}}{m_{\mathrm{B}}^{\gamma}} \quad \text{for all } p. \tag{5.27}$$

$\gamma \in [0,1]$ can be regarded as a degree of bipolarization intermediateness. The extreme values of γ equal to 0 and 1 correspond to absolute and relative polarization measures and orderings. Krtscha-type bipolarization orderings can then be made on the basis of $m^{(1-\gamma)}S(p)$. Lasso de la Vega et al. (2010) show that the only type of bipolarization orderings that are unit consistent are those of the Krtscha type.

5.5.8 Bipolarization with Ordinal Data

It is not difficult to think of applications of bipolarization to contexts in which the welfare variable is discrete and ordinal. Examples of such variables include education, class, and positional statuses as well as health indicators. Although such indicators have ordinal content (values of the variables can be ranked), the fact that they are not cardinal makes it difficult to mean or median normalize them, as is typically done for inequality analysis.

It may, however, still be possible to compare the extent of bipolarization over distributions of such variables. An example of such an exercise is found in Apouey (2007) for distributions of discrete and ordinal self-assessed health (SAH) data.[12] It is first assumed that a distribution exhibits no bipolarization when everybody has the same health condition, and that a distribution exhibits maximal polarization if half the population has the lowest SAH indicator and the other half has the highest one. It is then assumed that bipolarization can be expressed as the sum of the distances $|F(i) - 0.5|$ for each level of category i, $i = 1, \ldots, n$, ranked from lowest to highest values.

[12] See also Chakravarty and Maharaj (2013) for a related setting that uses generalized Gini indices.

It is then shown that

$$\mathrm{Apo}(\eta, F) = K\left[(0.5)^{\eta} - \frac{1}{n-1}\sum_{i=1}^{n-1}|F(i) - 0.5|^{\eta}\right], \tag{5.28}$$

where K is a strictly positive constant and $\eta > 0$ is the weight on the median category, which is the only bipolarization measure that satisfies a population invariance axiom and an increasing spread axiom. Bipolarization is maximal when $F(i) = 0.5$ for all $i < n$. An axiom of increased bipolarity is obeyed if and only if $\eta \in]0, 1[$ and therefore if $\mathrm{Apo}(\eta, F)$ is convex in $F(i)$.

Movements of $F(i)$ away from 0.5 increase bipolarization more if $F(i)$ is initially close to 0.5. An increase in bipolarity moves values of $F(i)$ close to 0.5 away from it and moves more extreme values of $F(i)$ closer to 0.5. Such an increase in bipolarity thus increases bipolarization.

5.6. SOCIAL POLARIZATION

5.6.1 Concepts and Motivation

Social polarization arises when people are clustered according to social characteristics and feel alienated from others that do not share these characteristics. The term is used when the factors that determine individuals' identity are culturally, ideologically, historically, biologically, or socially driven and do not depend solely on their income levels. Religion, race, ethnicity, language, education, and occupation are examples of characteristics along which society may be polarized. The study of social polarization is usually motivated by the view that, in many circumstances, income may not be the only relevant (or even be a relevant) dimension that might nourish identity and differences and thus generate conflict, as suggested by Esteban and Ray (1994), Montalvo and Reynal-Querol (2005b), Collier and Hoeffler (2004), and Easterly and Levine (1997), among many others. This has led to the relatively recent development of several social polarization measures, such as those of Reynal-Querol (2002), Apouey (2007), Permanyer (2010), and Permanyer and D'Ambrosio (2013). These are particularly useful in those contexts in which cardinal data are not available and in which polarization must be built on the basis of qualitative and nonordinal variables.

Religion may be seen as one of the most important of these qualitative characteristics. Reynal-Querol's (2002)—RQ—contention, for instance, is that religiously divided societies are more prone to intense conflicts because religious identity is fixed and nonnegotiable. She analyzed the effect of ethnic division on civil war as well as the role of political systems in preventing these conflicts, using the importance of religious polarization and animist diversity.

Others have focused on ethnic diversity to attempt to explain economic and social phenomena such as growth, investment, government efficiency, civil wars, and unemployment. Easterly and Levine (1997) explained part of the poor economic performance in Africa by the relatively high level of ethnic fragmentation found on the continent. Montalvo and Reynal-Querol (2002) argued that ethnic diversity leads to the choice of poor public policies and a poor design of human/physical capital accumulation in particular, which has a negative influence on long-run growth and encourages rent seeking. Mauro (1995) also contends that ethnic fractionalization increases corruption and political instability and decreases investment. Because corruption has a negative impact on investment, he concluded that ethnic diversity undermines growth, a view shared by Porta et al. (1999).

5.6.2 Measurement

To see how social polarization is measured in the literature, let us first recall the Esteban and Ray (1994) index of Equation (5.2):

$$\mathrm{ER}(\alpha, \mathbf{F}) = K\sum_{i=1}^{n}\sum_{j=1}^{n}\pi_i^{1+\alpha}\pi_j|y_i - y_j|. \tag{5.29}$$

In the case of social polarization, where income plays no role and where each person is identified with every other member of the group, the alienation function assumes values that are specific to group pairs and have no relationship to income. Denoting this alienation value by δ_{jk} for a pair of groups j and k, Duclos et al. (2004) suggested a natural simplification of the ER and DER polarization measures as:

$$\mathrm{DER_S}(\alpha, \mathbf{F}) = \sum_{j=1}^{N}\sum_{k=1}^{N}\pi_j^{1+\alpha}\pi_k\delta_{jk}. \tag{5.30}$$

Substituting the Euclidean distance $\delta(y_i, y_j) = |y_i - y_j|$ by the discrete distance

$$\delta(y_i, y_j) = \begin{cases} 0 & \text{if } y_i = y_j \\ 1 & \text{if } y_i \neq y_j, \end{cases} \tag{5.31}$$

a social polarization index is defined to be proportional to

$$\mathrm{DP}(\alpha, \mathbf{F}) = \sum_{i=1}^{n}\sum_{j\neq i}^{n}\pi_i^{1+\alpha}\pi_j \tag{5.32}$$

with $\alpha \in [0, \infty[$. Alienation is thus set to zero between individuals belonging to the same group and to one between individuals belonging to different social groups. Each value of α leads to a different social polarization index. Restricting the range of these values can be done using two axioms reminiscent of those in Esteban and Ray (1994).

Axiom MRQ 1

Let there be three population groups of sizes p, q, and r where $p > q \geq r$. If the two smaller groups are merged to form one new group with size $\widetilde{q} = q + r$, then polarization increases.

Montalvo and Reynal-Querol (2002) (see also Montalvo and Reynal-Querol, 2005a,b, 2008) show that the social polarization index $\mathrm{DP}(\alpha, \mathbf{F})$ satisfies Axiom MRQ 1 if and only if $\alpha \geq 1$. The importance of the identification effect must indeed be sufficiently strong. The impact of the disappearance of one group reduces the number of pairs of alienated groups; for $\alpha \geq 1$, this is offset by the identification effect of the formation of a larger group.

Axiom MRQ 2

Let the population be split into three groups of sizes p, q, and p. If there is an equal movement of the population from group q to the two other groups, then polarization increases.

The only social polarization index $\mathrm{DP}(\alpha, \mathbf{F})$ that satisfies Axiom MRQ 2 is the one with $\alpha = 1$. $\mathrm{DP}(1, \mathbf{F})$ is the Reynal-Querol (2002) polarization index:

$$\mathrm{RQ} = 1 - \sum_{i=1}^{n} \frac{(0.5 - \pi_i)^2 \pi_i}{0.25} = 4 \sum_{i=1}^{n} \sum_{j \neq i}^{n} \pi_i^2 \pi_j. \tag{5.33}$$

As shown in Equation (5.33), the RQ index was originally motivated and interpreted as one minus the average of the squared distances of group sizes from 0.5. In that formulation, the simple distribution of two equal-size groups is implicitly considered as the one with the most social polarization. Taking the square of the distances of group sizes from 0.5 captured the gap between group sizes and the symmetric two-group distribution. An increase in the number of groups or spreads of group sizes from 0.5 leads to lower social polarization.

Apart from fulfilling Axioms MRQ 1 and MRQ 2, the RQ index has two additional interesting properties. With four groups, minimum social polarization is obtained when groups are all of the same sizes. Second, with n groups of equal relative size $1/n$, social polarization decreases monotonically with n (see Figure 5.19).

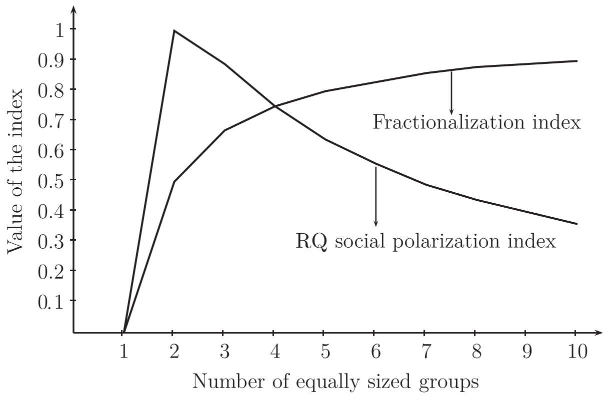

Figure 5.19 Fractionalization (FRAC) and social polarization (RQ) indices as a function of a number of equally sized groups. *Source: Montalvo and Reynal-Querol (2008).*

Chakravarty and Maharaj (2011b) also characterized the Reynal-Querol (2002) index of social polarization using alternative sets of independent axioms. Chakravarty and Maharaj (2012) further showed how a graph of cumulative population shares against the cumulative number of groups (ranked from the largest to the smallest ones) can rank some classes of social polarization indices of an RQ type and propose in the process a "generalized RQ index of order θ" given by

$$\mathrm{RQ}(\theta) = 4\sum_{i=1}^{n} \pi_i^2 (1-\pi_i) + \theta \sum_{1\le i_1<i_2<i_3\le n} \pi_{i_1}\pi_{i_2}\pi_{i_3}, \tag{5.34}$$

where $\theta \in [0,3]$ and $n \geq 3$. RQ(0) is the usual RQ index.

Much of the literature prior to Montalvo and Reynal-Querol (2002) has attempted to explain conflict through a social (often an ethnolinguistic) fragmentation index of the form:

$$\mathrm{FRAC} = 1 - \sum_{i=1}^{n} \pi_i^2. \tag{5.35}$$

The FRAC index, which is the complement to unity of the Hirschman–Herfindahl index (see Herfindahl, 1950; Hirschman, 1980), can be interpreted as the probability that two persons randomly drawn from a given society will not belong to the same social group. The probability that two randomly drawn individuals belong to the same group i is indeed π_i^2; one minus the sum of those probabilities across all groups gives FRAC.

The fractionalization index can also be derived from the Gini index, which is proportional to $\mathrm{ER}(0, \mathbf{F})$ in Equation (5.29). Replacing the Euclidean distance $|y_i - y_j|$ by the discrete distance in Equation (5.31), we obtain

$$\mathrm{DP}(1, \mathbf{F}) = \sum_{i=1}^{n} \sum_{j\neq i}^{n} \pi_i \pi_j = 1 - \sum_{i=1}^{n} \pi_i^2 = \mathrm{FRAC}. \tag{5.36}$$

Which of FRAC or of RQ should be a better predictor of conflicts has been a matter of debate. The distinction between the two is analogous to that between inequality and polarization. Horowitz (1985) argued that there should be less violence in highly homogeneous and highly heterogeneous societies and more conflict in societies in which a large ethnic minority coexists with an ethnic majority. An increase in social heterogeneity should initially increase potential conflict, but after some point, greater diversity should eventually imply lower potential for conflicts—see also Colomer (2001) and Collier and Hoeffler (2004). If this is correct, then an index of social polarization should capture the likelihood of conflict, or the intensity of potential conflict, better than an index of fractionalization.

The empirical literature provides some support to this view. Collier and Hoeffler (2004) found that religious fractionalization has no effect on the risk of conflict.

Montalvo and Reynal-Querol (2003, 2008) found little empirical evidence of an effect of fractionalization on growth, but did report an important effect of religious and ethnic polarization on civil wars, investment, and the share of government consumption out of GDP, and thus on growth. Evidence showing that fractionalization is a better predictor of conflict can nevertheless be found in Alesina et al. (2003).

One way to understand better the distinction between indices of social polarization and indices of fractionalization is to consider two populations A and B, each composed of three different groups (this example is discussed in Montalvo and Reynal-Querol, 2002). The sizes of the groups in population A are given by (0.49, 0.49, and 0.01) and the sizes in population B are given by (0.33, 0.33, and 0.34). Which of these two populations is more likely to witness conflict? Fractionalization is higher in B; social polarization is larger in A. The likelihood of two individuals belonging to two different groups is indeed larger in B, but A is closer to a distribution with two equal-size groups, and thus closer to maximal social polarization.

The index of fractionalization increases whenever two-group sizes are equalized; the RQ of social polarization index increases only when these two groups are relatively large ones. The value of α in $\mathrm{DP}(\alpha, \mathbf{F})$ cannot exceed 1, however, because with $\alpha > 1$ $\mathrm{DP}(\alpha, \mathbf{F})$ does not monotonically increase in moving from (0, 1, and 0) toward (0.5, 0, and 0.5)—and $\mathrm{DP}(\alpha, \mathbf{F})$ thus fails Axiom MRQ 2 when $\alpha > 1$.

The issue echoes the discussion of Axiom MRQ 2 on given earlier. If we shift population mass from one group equally to two other groups of equal size, then the axiom says that social polarization should increase. As mentioned earlier, the only admissible value of α for a $\mathrm{DP}(\alpha, \mathbf{F})$ measure to satisfy that axiom is 1. With $\alpha = 0$ in particular, fractionalization is not maximized with a distribution of two equal-sized groups; in fact, FRAC increases monotonically with n when n is the number of groups with equal relative sizes given by $1/n$ (Figure 5.19).

5.7. SOCIOEONOMIC POLARIZATION

5.7.1 Between- and Within-Group Income Inequality

The inequality literature has long used social characteristics to decompose income inequality. Based on this, Zhang and Kanbur (2001) suggested using that within-group inequality to capture internal heterogeneity and between-group inequality to measure external heterogeneity. They proposed the ratio of between-group inequality to within-group inequality as the following socioeconomic polarization index[13]:

[13] Chakravarty and Maharaj (2011a) considered generalized forms and orderings of polarization indices based on such between- and within-group inequality terms—see also Chakravarty et al. (2010).

$$\text{ZK} = \frac{\text{between-group inequality}}{\text{within-group inequality}}. \tag{5.37}$$

Obvious candidates of inequality indices for this kind of exercise are the generalized entropy indices that are well known to be exhaustively decomposable into between- and within-group components.[14] As within-group income differences decline, that is, as the groups become internally more equal (though not necessarily more identified, see the following discussion), differences across groups are, relatively speaking, magnified, and polarization rises. For given within-group differences, however, polarization increases as the group means drift apart and between-group inequality increases.

The use of within-group inequality to capture internal homogeneity is not compatible with the identification framework in the income polarization literature. To see why, consider Figure 5.18, which was discussed earlier. Think of two groups each being formed by two subgroups on the same side of the median line. As shown in the figure, a split of the two right-hand side groups increases internal homogeneity and therefore decreases within-group inequality. According to Equation (5.37), that should increase polarization, though this is not what the identification/alienation framework would necessarily conclude.

Another feature of socioeconomic polarization is that it may conflict with income polarization and income bipolarization, in part because socioeconomic polarization does not use income to form social groups. The presence of identical groups can lead to indices such as ZK to show no socioeconomic polarization, although the income distribution may exhibit any level of income polarization and bipolarization. In Figure 5.23, for instance, there may be no socioeconomic polarization, but substantial income polarization.

5.7.2 Identification/Alienation Hybrids

Several hybrids of the identification/alienation indices can be accommodated, using the idea that identification can be mediated not only by group membership, but also by income similarities as well, whereas the antagonism function remains defined on income differences. Duclos et al. (2004) proposed, for instance, a "social polarization index with income-mediated identification":

$$\text{DER}_{\text{H1}} = \sum_{i=1}^{n} (1 - n_i) \int_x f_i(y)^{\alpha} \mathrm{d}F_i(y) \tag{5.38}$$

where α is the usual parameter of polarization sensitivity.

[14] Deutsch and Silber (2010) used between- and within-group components of the Gini index to measure socioeconomic polarization.

Another hybrid considers alienation as well as identification in terms of income mediation; two individuals must belong to different groups and have different incomes to experience alienation. The polarization measure that is obtained is:

$$\mathrm{DER}_{\mathrm{H2}} = \sum_{j=1}^{n}\sum_{k\neq j}^{n}\int_x\int_y f_j(x)^{\alpha}|x-y|\mathrm{d}F_j(x)\mathrm{d}F_k(y). \tag{5.39}$$

Alienation uses income distances; identification is based on income and social characteristics alike.

Permanyer (2010) presented two axiomatically characterized socioeconomic polarization indices incorporating a variable alienation component. The focus is first on between-group alienation only and subsequently on within-group alienation as well. The starting point is the identification–alienation framework.

Assume that there are n exogenous social groups (based on religious, ethnic, or political characteristics, for instance) that can possibly inform an individual's sense of identity. Each individual also feels a degree of "radicalism" $y > 0$. Radicalism is defined by the degree with which an individual defends the identity/interests/objectives of his or her group. Radicalism serves two purposes. First, y measures the strength with which individuals compare themselves with others in different social groups. Second, y can fuel an individual's sense of identity/difference toward others in the same social group.

Thus, there are two potential sources of identification and two potential bases for alienation. Identification can depend either solely on the size of one's social group or on both the size of that group and on the degree of radicalism felt by individuals within that group. Alienation is felt toward those members of the other social groups, with an intensity given by the sum of the radicalism felt by individuals of different groups; different degrees of radicalism among individuals of the same group can also fuel alienation across members of that same group.

This setting is a departure from the income polarization and social polarization frameworks. Unlike income polarization, identity can be a function both of income and of membership into a social group, and there may or may not be alienation between members of a same group. Unlike social polarization, identity can be fueled by the degree to which members associate with the interests of their group, and not only by pure membership in the group; the intensity of alienation can also be permeated by that same degree of radicalism.

The alienation–identification framework is then adopted in Permanyer (2010), first by assuming that there is no within-group alienation. Identity depends only on group size n_i. Individuals feel perfectly identified with all the members of their own group—the groups are cohesive and membership into them is sufficient for defining individuals' sense of identity. Alienation across members of two different groups with radicalism x and y is defined as being a monotonically increasing function of the sum of radicalism, $x + y$. The higher the force with which individuals defend the interests of their group, the higher the animosity felt toward individuals of a different group; the sum of radicalism thus appears as a measure of tension between individuals of different groups. This is a departure from the usual alienation framework, in which distances (and not sums) capture alienation.

Using the expressions for alienation and identification, we then have

$$\mathrm{Per}(\mathbf{f}) = \sum_{i=1}^{n} \sum_{j \neq i}^{n} \int\int T(n_i, x+y) f_i(x) f_j(y) \mathrm{d}y \mathrm{d}x. \tag{5.40}$$

The rest of the analysis follows broadly the axiomatic framework of Duclos et al. (2004). Three axioms on movements of densities within and across groups and an additional population invariance axiom are imposed. Figure 5.20 illustrates the first axiom.

Consider a given group divided into two subgroups, the bigger one with a lesser degree of radicalism and the smaller subgroup with a greater degree of it. If these subgroups respectively increase and decrease their degrees of radicalism by the same amount, then the average degree of radicalism within the group increases. The first axiom (a within-group axiom) says that this should raise overall social economic polarization. It also implies that T is concave in $x+y$.

The second axiom is based on the net effect of a smaller group becoming less radical and of a bigger group becoming more radical. This is shown in Figure 5.21. This second axiom (a between-group axiom) says that the effect of the increase in radicalism in the bigger group should dominate the impact of the fall of radicalism in the second group; polarization should not decrease. It also implies that T is convex in $x+y$.

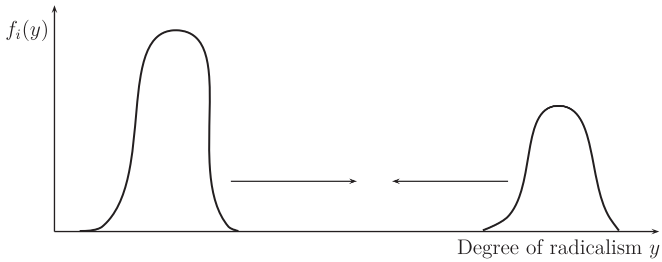

Figure 5.20 A slide of basic densities within a group increases socioeconomic polarization.

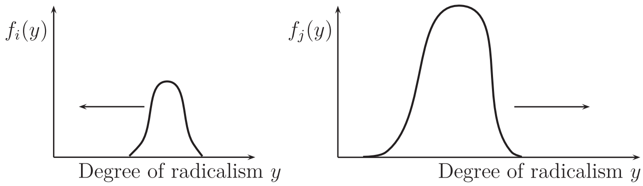

Figure 5.21 A smaller group becoming less radical and a bigger group becoming more radical does not decrease socioeconomic polarization.

The third axiom says that a movement of population from a large group to two equally smaller groups, with the same normalized density, should not decrease polarization. This implies that the identification effect should not be too large (and therefore imposes and upper bound on α in Equation (5.41)). An equalization of population sizes across these three groups with the same distribution of radicalism will thus generate more socioeconomic polarization than if one group dominates size. Added to the usual population invariance property, this necessarily leads to the index:

$$\mathrm{Per}(\alpha, \mathbf{F}) = \sum_{i=1}^{n} \sum_{j \neq i}^{n} \pi_i^{1+\alpha} \pi_j \left(\mu_i + \mu_j \right), \tag{5.41}$$

where $\alpha \in (0, 1]$. This measure of socioeconomic polarization generalizes the social polarization $\mathrm{DP}(\alpha, \mathbf{F})$ (and thus also the RQ index). Instead of setting alienation between groups to a constant, it is made sensitive to the size of radicalism and to different possible levels of animosity between groups. If the means μ_i are identical for all groups, then $\mathrm{Per}(\alpha, \mathbf{F})$ simplifies to a proportion of $\mathrm{DP}(\alpha, \mathbf{F})$. In the particular case of $\alpha = 0$, $\mathrm{Per}(\alpha, \mathbf{F})$ is generalization of the fractionalization index FRAC, and it simplifies to the classical fractionalization index when $\mu_i = \mu_j, \forall\, i \neq j$. The value of α has the same interpretation as the polarization sensitivity parameter in Esteban and Ray (1994); the larger it is, the greater the departure from (socioeconomic) inequality.

The lower bound of α in Equation (5.41) can be set above zero if we require polarization to fall as a number n of identical groups (with relative size $1/n$) increases, thus differentiating socioeconomic polarization from fractionalization and inequality. Permanyer (2010) then showed that the lower bound of α becomes $(2 - \log_2 3)/(\log_2 3 - 1) = 0.71$.

The preceding ignores within-group alienation in socioeconomic polarization. Alienation may exist between members of the same group if levels of radicalism differ; within a group, radical members may alienate the more moderate members and vice versa. Permanyer (2010) adapted this by letting between-group alienation be measured by a monotonically increasing function in $x + y$, but by supposing within-group alienation to be measured by a monotonically increasing function in $|x - y|$, as is usual in the identification/alienation framework. Under this setting, total polarization becomes

$$\begin{aligned} \mathrm{Per}(\mathbf{f}) = {} & \sum_{i=1}^{n} \int\!\!\int T(f_i(x), |x - y|) f_i(x) f_i(y)\, \mathrm{d}y\, \mathrm{d}x \\ & + \sum_{i=1}^{n} \sum_{j \neq i}^{n} \int\!\!\int T(f_i(x), x + y) f_i(x) f_j(y)\, \mathrm{d}y\, \mathrm{d}x. \end{aligned} \tag{5.42}$$

The first component on the right-hand side of Equation (5.42) represents the contribution of within-group polarization and the second component is the contribution of between-group polarization. Within- and between-group components are summed to obtain total polarization.

Using population invariance axioms similar to Axioms DER 2 and DER 3 and a "socioeconomic polarization axiom" that says that a population transfer across two initially identical groups should lower polarization, the index becomes

$$\mathrm{Per}(\alpha, \mathbf{f}) \equiv \sum_{i=1}^{n} \int\int f_i^{1+\alpha}(x) f_i(y)|x-y|\mathrm{d}y\mathrm{d}x + \sum_{i=1}^{n}\sum_{j\neq i}^{n} \int\int f_i^{1+\alpha}(x) f_j(y)(x+y)\mathrm{d}y\mathrm{d}x \tag{5.43}$$

with $\alpha \in [1/(3n-2), 1]$, or with $\alpha \in [0.5, 1]$ if we require polarization to fall as a number of identical groups increases.

Social polarization and income polarization do not deal with situations in which a society may be partitioned with respect to several variables, some of a social and others of an economic type. Consider, for instance, the case in which individuals may be male or female and may enjoy different health statuses. This is illustrated in Figures 5.22 and 5.23. In the usual social and income polarization settings, the situation in which all males (represented by the dark areas) have very poor heath and all females (represented by the white rectangles) have very good heath (Figure 5.22) leads to the same degree of polarization (and bipolarization) as the one (Figure 5.23) in which half of males and half of females have very poor heath and the other halves very good health. This is because income polarization does not take into account the effect of segregation by social

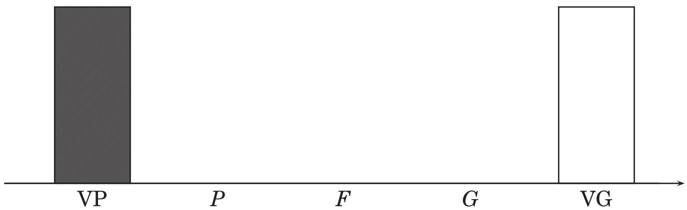

Figure 5.22 A hypothetical distribution of health statuses across two different social groups (males and females)—the initials stand for: very poor (VP), poor (P), fair (F), good (G), and very good (VG). *Source: Permanyer and D'Ambrosio (2013).*

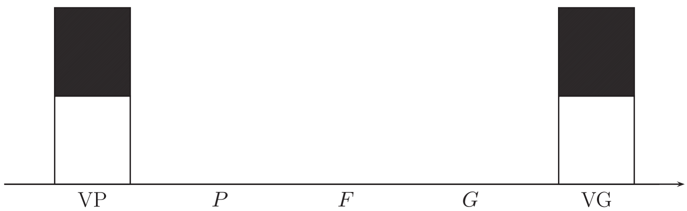

Figure 5.23 A hypothetical distribution of health statuses across two different social groups (males and females)—the initials stand for: very poor (VP), poor (P), fair (F), good (G), and Very Good (VG). *Source: Permanyer and D'Ambrosio (2013).*

characteristics and because social polarization does not consider distances in welfare across groups. It seems plausible, however, that the situation in Figure 5.22 may exhibit more tension and more polarization than the second, in which males and females are mixed in health status. Polarization should therefore presumably be sensitive to the joint distribution of social groups and of welfare statuses.

Permanyer and D'Ambrosio (2013) pursued this issue by first partitioning the population of individuals into exogenously given groups. Members of a given group identify with their peers within their group but feel alienated from all others. Identification for members of a particular group i depends on the size of the group to which they belong (n_i). Identification is a function only of group sizes. Alienation is assumed to be the same for every member of a particular group; between-group rather than between-individual alienation matters.

Alienation is captured by an overlap measure. This is different from the usual distance-based definition of alienation. Let $\theta_{i,j}$ be an overlap coefficient between groups i and j in a context of categorical welfare data, with C categories, and where $\pi_i(y_c)$ is the proportion of individuals in group i that have a level of welfare equal to y_c:

$$\theta_{i,j} = \sum_{c=1}^{C} \min\left\{\pi_i(y_c), \pi_j(y_c)\right\}. \tag{5.44}$$

Alternatively, with a continuous welfare variable y, we have:

$$\theta_{i,j} = \int \min\left\{\bar{f}_i(y), \bar{f}_j(y)\right\} \mathrm{d}y, \tag{5.45}$$

where $\bar{f}_i(y)$ is the normalized density of group i over welfare y. Hence, in capturing alienation, it is not distances that matter but rather the importance of the clustering of groups in certain areas of a welfare domain. This is different from social and income polarization. By Equations (5.44) and (5.45), $0 \leq \theta_{i,j} \leq 1$. When groups are disjoint, $\theta_{i,j} = 0$, and when groups overlap perfectly, $\theta_{i,j} = 1$. Alienation is defined by $1 - \theta_{i,j}$, which equals 1 in the case of completely disjoint groups and 0 in the case of perfectly overlapping groups.

Following the identification–alienation framework of Esteban and Ray (1994), polarization can be defined as the sum of all effective antagonisms, that is, as

$$\mathrm{PD_S} = \sum_{i=1}^{n} \sum_{j=1}^{n} n_i n_j T\left(n_i, 1 - \theta_{ij}\right). \tag{5.46}$$

Using axioms similar to Duclos et al. (2004) but adapted to a socioeconomic setting with multiple social groups, Permanyer and D'Ambrosio (2013) found that a socioeconomic polarization index of the form Equation (5.46) should be proportional to

$$\mathrm{PD_S} \equiv \sum_{i=1}^{n} \sum_{j=1}^{n} \pi_i^{1+\alpha} \pi_j \left(1 - \theta_{ij}\right), \tag{5.47}$$

where the degree of polarization sensitivity α lies within $[\alpha^*, 1]$, with $\alpha^* = (2 - \log_2 3)/(\log_2 3 - 1) = 0.71$.

A socioeconomic extension of Esteban et al.'s (2007) income polarization index is provided in Gradín (2000). The extension uses both income distribution and social differences to form groups, in contrast to the $\mathrm{EGR}(\alpha, \sigma, \mathbf{F})$ for which groups are determined on the basis of income differentials. The objective is essentially to assess by how much social polarization correlates with income polarization; the greater the correlation, the greater the polarization association between income and social characteristics.

The first socioeconomic polarization index (called "group polarization") considers a population of n subgroups defined on the basis of social characteristics, such as education level, skin color, gender, race, region, and so on, rather than income, as for the ER and EGR indices. The socioeconomic grouping induces a partitioning of the income distribution given by $\mathbf{F}^{\mathrm{g}}$. This leads to a socioeconomic polarization index given by

$$\mathrm{EGR}(\alpha, \sigma, \mathbf{F}^{\mathrm{g}}) = \mathrm{ER}(\alpha, \mathbf{F}^{\mathrm{g}}) - \sigma\epsilon(\mathbf{F}^{\mathrm{g}}). \tag{5.48}$$

This social categorization of the population leads to lower between-group income dispersion and higher within-group heterogeneity than the "optimal" EGR income partitioning $\mathbf{F}^*$. $\mathrm{EGR}(\alpha, \sigma, \mathbf{F}^{\mathrm{g}})$ is thus expected to be lower than $\mathrm{EGR}(\alpha, \sigma, \mathbf{F}^*)$. The lower the difference between these two expressions, the greater the ability of social groupings to explain income polarization.

Gradín (2000) also proposed an alternative measure of the association between income polarization and socioeconomic polarization (called "explained polarization"). To see how, consider $n+1$ income cutoffs $z = z_0, z_1, \ldots, z_n$ and the set of groups $\phi_j = \{i | m_i \in [z_{j-1}, z_j]\}$ (for $j = 1, \ldots, n$) made of those social groups i whose average income lies in $[z_{j-1}, z_j]$. $\mathbf{F}^{\mathrm{e}}$ then has elements given by $F_j^{\mathrm{e}}(y) = \sum_{i \in \phi_j} F_i(y)$. $\mathbf{F}$ is a partition of the population according to social characteristics $i = 1, \ldots, n$; $\mathbf{F}^{\mathrm{e}}$ is a repartition of that partition that reclassifies individuals according to the mean income of the group to which they belong along the thresholds $z = z_0, z_1, \ldots, z_n$; and the movement from $\mathbf{F}$ to $\mathbf{F}^{\mathrm{e}}$ is an economic reordering of social groups. $\mathrm{EGR}(\alpha, \sigma, \mathbf{F}^{\mathrm{e}})$ is then the level of polarization with socioeconomic grouping $\mathbf{F}^{\mathrm{e}}$.

Given this, we may wish to compute how much of income polarization can be explained by $\mathbf{F}^{\mathrm{e}}$. Gradín (2000) did this by defining a ratio of explained polarization given by:

$$\mathrm{EP}(\alpha, \beta, \mathbf{F}, \mathbf{F}^{\mathrm{e}}) = \frac{\mathrm{EGR}(\alpha, \beta, \mathbf{F}^{\mathrm{e}}) - \mathrm{EM}(\mathbf{F}^{\mathrm{e}})}{\mathrm{EGR}(\alpha, \beta, \mathbf{F}) - \mathrm{EM}(\mathbf{F})} \tag{5.49}$$

where EM is EGR when there is no between-group heterogeneity.

5.8. MULTIDIMENSIONAL POLARIZATION

Gigliarano and Mosler (2009) constructed multivariate socioeconomic polarization indices on the presumption that polarization should capture internal homogeneity, external heterogeneity, and similarity of group sizes. Compared to Zhang and Kanbur (2001), the measurement of group homogeneity and heterogeneity is refined by using multivariate distances. Multivariate decomposability into intragroup and intergroup components of inequality is then used to construct multidimensional polarization indices.

To see how, consider a distribution of N individuals along C types of endowments, represented by a matrix $\mathbf{X}$

$$\mathbf{X}=\begin{bmatrix} x_{11} & x_{12} & \cdots & x_{1C} \\ x_{21} & x_{22} & \cdots & x_{2C} \\ \vdots & & \ddots & \vdots \\ x_{N1} & x_{N2} & \cdots & x_{NC} \end{bmatrix}_{N\times C}$$

where x_{iq} denotes the endowment q of individual i. Using inequality decomposition, the multidimensional polarization index is given by:

$$\mathrm{GM}(\mathbf{X})=\zeta[\mathrm{GB}(\mathbf{X}),\mathrm{GW}(\mathbf{X}),S(\mathbf{X})], \tag{5.50}$$

where GB and GW are multivariate indices that measure inequality between and within groups, respectively, and where ζ is a function that is increasing in GB and S and is decreasing in GW. $S(\mathbf{X})$ is a measure of deviation from equally sized groups; it is maximal if all groups are of the same size. Particular forms of this index are given by

$$\mathrm{GM}_1(\mathbf{X})=\phi\left[\frac{\mathrm{GB}(\mathbf{X})}{\mathrm{GW}(\mathbf{X})+c}\right]S(\mathbf{X}), \tag{5.51}$$

$$\mathrm{GM}_2(\mathbf{X})=\psi[\mathrm{GB}(\mathbf{X})-\mathrm{GW}(\mathbf{X})]S(\mathbf{X}), \tag{5.52}$$

$$\mathrm{GM}_3(\mathbf{X})=\tau\left[\frac{\mathrm{GB}(\mathbf{X})}{\mathrm{GB}(\mathbf{X})+\mathrm{GW}(\mathbf{X})+c}\right]S(\mathbf{X}), \tag{5.53}$$

with constant c being positive and possibly dependent on the choice of indices GB and GW The functions ϕ, ψ, and τ are assumed to be continuous and strictly increasing, with $\phi(0)=\tau(0)=0$. These forms were subsequently developed by Gigliarano and Mosler (2009) using additively decomposable multivariate inequality measures. Similar procedures are proposed for multiplicatively decomposable inequality measures. Equation (5.51) is similar to Zhang and Kanbur (2001) except for the explicit role of group sizes $S(\mathbf{X})$ and for the fact that $\mathbf{X}$ is a matrix. Equation (5.52) is similar to the Foster and Wolfson (2010/1992) bipolarization measure with below and above median groups—although the definition of a "median frontier" in a multidimensional setting is not immediate.

Two alternative multivariate polarization indices with special relevance to the case of a population split into two groups are proposed in Anderson (2010). When these two groups are made of poor and nonpoor individuals, these indices can be used as multivariate relative poverty measures based on distances between them. Consider then a population composed of two groups: the poor and the nonpoor. They are assumed to be distributed according to two continuous multivariate unimodal distributions: $f_{\mathrm{p}}(\mathbf{x})$ for the poor and $f_{\mathrm{r}}(\mathbf{x})$ for the nonpoor, where $\mathbf{x}$ is a $1 \times C$ vector of characteristics. An "overlap" measure is defined as:

$$\mathrm{OV} = \int_{\mathbf{x}} \min \left\{ f_{\mathrm{p}}(\mathbf{x}) f_{\mathrm{r}}(\mathbf{x}) \right\} \mathrm{d}\mathbf{x}. \tag{5.54}$$

This is a multidimensional extension of the overlap measure of Equation (5.45). Assessing the degree of polarization between two groups when individuals have many characteristics amounts in this formulation to capturing the degree of commonality between the two distributions.

Anderson (2010) proposed an alternative index that can be used when attributes are mutually exclusive and do not overlap. Let $\mathbf{x}_{\mathrm{mp}}$ and $\mathbf{x}_{\mathrm{mr}}$ be the value of the characteristic vector at the modal point of the poor and the nonpoor distributions, respectively. The index is the area of the trapezoid formed by the modal peaks of the densities and the mean normalized Euclidean distance between these two points. Let μ_q be the mean of the q th characteristic in the pooled population. When the poor and nonpoor distributions are separately identified in C dimensions, multidimensional polarization is written as:

$$\mathrm{BIPOL_I} = 0.5\left[f_{\mathrm{p}}\left(\mathbf{x}_{\mathrm{mp}}\right) + f_{\mathrm{r}}\left(\mathbf{x}_{\mathrm{mr}}\right)\right] \frac{1}{\sqrt{C}} \sqrt{\sum_{q=1}^{C} \frac{\left(x_{\mathrm{mpq}} - x_{\mathrm{mrq}}\right)^2}{\mu_q}}. \tag{5.55}$$

This can be interpreted as a multivariate relative poverty index without formal poverty frontiers, the index being based on distances between two identified groups, poor and nonpoor. Note, however, that two distributions of the poor and nonpoor may not be separately identified, in which case it may be difficult to apply an index like Equation (5.55). Unique modal distances may also not exist between the poor and the nonpoor. Even if they exist, it is not clear that they would necessarily be appropriate measures of deprivation over the entire distributions: Many different multivariate distributions can exhibit similar distances between such modes but may yet represent quite different allocations of welfare across the poor and the nonpoor.

A multidimensional extension of DER's identification/alienation framework can also be designed. A natural procedure for that is found in Anderson (2011). The extension is multidimensional in the sense that both identification and alienation depend on the joint distribution of multiple socioeconomic attributes. The multivariate distribution can also be defined over a collection of both discrete and continuous variables.

To see how, let $\mathbf{u}_i$ and $\mathbf{v}_j$ be stacked vectors of continuous and discrete variables, with dimension k (for the continuous variables) and h (for the discrete variables) and for individuals i and j, respectively. A multivariate polarization index taking into account both continuous and discrete variables is then given by

$$\mathrm{AN}(\alpha)=\int_u\int_v [f(u)^{\alpha}||\mathbf{u}-\mathbf{v}||\mathrm{d}F(\mathbf{u})\mathrm{d}F(\mathbf{v}), \tag{5.56}$$

where $||.||$ represents a C-dimensional Euclidean norm defined by

$$||\mathbf{u}_i-\mathbf{v}_j||=\sqrt{\frac{C\sum_{q=1}\left(u_{iq}-v_{jq}\right)^2}{C}}. \tag{5.57}$$

This is the normalized Euclidean distance between individuals i and j, where u_{iq} is the q th variable of individual i and $C=k+h$.

5.9. POLARIZATION IN PRACTICE

A few empirical studies on polarization have been conducted both to illustrate the use of the various indices that have been proposed and to motivate the study of polarization (by looking at the links between polarization, inequality, and conflict, for instance). We end this chapter with brief remarks on such empirical evidence: first, on the links between polarization and inequality; second, on polarization comparisons; and finally, on the linkages between polarization and conflict.

5.9.1 Polarization and Inequality

Wolfson (1994) empirically investigated the divergence between inequality and bipolarization using time-series data from the Canadian Surveys of Consumer Finance from 1967 to 1991. Although inequality and polarization often move in the same direction, from 1973 to 1981 they diverged.

Chakravarty and Majumder (2001) used Indian household expenditure survey data for 1987–1988 and 1993–1994 to compare inequality and polarization across time, states, and rural and urban areas. In some states in rural India, overall inequality decreased. The inequality ranking of states is unchanged between the two periods, but polarization rankings do vary. In some states, polarization and inequality moved in opposite directions regardless of polarization parameter values, reinforcing the view that polarization and inequality can behave differently.

Using data come from 28 Chinese provinces between 1983 and 1995, Zhang and Kanbur (2001) found that, contrary to other earlier empirical evidence, polarization measures do not generate significantly different results from standard measures of inequality. Polarization and inequality measures agree broadly over the period considered. This motivates them to consider a measure of socioeconomic polarization ZK, which they find empirically useful to examine the case of the United States, where socioeconomic polarization appears to exist between blacks and whites, and the case of China, where differences between rural and urban as well as between coastal and inland groups are important.

Some of the most extensive empirical evidence on the association between inequality and polarization can be found in Duclos et al. (2004). DER analyze polarization using several waves of LIS data from 21 countries. Their empirical analysis shows that polarization is empirically different from inequality. DER($\alpha = 0$) and the Gini index are by definition identical. When $\alpha = 0.25$, the Gini coefficient and the polarization index yield similar rankings. The correlation between inequality and polarization rankings falls when the polarization parameter α increases. Much of the reordering of countries as α increases to 1 occurs at low values of α. Rank differences between the Gini coefficient and the polarization index are important when $\alpha = 1$, with a Pearson rank correlation coefficient often lower than 0.7.

Figure 5.24 shows the Duclos et al. (2004) estimates for $\alpha = 1$ and for the 21 countries of LIS Wave 3. For these countries, a linear regression of inequality on polarization yields an R^2 of 0.8—understandably large but not perfect. The Czech Republic has the lowest Gini index of all countries, but ranks 11 out of 21 in terms of polarization. Conversely, Canada, Australia, and the United States exhibit large inequality, but relatively low polarization. The bulk of cross-country variation in polarization comes both from a significant variation in average identification and from variability in average alienation (and not from the covariance between identification and alienation—recall the discussion at the end of section 4.2); this explains why inequality and polarization are correlated but still empirically quite different. The United Kingdom and the United States also provide an interesting comparison. Both have a similar level of average

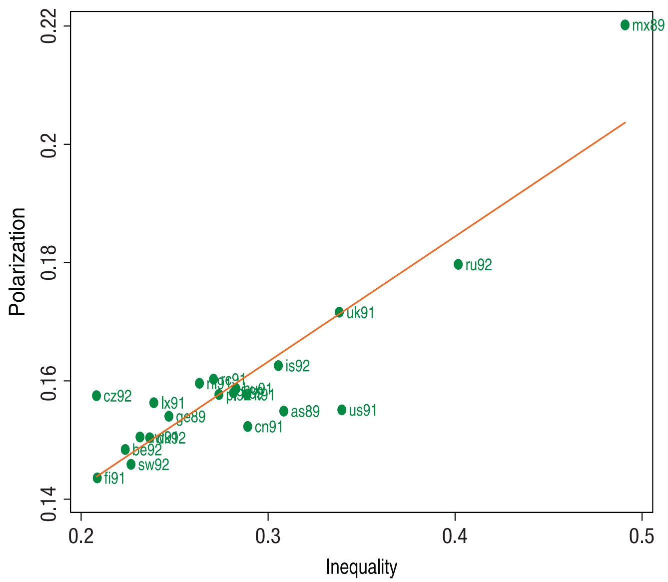

Figure 5.24 Polarization (measured by the DER ($\alpha = 1$) index) and inequality for 21 countries, LIS Wave 3. *Data source:* Duclos et al. (2004).

alienation, but the United Kingdom's density has sharper peaks, with the United States' density being remarkably flat with thick tails. The United Kingdom then ends up with a higher level of polarization, especially with higher values of α.

5.9.2 Empirical Polarization Comparisons

Using their range-free dominance techniques, Foster and Wolfson (2010/1992) compared bipolarization in the United States and Canada between 1979/1981 and 1988. Polarization and inequality are increasing in the United States but stable in Canada. The United States is robustly more polarized and unequal than Canada.

Duclos and Échevin (2005) applied their first-order bipolarization ordering techniques to rank 29 countries. They established bipolarization comparisons for 32% of the pairs of countries. This percentage increases to 57% when orderings are established solely on sample estimates and statistical uncertainty is ignored. Mexico has the highest level of bipolarization of all 29 countries, the ranking being statistically significant with respect to 26 countries, followed by Russia and the United States.

The extended polarization measure developed by Esteban et al. (2007) is applied to the income distribution of five OECD countries, namely the United States, the United Kingdom, Canada, Germany, and Sweden for the period 1974–2000. The main temporally observed pattern is a decrease in the Esteban and Ray (1994) polarization index combined with a moderate decline in within-group dispersion. Because the Esteban et al. (2007) index is a difference between these two factors, the net pattern is a decrease in the EGR index, especially in Canada and Germany. In 1974, at the beginning of the period, only Sweden presented relatively low polarization; Germany and the United Kingdom had similar levels of polarization, being nearly as polarized as Canada and the United States. By 2000, the United States and the United Kingdom were highly polarized relative to Sweden, Germany, and Canada.

Using the intermediate polarization measure, Chakravarty and D'Ambrosio (2010) compared polarization across four southern European countries, Greece, Italy, Spain, and Portugal. With regard to absolute polarization, Italy is the most polarized country on average, followed by Spain. But with respect to relative and intermediate polarization, Italy is the least polarized country on average, whereas Portugal is the country showing the highest level of polarization.

Anderson (2011) combined the indices of Esteban and Ray (1994) and Duclos et al. (2004) to consider polarization across discrete and continuous variables. Unidimensional polarization is found to have increased between 1990 and 2001 in the six Chinese provincial distributions of urban households considered, over the dimensions of income, living space, and education separately. When the three variables are combined in a multidimensional space, polarization is stable over 1990–2001 for smaller values of polarization aversion and decreasing for higher values.

5.9.3 Polarization and Conflict

Reynal-Querol (2002) estimated the impact of religious polarization and animist diversity on the incidence of ethnic civil war. Her main finding is that religious divisions seem more important than language divisions and natural resources in explaining social ethnic conflicts. She found in particular a positive and robust impact of animist diversity and religious polarization (but not of language fractionalization) on the incidence of ethnic civil war.

The effect of polarization and fractionalization on the incidence of civil and ethnic wars and, indirectly, on economic growth was further studied in Montalvo and Reynal-Querol (2005a). No relationship between fractionalization and conflict emerges for more than two groups. Ethnic polarization has a positive and significant impact on the prevalence of civil wars, as does religious polarization. Fractionalization and polarization are even negatively correlated at higher levels of fractionalization.

Montalvo and Reynal-Querol (2003) further support the evidence (reported in Montalvo and Reynal-Querol, 2002) that religious polarization is more appropriate for measuring the effect of potential conflict on economic development than the traditional fractionalization index. Religious polarization has a negative and significant effect on development through its effect on investment, government expenditure, and the frequency of civil wars. No effect of religious and ethnic fractionalization is found on the incidence of ethnic and civil wars on growth or on investment.

In an extension to the preceding, Montalvo and Reynal-Querol (2005b) reported that ethnolinguistic fractionalization has no statistically significant effect on the incidence of civil war, but that ethnic polarization does have a positive and statistically significant impact. Montalvo and Reynal-Querol (2008) further found that polarization has a positive and significant effect on genocide, whereas fractionalization does not.

Unlike social polarization indices such as that of Reynal-Querol (2002), the socioeconomic polarization index of Permanyer (2010) takes into account the extent of alienation between individuals. Using data from the World Value Surveys on 65 countries, the indices of Reynal-Querol (2002) and Permanyer (2010) are found to be positively but weakly correlated. The evidence in Permanyer (2010) also suggests that socioeconomic polarization indices could be better predictors of the occurrence of conflicts than purely social polarization indices.

Finally, Esteban et al. (2012a) (see also Esteban et al. 2012b) assessed the empirical role of different notions of group division and group dispersion in explaining different types of conflict. Types of conflict differ according to whether it is the allocation of public or of private goods that is the object of dispute; their outcomes also vary according to levels of group cohesion. The exercise helps explore the empirical validity of the theoretical model described at the beginning of this chapter (see section 2). Esteban et al. (2012a) found that the extent of social polarization and fractionalization always empirically matters regardless of model specification. This suggests that sources of disputes both over public and over private goods matter in explaining conflict. Furthermore, and as predicted by the theoretical model, it is found that the greater the degree of relative publicness of conflict prizes, the greater the importance of polarization (which takes into account across-groups distances in utilities of public goods) relative to fractionalization (which does not).

5.10. CONCLUSION

Interest in the understanding and measurement of polarization is relatively recent. This chapter has reviewed some of the conceptual foundations of polarization; it has described how polarization can be measured in an economic, social, and/or hybrid socioeconomic perspective; it has reviewed briefly the empirical and theoretical polarization/conflict polarization literature; and it has distinguished polarization from inequality and other ways of considering distances between individuals and groups.

Given the increasing interest in the causes and effects of polarization, one would expect further advances in its understanding. On the measurement side, one can envisage, for instance, the development of techniques for decomposing polarization across socioeconomic groups, components of welfare, and features of the welfare distribution (such as modal structure, inequality, and measures of overlap); for making robust comparisons of polarization across time and societies; and for performing statistical inference on the levels and rankings of polarization. One can also foresee advances in the understanding of polarization levels and polarization dynamics, regarding, for instance, the role and the importance of socioeconomic changes (such as the effect of group sizes and distances) and the differential impact of alienation and identification across time. The dynamic impact of polarization on tensions and conflicts as well as the reverse impact are also plausible and important features of future research on polarization. Finally, the possible effect of growth, policy, and redistribution (in particular) on polarization, as opposed to other aspects of the income distribution, would also seem to constitute important areas for future research on polarization.

Abstract

This chapter discusses the formal and informal techniques that are commonly used to give quantitative answers in the field of distributional analysis. To this end, it covers subjects including inequality, poverty, and the modeling of income distributions. It also deals with parametric and nonparametric approaches and the way in which imperfections in data may be handled in practice.

6.1. INTRODUCTION

This chapter is about the techniques, formal and informal, that are commonly used to give quantitative answers in the field of distributional analysis—covering subjects such as inequality, poverty, and the modeling of income distributions.

At first sight, this might not appear to be the most exciting of topics. Discussing statistical and econometric techniques could appear to be purely secondary to the important questions in distributional analysis. However, this is not so. At a very basic level, without data what could be done? Clearly if there were a complete dearth of quantitative information about income and wealth distributions, we could still talk about inequality, poverty, and principles of economic justice. But theories of inequality and of social welfare would stay as theories without practical content. Knowing how to use empirical evidence in an appropriate manner is essential to the discourse about the welfare economics of income distribution and to the formulation of policy. Furthermore, understanding the nature and the limitations of the data that are available—or that may become available—may help to shape one's understanding of quite deep points about economic inequality and related topics; good practice in quantitative analysis can foster the development of good theory.

6.1.1 Why Statistical Methods?

If we carry out a simple computation of the values of an inequality or poverty measure, computed from two different samples, we will usually find greater inequality or poverty in one sample, *even if the two samples come from the same population*. Clearly simple computation alone is not enough to draw useful conclusions from the raw data: Statistical methods are required to test the hypothesis that the two values are not statistically different. For instance, Table 6.1 reports the values of the Gini and Theil inequality indices,[1] with confidence intervals at 95%, computed from two samples of 1000 observations drawn from the same distribution: The two samples are independent, with observations drawn independently from the Singh–Maddala distribution with parameters $a=2.8$, $b=0.193$, and $q=1.7$, which closely mimics the net income of German households, up to a scale factor (Brachmann et al., 1996). Clearly the values of the Gini and Theil indices are greater in sample 1 than in sample 2. However, the confidence intervals (in brackets) intersect for both inequality measures, which leads us to not reject the hypothesis that the level of inequality is the same in the two samples.

There is a wide variety of inequality indices in common use. Different indices, with different properties, could lead to opposite conclusions in practice. Lorenz curves comparisons can be very useful because a (relative) Lorenz curve always lying above another one implies that any comparisons of relative inequality measures would lead to similar conclusions—a result that holds for any inequality measures respecting anonymity, scale invariance, replication invariance, and the transfer principle (Atkinson, 1970). In practice, we have on hand a finite number of observations, and empirical Lorenz dominance can be observed many times when the two samples come *from the same population*. In the case of two independent samples of 1000 observations drawn from the same Singh–Maddala distribution, we obtain sample Lorenz dominance 22% of cases. Dardanoni and Forcina (1999) argued that it can be as high as 50% of cases due to the fact that empirical Lorenz curve ordinates are typically strongly correlated. This demonstrates the need to use statistical methods.

The point about simple computation being insufficient is also easily demonstrated in the case of Lorenz curves: Figure 6.1 shows the difference between the empirical Lorenz curves obtained from two independent samples drawn from the same distribution, with confidence intervals at 95% calculated at the population proportions $q=0.01, 0.02, \ldots, 0.99$. The ordinates are always positive, so it is clear that one empirical Lorenz curve always dominates the other. However, the confidence intervals show that *each* Lorenz

Table 6.1 Inequality indices with confidence intervals at 95%

	Sample 1	**Sample 2**
Gini	0.303	0.285
	[0.286; 0.320]	*[0.271; 0.299]*
Theil	0.158	0.135
	[0.133; 0.183]	*[0.120; 0.151]*

[1] For formal definitions see Equations (6.51), (6.69), and (6.70).

curve ordinate difference is never significantly different from zero; as a result Lorenz dominance in the population is not as clear as simple computation from the sample might suggest. To be able to make conclusions on dominance or nondominance, we need to test simultaneously that *all* ordinate differences are statistically greater than zero, or not less than zero. Appropriate test statistics need to be used to make such multiple comparisons.

In this chapter, we will provide a survey of the theory and methods underlying good practice in the statistical analysis of income distribution. We also offer a guide to the tools that are available to the practitioner in this field.

6.1.2 Basic Notation and Terminology

Throughout the chapter, certain concepts are used repeatedly, and so it is convenient to list some of the terms that are used repeatedly.

- *Income* y. Here "income"; this is merely a convenient shorthand for what in reality may be earnings, wealth, consumption, or something else. We will suppose that y belongs to a set $\mathbb{Y} = [\underline{y}, \overline{y})$, an interval on the real line $\mathbb{R}$.
- *Population proportion* q. For convenience, we will write $q \in \mathbb{Q} := [0,1]$.
- *Distribution* F. This is the cumulative distribution function (CDF) so that, for any $y \in \mathbb{Y}$, $F(y)$ denotes the proportion of the population that has income y or less. Where

the density is defined, we will write the density at $y \in \mathbb{Y}$ as $f(y)$. The set of all distribution functions will be denoted $\mathbb{F}$.

- *Indicator function* $\iota(\cdot)$. Suppose there is some logical condition D, which may or may not be true. Then $\iota(\cdot)$ is defined as:

$$\iota(D) = \begin{cases} 1 & \text{if } D \text{ is true} \\ 0 & \text{if } D \text{ is not true} \end{cases} \tag{6.1}$$

6.1.3 A Guide to the Chapter

We begin with a discussion of some of the general data issues that researchers should bear in mind (Section 6.2). Section 6.3 deals with the issues that arise if we want to try to "model" an income distribution: The motivation for this is that sometimes it makes sense to approach the analysis of income distributions in two stages: (1) using a specific functional form or other mathematical technique to capture the evidence about the income distribution in an explicit model, and (2) making inequality comparisons in terms of the modeled distributions. Section 6.4 deals with the general class of problem touched on in our little example outlined in Table 6.1: The emphasis is on hypothesis testing using sample data, and we cover both inequality and poverty indices. As a complement to this, Section 6.5 deals with the class of problem highlighted in Figure 6.1: We look at a number of "dominance" questions that have a similarity with the Lorenz problem described there. Section 6.6 returns to mainly data-related questions: how one may deal with some of the practical issues relating to imperfections in data sets. Finally, in Section 6.7, we draw together some of the main themes that emerge from our survey of the field.

6.2. DATA

6.2.1 Data Sources

It is not difficult to imagine instances where there is a known, finite set of income-receivers and where the income associated with each income-receiver is observable (example: if there are 50 states in a federation and one wishes to analyze the change in the distribution of announced military contracts awarded by the federal government among those 50 states). Under those circumstances, a complete enumeration of the relevant "population" (the 50 states) is possible, and the income of each member of this "population" is measured with complete accuracy (from the federal government announcement). There is very little to do in terms of statistical analysis and no data problem. But this kind of example is rarely encountered in practice and might be dismissed as somewhat contrived. It is much more common to have to deal with situations in which an enumeration of the population is impossible and we have to rely on some sort of sample.

6.2.1.1 Administrative Data

Governments and government agencies have long published summaries of income distributions in grouped form; in many countries, official data providers have gone further and made available to researchers microdata from official sources that could be used, for example, to analyze the distribution of income and wealth. The data made available in this way used to be of similar size to sample surveys (discussed later). However, it is increasingly the case that very large data sets have been opened up for research, an order of magnitude larger—effectively complete collections of administrative data rather than official samples from them. It might be tempting to treat these as methodologically equivalent to the complete enumeration case described earlier. But this would overlook two points. First, administrative data will only contain what is legally permissible and what government agencies find convenient to release. If, for example, one is interested in the distribution of personal incomes, a very large data set of tax records could be extremely useful, but it will miss many of those persons who are not required to file tax returns. Second, the design of the data set may not match what the social scientist or economist would wish: For example, if one wishes to adjust the data to allow for differences in need according to the type of household or family in which each person lives, the required information for constructing an appropriate equivalence scale may not be present in the same data set.

6.2.1.2 Survey Data

The problems from administrative data stem largely from the fact that the data are the by-product of information gathered for other purposes. It is clear that specially designed surveys have a potential advantage in this respect. However, although surveys are usually purpose-built (and often purpose-built using advice from social scientists), one also has to be cautious about their limitations. This concerns the smaller size and worse response rate than the administrative data counterparts. Once again the survey design may exclude some sections of the population (a survey based on households would obviously miss people who are homeless and those in institutions), and where there is an attempt to create longer series of surveys, the criteria for the design of contemporary surveys may follow a standardized format determined by conventions that are no longer relevant.

6.2.2 Data Structure

In implementing the statistical criteria discussed in this chapter, one needs to be clear about the relevant assumptions concerning the way the sample was drawn.

6.2.2.1 Simple Design

In the majority of this chapter, we will take it that simple random sampling is an appropriate assumption. By this we mean that the sample has been designed in such a way that each member of the population has an equal probability of being included in the sample.

This can be taken as an ideal case that enables one to focus on the central issues of statistical inference. Even the supposedly "ideal" case may not be ideal in practice if the sampling frame is inappropriate—it could be out of date or it could be specified in such a way that part of the population is excluded (see the remarks earlier about homeless people).

6.2.2.2 Complex Design

In practice, there are often simple practical reasons why something other than simple random sampling is used.[2] Two features in particular are often built into the design of the sample. *Clustering* the observations by geographical location may reduce the costs of running the survey, both in terms of initial visits to carry out the survey and in follow-up visits for monitoring and completing missing information. *Stratification* is a common technique for deliberately oversampling certain categories of respondent to ensure that there is adequate representation in the combined sample of certain types of individuals or households that are of particular interest but that are likely to show up comparatively rarely either because they are genuinely rare in the population or because they are less likely to respond to the survey (for example, it is commonly found that richer households are overrepresented in the "nonresponse" category, and if one were just to ignore that possibility, there would be the danger of having a biased sample). In effect one divides up the population of interest into subpopulations and chooses a sample for each subpopulation—each stratum—at an appropriate sampling rate.

Although the assumption of a simple random sample sweeps aside practical problems associated with the design of the survey, this idealized case gives us a good base for explaining the core issues in estimation and inference. At appropriate points in Sections 6.4 and 6.5, we will comment on the extensions to the complex data case and other related issues.[3]

Other problems with the data merit special discussion. We briefly outline the nature of these problems here and then return to a formal analysis of them (in Section 6.6) after we have extensively discussed conventional inference problems in the preceding sections.

6.2.3 Data Problems

6.2.3.1 Measurement Error and Data Contamination

Measurement error in income distribution analysis can be handled in a way similar to measurement error in other contexts. Observed income is true income adjusted by an error term (Chesher and Schluter, 2002), and the resulting model resembles the problem of

[2] See Deaton (1997) for a full discussion of the issues involved.

[3] For example, if the data are based on a simple survey of households, but one wants to infer something about the distribution of individuals, one needs to weight each household observation by an amount proportional to the number of persons in the household; this structure is similar to the weights introduced by stratification.

decomposition by factor source; *data contamination* can be represented as a mixture of a true distribution and a contamination distribution. The resulting model resembles the problem of decomposition by population subgroup (Cowell, 2000; Cowell and Fiorio, 2011). However, the appropriate model for analyzing this second type of problem uses tools that are useful for the analysis of questions beyond the narrow data contamination question. This will be discussed in Sections 6.4–6.6.

6.2.3.2 Incomplete Information

In many practical applications, we need to deal with situations in which some parts of the sample space are excluded completely from the sample data or where information in part of the sample is missing; for convenience we will refer to this part of the sample as the "excluded" subset, even though some information may be available. The exclusion of information may be imposed by the data provider, for example, because of reasons of confidentiality, or it may be introduced by the researcher to deal pragmatically with some other problem in the data.

Table 6.2, taken from Cowell and Victoria-Feser (2003), sets out the main cases that are of interest. There are two principal issues for the researcher to consider, as follows:

Boundaries of the excluded subset. What determines the boundaries of the excluded subset of the sample space? There are two possible cases summarized in the rows of Table 6.2: (i) a subset of $\mathbb{Y}$ is specified, or (ii) a subset of $\mathbb{Q}$ is specified. In the first case, the income-boundaries of the excluded subset $(\underline{z}, \overline{z})$ are fixed, but the proportions of the excluded subsets $(\underline{\beta}, \overline{\beta})$ are unknown, although these proportions can be estimated if enough information is available. In the second case, the boundaries of the excluded sample are fixed by the trimming proportions in the lower and upper tail $(\underline{\beta}, \overline{\beta})$, and the incomes at the boundary of the excluded samples $(\underline{z}, \overline{z})$ are unknown.

Information in the excluded subset. There are several assumptions about the availability of information in the excluded part of the sample. The situation is going to depend on the particular problem in hand, and the principal cases are summarized in the columns of Table 6.2. At one extreme, the excluded subset is just *terra incognita* (left-hand column). On the other hand, it may be that the data provider makes available several summary statistics related to excluded subset (right-hand column).

Table 6.2 Types of incomplete information

	Information about excluded sample		
	None	**Sample proportion**	**Multiple statistics**
Incomes below $\underline{z}$ and above $\overline{z}$ excluded	**A**	**B**	**C**
Lowest $100.\underline{\beta}\%$ and highest $100.\overline{\beta}\%$ excluded	**D**	**(E)**	**(F)**

So, in principle there are altogether six possible cases, but in practice only four are relevant:[4]

- Case A is the standard form of truncation.
- Case B represents "censoring"; in this case there are point masses at the boundaries $\left(\underset{\sim}{z}, \overline{z}\right)$ that estimate the population-share of the excluded part.[5]
- Case C is an extension of standard estimation problem with grouped data (Gastwirth et al., 1986).
- Case D represents the case of trimming.

The implications of these issues for distributional analysis are considered in Section 6.6.2.

6.2.4 Grouped Data

For reasons of economy and convenience, it used to be common practice for statistical offices to make income distribution data available only in grouped form (see Case C in Table 6.2). Typically, this would involve a simple table with a comprehensive set of pre-set income intervals, the numbers of individuals or households falling into each interval, and (sometimes) the average income associated with each interval. Tabulated data are less usual today, although researchers are increasingly using historical data to construct long-run time series. So, it is useful to consider briefly the analytical issues that arise in connection with this type of data.

One way of using such data effectively is to estimate the underlying income distribution using parametric modeling. This can be done either by using interpolation methods in each of the intervals (see, for example, Cowell, 2011) or by fitting a distribution to the bulk of the data—suitable parametric methods are discussed in Section 6.3.1. Nonparametric methods are necessarily quite limited because of the restrictions imposed by the data.[6] However, an interesting problem presented by any sort of grouped data is to compute bounds on inequality indices. One uses the available information to compute a maximum-inequality distribution and a minimum inequality distribution by making alternative extreme assumptions about the way the data are distributed within each interval (Cowell, 1991; Gastwirth, 1972, 1975).

[4] If, as is usual, trimming is something that is done voluntarily by the user rather than being imposed by the data provider, then Cases E and F are not relevant in practice.

[5] A standard example of this "top-coding" of some income components in the Current Population Survey—observations above a given value $\overline{Z}$ are recorded as $\overline{Z}$ (Polivka, 1998). In practical applications of distributional analysis, such as inferring inequality trends, researchers have adopted a number of work rounds such as multiplying top-coded values by a given factor (Autor et al., 2008; Lemieux, 2006) or attempting imputations for missing data (Burkhauser et al., 2010; Jenkins et al., 2011).

[6] The problem of statistical inference with grouped data is discussed in Hajargasht et al. (2012).

6.3. DENSITY ESTIMATION

The analysis of a probability density function is a powerful tool to describe several properties of a variable of interest. For instance, Figure 6.2 shows the estimated density function of GDP per capita in 121 countries across the world in 1988.[7] We can see that the density function is bimodal. The existence of two modes suggests that there are two distinct groups: one composed of the "richest" countries and another consisting of the "poorest." The second mode is much less pronounced than the first, which indicates that the two groups are not of the same size; there are relatively few "rich" countries and distinctly more "poor" countries. Further, the first mode is located just to the left of the value 0.5 on the *X*-axis, whereas the second is found at around 3. We can thus conclude from this figure that, on average in 1988, "rich" countries enjoyed a level of GDP per capita that was around three times the average, whereas that of "poor" countries was only half of the average level. It is clear from this example that much more information is

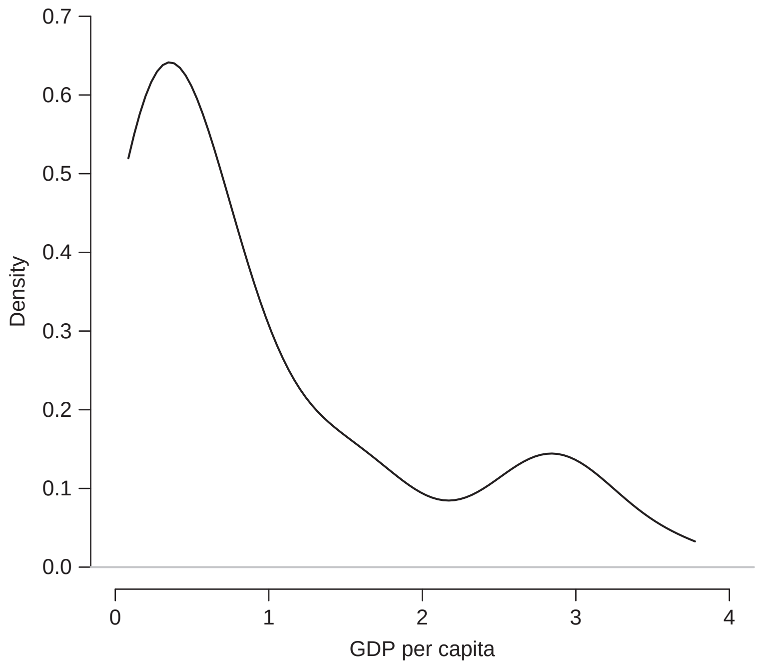

Figure 6.2 Kernel density estimation of GDP per capita in 121 countries normalized by the global mean.

[7] The data are unweighted (each country as equal weight) and are taken from the *Penn World Table* of Summers and Heston (1991). The horizontal axis is the per capita GDP for each country normalized by the (unweighted) mean over all countries.

available from the full distribution of a variable than the restricted information provided by standard descriptive statistics, as the mean, variance, skewness, or kurtosis, which summarize each limited properties of the distribution on single values.

In the multivariate case, the conditional density function can provide useful insights on the relationship between several variables. For instance, Figure 6.3 shows the estimated density functions of wages conditional to experience for individuals with the same level of education.[8] We can see that as experience increases, the conditional distribution becomes bimodal, and the gap between the two modes increases. It suggests that the population is composed by two subgroups, and the marginal impact of experience on wages is not the same for the two groups. A standard regression tracks the dynamics of the first moment of the conditional distribution only and then cannot highlight the features just described. Here, a linear regression of wages on experience would estimate the marginal impact of experience on the average of wages for all individuals, whereas the graphical analysis suggests that experience does not affect individual's wages identically. Mixture models of regressions would be more appropriate in such cases.

In practice, the functional form of the density function is often unknown and has to be estimated. For a long time, the main estimation method was mainly parametric. However, a parametric density estimation requires the choice of a functional form *a priori*, and most of them do not fit multimodal distribution. In the last two decades, nonparametric and semiparametric estimation methods have been extensively developed. They are often used in empirical studies now and allow us to relax the specific assumptions underlying parametric estimation method, but they require in general more data on hand.

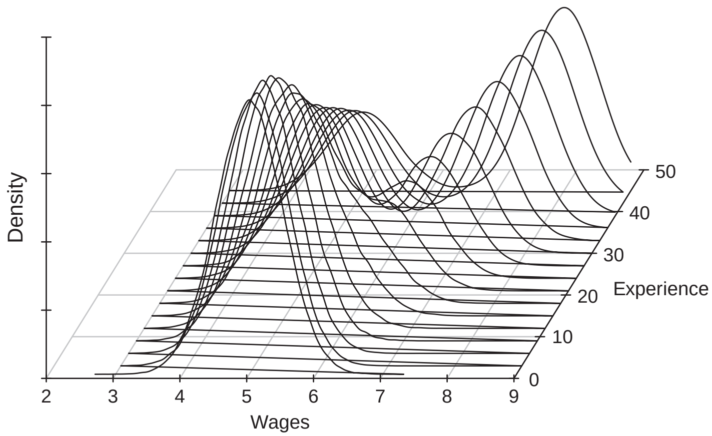

Figure 6.3 Conditional density estimates of wages on experience.

[8] The data are simulated.

In this section, we will present parametric, nonparametric, and semiparametric density estimation methods. Standard parametric methods are presented in Section 6.3.1, kernel density methods in Section 6.3.2, and finite mixture models in Section 6.3.3.

6.3.1 Parametric Estimation

We say that a random variable Y has a probability density function f, if the probability that Y falls between a and b is defined as:

$$\mathrm{Prob}(a < Y < b) = \int_a^b f(y)\mathrm{d}y,$$

where a and b are real values and $a < b$. The density function f is defined as nonnegative everywhere, and its integral over the entire space is equal to one.

A parametric estimation requires one to specify *a priori* a functional form of the density function, that is, to know the density function up to some parameters. The density function can then be written $f(y; \theta)$, where θ is a vector of k unknown parameters and y a vector of n observations. The problem remains of estimating θ; this is usually done by maximizing the likelihood to observe the actual values in a sample. If the data are independent and identically distributed (IID), the joint density function of n observations y_1, $y_2, \ldots, y_n$ is equal to the product of the individual densities:

$$f(y; \theta) = \prod_{i=1}^{n} f(y_i; \theta).$$

The estimation of the density function therefore requires the maximization of this function with respect to θ. Because the logarithmic function is positive and monotone, it is equivalent to maximize

$$\ell(y; \theta) = \log f(y; \theta) = \sum_{i=1}^{n} \log f(y_i; \theta),$$

from which the solution is often much simpler. This estimation method is known as the maximum likelihood method.

6.3.1.1 Pareto

Pareto (1895) initiated the modeling of income distribution with a probability density function[9] that is still in common use for modeling the upper tail of income and wealth distributions. Beyond a minimal income, he observed a linear relationship between the logarithm of the proportion of individuals with incomes above a given level and the

[9] What is now commonly described as *the* Pareto distribution is more precisely referred to as "Pareto type I." For other, more general, forms introduced by Pareto and their relationship to the Pareto type I see Cowell (2011) and Kleiber and Kotz (2003).

logarithm of this given level of income. This observation has been made in many situations and suggests a distribution that decays like a power function; such behavior characterizes a heavy-tailed distribution.[10] The Pareto CDF is given by

$$F(y;\alpha) = 1 - \left[\frac{y}{y_0}\right]^{-\alpha}, \quad y > y_0 \tag{6.2}$$

with density

$$f(y;\alpha) = \alpha y^{-\alpha-1} y_0^{\alpha} \tag{6.3}$$

If p_y denotes the proportion of the population with incomes greater than or equal to y (for $y \geq y_0$), then we have

$$\log p_y = \log A - \alpha \log y \tag{6.4}$$

where $A := y_0^{\alpha}$. The Pareto index α is the elasticity of a reduction in the number of income-receiving units when moving to a higher income class. The larger the Pareto index, the smaller the proportion of very high-income people. The Pareto distribution often fits wealth distributions and high levels of income well—see Figure 6.4—but it is not designed to fit low levels of income. Other distributions have then been proposed in the literature.

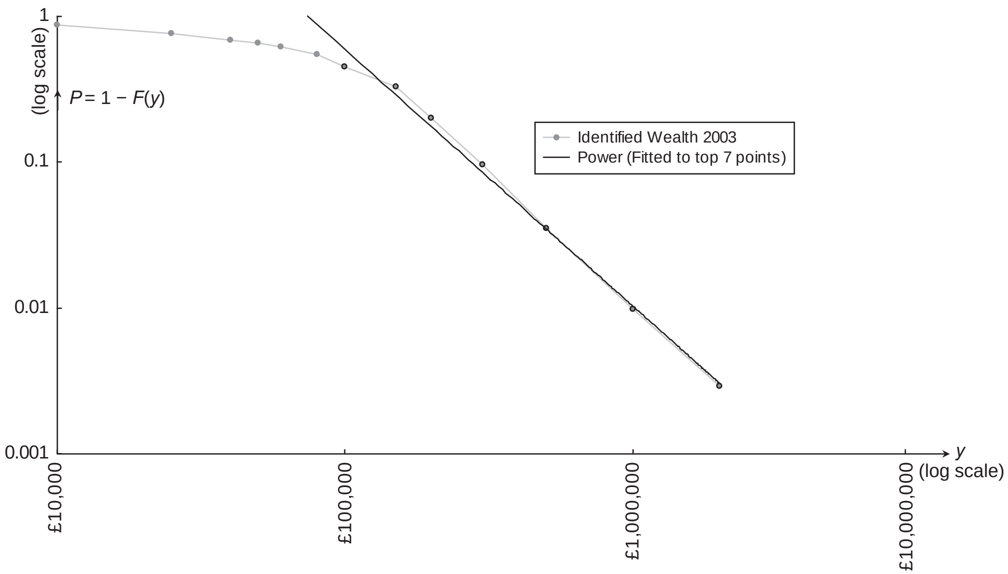

Figure 6.4 Pareto distribution. UK Identified wealth 2003. *Source: Inland Revenue Statistics 2006, Table 13.1*.

[10] A "heavy-tailed" distribution F is one for which $\lim_{y\to\infty} e^{\lambda y}[1 - F(y)] = \infty$, for all $\lambda > 0$: it has a tail that is heavier than the exponential.

6.3.1.2 Lognormal

Gibrat (1931) highlighted the central place of the lognormal distribution in many economic situations. His *law of proportionate effect* says that if the variation of a variable between two successive periods of time is a random proportion of the variable at the first period, then the variable follows a lognormal distribution.[11] He successfully fitted lognormal distributions with many different data sets, as for instance income, food expenditures, wages, bequests, rents, real estate, firm profits, firm size, family size, and city size. The lognormal distribution has then been very popular in empirical work[12] and is often appropriate for studies of wages—see Figure 6.5. However, the fit of the upper tail of more broadly based income distributions appears to be quite poor. The tail of the lognormal distribution decays faster than the Pareto distribution, at the rate of an exponential function rather than of a power function. It has led to the use of other distributions with two to five parameters to get a better fit of the data over the entire distribution.

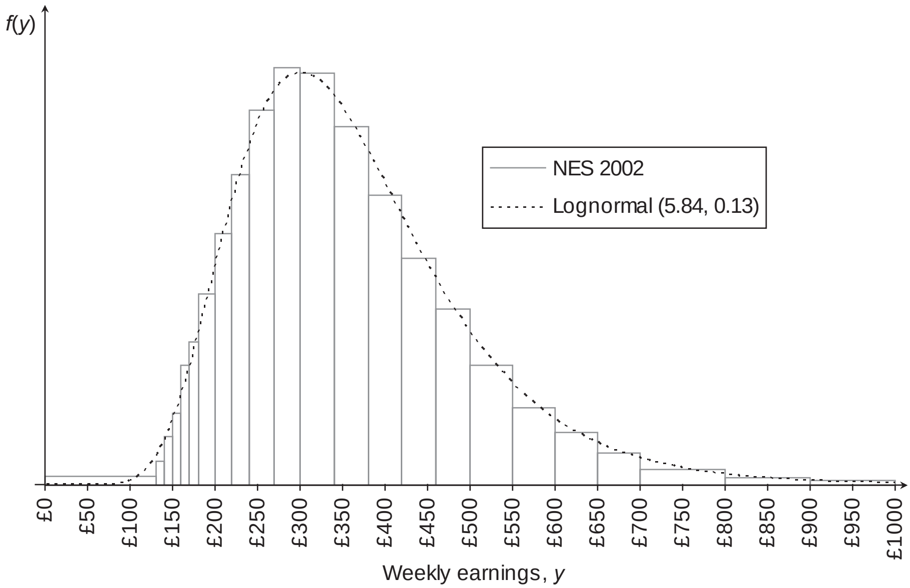

Figure 6.5 Lognormal distribution. UK Male Manual Workers on Full-Time Adult Rates. *Source: New Earnings Survey 2002, Part A Table A35.*

[11] If $X_t - X_{t-1} = \varepsilon_t X_{t-1}$, then $\sum_{i=1}^{n} \varepsilon_t = \sum_{i=1}^{n} \frac{X_t - X_{t-1}}{X_{t-1}} \approx \log X_n - \log X_0$. From a central limit theorem (CLT), log X_n follows asymptotically a Normal distribution.

[12] In addition, it has nice properties related to the measurement of inequality (Cowell, 2011), it is closely related to the Normal distribution, and it fits homogeneous subpopulations quite well (Aitchison and Brown, 1957).

6.3.1.3 Generalized Beta

The gamma and Weibull distributions have shown good fit in empirical studies.[13] The lognormal, gamma, and Weibull density functions are two-parameter distributions; they share the property that Lorenz curves do not intersect, contrary to what is observed in several datasets. To allow intersecting Lorenz curves, three-parameter distributions should be used, as the generalized gamma (GG), Singh–Maddala (SM), and Dagum distributions.[14] As shown by McDonald and Xu (1995), all the previously mentioned distributions are special or limiting cases of the five-parameter generalized beta distribution, defined by the following density function:

$$\mathrm{GB}(y; a, b, c, p, q) = \frac{|a| y^{ap-1}\left[1-(1-c)(y/b)^a\right]^{q-1}}{b^{ap} B(p, q)\left[1+c(y/b)^a\right]^{p+q}}, \tag{6.5}$$

for $0 < y^a < b^a/(1-c)$ and is equal to zero otherwise. $\mathrm{B}(p, y) := \int_0^1 t^{p-1}(1-t)^{q-1}\,\mathrm{d}t$ is the beta function, $0 \le c \le 1$ and b, p, and q are positive. Figure 6.6 shows graphically the relationships between distributions.[15] As an example of the paths through this diagram, take the case where $c=0$ in (6.5): we find the Generalized Beta of the first kind

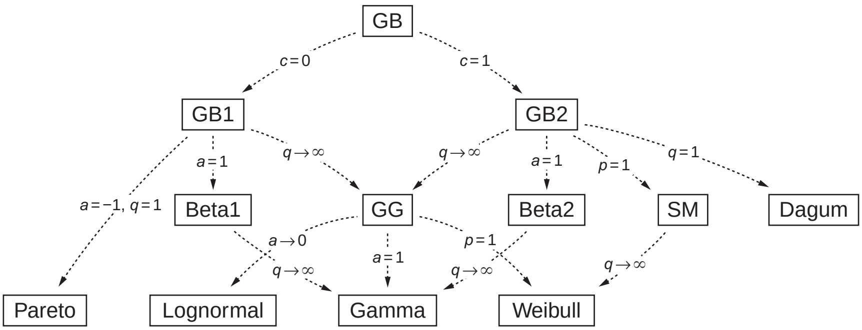

Figure 6.6 Parametric distributions tree. *Source: Bandourian et al., 2003.*

[13] Among others, Salem and Mount (1974) show that the gamma distribution fits better than the lognormal for income data in the United States for the years 1960 to 1969; Bandourian et al. (2003) found the Weibull distribution to be the best two-parameter distribution for income distribution in many countries

[14] See Stacy (1962), Singh and Maddala (1976), and Dagum (1977). The Singh–Maddala and Dagum distributions are also known as, respectively, the Burr 12 and Burr 3 distributions.

[15] GB1 and GB2 are, respectively, the generalized beta of the first and second kinds introduced by McDonald (1984). Beta1 and Beta2 are, respectively, the beta of first and second kinds. An alternative three-parameter approach that giving a good representation of income distributions in practice is provided by the Pareto–Lévy class (Dagsvik et al., 2013; Mandelbrot, 1960); unfortunately, except in a few cases, the probability distributions associated with this class cannot be represented in closed form.

$$\mathrm{GB1}(y; a, b, p, q) = \frac{|a| y^{ap-1}[1-(y/b)^a]^{q-1}}{b^{ap}\mathrm{B}(p, q)}. \tag{6.6}$$

Going a stage further, the special case of (6.6) with $a = 1$ gives the Beta distribution of the first kind

$$\mathrm{B1}(y; b, p, q) = \frac{y^{p-1}[1-(y/b)]^{q-1}}{b^{p}\mathrm{B}(p, q)}, \tag{6.7}$$

As an alternative route from (6.6), setting $a = -1$ and $q = 1$ we obtain $b^p y^{-p-1}$, which, with a change of notation, is clearly the density function of the Pareto type I distribution (6.3). For more details on continuous univariate distributions, see Johnson et al. (1994) and Kleiber and Kotz (2003).

Income distributions have been extensively estimated with parametric density functions in the literature; see, for instance, Singh and Maddala (1976), Dagum (1977, 1980, 1983), McDonald (1984), Butler and McDonald (1989), Majumder and Chakravarty (1990), McDonald and Xu (1995), Bantilan et al. (1995), Victoria-Feser (1995, 2000), Brachmann et al. (1996), Bordley et al. (1997), Tachibanaki et al. (1997), and Bandourian et al. (2003). In most of these empirical studies, the generalized beta of the second kind, the Singh–Maddala and the Dagum distributions perform better than other two/three-parameter distributions.

6.3.1.4 Goodness of Fit

Goodness-of-fit test statistics are used to test whether a given sample of data is drawn from an estimated probability distribution. They are used to know if an estimated density function is appropriate and fits the data well. Several statistics have been proposed in the literature. The well-known Pearson chi-squared statistic is defined as: $\chi^2 = \sum_{i=1}^{m} (O_i - E_i)^2 / E_i$, where O_i is the observed percentage in the ith histogram interval, E_i is the expected percentage in the ith histogram interval, and m is the number of histogram intervals. This measure summarizes discrepancies between frequencies given by a histogram obtained from the data and those expected from the estimated density function. A statistic not significantly different from zero suggests that the estimated density function fits well the unknown density function that generated the data. In finite samples, this statistic is known to have poor finite sample power properties, that is, to underreject when the estimated density function is not appropriate; see Stephens (1986). Then the Pearson chi-square test is usually not recommended as a goodness-of-fit test. Empirical distribution function (EDF)-based statistics perform better. Given a set of observations $\{y_1, y_2, \ldots, y_n\}$, the EDF is defined as

$$F^{(n)}(y) = \frac{1}{n} \sum_{i=1}^{n} \iota(y_i \le y) \tag{6.8}$$

where $\iota(\cdot)$ is the indicator function defined in (6.1). When the observations are independently and identically distributed, it is a consistent estimator of the CDF. EDF-based statistics measure the discrepancy between the EDF and the estimated CDF. They are not sensitive to the choice of the histogram's bins as in the Pearson chi-squared statistic. For instance, the Kolmogorov–Smirnov statistic is equal to

$$\sup_y |F^{(n)}(y) - F(y, \hat{\theta})| \tag{6.9}$$

where $F(y, \hat{\theta})$ is an estimated CDF from a parametric family function with parameters θ. Other statistics can be expressed as

$$n\int_{-\infty}^{\infty} \left(F^{(n)}(y) - F(y, \hat{\theta})\right)^2 w(y)\mathrm{d}F(y, \hat{\theta}), \tag{6.10}$$

where $w(y)$ is a weighting function. The Cramér–von Mises statistic corresponds to the special case $w(y) = 1$, while the Anderson–Darling statistic puts more weight in the tails, with $w(y) = \left[F(y, \hat{\theta})\left(1 - F(y, \hat{\theta})\right)\right]^{-1}$. In finite samples, the Anderson–Darling test statistic outperforms the Cramér–von Mises statistic, which in turn outperforms the Kolmogorov–Smirnov test statistic, see Stephens (1986).

In distributional analysis, goodness-of-fit test statistics and inequality measures do not usually share the same intellectual foundation. The former are based on purely statistical criteria, whereas the latter are typically based on an axiomatic that may be associated with social welfare analysis or other formal representations of inequality in the abstract. Cowell et al. (2014) developed a family of goodness-of-fit tests founded on standard tools from the economic analysis of income distributions, defined as:

$$G_\xi = \frac{1}{(\xi^2 - \xi)} \sum_{i=1}^{n} \left[\left[\frac{u_i}{\mu_u}\right]^\xi \left[\frac{2i}{n+1}\right]^{1-\xi} - 1 \right], \tag{6.11}$$

where $\xi \in \mathbb{R} \setminus \{0, 1\}$ is a parameter, $u_i = F(y_{(i)}; \hat{\theta}), \mu_u = \frac{1}{n}\sum_{i=1}^{n} u_i$ and $y_{(i)}$ is the ith order statistic (the ith smallest observation). G_ξ is closely related to Generalized Entropy (GE) inequality indices—see Equations (6.49)–(6.51). GE inequality measures are divergence measures between the EDF and the most equal distribution, where everybody gets the same income. They tell us how far an empirical distribution is from the most equal distribution.[16] Goodness-of-test statistics G_ξ are divergence measures between the EDF and an estimated parametric CDF. They tell us how far an empirical distribution is from an

[16] See Cowell et al. (2013) for an extension to the choice of any other "reference" distribution, giving for instance inequality measures telling us how far an empirical distribution is from the most *unequal* distribution.

estimated parametric distribution.[17] It has excellent size and power properties as compared with other, commonly used, goodness-of-fit tests. It has the further advantage that the profile of the G_ξ statistic as a function of ξ can provide valuable information about the nature of the departure from the target family of distributions, when that family is wrongly specified.

6.3.2 Kernel Method

6.3.2.1 From Histogram to Kernel Estimator

Histograms are the most widely used nonparametric density estimators. However, they have several drawbacks that kernel density method allows us to handle.

Figure 6.7 illustrates several problems arising with histograms, using GDP per capita in 121 countries in 1988 (solid line). The left plot is given with five bins of the same length between 0 and 5. The middle plot is similar but the position of the bins has changed; they are between –0.5 and 4.5. The two pictures are very different, even if they estimate the same distribution. The left panel shows a unimodal distribution, whereas the middle panel shows a bimodal distribution. Histograms are then sensitive to the point at which we start drawing bins. The right panel is given with 10 bins of the same length between 0 and 5. Once again, it gives a different picture of the same distribution. Histograms are thus sensitive to the number of bins used, which is also relatively arbitrary. Moreover, and most obviously, the pictures given by histograms provide discontinuities at the edge of each bin, which may not be an appropriate property of the true underlying distribution.

To avoid having to make an arbitrary choice on the position and the number of bins, we can use intervals that may overlap, rather than being separate from each other. The principle here is to estimate a density function at one point by counting the number of observations that are close to this evaluation point. For a sample of n observations, $y_1, \ldots, y_n$, the naive density estimator is given by:

$$\hat{f}(y) = \frac{1}{nh}\sum_{i=1}^{n} \iota\left(y - \frac{h}{2} < y_i < y + \frac{h}{2}\right), \tag{6.12}$$

where h is the width of the intervals and $\iota(\cdot)$ is the indicator function (6.1). In this equation, the estimate of the density at point y is given by the proportion of observations that

[17] The term in the first bracket in (6.11) is related to the CDF, $u_i/\mu_u = F(y_{(i)}, \hat{\theta})/\mu_u$, whereas the term in the second bracket is related to the EDF, $2i/(n+1) = v_i/\mu_v$ where $v_i = \hat{F}^{(n)}(y_{(i)}) = i/n$ and $\mu_v = n^{-1}\sum_{i=1}^{n} v_i = \sum_{i=1}^{n} i/n^2 = (n+1)/(2n)$. Using the most equal distribution and replacing u_i and v_i by their q-quantile counterparts, $F^{-1}(q_i = i/n, \hat{\theta}) = \hat{\mu}_y$ and $\hat{F}^{(n)^{-1}}(q_i = i/n) = y_{(i)}$, give GE measures. Note that u_i and v_i have bounded support ($u_i, v_i \in [0, 1]$), a property required to show that the asymptotic distribution of G_ξ exists, see Davidson (2012).

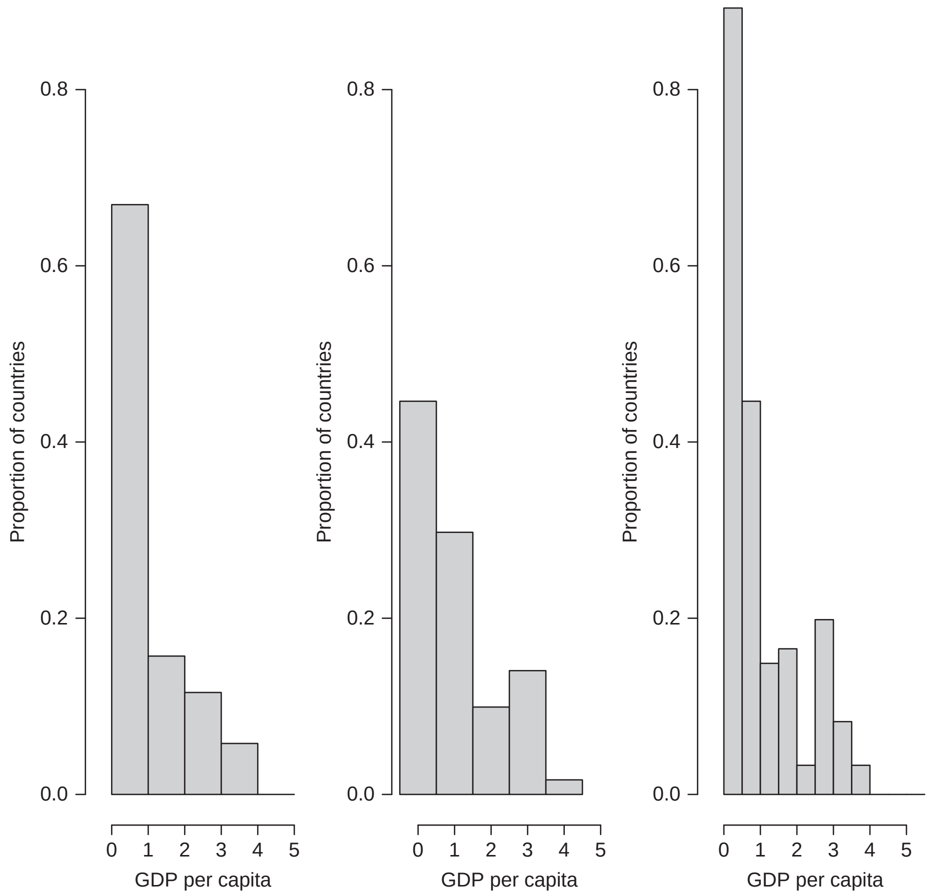

Figure 6.7 Histogram's sensitivity to the position and the number of bins.

are within a distance of $h/2$ or less from point y. The global density is obtained by sliding this window of width h along all the evaluation points.

Figure 6.8 presents the naive estimation of the density of GDP per capita across different countries in 1988. Compared to histograms, the naive estimator reveals much more detail about the curvature of the density function. However, discontinuities are still present.

The kernel estimator is a generalization of the naive estimator, which allows us to overcome the problem of differentiability at all points. The discontinuity problem comes from the indicator function $\imath(\cdot)$, which allocates a weight of one to all the observations that belong to the interval centered on y and zero weight to the other observations. The principle of kernel estimation is simple: Rather than giving all observations in the interval the same weight, the allocated weight is greater the closer the observation is to y. The

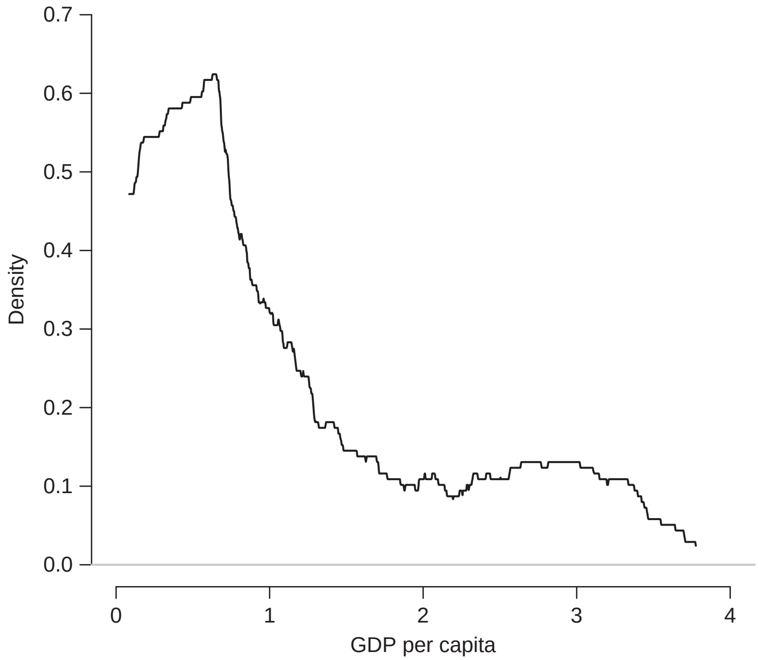

Figure 6.8 Naive estimator of GDP per capita.

transition from 1 to 0 in the weights is then carried out gradually, rather than abruptly. The kernel estimator is obtained by replacing the indicator function by a kernel function $K(\cdot)$:

$$\hat{f}(y) = \frac{1}{nh}\sum_{i=1}^{n} K\left(\frac{y - y_i}{h}\right). \tag{6.13}$$

For $\hat{f}(y)$ to conserve the properties of a density function, the integral of the kernel function over the entire space has to be equal to one. Any probability distribution can then be used as kernel function. The Gaussian and the Epanechnikov distributions are two kernels commonly used in practice.[18] Kernel density estimation is known to be sensitive to the choice of the bandwidth h, whereas it is not really affected by the choice of the kernel function.

[18] The Gaussian kernel corresponds to the choice of the standard Normal distribution: $K(x) = e^{-x^2/2}/\sqrt{2\pi}$. Epanechnikov (1969) proposed a second-degree polynomial, adjusted to satisfy the properties of a density function: $K(x) = 3(1 - x^2/5)/\left(4\sqrt{5}\right)$ if $|x| < \sqrt{5}$ and 0 otherwise.

6.3.2.2 Bandwidth Selection

The question of which value of h is the most appropriate is particularly a thorny one, even if automatic bandwidth selection procedures are often used in practice. Silverman's rule of thumb is mostly used, which is defined as follows:[19]

$$\hat{h}_{\text{opt}} = 0.9 \min\left(\hat{\sigma}; \frac{\hat{q}_3 - \hat{q}_1}{1.349}\right) n^{-1/5}, \tag{6.14}$$

where $\hat{\sigma}$ is the standard deviation of the data, and $\hat{q}_3$ and $\hat{q}_1$ are, respectively, the third and first quartiles calculated from the data. This rule boils down to using the minimum of two estimated measures of dispersion: the variance, which is sensitive to outliers, and the interquartile range. It is derived from the minimization of an approximation of the mean integrated squared error (MISE), a measure of discrepancy between the estimated and the true densities, where the Gaussian distribution is used as a reference distribution. This rule works well in numerous cases. Nonetheless, it tends to oversmooth the distribution when the true density is far from the Gaussian distribution, for example if it is multimodal and highly skewed. Figure 6.2 is a kernel density estimation of GDP per capita with Silverman's rule-of-thumb bandwidth selection. It appears as a smoothed version of the naive estimator in Figure 6.8. Several other data-driven methods for selecting the bandwidth have been developed such as cross-validation (CV) (Bowman, 1984; Rudemo, 1982; Stone, 1974) and plug-in methods (Ruppert et al., 1995; Sheather and Jones, 1991), among others.

Rather than using a Gaussian reference distribution in the approximation of the MISE, the *plug-in* approach consists of using a prior nonparametric estimate, and then choosing the h that minimizes this function. This choice of bandwidth does not then produce an empirical rule as simple as that proposed by Silverman, as it requires numerical calculation. For more details, see Sheather and Jones (1991).

Rather than minimizing the MISE, the underlying idea of CV *by least squares* is to minimize the integrated squared error (ISE). In other words, we use the same criterion, but not expressed in terms of expectations. The advantage of the ISE criterion is that it provides an optimal formula for h for a given sample. The counterpart is that two samples drawn from the same density will lead to two different optimal bandwidth choices. The ISE solution consists in finding the value of h that minimizes: $\text{ISE}(h) = \int \left[\hat{f} - f\right]^2 dy = \int \hat{f}^2 dy - 2\int \hat{f} f\, dy + \int f^2 dy$, where, for simplicity, f and $\hat{f}$ correspond to $f(y)$ and $\hat{f}(y)$. The last term in this equation does not contain h and thus plays no role in the minimization. Furthermore, the term $\int \hat{f} f\, dy$ is exactly $E\left(\hat{f}\right)$. Let $\hat{f}_{-i}$ be the estimator of the density based on the sample containing all the observations except for y_i.

[19] See Equation (3.31) in Silverman (1986, p. 48).

An unbiased estimator of $E(\hat{f})$ is given by $n^{-1}\sum_{i=1}^{n}\hat{f}_{-i}$. The minimization of the ISE criterion thus requires us to minimize the following expression:

$$\mathrm{CV}(h) = \int \hat{f}^2(y)\mathrm{d}y - \frac{2}{n}\sum_{i=1}^{n}\hat{f}_{-i}(y_i).$$

This method is also called *unbiased* CV, as $\mathrm{CV}(h) + \int f^2 \mathrm{d}y$ is an unbiased estimator of MISE. The value of h that minimizes this expression converges asymptotically to the value that minimizes the MISE.

6.3.2.3 Adaptive Kernel Estimator

In the kernel density estimation presented earlier, the bandwidth remains constant at all points where the distribution is estimated. This constraint can be particularly onerous when the concentration of data is markedly heterogeneous in the sample. There would be advantages to using narrower bandwidths in dense parts of the distribution (the middle) and wider ones in the more sparse parts (the tails). The adaptive kernel estimator is defined as follows:

$$\hat{f}(y) = \frac{1}{n}\sum_{i=1}^{n}\frac{1}{h\lambda_i}K\left(\frac{y-y_i}{h\lambda_i}\right),$$

where λ_i is a parameter that varies with the local concentration of the data. An estimate of the density at point y_i, denoted by $\widetilde{f}(y_i)$, measures the concentration of the data around this point: a higher value of $\widetilde{f}(y_i)$ denotes a greater concentration of data, whereas smaller values indicate lighter concentrations. The parameter λ_i can thus be defined as being inversely proportional to this estimated value: $\lambda_i = \left[g/\widetilde{f}(y_i)\right]^{\theta}$, where g is the geometric mean of $\widetilde{f}(y_i)$ and θ is a parameter that takes on values between 0 and 1.[20] The parameter λ_i is smaller when the density is greater (notably toward the middle of the distribution) and larger when the density is lighter (in the tails of the distribution).

Figure 6.9 presents the adaptive kernel density estimation of GDP per capita across different countries in 1988. Compared to the simple kernel density estimation, with fixed bandwidth (dashed line), the first mode is higher, and the second mode lower.

Several empirical studies on income distribution have used kernel density estimation, among others, see Marron and Schmitz (1992), Jenkins (1995), Cowell et al. (1996), Daly et al. (1997), Quah (1997), Burkhauser et al. (1999), Bourguignon and Morrisson (2002), Pittau and Zelli (2004), Jenkins and Van Kerm (2005), and Sala-i-Martin (2006).

[20] In practice, an initial fixed-bandwidth kernel estimator can be employed as $\widetilde{f}(y_i)$, with $\theta = 1/2$ and λ obtained with Silverman's rule of thumb.

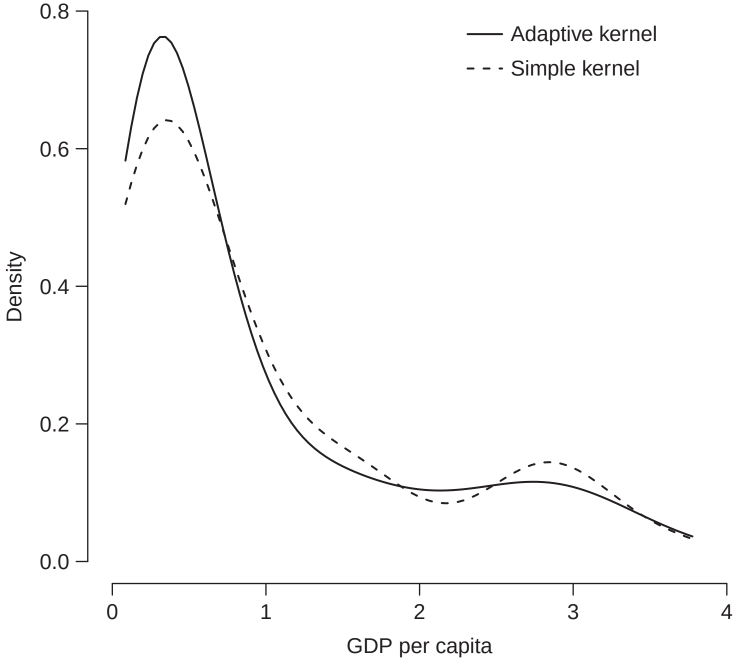

Figure 6.9 Adaptive kernel estimation of GDP per capita.

6.3.2.4 Multivariate and Conditional Density

The extension to the multivariate case is straightforward. The joint density of two variables y and x, for which we have n observations, can be estimated with a bivariate kernel function

$$\hat{f}(y, x) = \frac{1}{nh_1 h_2} \sum_{i=1}^{n} K\left(\frac{y_i - y}{h_1}; \frac{x_i - x}{h_2}\right), \tag{6.15}$$

which is equivalent to the product of two univariate kernels in the Gaussian case. The extension to the d-dimensional case is immediate, via the use of multivariate kernels in d-dimensions. Scott (1992) extends Silverman's rule of thumb as follows: $h_j = n^{-1/(d+4)}\hat{\sigma}_j$, where $\hat{\sigma}_1$ and $\hat{\sigma}_2$ are the sample standard deviations of, respectively, y and x. In practice, kernel density estimation is rarely used with more than two dimensions. With three or more dimensions, not only may the graphical representation be problematic, but the precision of the estimation may be also. Silverman (1986) showed that the number of observations required to guarantee a certain degree of reliability rises explosively with the number of dimensions. This problem is known as the *curse of dimensionality*.

A conditional density function is equal to the ratio of a joint distribution and a marginal distribution, $f(y|x) = f(x, y)/f(x)$. A kernel conditional density estimation is then given by

$$\hat{f}(y|x) = \frac{\frac{1}{h_1 h_2}\sum_{i=1}^{n} K\left(\frac{y_i - y}{h_1}; \frac{x_i - x}{h_2}\right)}{\frac{1}{h_3}\sum_{i=1}^{n} K\left(\frac{x_i - x}{h_3}\right)}. \tag{6.16}$$

When several conditional variables are considered, the bandwidth selection obtained by CV can mitigate the curse of dimensionality problem if some of them are irrelevant (Fan and Yim, 2004; Hall et al., 2004). Several recent studies have focused on conditional analysis in a nonparametric framework. To evaluate policy effects, the impact of a counterfactual change in the distribution of some covariates on the unconditional distribution of some variable of interest has been investigated in DiNardo et al. (1996), Donald et al. (2000), Chernozhukov et al. (2009), Rothe (2010), and Donald et al. (2012). For more details on kernel density estimation, see Silverman (1986), Paul (1999), Li and Racine (2006), and Ahamada and Flachaire (2010).

6.3.3 Finite Mixture Models

6.3.3.1 A Group Decomposition Approach

A population can be decomposed into several distinct groups in many different ways. The density function of the population is then equal to the sum of the densities associated with each of the different groups. Let us consider κ groups, with the density function of each group being parametric, $f_k(y; \theta_k)$ for $k = 1, \ldots, \kappa$ where θ is a set of parameters. Then, the density function of the population can be written,

$$f(y; \theta) = \sum_{k=1}^{\kappa} \pi_k f_k(y; \theta_k) \tag{6.17}$$

where π_k is the proportion of the population belonging to subgroup k. The conditions $0 \le \pi_k \le 1$ and $\sum_{k=1}^{K} \pi_k = 1$ are required to guarantee that the population density integrates to one over the support. A density estimation by mixture models is obtained by replacing the unknown parameters by estimated parameters. In finite mixture models, the group to which each individual belongs is not observed.[21] They thus allow us to capture the effect of unobserved heterogeneity. They can also be used for classification purpose. Bayes' theorem allows us to deduce the *a posteriori* probability that an observation i belongs to the group k:

[21] When the groups are known and also the densities associated to each groups, the mixture model is entirely parametric and can be estimated by maximum likelihood (see Section 6.3.1).

$$\pi_{ik} = \frac{\pi_k f_k(y_i;\theta_k)}{\sum_{k=1}^{\kappa} \pi_k f_k(y_i;\theta_k)}. \tag{6.18}$$

Replacing the unknown parameters by consistent estimates, these individual probabilities can be used to classify the observations into the different groups.

The estimation of a density by a mixture model allows us to bring out the link between parametric and nonparametric estimation. If we consider one single group ($\kappa = 1$), then the mixture models amount to just one parametric function. Adding additional groups allows us to estimate more complicated densities, which cannot be modeled with one sole group; adding more groups allows us to reflect the heterogeneity of the population. Mixture models thus permit much greater modeling flexibility. In the extreme case, where we have as many groups as we do observations ($\kappa = n$), the mixture is equivalent to the estimation of a density by kernel methods (see Section 6.3.2).[22] For values of κ between 1 and the size of the sample n, the mixture model can thus be seen as a semiparametric compromise between parametric estimation and nonparametric kernel estimation. The parametric aspect is reflected in the fact that the density is expressed as a sum of parametric density functions; the nonparametric aspect is captured by the presence of a number of different groups.

The theory of mixture models tells us that, under regularity conditions, any probability density can be consistently estimated as a mixture of Normal distributions.[23] Figure 6.10 depicts a number of different mixtures of two Normal distributions, of which the density can be written as $\pi_1\phi(y;\mu_1,\sigma_1)+\pi_2\phi(y;\mu_2,\sigma_2)$, where $\phi(\cdot)$ is the density of the Normal distribution, with mean μ_k and variance σ_k, for $k = 1, 2$. The global density and the two individual components are represented in the same figure.[24] From global densities (solid lines), we can see that a wide variety of densities can be represented by a mixture of only two Normal distributions, as top flat (panel a), bimodal (panel b), skewed (panel c), and thick upper-tailed (panel d) distributions. Many further examples can be provided to illustrate the very wide variety of distributions that can be characterized by a mixture of κ Normal distributions: see, among others, Marron and Wand (1992). All these examples reveal the great flexibility of finite mixture models in estimating densities.

[22] If $K = n$ and $\pi_1 = \cdots = \pi_K = 1/n$, Equation (6.17) is then equivalent to Equation (6.13) where the $f_k(\cdot)$ function is the kernel function $K(\cdot)$.

[23] See Escobar and West (1995), Ferguson (1983), Titterington, Makov, and Smith (1985), McLachlan and Peel (2000), and Ghosal and van der Vaart (2001).

[24] In panel (a), $\pi_1 = \pi_2 = 0.5$, $\sigma_1 = \sigma_2 = 1$, $\mu_1 = 0$, $\mu_2 = 2$. In panel (b), $\pi_1 = \pi_2 = 0.5$, $\sigma_1 = \sigma_2 = 1$, $\mu_1 = 0$, $\mu_2 = 4$. In panel (c), $\pi_1 = 0.6$, $\pi_2 = 0.4$, $\sigma_1 = \sigma_2 = 1$, $\mu_1 = 0$, $\mu_2 = 2$. In panel (d), $\pi_1 = 0.75$, $\pi_2 = 0.25$, $\sigma_1 = 1$, $\sigma_2 = 2$, $\mu_1 = 0$, $\mu_2 = 2$.

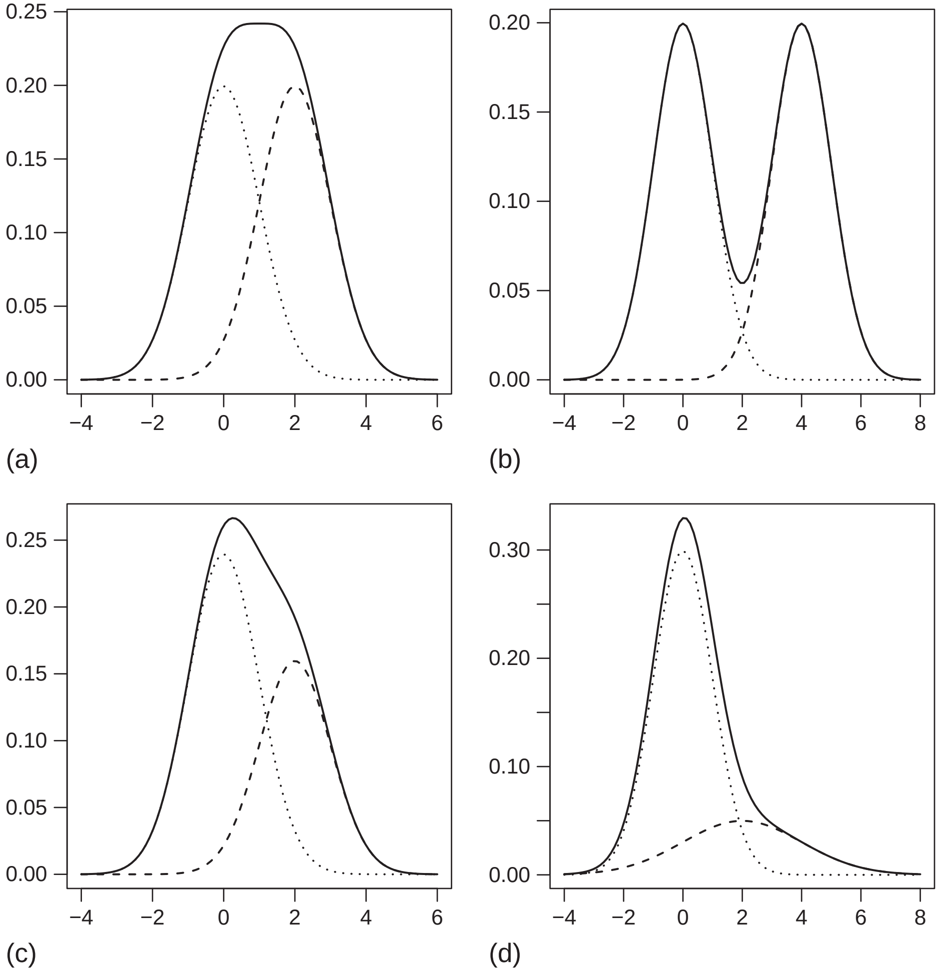

Figure 6.10 Mixtures of two Normal distributions.

6.3.3.2 Number of Components and Number of Groups

For a given number of κ, we can estimate the unknown parameters by maximum likelihood.[25] The number κ, known as the number of components, can be selected by minimizing a criterion, as the Bayesian Information Criterion (BIC),

$$\mathrm{BIC} = -2\hat{\ell} + \#\mathrm{param}\log n, \tag{6.19}$$

[25] The EM algorithm of Dempster et al. (1977) is often used. Bayesian methods can also be employed, see Robert and Casella (2005) and Frühwirth-Schnatter (2006).

where $\hat{\ell}$ is the estimated log-likelihood, #param is the number of parameters to estimate, and n is the number of observations. If the main concern is the best fit of the overall density, this selection criterion is appropriate. However, if the main concern is the detection of distinct groups, the choice of κ is less simple. Indeed, there is no automatic correspondence between the choice of κ and the number of underlying groups in the population. For instance, panel (d) in Figure 6.10 shows that the second component is required to fit a thick upper tail, but it does not clearly identify a distinct group from the first component. Indeed, the two distributions of the groups intersect a lot. Here, the number of component κ is not necessarily equivalent to the number of groups. It illustrates that the definition of what constitutes a distinct group and its detection can be a difficult task in finite mixture models.[26]

Figure 6.11 shows kernel density estimation (on the left) and estimation by a mixture of lognormal distributions (on the right) of the income distribution in the

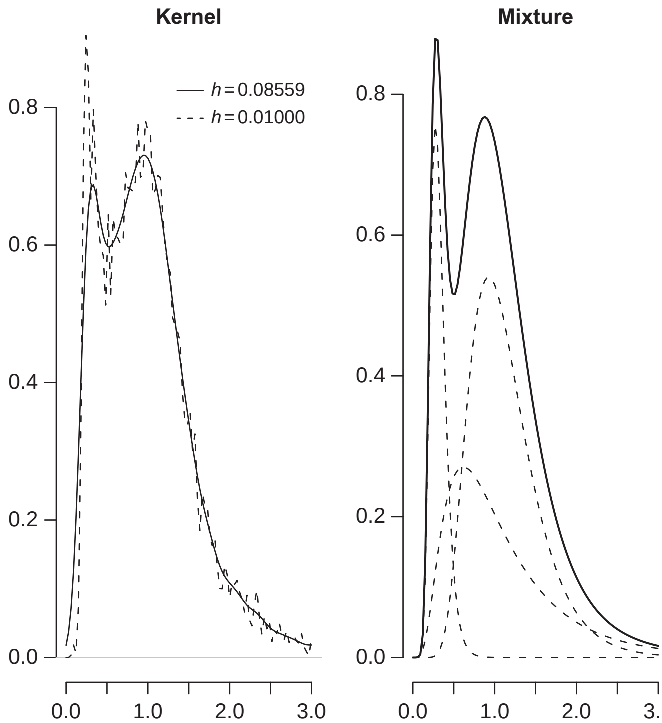

Figure 6.11 Income distribution in the United Kingdom in 1973 (incomes normalized by contemporary mean).

[26] A more appropriate method could be to test the number of modes of the distribution, see Ray and Lindsay (2005).

United Kingdom in 1973. A lognormal distribution is heavy tailed, in the sense that it has an upper tail that is heavier than an exponential. Then, it is more appropriate to use finite mixtures of lognormals rather than finite mixture of normals to fit income distributions, which are typically heavy tailed. The estimation of the density by a mixture of lognormal distributions is obtained from an estimation of the density of log-incomes by a mixture of Normal distributions.[27] The value of the bandwidth given by Silverman's empirical rule ($h=0.08559$) allows us to reproduce the kernel density estimation results in Marron and Schmitz (1992). Kernel estimation with a smaller value of $h(0.01)$ are overlaid in the same figure. The comparison of the two estimators reveals that the results differ significantly: with $h=0.08559$, the first mode is smaller than the second, whereas with $h=0.01$ the reverse holds. This confirms that the kernel estimation with Silverman's rule of thumb does indeed tend to oversmooth the function when the underlying distribution is multimodal and highly skewed distribution (see Section 6.3.2). In our example, the Silverman selection choice tends to flatten out considerably the first mode relative to the second. The right panel shows the density estimation with a mixture of lognormal distributions, obtained by minimizing the BIC. The overall distribution appears to be a smoothed representation of the kernel density estimation with $h=0.01$. In addition, the mixture estimation identifies three separate components. The first and the third components do not overlap a lot; they can be associated to two distinct modes. The second component overlaps to a considerable extent with the third and to a lesser extent with the first. The presence of this second component allows a better fit of the right-hand side tail of the distribution, but cannot be clearly associated to a distinct group.

A very few empirical studies have used finite mixture models to estimate income distributions. Flachaire and Nuñez (2007) studied the distribution of household income in the United Kingdom with a mixture of lognormal distributions. Pittau and Zelli (2006) and Pittau et al. (2010) studied the evolution of per capita income distributions across EU regions and countries. Chotikapanich and Griffiths (2008) estimated the Canadian income distribution using a mixture of Gamma distributions. Lubrano and Ndoye (2011) modeled the income distribution using a Bayesian approach and a mixture of lognormal densities.[28]

6.3.3.3 Group Profiles Explanation

In addition to the estimate of a density function of any form, finite mixture estimation can be used to explain the profiles of the different groups underlying the overall population. This can be done by introducing covariates in the probabilities π_k:

[27] From $f(x;\Theta)=\sum_{k=1}^{K}\pi_k\phi(x;\mu_k,\sigma_k)$, we have $f(y;\Theta)=\sum_{k=1}^{K}\pi_k\Lambda(y;\mu_k,\sigma_k)$ where $x=\log y$.

[28] Paap and Van Dijk (1998) considered mixtures of two distributions, using Normal, lognormal, Gamma, and Weibull distributions. However, their approach is entirely parametric, with the number of components and the densities of each groups fixed *a priori*.

$$f(y|z;\Theta) = \sum_{k=1}^{K} \pi_k(z, \alpha_k) f_k(y; \theta_k), \tag{6.20}$$

where $z = \{z_1, \ldots, z_l\}$ is a vector of l observed variables and $\alpha_k = \{\alpha_{1k}, \ldots, \alpha_{lk}\}$ is a vector of l unknown parameters. This model defines a conditional density function, which takes into account directly the fact that the probability of group membership may be a function of individual characteristics (a white-collar worker has a greater probability of belonging to the group of the richest households than does a blue-collar worker). As well as the nonparametric estimation of the density and the decomposition into different groups, covariates also explain the variability between groups. The relationship between the probabilities π_k and the covariates z can be specified with an ordered logit/probit or multinomial regression model, and the unconditional density can be obtained as follows:

$$f(y; \Theta) = \sum_{k=1}^{K} \overline{\pi}_k \phi(y; \mu_k, \sigma_k) \quad \text{with} \quad \overline{\pi}_k = \frac{1}{n} \sum_{i=1}^{n} \pi_k(z_i, \alpha_k),$$

where z_i represents the vector of characteristics of the ith observation, and n is the number of observations. In other words, $\pi_k(z_i, \alpha_k)$ is the probability that the individual i with characteristics z_i belong to the group k. For more details, see Ahamada and Flachaire (2010).

Figure 6.12 reproduces the results of the estimation of the distribution of household income in the United Kingdom in 1979 and 1988, obtained in Flachaire and Nuñez (2007), by a mixture of lognormal distributions.[29] The decomposition into groups of the mixture estimator does emphasize clear changes over time that would be difficult to see from the comparisons of the overall distributions. The analysis by groups shows that, in 1988, a small separate group had formed to the extreme left of the distribution, whereas that situated to the far right of the distribution had grown in size. Table 6.3 reproduces the estimated coefficients (with standard errors in parentheses) associated to the following covariates: z_1 for a retired household, z_2 for single-parent families,

Table 6.3 Coefficient estimates of covariates

	z_1	z_2	z_3	z_4	z_5
1979	−1.77 (0.059)	−0.67 (0.106)	0.61 (0.050)	−1.16 (0.086)	−0.44 (0.020)
1988	−1.33 (0.058)	−0.69 (0.106)	0.78 (0.053)	−1.44 (0.068)	−0.35 (0.022)

[29] The analysis here uses the same data as Marron and Schmitz (1992), with the exception that the incomes are normalized via an equivalence scale in order to account for differences in household size.

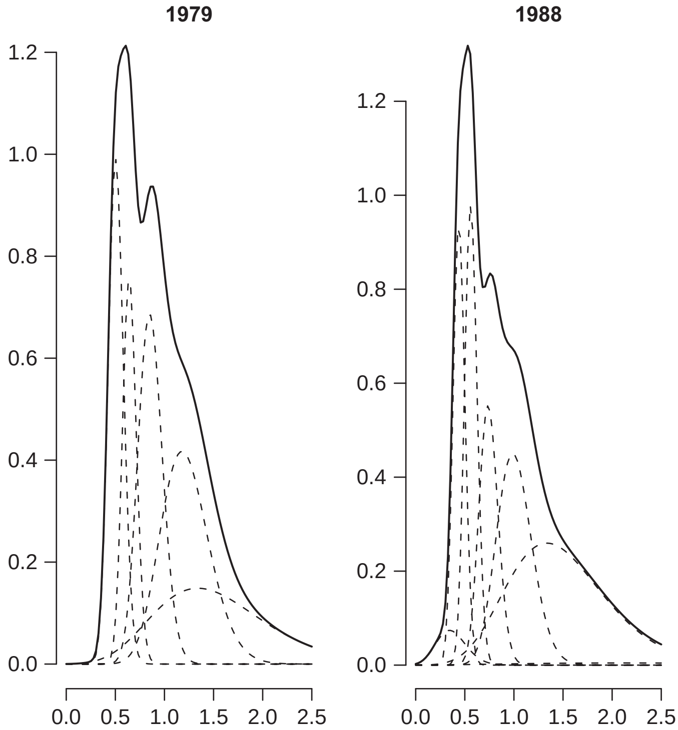

Figure 6.12 Income distribution in the United Kingdom in 1979 and 1988 (incomes normalized by contemporary mean).

z_3 for households where all the adults work, z_4 if there is no adult working in the household (in a nonretired household), and z_5 for the number of children.

An ordered probit model is used to specify the relationship between the probabilities and the covariates. If a coefficient is positive (negative), then the position of an observation with the associated variable moves to the right (left) of the distribution as the variable z_l increases. On the other hand, a value of $\alpha_{l,}$ that is not significantly different from zero, indicates that the characteristic z_l does not help us to explain the decomposition of the sample into the different groups. From the results, we can see that retired (z_1) and nonworking (z_4) households are more likely to be found toward the bottom of the income distribution, and households where all adults work (z_3), on the contrary, are more likely to be found toward the right of the distribution. In addition, the position of retired households has improved over this period, whereas that of households where no one works has deteriorated. These results emphasize the usefulness of mixture models, which yield an overall picture of the distribution of income and how this has changed over time, with richer results than those obtained from other commonly employed techniques.

6.3.3.4 Finite Mixture of Regressions

Covariates have been introduced in the probabilities to characterized group profiles. They can be also introduced into the modeling of the densities in each of the groups, leading us to consider mixtures of regression models. Let us consider a mixture of Normal distributions with variance σ_k^2 and mean being conditional on some covariates, $\mu_k = x\beta_k$, which can be written as:

$$f(y|x;\Theta) = \sum_{k=1}^{\kappa} \pi_k \phi(y|x;\beta_k, \sigma_k). \tag{6.21}$$

If there are two groups ($\kappa = 2$), one just needs to consider the following model:

$$\begin{aligned} &\text{Group 1}: y = x\beta_1 + \varepsilon_1, \quad \varepsilon_1 \sim N\left(0, \sigma_1^2\right), \\ &\text{Group 2}: y = x\beta_2 + \varepsilon_2, \quad \varepsilon_2 \sim N\left(0, \sigma_2^2\right), \end{aligned}$$

where ϵ_1 and ϵ_2 are independent and identical Normally distributed error terms within each group, with variances of σ_1^2 and σ_2^2, respectively. In this model, we consider that the population is composed of two different groups, for which the relationship between the dependent and explanatory variables is different, and the observations come from the different groups in the population in unknown proportions. This specification would be particularly appropriate if we assume that the marginal impact of covariates may be different in each of the groups, as suggested in Figure 6.3. Covariates could be introduced at the same time in the probabilities to explain group profiles.

To illustrate, consider a simple Mincer earnings equation, which explains the logarithm of an individual's earnings by their number of years of education and number of years of labor-market experience. One way of testing for earnings differences between men and women is to test if the parameters of the earnings equation are statistically significantly different between the two groups of individuals, via a Chow test (Chow, 1960). Table 6.4 shows ordinary least squares (OLS) estimation results from linear regression models for the groups of men and of women (columns 1 and 2), using data from a household survey carried out by the U.S. Census Bureau in May 1985.[30] A Chow test, equal to 14.19, rejects the null hypothesis that the two sets of coefficients are identical. As the dependent variable is the log of earnings, the estimation results show that one additional year of education increases earnings by around 7.9% for men and 10.9% for women on average. The earnings profiles as a function of labor-market experience are different between the two groups. These are traced out in Figure 6.13 for 8 years of education, from which we can see that the gender gap is sharply increasing with labor-market experience during the first 30 years.[31]

[30] The data come from Chapter 5 of Berndt (1990).

[31] The curve for the group of men corresponds to the polynomial $y = 0.66194 + 8 \times 0.07941 + 0.04484 \times x - 0.00066 \times x^2$ and that for the group of women to $y = 0.22254 + 8 \times 0.10915 + 0.02597 \times x - 0.00038 \times x^2$. The gap between the two curves widens with experience at first before narrowing again after around 30 years of labor-market experience.

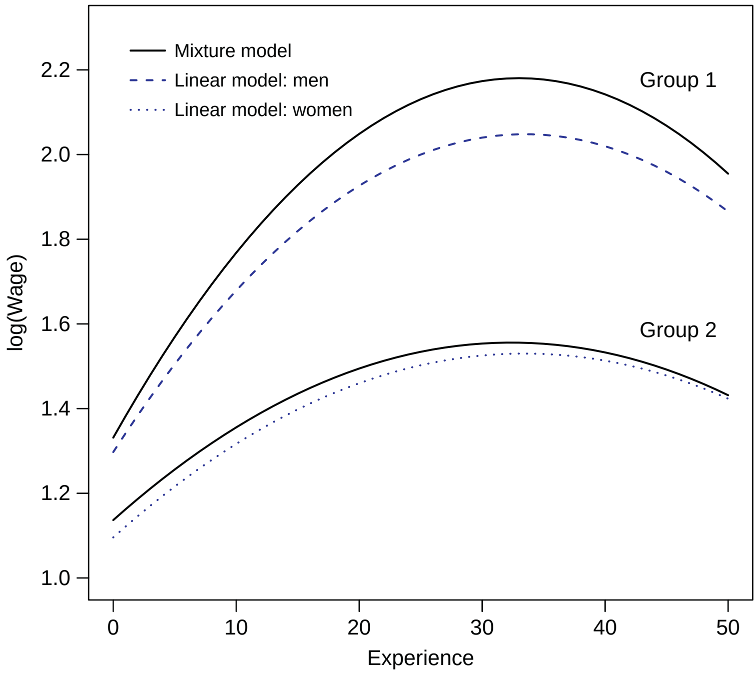

Figure 6.13 The relationship between earnings and labor-market experience.

In the linear model approach, we define *a priori* two groups of individuals—men and women. By contrast, in a mixture model approach, we do not specify the groups *a priori*, we let the data identify homogeneous groups with respect to the relationship between the dependent and explanatory variables. Table 6.4 shows estimation results from a mixture model (columns 3 and 4); the BIC suggests that there are two groups. The estimation results show that one additional year of education increases earnings by around 8.2% for individuals in the first group and 9.8% for individuals in the second, on average. The impact of experience on earnings are traced in Figure 6.13 for 8 years of education (solid lines).[32] From this figure, the gap between the two groups is much larger than the gap between the groups of men and of women obtained from linear models.

The use of concomitant variables in the mixture model allows us to characterize the profile of the groups. Two dummy variables are taken into account as concomitant variables. The first is for the individual being a woman (Female), and the second for the individual being a union member (Union Member). In Table 6.4, column 4, the positive and significant coefficient on the "Female" variable indicates that women are more likely to belong to the second group than to the first group. The negative significant coefficient on "Union Member" shows that unionized workers are less likely to belong to the second than to the first group.[33] A classification shows that 96.3% of women belong to group 2, whereas the analogous percentage of men is only 19%.[34] Equally, the percentage of union members classified in group 1 is 80.2%. Last, the results of this analysis suggest that, for the vast majority of women, the relationship between earnings and experience is much flatter than that for most men and union members, holding everything else equal. The gap obtained is much larger than those obtained by considering all men and all women in two distinct groups.

For more details on mixture models of regression, see McLachlan and Peel (2000), Frühwirth-Schnatter (2006), and Ahamada and Flachaire (2010).

6.3.4 Finite Sample Properties

In this section, we study the quality of the fit of nonparametric density estimation in finite samples. To asses the quality of the density estimation, we need to use a distance measure between the estimated density and the true density. We use the mean integrated absolute errors (MIAE) measure,

[32] The curve for the first group corresponds to the polynomial $y = 0.67517 + 8 \times 0.08202 + 0.05147 \times x - 0.00078 \times x^2$, and that of the second to $y = 0.34909 + 8 \times 0.09844 + 0.02590 \times x - 0.0004 \times x^2$.

[33] This coefficient is significant at the 1% level according to an LR test.

[34] An individual is assigned to a group when his individual *a posteriori* probability of belonging to this group is higher than the probabilities to belong to other groups, see (6.18).

$$\mathrm{MIAE} = E\left(\int_0^{\infty} \left|\hat{f}(y) - f(y)\right| \mathrm{d}y\right). \tag{6.22}$$

In our experiments, data are generated from two unimodal distributions: lognormal, $\Lambda(y;\ 0,\ \sigma)$, and Singh–Maddala distributions, $\mathrm{SM}(y;\ 2.8,\ 0.193,\ q)$. We also use a bimodal distribution: a mixture of two Singh–Maddala distributions: $\frac{2}{5}\mathrm{SM}(y; 2.8, 0.193, 1.7) + \frac{3}{5}\ \mathrm{SM}(y; 5.8, 0.593, q)$, plotted in Figure 6.14. As σ increases and q decreases, the upper tail of the distribution decays more slowly. The sample size is $n = 500$, and the MIAE criterion is calculated as the average of $\int_0^{\infty} |f(y) - f(y)| \mathrm{d}y$ computed for 1000 samples.

Table 6.5 shows the quality of the fit for several density estimation methods. We first consider standard kernel estimator, with fixed bandwidth selected by the Silverman rule-of-thumb (Silv.), by cross-validation (CV) and by the plug-in (Plug-in) methods. Then, we consider adaptive kernel methods based on each of the previous fixed bandwidths. Finally, we consider density estimation based on mixture of lognormal distributions.[35]

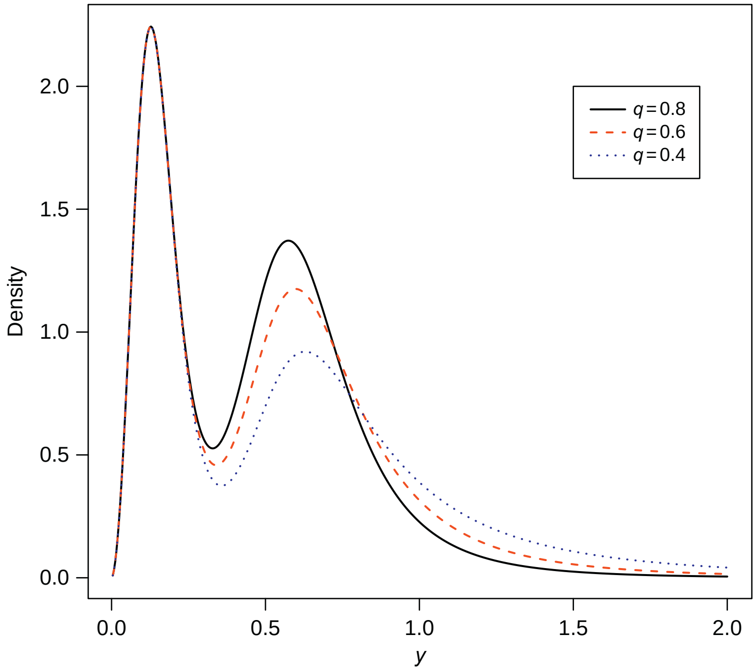

Figure 6.14 Mixture of two Singh–Maddala distributions.

[35] The density function of the logarithmic transformation of the data is estimated by a mixture of normal distributions and the number of components is selected with the BIC.

Table 6.5 Quality of density estimation (MIAE), $n = 500$

	Standard kernel			Adaptive kernel			Mixture lognormal
	Silv.	**CV**	**Plug-in**	**Silv.**	**CV**	**Plug-in**	
Lognormal							
$\sigma = 0.5$	0.1044	0.1094	0.1033	0.0982	0.1098	0.1028	0.0407
$\sigma = 0.75$	0.1326	0.1326	0.1252	0.1098	0.1283	0.1179	0.0407
$\sigma = 1$	0.1643	0.1716	0.1522	0.1262	0.1609	0.1362	0.0407
Singh–Maddala							
$q = 1.7$	0.0942	0.1009	0.0951	0.0915	0.0994	0.0934	0.0840
$q = 1.2$	0.1039	0.1100	0.1048	0.0947	0.1050	0.0994	0.0920
$q = 0.7$	0.1346	0.1482	0.1326	0.1049	0.1349	0.1175	0.0873
Mixture of two Singh–Maddala							
$q = 0.8$	0.2080	0.1390	0.1328	0.1577	0.1356	0.1224	0.1367
$q = 0.6$	0.2458	0.1528	0.1463	0.1896	0.1457	0.1293	0.1464
$q = 0.4$	0.2885	0.1953	0.1733	0.2234	0.1812	0.1450	0.1366

The results in Table 6.5 show that, for standard and adaptive kernel methods, the quality of the fit deteriorates as the upper tail becomes heavier (as σ increases and q decreases, MIAE increases). Moreover, standard kernel method with the Silverman's rule-of-thumb bandwidth fails when the distribution is multimodal and highly skewed (case of two Singh–Maddala distributions), compared to other methods. Finally, our results suggest that, in the cases of heavier-tailed distributions, the adaptive kernel based on the plug-in bandwidth and the mixture of lognormals perform better than standard kernel methods.

6.4. WELFARE INDICES

We can use the term *welfare indices* to cover a number of specific tools of distributional analysis that are of interest to economists and social scientists. These include social welfare functions, inequality measures, and poverty indices. Our approach is to characterize some basic classes of indices, to introduce some standard results that enable us to describe the statistical properties of these indices, and then to apply the analysis to particular welfare indices that are of interest to students of income distribution. The applications here will be to inequality and poverty indices.

6.4.1 Basic Cases

It is useful begin with two of the simplest welfare indices, the quantile and the income cumulation. Quantiles and income cumulations are themselves incomes and so belong to the interval $\mathbb{Y} = [\underline{y}, \overline{y})$, introduced in Section 6.1.2. Once again we work with distribution functions $F \in \mathbb{F}$ so that the total population in the distribution is implicitly normalized to 1.

Let $q \in \mathbb{Q}$ denote an arbitrary population proportion; then we may define Q the *quantile functional* from $\mathbb{F} \times \mathbb{Q}$ to $\mathbb{Y}$ as

$$Q(F; q) := \inf\{y | F(y) \geq q\} \tag{6.23}$$

(Gastwirth, 1971). For any distribution F the quantile functional gives the smallest income in $\mathbb{Y}$ such that $100q$ percent of the population have exactly that income or less. In cases where the distribution F is understood, we can use a shorthand form for the qth quantile

$$y_q := Q(F; q). \tag{6.24}$$

The functional Q provides the basis for several intuitive approaches to the analysis of income distribution. For example, commonly used quantile ratios — such as the "90/10" ratio, the "90/50" ratio (Alvaredo and Saez, 2009; Autor et al., 2008; Burkhauser et al., 2009)—are found by taking pairs of instances of (6.23) with appropriate q-values: y_{90}/y_{10}, y_{90}/y_{50} and so on.

Likewise C, the *cumulative income functional* from $\mathbb{F} \times \mathbb{Q}$ to $\mathbb{Y}$ is defined as

$$C(F; q) := \int_{\underline{y}}^{y_q} y \mathrm{d}F(y) \tag{6.25}$$

(Cowell and Victoria-Feser, 2002); for any distribution F the cumulative functional gives the total income received by the bottom $100q$ percent of the population. Again, in cases where the distribution F is understood, we can use the shorthand form for the qth cumulation: $c_q := C(F; q)$. A word of caution here: remember that the population is normalized to one; this convention is also embedded in the income cumulations (6.25). In particular, if we set $q = 1$ in (6.25), we get

$$c_1 = C(F; 1) = \mu(F), \tag{6.26}$$

the mean of the distribution F. We can find other intuitive approaches to the analysis of income distribution using C: For example, the income share of the poorest $100q$ percent of the population is obtained from two cumulants defined in (6.25) as

$$\frac{c_q}{c_1} = \frac{C(F; q)}{C(F; 1)}. \tag{6.27}$$

However, this is just a beginning. The indices generated by Q and C in (6.23) and (6.25) are but two well-known examples of a large class of welfare indices that can be expressed in *additively decomposable* form

$$W_{\mathrm{AD}}(F) := \int \phi(y) \mathrm{d}F(y), \tag{6.28}$$

up to a transformation involving $\mu(F)$, where $\phi : \mathbb{Y} \times \mathbb{Y} \to \mathbb{R}$ is piecewise differentiable. Decomposability here means decomposable by population subgroups (Cowell and Fiorio, 2011). This property can be seen more intuitively in the special case of a discrete distribution. If F consists of m point masses consisting of mass f_i located at income y_i $i = 1, \ldots, m$ then (6.28) becomes

$$\sum_{i=1}^{m} f_i \phi(y_i). \tag{6.29}$$

It is clear that the form of (6.29) implies that the welfare index can be found by evaluating income y_i in each of the m separate groups, weighting by the population of the group and aggregating.

Of course, it is not only the rather restrictive class W_{AD} that is interesting for distributional analysis. Many welfare indices can be conveniently expressed in the more general *quasi-additively decomposable* form

$$W_{\mathrm{QAD}}(F) := \int \varphi(y, \mu(F)) \mathrm{d}F(y) \tag{6.30}$$

where $\varphi : \mathbb{Y} \times \mathbb{Y} \to \mathbb{R}$ is piecewise differentiable, and most of the other commonly used welfare indices that cannot be expressed in the form (6.30) can be expressed in the *rank-dependent* form

$$W_{\mathrm{RD}}(F) := \int \psi(y, \mu(F), F(y)) \mathrm{d}F(y), \tag{6.31}$$

where ψ is piecewise differentiable. We will discuss specific examples from the W_{QAD} and W_{RD} classes of functionals in Sections 6.4.3 and 6.4.4 on inequality and poverty measures.

6.4.2 Asymptotic Inference

In this section and in Sections 6.4.3 and 6.4.4, we focus on estimation and inference problems for cases where the sample size n may be considered to be arbitrarily large.[36] The small sample problem is discussed in Section 6.4.5. Furthermore, for the moment we will concentrate only on *distribution-free* approaches that do not require any estimation of the density function, parametric, or even nonparametric; the parametric approach is considered in Section 6.4.6.

There are several methods that we can use to derive the tools that we need. Here, we will make extensive use of an approach that enables us to derive the asymptotic results quickly and simply and that lays the basis for further discussions in Section 6.6.[37]

[36] For an overview of literature, see Cowell (1999).
[37] This approach draws heavily on Cowell and Victoria-Feser (2003).

6.4.2.1 The Influence Function

The principal analytical tool employed here is the *influence function* (IF), which can be used here as a device to quantify the effect of a perturbation on some given theoretical distribution. So, assume that $F \in \mathbb{F}$ is the distribution in question and that $H^{(z)} \in \mathbb{F}$ is another distribution that consists just of a single point mass at z,

$$H^{(z)}(y) = \iota(y \geq z), \tag{6.32}$$

where $\iota(\cdot)$ is the indicator function (6.1). Then the mixture distribution

$$G := [1-\delta]F + \delta H^{(z)}, 0 \leq \delta \leq 1 \tag{6.33}$$

can be taken as a representation of the perturbation of the distribution F by the point mass, where δ represents the relative size of the perturbation. Now we need a way of quantifying the importance of this perturbation of F: consider a functional $T : \mathbb{F} \to \mathbb{R}^m$ that represents some statistic in which we are interested. The IF measures the impact of the perturbation on the statistic T for infinitesimal δ, namely,

$$\mathrm{IF}(z; T, F) := \lim_{\delta \downarrow 0} \left[\frac{T(G) - T(F)}{\delta} \right] \tag{6.34}$$

which becomes $\frac{\partial}{\partial \delta} T(G)|_{\delta \to 0}$ if T is differentiable.

The IF is particularly useful in analyzing the problem of data contamination (see Section 6.6.1). But the IF has other convenient applications: its relevance to this part of our discussion is that it may be used to derive asymptotic results such as asymptotic covariance matrices. If the distribution G is "near" F (as in Equation (6.33) for small δ) then the first-order von Mises expansion of T at F evaluated in G is given by

$$T(G) = T(F) + \int \mathrm{IF}(y; T, F)\mathrm{d}(G - F)(y) + \text{remainder}$$

When the observations are independently and identically distributed according to F then, by the Glivenko–Cantelli theorem, the empirical distribution $F^{(n)} \to F$. So we may replace G by $F^{(n)}$ for sufficiently large n and obtain

$$T\left(F^{(n)}\right) \approx T(F) + \frac{1}{n}\sum_{i=1}^{n} \mathrm{IF}(y_i; T, F) + \text{remainder}$$

from which we obtain (Hampel et al., 1986, p. 85):

Lemma 1

When the remainder becomes negligible as $n \to \infty$, by the CLT, $\sqrt{n}\left(T\left(F^{(n)}\right) - T(F)\right)$ is asymptotically normal with asymptotic covariance matrix

$$\int \mathrm{IF}(y; T, F)\mathrm{IF}^{\top}(y; T, F)\mathrm{d}F(y) \tag{6.35}$$

Regularity conditions can be found in Reeds (1976), Boos and Serfling (1980), and Fernholz (1983).

Lemma 1 constitutes the basis of the results that follow. Given a statistic T, one just needs to compute its IF to obtain the asymptotic covariance matrix. For inequality and poverty measures (unidimensional statistics), T is a functional $\mathbb{F} \to \mathbb{R}$. In many cases, we can express the IF as a random variable Z minus its expectation,

$$\mathrm{IF}(y, T, F) = Z - E(Z) \tag{6.36}$$

For unidimensional statistics, from Lemma 1, $\sqrt{n}\left(T\left(F^{(n)}\right) - T(F)\right)$ is then asymptotically normal with asymptotic variance equal to

$$\int \mathrm{IF}(y, T, F)^2 \mathrm{d}F(y) = \int (Z - E(Z))^2 \mathrm{d}F(Z), \tag{6.37}$$

which is nothing but the variance of Z. This result allows us to estimate the asymptotic variance of the statistic from a sample using

$$\widehat{\mathrm{var}}\left(T\left(F^{(n)}\right)\right) = \frac{1}{n}\widehat{\mathrm{var}}(Z) = \frac{1}{n^2}\sum_{i=1}^{n}(Z_i - \overline{Z})^2 \tag{6.38}$$

where Z_i, for $i = 1, \ldots, n$ are sample realizations of Z and $\overline{Z} = \frac{1}{n}\sum_{i=1}^{n} Z_i$. From a sample, the asymptotic variance of the statistic is simple to estimate; it is the empirical variance of $Z_1, \ldots, Z_n$ divided by n.

The main issue here is to provide IFs and to express them as a function of Z as in (6.36), for a wide range of welfare indices and ranking tools, as well as for different forms of data. Moreover, for some important cases, we will also develop analytically the formula in (6.35) so that the approach for computing asymptotic covariance matrices based on the IF can be compared to those from other approaches in the literature.[38]

6.4.2.2 Background Results

Several useful results in income distribution analysis can be found from a simple application of the IF; in particular, we have two key properties for the fundamental functionals introduced in Section 6.4.1 (Cowell and Victoria-Feser, 2002). Applying (6.23) to the distribution in (6.33), we get the qth quantile in the mixture distribution:

$$Q(G, q) = Q\left(F, \frac{q - \iota\left(y_q \geq z\right)\delta}{1 - \delta}\right) \tag{6.39}$$

[38] For previous suggestions on the use of the IF for estimating asymptotic variances, see, for example, Efron (1982) and Deville (1999).

where $y_q = Q(F, q)$ is the qth quantile for the (unmixed) income distribution. Let f be the density function for the distribution function F; then, differentiating (6.39) with respect to δ and setting $\delta = 0$, we obtain the following result.

Lemma 2

The IF for the quantile functional is

$$\mathrm{IF}(z; Q(\cdot, q), F) = \frac{q - \iota(Q(F; q) \geq z)}{f(Q(F; q))} = \frac{q - \iota(y_q \geq z)}{f(y_q)}. \tag{6.40}$$

Likewise, if we apply (6.25) to the distribution in (6.33), we get the qth income cumulation in the mixture distribution:

$$C(G; q) = [1 - \delta] \int_{\underline{y}}^{Q(G; q)} y \mathrm{d}F(y) + \delta z \tag{6.41}$$

where $Q(G, q)$ is given by (6.39). Once again, differentiating (6.41) with respect to δ and setting $\delta = 0$ we obtain another basic result.

Lemma 3

The IF for the cumulative income functional is

$$\begin{aligned} \mathrm{IF}(z; C(\cdot; q), F) &= qQ(F; q) - C(F; q) + \iota(q \geq F(z))[z - Q(F; q)] \\ &= qy_q - c_q + \iota(y_q \geq z)[z - y_q] \end{aligned}. \tag{6.42}$$

We will find that these results are useful not only for welfare indices considered in this section but also for distributional comparisons treated in Section 6.5.

6.4.2.3 QAD Welfare Indices

Let us first deal with the broad W_{QAD} class, the welfare indices that are quasi-additively decomposable; we will turn to the important, but more difficult, rank-dependent class W_{RD} later. Fortunately, this class covers a great number of commonly used tools of distributional analysis; fortunately also the properties are straightforward. Given a sample $y_1, \ldots, y_n$, the sample analogues of W_{QAD} defined in (6.30) are given by

$$\hat{W}_{\mathrm{QAD}} := W_{\mathrm{QAD}}\left(F^{(n)}\right) = \frac{1}{n} \sum_{i=1}^{n} \varphi(y_i, \hat{\mu}) \tag{6.43}$$

where $F^{(n)}$ is the EDF defined in Equation (6.8) and $\hat{\mu}$ is the sample mean:

$$\hat{\mu} := \mu\left(F^{(n)}\right) = \frac{1}{n} \sum_{i=1}^{n} y_i. \tag{6.44}$$

Substituting the mixture distribution (6.33) into (6.30), differentiating with respect to δ and evaluating at $\delta = 0$, we find the IF for the QAD class as:

$$\mathrm{IF}\left(z;\, W_{\mathrm{QAD}},\, F\right) = \varphi(z,\mu(F)) - W_{\mathrm{QAD}}(F) + [z-\mu(F)]\int \varphi(z,\mu(F))\mathrm{d}F(z) \tag{6.45}$$

where φ_μ denotes the partial derivative with respect to the second argument. This IF can be expressed as in (6.36), that is, as a random variable Z minus its expectation,

$$\mathrm{IF}\left(y,\, W_{\mathrm{QAD}},\, F\right) = Z - E(Z), \tag{6.46}$$

where

$$Z = \varphi(y,\mu(F)) + y\int \varphi_\mu(y,\mu(F))\mathrm{d}F(y). \tag{6.47}$$

From (6.36) and (6.37), the asymptotic variance of $\sqrt{n}\left(\hat{W}_{\mathrm{QAD}} - W_{\mathrm{QAD}}\right)$ is then equal to the variance of Z. From (6.38), the asymptotic variance of $\hat{W}_{\mathrm{QAD}}$ can be estimated from a sample using

$$\widehat{\mathrm{var}}\left(\hat{W}_{\mathrm{QAD}}\right) = \frac{1}{n}\widehat{\mathrm{var}}(Z). \tag{6.48}$$

6.4.3 Application: Inequality Measures

Almost all commonly used inequality indices other than the Gini coefficient can be written in the form $\Psi(W_{\mathrm{QAD}}(F),\mu(F))$ where $\Psi:\mathbb{R}^2 \to \mathbb{R}$. So we can use the results on the broad W_{QAD} class to derive the sampling distribution for a large range of inequality measures. We consider two leading examples in Sections 6.4.3.1 and 6.4.3.2.

6.4.3.1 The Generalized Entropy Class

We consider first an important family of inequality measures that belongs to the additively decomposable class (6.28). Members of the GE class (characterized by the parameter ξ) are defined by Equations (6.49)–(6.51)

$$I_{\mathrm{GE}}^{\xi}(F) = \frac{1}{\xi^2-\xi}\left[\int_{\underline{y}}^{\bar{y}}\left[\frac{y}{\mu(F)}\right]^{\xi}\mathrm{d}F(y) - 1\right], \xi\in\mathbb{R},\quad \xi\neq 0,1 \tag{6.49}$$

$$I_{\mathrm{GE}}^{0}(F) = -\int_{\underline{y}}^{\bar{y}}\log\left(\frac{y}{\mu(F)}\right)\mathrm{d}F(y) \tag{6.50}$$

$$I_{\mathrm{GE}}^{1}(F) = \int_{\underline{y}}^{\bar{y}}\frac{y}{\mu(F)}\log\left(\frac{y}{\mu(F)}\right)\mathrm{d}F(y) \tag{6.51}$$

Clearly the GE class belongs to the decomposable class of indices given in (6.28), a subset of the broad W_{QAD} class. The parameter ξ of the GE class characterizes the sensitivity to income differences in different parts of the income distribution. The more positive (negative) ξ is, the more sensitive is the inequality measure to income differences at the top (bottom) of the distribution. The mean logarithmic deviation (MLD) index, $I^0_{\mathrm{GE}}(F)$, is the limiting case when $\xi = 0$. The Theil index, $I^1_{\mathrm{GE}}(F)$, is the limiting case of the GE when $\xi = 1$. The sample analogues of these indices are given by

$$\hat{I}^{\xi}_{\mathrm{GE}} := I^{\xi}_{\mathrm{GE}}\left(F^{(n)}\right) = \begin{cases} \left[n\left(\xi^2 - \xi\right)\right]^{-1} \sum_{i=1}^{n} \left[(y_i/\hat{\mu})^{\xi} - 1\right] & \text{for } \xi \neq 0, 1 \\ -n^{-1} \sum_{i=1}^{n} \log(y_i/\hat{\mu}) & \text{for } \xi = 0 \\ n^{-1} \sum_{i=1}^{n} (y_i/\hat{\mu}) \log(y_i/\hat{\mu}) & \text{for } \xi = 1 \end{cases} \tag{6.52}$$

Using (6.46)–(6.48), we find that the variance of the GE measures can be estimated by

$$\widehat{\mathrm{var}}\left(\hat{I}^{\xi}_{\mathrm{GE}}\right) = \frac{1}{n^2} \sum_{i=1}^{n} (Z_i - \overline{Z})^2 \tag{6.53}$$

where

$$Z_i = \begin{cases} \left(\xi^2 - \xi\right)^{-1} (y_i/\hat{\mu})^{\xi} - \xi (y_i/\hat{\mu}) \left[\hat{I}^{\xi}_{\mathrm{GE}} + \left(\xi^2 - \xi\right)^{-1}\right] & \text{for } \xi \neq 0, 1 \\ (y_i/\hat{\mu}) \log y_i & \text{for } \xi = 0 \\ (y_i/\hat{\mu}) \left[\log(y_i/\hat{\mu}) - \hat{I}^{1}_{\mathrm{GE}} - 1\right] & \text{for } \xi = 1 \end{cases} \tag{6.54}$$

From a sample $y_1, \ldots, y_n$, the values of $Z_1, \ldots, Z_n$ can be calculated for a fixed ξ. The variance estimate of the generalized index is then computed as the empirical variance of $Z_1, \ldots, Z_n$ divided by n.

To show the results in (6.54), let us consider the case $\xi \neq 0, 1$, from which we have

$$\varphi(y, \mu(F)) = \frac{1}{\xi^2 - \xi} \left[\left[\frac{y}{\mu(F)}\right]^{\xi} - 1\right] \tag{6.55}$$

$$\varphi_{\mu}(y, \mu(F)) = \frac{-\xi}{\xi^2 - \xi} \left[\frac{y^{\xi}}{\mu(F)^{\xi+1}}\right] = -\frac{\xi}{\mu} \left(\varphi(y, \mu(F)) + \frac{1}{\xi^2 - \xi}\right) \tag{6.56}$$

Substituting (6.55) and (6.56) into (6.47) gives the result in (6.54), where y is replaced by its sample realization y_i. The same methodology can be applied for the cases $\xi = 0$ and $\xi = 1$.

Clearly the same approach can be applied to functions of moments of the distribution such as the coefficient of variation. Likewise, the statistical properties of the Atkinson class of inequality indices (Atkinson, 1970)

$$I_{\text{Atk}}^{\xi}(F) = 1 - \left[\int_{\underline{y}}^{\overline{y}} \left[\frac{y}{\mu(F)} \right]^{\xi} \mathrm{d}F(y) \right]^{1/\xi}, \quad \xi < 1 \tag{6.57}$$

can easily be derived from (6.53).[39]

The standard approach to obtain the results for the GE class and associated indices is by expressing the indices as a function of moments of the distribution and using the delta method. We can show that both IF and delta approaches give the same results. Indeed, from (6.28) and (6.29), a decomposable inequality measure can written as a function of two moments,

$$I = \psi(\nu; \mu) \quad \text{with} \quad \mu = E(y) \quad \text{and} \quad \nu = E(\phi(y)), \tag{6.58}$$

where ϕ and ψ are functions $\mathbb{R}^2 \to \mathbb{R}$ and ψ is monotonic increasing in its first argument; in particular, this is true for the I_{GE}^{ξ} and I_{Atk}^{ξ} families. The estimation of inequality indices is usually obtained by replacing the unknown moments of the distribution by consistent estimates. The moments are directly estimated by their sample counterparts. Let us consider y_i, for $i = 1, \ldots, n$, a sample of IID observations drawn from F. The estimator of the inequality measure can be expressed as a nonlinear function of two consistently estimated moments,

$$\hat{I} = \psi(\hat{\nu}; \hat{\mu}) \quad \text{with} \quad \hat{\mu} = \frac{1}{n}\sum_{i=1}^{N} y_i \quad \text{and} \quad \hat{\nu} = \frac{1}{n}\sum_{i=1}^{N} \phi(y_i). \tag{6.59}$$

From the CLT, this estimator is also consistent and asymptotically Normal, with asymptotic variance that can be calculated by the delta method. Specifically, the asymptotic variance is equal to

$$\operatorname{var}(\hat{I}) = \left(\frac{\partial \psi}{\partial \nu} \right)^2 \operatorname{var}(\hat{\nu}) + 2 \left(\frac{\partial \psi}{\partial \nu} \frac{\partial \psi}{\partial \mu} \right) \operatorname{cov}(\hat{\nu}, \hat{\mu}) + \left(\frac{\partial \psi}{\partial \mu} \right)^2 \operatorname{var}(\hat{\mu}). \tag{6.60}$$

An estimate of the asymptotic variance can be obtained by replacing the moments and their variances and covariance by consistent estimates. For the case $\xi = 0$, the MLD index can be written $I_{\text{GE}}^{0} = \log \mu - \nu$ where $\nu = \int \log y \mathrm{d}F(y)$. From (6.60), the asymptotic variance given by the delta method is equal to

[39] From (6.49), (6.50), and (6.57), we have $I_{\text{Atk}}^{\xi}(F) = 1 - [(\xi^2 - \xi) I_{\text{GE}}^{\xi}(F) + 1]^{1/\xi}, \quad \xi \neq 0$ and $I_{\text{Atk}}^{0}(F) = 1 - \exp(-I_{\text{GE}}^{0}(F))$. Variances of Atkinson indices can thus be written as functions of variances of GE indices using the delta method.

$$\frac{1}{\mu^2}\mathrm{var}(\hat{\mu}) - \frac{2}{\mu}\mathrm{cov}(\hat{\mu}, \hat{\nu}) + \mathrm{var}(\hat{\nu}). \tag{6.61}$$

From the IF approach, we have $Z = y/\mu - \log y$, and the asymptotic variance of the MLD index is the variance of Z divided by n,

$$\frac{1}{n}\mathrm{var}(Z) = \frac{1}{n}\left[\frac{1}{\mu^2}\mathrm{var}(y) - \frac{2}{\mu}\mathrm{cov}(y, \log y) + \mathrm{var}(\log y)\right]. \tag{6.62}$$

The two Equations (6.61) and (6.62) are identical, which demonstrates that the delta and the IF methods give the same results. It can be also demonstrated for $\xi \neq 0$.[40]

6.4.3.2 The Mean Deviation and Its Relatives

Now consider the mean deviation, an inequality index that does not belong to the class of decomposable indices (6.28), but does belong to the quasi-additive class (6.30).

$$I_{\mathrm{MD}}(F) := \int |y - \mu(F)| \mathrm{d}F(y).$$

Noting that $I_{\mathrm{MD}}(F)$ can be rewritten as

$$I_{\mathrm{MD}}(F) = 2\int \iota_y [y - \mu(F)] \mathrm{d}F(y) \tag{6.63}$$

where $\iota_y := \iota(y \geq \mu(F))$, the IF is

$$\mathrm{IF}(z; I_{\mathrm{MD}}, F) = 2[\iota_z + \overline{q} - 1][z - \mu(F)] - I_{\mathrm{MD}}(F) \tag{6.64}$$

where $\overline{q} := F(\mu)$. The asymptotic variance of the MD index can be obtained, rewriting the IF as a random variable minus its expectation $\mathrm{IF}(y; I_{\mathrm{MD}}, F) = Z - E(Z)$. From (6.64), we have

$$Z = 2(\overline{q} - 1)y + 2\iota_y[y - \mu(F)] \tag{6.65}$$

From Lemma 1, (6.36), (6.37), the asymptotic variance of $\sqrt{n}\left(I_{\mathrm{MD}}\left(F^{(n)}\right) - I_{\mathrm{MD}}(F)\right)$ is then equal to the variance of Z.

From a sample $(y_1, \ldots, y_n)$, the mean deviation index can be estimated as:

$$\hat{I}_{\mathrm{MD}} := I_{\mathrm{MD}}\left(F^{(n)}\right) = \frac{1}{n}\sum_{i=1}^{n} |y_i - \hat{\mu}|. \tag{6.66}$$

[40] For extensions to the case of weighted data and complex survey design, see Zheng and Cushing (2001), Cowell and Jenkins (2003), Biewen and Jenkins (2006), and Verma and Betti (2011). For an alternative approach to estimation of Atkinson indices using a Box–Cox transformation, see Guerrero (1987).

The asymptotic variance can be estimated as the empirical variance of $(Z_1, \ldots, Z_n)$ divided by n,

$$\widehat{\mathrm{var}}\left(\hat{I}_{\mathrm{MD}}\right) = \frac{1}{n^2}\sum_{i=1}^{n}(Z_i - \overline{Z})^2, \tag{6.67}$$

where

$$Z_i = 2(\hat{q} - 1)y_i + 2(y_i - \hat{\mu})\iota(y_i \geq \hat{\mu}), \tag{6.68}$$

and

$$\hat{q} := F^{(n)}(\hat{\mu}) = n^{-1}\sum_{i=1}\iota(y_i \leq \hat{\mu})$$

The same methodology with some extra terms can be used to derive the asymptotic variance of the more commonly used relative mean deviation or Pietra ratio

$$\int\left|\frac{y}{\mu(F)} - 1\right|\mathrm{d}F(y).$$

In the literature, the asymptotic variance is usually obtained with the IF method without using it expressed as a function of a random variable minus its expectation. It gives similar numerical results, but formulas and implementation are more complicated. For instance, using Lemma 1 and Equations (6.64) and (6.63), the asymptotic variance of the mean deviation can be derived as follows:

$$\begin{aligned}\int \mathrm{IF}(z; I_{\mathrm{MD}}, F)^2\mathrm{d}F(z) &= 4\int[\iota_z + \overline{q} - 1]^2[z - \mu(F)]^2\mathrm{d}F(z) + I_{\mathrm{MD}}(F)^2 \\ &\quad - 2I_{\mathrm{MD}}(F)\int 2\iota_z[z - \mu(F)]\mathrm{d}F(z) \\ &= 4[\overline{q} - 1]^2\int_{\underline{y}}^{\mu(F)}\left[z - \mu(F)\right]^2 + 4\overline{q}^2\int_{\mu(F)}^{\overline{y}}[z - \mu(F)]^2 - I_{\mathrm{MD}}(F)^2\end{aligned}$$

This formula for the asymptotic variance of the mean deviation index is the same as derived in Gastwirth (1974).

6.4.3.3 The Gini Coefficient

The general form (6.31) is cumbersome, but we can fairly easily derive results for the most important member of this class, namely, the Gini coefficient.

The Gini index can be expressed in a number of different forms. Let us consider the following expressions,

$$I_{\text{Gini}}(F) = \frac{1}{2\mu}\int\int |y - y'| \mathrm{d}F(y)\mathrm{d}F(y'), \tag{6.69}$$

$$= 1 - 2\int_0^1 L(F; q)\mathrm{d}q, \tag{6.70}$$

where $L(F;\ q) = C(F;\ q)/\mu(F)$ is the qth ordinate of the Lorenz curve—see Equation (6.122). Equation (6.69) presents the Gini as the normalized average absolute difference between all the possible pairs of incomes in the population, whereas Equation (6.70) shows that the Gini index is twice the area between the Lorenz curve and the 45° line.

Applying the IF method to the form (6.70), we find the IF of I_{Gini} to be given by Monti (1991):

$$\mathrm{IF}(z; I_{\text{Gini}}, F) = 1 - I_{\text{Gini}}(F) - \frac{2C(F;F(z))}{\mu(F)} + z\frac{1 - I_{\text{Gini}}(F) - 2[1 - F(z)]}{\mu(F)} \tag{6.71}$$

The asymptotic variance of the Gini coefficient has been derived from the IF in Cowell and Victoria-Feser (2003), Bhattacharya (2007), Barrett and Donald (2009), and Davidson (2009a, 2010). A simple formula can be obtained, noting that the IF of the Gini index can be expressed as a random variable minus its expectation, $\mathrm{IF}(z;\ I_{\text{Gini}},\ F) = (Z - E(Z))/\mu(F)$, where[41]

$$Z = [1 - I_{\text{Gini}}(F)]z - 2[C(F;F(z)) + z(1 - F(z))] \tag{6.72}$$

Using Lemma 1, (6.36) and (6.37), one immediately gets the asymptotic variance of $\sqrt{n}\left(I_{\text{Gini}}\left(F^{(n)}\right) - I_{\text{Gini}}(F)\right)$, equal to the variance of Z divided by the square of the mean, $\mathrm{var}(Z)/\mu(F)^2$.

The computation of the Gini index and its variance can be easily obtained in practice. If we define the "positional weight"

$$\kappa(y) := \frac{F(y^-) + F(y^+) - 1}{\mu(F)},$$

where $F(y^-) := \lim_{x\uparrow y} F(x)$ and $F(y^+) := \lim_{x\downarrow y} F(x)$, then the definition (6.69) can alternatively be expressed in the following convenient forms[42]:

$$I_{\text{Gini}}(F) = \int \kappa(y) y \mathrm{d}F(y) \tag{6.73}$$

[41] Note that $E[C(F;\ F(z))] = E[z\ [1 - F(z)]] = [1 - I_{\text{Gini}}(F)]\ \mu(F)/2$.

[42] Using the definition of the Lorenz curve in (6.70), interchanging the order of the integration and simplifying give the result (Davidson, 2009a). For an extensive list of alternative equivalent ways of writing the Gini coefficient—including our expressions (6.69), (6.70), (6.73), and (6.74)—see Yitzhaki and Schechtman (2013).

$$= \frac{2}{\mu} \operatorname{cov}(y, F(y)) \tag{6.74}$$

In other words, the Gini is also equal to the weighted sum of incomes using the κ weights (6.73) and is equal to $2/\mu$ times the covariance between y and $F(y)$ (6.74). For the distribution-free approach, we replace $\mu(F)$ by the sample mean $\hat{\mu}$ and the covariance by an unbiased estimate in (6.74). It leads us to compute the Gini index as:

$$\hat{I}_{\text{Gini}} = I_{\text{Gini}}\left(F^{(n)}\right) = \sum_{i=1}^{n} \kappa_i y_{(i)} \tag{6.75}$$

where the $y_{(i)}$, $i = 1, \ldots, n$, are the order statistics $(y_{(1)} \leq y_{(2)} \leq \cdots \leq y_{(n)})$ and[43]

$$\kappa_i := \frac{2i - n - 1}{\hat{\mu} n (n-1)}.$$

Davidson (2009a) shows that (6.75) is a bias-corrected estimator of the Gini index[44] and proposed estimating the variance of the Gini index as:

$$\widehat{\operatorname{var}}\left(\hat{I}_{\text{Gini}}\right) = \frac{1}{(n\hat{\mu})^2} \sum_{i=1}^{n} (Z_i - \overline{Z})^2 \tag{6.76}$$

where

$$Z_i = -\left(\hat{I}_{\text{Gini}} + 1\right) y_{(i)} + \frac{2i-1}{n} y_{(i)} - \frac{2}{n} \sum_{j=1}^{i} y_{(j)} \tag{6.77}$$

and $\overline{Z} = n^{-1} \sum_{i=1}^{n} Z_i$. Here, the Z_i terms are estimates of the realizations of Z defined in (6.72), where the value of $F(y_{(i)})$ is estimated by $F^{(n)}(y_{(i)}) = (2i-1)/(2n)$.[45] Davidson (2010) extends this approach to derive a variance estimator for the family of S-Gini indices.

[43] Clearly (6.75) is the empirical counterpart of the weighted sum (6.73). Also, using $\operatorname{Cov}(y, F(y)) = E(yF(y)) - E(y)E(F(y))$ in (6.74) and replacing $E(yF(y))$ by $(n-1)^{-1} \sum_{i=1}^{n} y_{(i)}(i/n)$ and $E(y)E(F(y))$ by $\hat{\mu}(n-1)^{-1} \sum_{i=1}^{n} (i/n)$ gives (6.75).

[44] Equation (6.75) is equal to $n/(n-1)$ times Equation (6.5) in Davidson (2009a).

[45] Other estimates of the variance of the Gini index have been proposed in the literature, but they are either complicated or quite unreliable. Nygård and Sandström (1985), Sandström et al. (1988), Cowell (1989), Schechtman (1991), and Bhattacharya (2007) provide formulas that are not easy to implement. A simple method based on OLS regression has been proposed by Ogwang (2000) and Giles (2004), but the standard errors obtained are unreliable, as shown by Modarres and Gastwirth (2006). For a recent review of this literature, see Langel and Tillé (2013) or Yitzhaki and Schechtman (2013); for applications to complex survey designs see Binder and Kovacevic (1995) and Kovacevic and Binder (1997).

6.4.4 Application: Poverty Measures

For a poverty index, we need a poverty line that may be an exogenously given constant ζ or may depend on the income distribution $\zeta(F)$. An important class of poverty indices can then be described in the following way:

$$P(F) := \int p(y, \zeta(F))\mathrm{d}F(y) \tag{6.78}$$

where p is a *poverty evaluation function* that is nonincreasing in y and takes the value zero for $y \geq \zeta(F)$. Once again we need the IF, which is given by

$$\mathrm{IF}(z; P, F) = p(z, \zeta(F)) - P(F) + \int p_\zeta(y, \zeta)\mathrm{d}F(y)\mathrm{IF}(z; \zeta, F) \tag{6.79}$$

where p_ζ is the differential of p with respect to its second argument (Cowell and Victoria-Feser, 1996a). It is clear from (6.79) that the form for the asymptotic variance of the poverty index will depend on the precise way in which the poverty line depends on the income distribution. The following specifications cover almost all the versions encountered in practice

$$\zeta(F) = \zeta_0 + \gamma\mu(F), \tag{6.80}$$

or

$$\zeta(F) = \zeta_0 + \gamma y_q, \quad q \in \mathbb{Q}, \tag{6.81}$$

where y_q is defined in (6.24). The interpretation is that the poverty line could be tied to the mean, as in (6.80), in which case we have

$$\mathrm{IF}(z; \zeta, F) = \gamma \mathrm{IF}(z; \mu, F) = \gamma[z - \mu(F)] \tag{6.82}$$

or to a quantile (6.81), such as the median, in which case we have

$$\mathrm{IF}(z; \zeta, F) = \gamma \frac{q - \iota(y_q \geq z)}{f(y_q)}. \tag{6.83}$$

The asymptotic variance can be immediately calculated from Equations (6.79) and (6.82) or (6.83). Let us take the simple case where $\gamma = 0$[46] so that one has the exogenous poverty line ζ_0. Equation (6.79) yields the IF $p(z, \zeta_0) - P(F)$ and so, using Lemma 1, we find the asymptotic variance of $P(F)$ in (6.78) to be

$$\int p(z, \zeta_0)^2 \mathrm{d}F(z) - P(F)^2.$$

[46] Note that if $\gamma > 0$ then to estimate the asymptotic variance of P using (6.82) one needs information on the whole distribution; with (6.83) one needs a density estimate at y_q.

The asymptotic variance of the poverty index is then equal to the variance of the poverty evaluation function, var($p(y, \zeta_0)$). We can see that the preceding IF is expressed as a function of a random variable minus its expectation,

$$\mathrm{IF}(y; P, F) = Z - E(Z) \quad \text{where } Z = p(y, \zeta_0) \tag{6.84}$$

From (6.36) and (6.37), the asymptotic variance is the variance of Z.

A second important class of poverty indices consists of those in the *rank-dependent* form—compare (6.31) above—and can be described in the following way:

$$P_{\mathrm{RD}}(F) := \int p(y, \zeta(F), F(y))\mathrm{d}F(y) \tag{6.85}$$

Comparing (6.85) with (6.78), we see that the poverty evaluation function p has an extra argument reflecting the individual's rank in the population. The IF for this class of poverty measures is more complicated (Cowell and Victoria-Feser, 1996a), and we deal with this separately in Sections 6.4.4.2 and 6.4.4.3.

6.4.4.1 Foster–Greer–Thorbecke (FGT)

For a fixed poverty line ζ_0 the widely used class of poverty indices introduced by Foster et al. (1984) belongs to the class (6.78) and has the form

$$P^{\xi}_{\mathrm{FGT}}(F) = \int_0^{\zeta_0} \left(\frac{\zeta_0 - y}{\zeta_0}\right)^{\xi} \mathrm{d}F(y) \quad \xi \geq 0, \tag{6.86}$$

When $\xi = 0$, the FGT poverty measure is equal to the headcount ratio, which gives the proportion of individuals living in poverty, $F(\zeta_0)$. This index is insensitive to the distribution of incomes among the poor and, therefore, to the depth of poverty. When $\xi = 1$, the FGT poverty measure is the poverty gap index, which considers how far, on the average, the poor are from that poverty line. This index captures the depth of poverty, but it is insensitive to some types of transfers among the poor and, therefore, to some distributional aspects of poverty. Let y_i, $i = 1, \ldots, n$, be an IID sample from the distribution F. The FGT poverty indices (6.86) can be estimated consistently as follows:

$$\hat{P}^{\xi}_{\mathrm{FGT}} := P^{\xi}_{\mathrm{FGT}}\left(F^{(n)}\right) = \frac{1}{n}\sum_{i=1}^{n_p} \left(\frac{\zeta_0 - y_{(i)}}{\zeta_0}\right)^{\xi}, \tag{6.87}$$

where n_p is the number of individuals with incomes not greater than the poverty line, that is, the number of poor, and $y_{(i)}$, $i = 1, \ldots, n$ are the order statistics $(y_{(1)} \leq y_{(2)} \leq \cdots \leq y_{(y)})$. This estimate is asymptotically Normal, with a variance that can be estimated as:[47]

[47] See Kakwani (1993).

$$\widehat{\text{var}}\left(\hat{P}^{\xi}_{\text{FGT}}\right) = \frac{1}{n}\left(\hat{P}^{2\xi}_{\text{FGT}} - \left(\hat{P}^{\xi}_{\text{FGT}}\right)^2\right). \tag{6.88}$$

We can also estimate the asymptotic variance of the FGT index using the IF expressed as a function of a random variable minus its expectation. From (6.78), (6.84), and (6.86), we have $\text{IF}(y, P^{\xi}_{\text{FGT}}, F) = Z - E(Z)$, where

$$Z_i = \left|1 - \frac{y}{\zeta_0}\right|^{\xi} \iota(y \le \zeta_0) \tag{6.89}$$

From Lemma 1, (6.36), and (6.37), the asymptotic variance of $\sqrt{n}\left(P_{\text{FGT}}\left(F^{(n)}\right) - P_{\text{FGT}}(F)\right)$ is then equal to the variance of Z. From a sample $(y_1, \ldots, y_n)$, let us define

$$Z_i = \begin{cases} \left[\left(\zeta_0 - y_{(i)}\right)/\zeta_0\right]^{\xi} & \text{for } i \le n_p \\ 0 & \text{for } i > n_p \end{cases} \tag{6.90}$$

where the $y_{(i)}$, $i = 1, \ldots, n$ are the order statistics. We can see that

$$\hat{P}^{\xi}_{\text{FGT}} = \frac{1}{n}\sum_{i=1}^{n} Z_i = \overline{Z} \quad \text{and} \quad \widehat{\text{var}}\left(\hat{P}^{\xi}_{\text{FGT}}\right) = \frac{1}{n^2}\sum_{i=1}^{n}(Z_i - \overline{Z}). \tag{6.91}$$

The FGT index can be estimated by the mean of Z_i, for $i = 1, \ldots, n$, with a variance estimated by the empirical variance of Z_i, divided by n. The two approaches, in Equations (6.87), (6.88), and (6.91), give similar numerical results.[48]

6.4.4.2 Sen Poverty Index

The Sen poverty index (Sen, 1976) belongs to the class (6.85) and can be expressed as the average of the headcount ratio and the poverty gap index, weighted by the Gini coefficient among the poor,

$$P_{\text{Sen}}(F) = P^0_{\text{FGT}} I^p_{\text{Gini}} + P^1_{\text{FGT}}(1 - I^p_{\text{Gini}}), \tag{6.92}$$

where I^p_{Gini} is the Gini index computed with incomes below the poverty line. When the distribution of incomes among the poor is equal, $I^p_{\text{Gini}} = 0$, the Sen index is equal to the headcount ratio ($P_{\text{Sen}} = P^0_{\text{FGT}}$). When the distribution of incomes among the poor is extremely unequal, $I^p_{\text{Gini}} = 1$, the Sen index is equal to the poverty gap index ($P_{\text{Sen}} = P^1_{\text{FGT}}$).The Sen poverty measure can be written

$$P_{\text{Sen}}(F) = \frac{2}{\zeta_0 F(\zeta_0)}\int_0^{\zeta_0} (\zeta_0 - y)(F(\zeta_0) - F(y))\mathrm{d}F(y) \tag{6.93}$$

[48] The problem of estimation in the presence of complex survey design is addressed in Howes and Lanjouw (1998), Zheng (2001), Berger and Skinner (2003), and Verma and Betti (2011).

From Davidson (2009a), we can derive the IF as a function of a random variable minus its expectation, $\mathrm{IF}(z, P_{\mathrm{Sen}}, F) = \frac{2}{\zeta_0 F(\zeta_0)}(Z - E(Z))$, where[49]

$$Z = \left[\zeta_0 F(\zeta_0) - \frac{\zeta_0 P_S}{2} - zF(\zeta_0) + zF(z) - C(F;F(z))\right]\iota(z \le \zeta_0) \tag{6.94}$$

A consistent estimate of the Sen poverty index can be obtained by replacing F by $F^{(n)}$ in (6.93),[50]

$$\hat{P}_{\mathrm{Sen}} := P_{\mathrm{Sen}}\left(F^{(n)}\right) = \frac{2}{nn_p\zeta_0}\sum_{i=1}^{n_p}\left(\zeta_0 - y_{(i)}\right)\left(n_p - i + \frac{1}{2}\right), \tag{6.95}$$

where the value of $F(y_{(i)})$ is estimated by $F^{(n)}(y_{(i)}) = (2i-1)/(2n)$. This estimate is asymptotically Normal, with a variance that can be computed as follows:

$$\widehat{\mathrm{var}}\left(\hat{P}_{\mathrm{Sen}}\right) = \frac{4}{\left(\zeta_0 n_p\right)^2}\sum_{i=1}^{n}(Z_i - \overline{Z})^2 \tag{6.96}$$

where

$$Z_i = \frac{\zeta_0}{2}\left(\frac{2n_p}{n} - \hat{P}_{\mathrm{Sen}}\right) - \frac{2n_p - 2i + 1}{2n}y_{(i)} - \frac{1}{n}\sum_{j=1}^{i} y_{(j)} \tag{6.97}$$

for $i = 1, \ldots, n_p$, and $Z_i = 0$ for $i = n_p + 1, \ldots, n$, with $\overline{Z} = n^{-1}\sum_{i=1}^{n} Z_i$. Here, Z_i are estimates of the realizations of Z defined in (6.94).[51]

6.4.4.3 Sen–Shorrocks–Thon Poverty Index

The Sen–Shorrocks–Thon (SST) index is a convenient modified version of the Sen poverty index, defined as follows,

$$P_{\mathrm{SST}}(F) = P^0_{\mathrm{FGT}} P^1_{\mathrm{FGT}_g}\left(1 + I^{pg}_{\mathrm{Gini}}\right) \tag{6.98}$$

where $P^1_{\mathrm{FGT}_g}$ is the poverty gap index computed with incomes below the poverty line, and I^{pg}_{Gini} is the Gini coefficient computed with individuals' poverty gap ratios rather than individuals' incomes for the whole population $((\zeta_0 - y_i)/\zeta_0$ rather than y_i,

[49] In Equation (6.50) in Davidson (2009a), replacing y_i in the expression of the summand by z yields the IF. The relationship to the IF is not related in the last paper; it is related in Davidson (2010), where the same method is used with S-Gini indices.

[50] This expression does not coincide exactly with Sen's own definition for a discrete population. See Appendix A in Davidson (2009a) for a discussion of this point.

[51] Another variance estimator has been proposed by Bishop et al. (1997).

for $i = 1, \ldots, n$).[52] The Gini coefficient of poverty gap ratios can be viewed as a measure of poverty inequality in a society. The SST index satisfies the transfer and continuity axioms, whereas the Sen index does not.[53]

This index can be decomposed into

$$\Delta \log P_{\mathrm{SST}} = \Delta \log P^0_{\mathrm{FGT}} + \Delta P^1_{\mathrm{FGT}_g} + \Delta \log\left(1 + I^{pg}_{\mathrm{Gini}}\right) \tag{6.99}$$

A percentage change in SST can then be viewed as the sum of percentage changes in the proportion of poor, the average poverty gap among the poor, and one plus the Gini index of poverty gaps for the population. The poverty is decomposed in three aspects: Are there more poor? Are the poor poorer? Is there higher poverty inequality in the society?

The SST poverty index can be written

$$P_{\mathrm{SST}}(F) = \frac{2}{\zeta_0}\int_0^{\zeta_0} (\zeta_0 - y)(1 - F(y))\mathrm{d}F(y) \tag{6.100}$$

As in Section 6.4.4.2, we derive the IF as a function of a random variable minus its expectation, $\mathrm{IF}(z, P_{\mathrm{SST}}, F) = \frac{2}{\zeta_0}(Z - E(Z))$, where[54]

$$Z = [\zeta_0(1 - F(\zeta_0)) - z(1 - F(z)) + C(F;F(\zeta_0)) - C(F;F(z))]\iota(z \le \zeta_0) \tag{6.101}$$

The SST poverty index can be consistently estimated as:[55]

$$\hat{P}_{\mathrm{SST}} := P_{\mathrm{SST}}\left(F^{(n)}\right) = \frac{2}{\zeta_0 n(n-1)}\sum_{i=1}^{n_p}\left(\zeta_0 - y_{(i)}\right)(n - i) \tag{6.102}$$

It is asymptotically Normal, with an estimator of the variance given by

$$\widehat{\mathrm{var}}\left(\hat{P}_{\mathrm{SST}}\right) = \frac{4}{\zeta_0^2 (n-1)^2}\sum_{i=1}^{n}(Z_i - \overline{Z})^2 \tag{6.103}$$

where

[52] The original index was proposed by Shorrocks (1995). Xu and Osberg (2002) show that it can be written as Equation (6.98). They also show that the Sen index is equal to $S = P^0_{\mathrm{FGT}} P^1_{\mathrm{FGT}_g}(1 + I^{pg}_{\mathrm{Gini}})$ and therefore that the SST index differs from the Sen index because it uses the Gini index of poverty gap ratios for the whole population, whereas the Sen index uses the Gini index of poverty gap ratios for the poor.

[53] The (strong upward) transfer axiom states that an increase in a poverty measure should occur if the poorer of the two individuals involved in an upward transfer of income is poor, and even if the beneficiary crosses the poverty line.

[54] In the first equation of column two in Davidson (2009a, p. 39), replacing y_i in the expression of the summand by z yields the IF. The relationship to the IF is not related in the last paper; it is related in Davidson (2010), where the same method is used with S-Gini indices.

[55] The SST index defined by Shorrocks (1995) is obtained by replacing F by $\hat{F}$ in (6.100). Here, (6.102) is a simplified version of the bias-corrected estimator in the last equation in Davidson (2009a, p. 37). In the case of complex survey data, see Osberg and Xu (2000).

$$Z_i = \zeta_0\left(1-\frac{n_p}{n}\right) - \frac{2n-2i+1}{2n}y_{(i)} + \frac{1}{n}\sum_{j=1}^{n_p} y_{(j)} - \frac{1}{n}\sum_{j=1}^{i} y_{(j)} \tag{6.104}$$

for $i=1, \ldots, n_p$, and $Z_i=0$ for $i=n_p+1, \ldots, n$, with $\overline{Z}=n^{-1}\sum_{i=1}^{n} Z_i$. Here, Z_i are estimates of the realizations of Z defined in (6.101).

6.4.5 Finite Sample Properties

6.4.5.1 Asymptotic and Bootstrap Methods

Asymptotic Normality allows us to perform asymptotic inference. In practice, we are concerned with finite samples, and asymptotic inference can be unreliable. When asymptotic inference does not perform well in a finite sample, bootstrap methods can be used to perform accurate inference. The bootstrap appears to be an ideal method for inference with inequality and poverty indices because the observations of the sample are often IID.

Let us consider a welfare index W and its sample counterpart $\hat{W}$. An asymptotic confidence interval at 95% would be computed as

$$\mathrm{CI}_{\mathrm{asym}} = \left[\hat{W} - c_{0.975}\widehat{\mathrm{var}}\left(\hat{W}\right)^{1/2}; \hat{W} - c_{0.025}\widehat{\mathrm{var}}\left(\hat{W}\right)^{1/2}\right] \tag{6.105}$$

where $c_{0.025}$ and $c_{0.975}$ are the 2.5th and 97.5th percentiles of the asymptotic distribution of the t-statistic, $t=\left(\hat{W}-W_0\right)/\widehat{\mathrm{var}}\left(\hat{W}\right)$, where W_0 is the true value of the welfare index. In general, the asymptotic distribution of the t-statistic is the standard Normal distribution, from which we have $c_{0.975}=-c_{0.025}\approx 1.96$.

When the bootstrap is used in combination with the asymptotic variance estimate, asymptotic refinements can be obtained over asymptotic methods.[56] To compute a bootstrap confidence interval, we generate B samples of size n by resampling with replacement from the observed sample. For bootstrap sample b, we compute the index $\hat{W}_b^*$, its variance estimate $\widehat{\mathrm{var}}\left(\hat{W}_b^*\right)$, and the t-statistic $t_b^*=\left(\hat{W}_b^*-\hat{W}\right)/\widehat{\mathrm{var}}\left(\hat{W}_b^*\right)^{1/2}$. A bootstrap confidence interval at 95% would be computed as

$$\mathrm{CI}_{\mathrm{boot}} = \left[\hat{W} - c^*_{0.975}\widehat{\mathrm{var}}\left(\hat{W}\right)^{1/2}; \hat{W} - c^*_{0.025}\widehat{\mathrm{var}}\left(\hat{W}\right)^{1/2}\right] \tag{6.106}$$

where $c^*_{0.025}$ and $c^*_{0.975}$ are the 2.5th and 97.5th percentiles of the EDF of the bootstrap t-statistics, that is, the $\lceil 0.025B\rceil$ and $\lceil 0.975B\rceil$ order statistics of the t_b^*, where $\lceil x\rceil$ denotes the smallest integer not smaller than x. In this approach, the unknown distribution of the population is replaced by the EDF of the original sample, from which we generate bootstrap samples and compute t-statistics testing the (true) hypothesis that the index is equal

[56] See Beran (1988). It means that the bootstrap method presented in this section provides an asymptotic refinement over the percentile bootstrap proposed in Mills and Zandvakili (1997).

to $\hat{W}$. The simulated distribution of the bootstrap t-statistics is used, as an approximation of the unknown distribution of t, to calculate critical values.

The bootstrap can also be used to test hypotheses and to compute p-values. To test the hypothesis that the population value of the index is W_0, for a one-tailed test, the bootstrap p-value would be the proportion of the t_b^* that are more extreme than the t-statistic computed from the observed sample t. Here, the bootstrap test is also based on the EDF of the bootstrap t-statistics t_b^*. The null hypothesis is rejected at a significance level 0.05 if the bootstrap p-value is less than 0.05. To test the hypothesis that two indices are the same from two populations, a suitable t-statistic is $\tau = \left(\hat{W}_1 - \hat{W}_2\right)/\left(\widehat{\text{var}}\left(\hat{W}_1\right) + \widehat{\text{var}}\left(\hat{W}_2\right)\right)^{1/2}$ when the samples are independent. For bootstrap sample b, the bootstrap statistic is computed then as $\tau_b^* = \left(\hat{W}_{1b}^* - \hat{W}_{2b}^* - \hat{W}_1 + \hat{W}_2\right)/\left(\widehat{\text{var}}\left(\hat{W}_{1b}^*\right) + \widehat{\text{var}}\left(\hat{W}_{2b}^*\right)\right)^{1/2}$. When the samples are dependent, the statistic should take account of the covariance, and the bootstrap samples should be generated by resampling pairs of observations with replacement. Again, the bootstrap p-value would be the proportion of the τ_b^* that is more extreme than τ.

6.4.5.2 Simulation Evidence

We now turn to the performance in a finite sample of inference based on inequality and poverty measures. The coverage rate of a confidence interval is the probability that the random interval does include, or cover, the true value of the parameter. A method of constructing confidence intervals with good finite sample properties should provide a coverage rate close to the nominal confidence level. For a confidence interval at 95%, the nominal coverage rate is equal to 95%. In this section, we use Monte Carlo simulation to approximate the coverage rate of asymptotic and bootstrap confidence intervals in several experimental designs.

In our experiments, data are generated from lognormal distributions, $\Lambda(y;\, 0,\, \sigma)$, and from Singh–Maddala distributions, $\text{SM}(y;\, 2.8,\, 0.193,\, q)$. As σ increases and q decreases the upper tail of the distribution decays more slowly. The sample size is $n=500$, the number of bootstrap samples is $B=499$, and the number of experiments is $N=10{,}000$.[57] When poverty indices are used, the poverty line is computed as half the median.

Table 6.6 presents coverage of asymptotic and bootstrap confidence intervals at the 95% level for the Theil, MLD, Gini, and SST indices. The results show that asymptotic and bootstrap confidence intervals are reliable when we consider the SST poverty index. Indeed, the coverage rates of the SST index are always close to the nominal coverage rate of 95%. In contrast, when we consider inequality measures, bootstrap confidence intervals outperform asymptotic confidence intervals, but they become less reliable as σ increases and q decreases. In other words, asymptotic and bootstrap inferences deteriorate

[57] For well-known reasons—see Davison and Hinkley (1997) or Davidson and MacKinnon (2000)—the number of bootstrap resamples B should be chosen so that $(B+1)/100$ is an integer.

Table 6.6 Coverage of asymptotic and bootstrap confidence intervals at the 95% level for the Theil, MLD, Gini, and SST indices, $n=500$

	Theil		MLD		Gini		SST	
	asym	**boot**	**asym**	**boot**	**asym**	**boot**	**asym**	**boot**
Lognormal								
$\sigma=0.5$	0.927	0.936	0.936	0.942	0.942	0.943	0.926	0.952
$\sigma=1.0$	0.871	0.913	0.922	0.936	0.922	0.936	0.945	0.940
$\sigma=1.5$	0.746	0.854	0.888	0.921	0.876	0.920	0.964	0.937
Singh–Maddala								
$q=1.7$	0.915	0.931	0.938	0.945	0.945	0.944	0.945	0.950
$q=1.2$	0.856	0.905	0.913	0.930	0.925	0.934	0.945	0.951
$q=0.7$	0.647	0.802	0.820	0.890	0.847	0.906	0.939	0.946

as the upper tail of the underlying distribution is heavier. For instance, asymptotic confidence intervals cover the true value of the Theil index 64.7% of times when the underlying distribution is the Singh–Maddala with $q=0.7$. Bootstrap confidence intervals provide better results, with a coverage rate of 80.2%, but it is still significantly different from the expected 95%. Note that the Theil index is known to be more sensitive to the upper tail of the distribution than the MLD and Gini, and confidence intervals with the Theil index are slightly less reliable than with the MLD and Gini indices.

These results illustrate that asymptotic and bootstrap inference on inequality measures is sensitive to the exact nature of the upper tail of the income distribution. Bootstrap inference on inequality measures are expected to perform reasonably well in moderate and large samples, unless the tails are quite heavy.[58] Moreover, asymptotic and bootstrap inference on poverty measures perform well in finite samples.

6.4.5.3 Inference with Heavy-Tailed Distributions

When the distribution is one with quite a heavy upper tail, asymptotic and bootstrap inferences are known to perform poorly in finite samples. Several approaches have been proposed in the literature to obtain more reliable inference.

Schluter and van Garderen (2009) and Schluter (2012) proposed normalizing transformation of the index, before using the bootstrap, in order to use a statistic with a distribution closer to the Normal. Let g denote a transformation of the index W; a standard bootstrap confidence interval can be obtained on the transformed index $g(W)$ and, therefore, on the untransformed index by inverting the relation between the welfare index and the parameters. Let $c^*_{0.025}$ and $c^*_{0.975}$ be the 2.5th and 97.5th percentiles of the EDF of the bootstrap t-statistics

[58] Additional results with other distributions, other indices, and hypotheses testing can be found in Davidson and Flachaire (2007), Cowell and Flachaire (2007), and Davidson (2009a, 2010, 2012).

$$t_b^* = \frac{g(\hat{W}_b^*) - g(\hat{W})}{g'(\hat{W}_b^*)\widehat{\text{var}}(\hat{W}_b^*)^{1/2}},$$

where g' is the first derivative of g, a bootstrap confidence interval at 95% for W would then be defined as

$$\left[g^{-1}\left(g(\hat{W}) - c_{0.025}^* g'(\hat{W})\widehat{\text{var}}(\hat{W})^{1/2}\right); g^{-1}\left(g(\hat{W}) - c_{0.975}^* g'(\hat{W})\widehat{\text{var}}(\hat{W})^{1/2}\right)\right],$$

if g^{-1} is nondecreasing, otherwise $c_{0.025}^*$ and $c_{0.975}^*$ should be interchanged. For instance, Schluter (2012) exploits a systematic relationship between the inequality estimate and its estimated variance to propose variance stabilizing transforms of the index. He suggests computing confidence intervals based on the following transform of the index,

$$g(W) = -\frac{2}{\gamma_2}\exp\left(-\frac{\gamma_1}{2} - \frac{\gamma_2}{2}W\right), \tag{6.107}$$

where γ_1 and γ_2 are the intercept and the slope of a (systematic) linear relation between the index $\hat{W}$ and the logarithmic transformation of its variance estimates $\widehat{\text{var}}(\hat{W})$, and $\gamma_2 > 0$. The parameters γ_1 and γ_2 are estimated by OLS estimation from the regression

$$\log \widehat{\text{var}}(\hat{W}) = \gamma_1 + \gamma_2 \hat{W} + \varepsilon,$$

where realizations of $\widehat{\text{var}}(\hat{W})$ and $\hat{W}$ are obtained by a preliminary bootstrap. For the specific transform (6.107), the inverse function is equal to

$$g^{-1}(x) = -\frac{2}{\gamma_2}\log\left(-\frac{\gamma_2}{2}x\right) - \frac{\gamma_1}{\gamma_2} \tag{6.108}$$

A bootstrap confidence interval at 95% can be computed using (6.107) and (6.108) in the confidence interval defined earlier.

Davidson and Flachaire (2007) and Cowell and Flachaire (2007) considered a semi-parametric bootstrap, where bootstrap samples are generated from a distribution that combines a parametric estimate of the upper tail with a nonparametric estimate of the rest of the distribution. The upper tail is modeled by a Pareto distribution with parameter α estimated by the Hill estimator on the k greatest order statistics of a sample of size n, for some integer $k \leq n$,

$$\hat{\alpha} := \left(\frac{1}{k}\sum_{i=0}^{k-1} \log y_{(n-i)} - \log y_{n-k+1}\right)^{-1} \tag{6.109}$$

where $y_{(j)}$ is the jth order statistic of the sample. Each observation of a bootstrap sample is, with probability p_{tail}, a drawing from the CDF of the Pareto distribution $F(y) = 1 - (y/y_0)^{-\hat{\alpha}}, y > y_0$, where y_0 is the order statistic of rank $n(1 - p_{\text{tail}})$, and, with probability $1 - p_{\text{tail}}$, a drawing from the empirical distribution of the sample of smallest

$n(1-p_{\text{tail}})$-order statistics. For the bootstrap to test a true null hypothesis, we need to compute the value of the welfare index for the bootstrap distribution defined earlier. The CDF of the bootstrap distribution can be written as

$$F_s(y) = \frac{1}{n}\sum_{i=1}^{n(1-p_{\text{tail}})} \iota\left[y_{(i)} \le y\right] + \iota[y \ge y_0]p_{\text{tail}}\left(1-(y/y_0)^{-\hat{\alpha}}\right), \tag{6.110}$$

where $\iota(\cdot)$ is the indicator function (6.1). Indices of interests are functionals of the income distribution and so the index for this bootstrap distribution, $\hat{W}_s$, can be computed.[59] A bootstrap confidence interval can be computed as defined in (6.106), where $c^*_{0.025}$ and $c^*_{0.975}$ are the 2.5th and 97.5th percentiles of the EDF of the bootstrap t-statistics $t^*_b = \left(\hat{W}^*_b - \hat{W}_s\right)/\widehat{\text{var}}\left(\hat{W}^*_b\right)^{1/2}$ In practice, k and p_{tail} are chosen *a priori*. The number of observations k used to compute the Hill estimator can be selected such that $\hat{\alpha}$ does not vary significantly when more observations are taken, and p_{tail} can be chosen such that the resampling from the Pareto distribution is based on a smaller proportion of observation than k/n. It leads the previous authors to select $k = n^{1/2}$ and $p_{\text{tail}} = hk/n$ with $0 < h \le 1$ in their experiments.

An alternative approach could be to generate bootstrap samples from a distribution estimated by finite mixture models. It allows us to estimate any density function, by allowing the number of components to vary, and, once the number of component is selected, to use a parametric distribution to generate bootstrap samples (see Section 6.3.3). For the bootstrap to test a true null hypothesis, we need to compute the value of the welfare index for the mixture distribution, $\hat{W}_m$. With additively decomposable inequality measures, the index for the mixture distribution is easy to calculate because the mixture distribution is a decomposition by groups. For instance, the class of GE indices can be expressed as a simple additive function of within-group and between-group inequality. Let there be K groups, and let the proportion of the population falling in group k be p_k, the class of GE indices is equal to[60]

$$I^{\xi}_{\text{GE}} = \sum_{k=1}^{K} p_k\left[\frac{\overline{y}_k}{\overline{y}}\right]^{\xi} I^{\xi}_{\text{GE},k} - \frac{1}{\xi^2-\xi}\left(\sum_{k=1}^{K} p_k\left[\frac{\overline{y}_k}{\overline{y}}\right]^{\xi} - 1\right) \tag{6.111}$$

where $\overline{y}_k$ is the mean income in group k, $\overline{y}$ is the mean income of the population $\left(\overline{y} = K^{-1}\sum_{k=1}^{K} p_k\overline{y}_k\right)$, and $I^{\xi}_{\text{GE},k}$ is the GE index in group k. For an income distribution estimated as a finite mixture of lognormal distributions,

[59] For instance, the Theil index would be equal to $\hat{I}_s = \nu_s/\mu_s - \log\mu_s$, where $\mu_s = n^{-1}\sum_{i=1}^{n(1-p_{\text{tail}})} y_{(i)} + p_{\text{tail}}\hat{\alpha}y_0/(\hat{\alpha}-1)$ and $\nu_s = n^{-1}\sum_{i=1}^{n(1-p_{\text{tail}})} y_{(i)}\log y_{(i)} + p_{\text{tail}}[\log y_0 + 1/(\hat{\alpha}-1)]\hat{\alpha}y_0/(\hat{\alpha}-1)$.

[60] See Cowell (2011).

$$F_m(y) = \sum_{k=1}^{K} \hat{\pi}_k \Lambda(y; \hat{\mu}_k, \hat{\sigma}_k), \tag{6.112}$$

the value of the GE index is then equal to (6.111) with $p_k = \hat{\pi}_k$ and $\overline{y}_k = \exp\left(\hat{\mu}_k + \hat{\sigma}_k^2/2\right)$. The Gini index is not additively decomposable, but a formula can be found in Young (2011) for a mixture of lognormal distributions. Bootstrap samples are generated from the mixture distribution $F_m(y)$, and a bootstrap confidence interval is computed as defined in (6.106), where $c^*_{0.025}$ and $c^*_{0.975}$ are the 2.5th and 97.5th percentiles of the EDF of the bootstrap t-statistics $t^*_b = \left(\hat{W}^*_b - \hat{W}_s\right)/\widehat{\text{var}}\left(\hat{W}^*_b\right)^{1/2}$.

Table 6.7 presents coverage of asymptotic and bootstrap confidence intervals at the 95% level for the Theil index, with $n = 500$. The first two columns correspond to asymptotic (asym) and standard bootstrap (boot) methods; they reproduce the results given in Table 6.6, given here as benchmarks. The other columns show the results for the alternative bootstrap methods presented earlier. Results obtained by the approach proposed by Schluter (2012) are presented in the third column (varstab), bootstrapping a variance stabilizing transform of the Theil index. In the fourth column, the semiparametric bootstrap proposed by Davidson and Flachaire (2007) and Cowell and Flachaire (2007) is used to generate bootstrap samples (semip), with $k = n^{1/2}$ and $h = 0.6$. Finally, bootstrap samples generated from a mixture of lognormal distributions are considered in the last column (mixture). The simulation results show that, in the presence of very heavy-tailed distributions ($\sigma = 1.5$, $q = 0.7$), significant improvements can be obtained with alternative methods over asymptotic and standard bootstrap methods. However, none of the alternative methods provides very good results overall.

6.4.5.4 *Testing Equality of Inequality Measures*

Confidence intervals are often used to make comparisons between two or more samples. The values of an index computed from independent samples are statistically different if

Table 6.7 Coverage of asymptotic and bootstrap confidence intervals at the 95% level for the Theil index, for several bootstrap approaches, $n = 500$

	asym	boot	varstab	semip	mixture
Lognormal					
$\sigma = 0.5$	0.927	0.936	0.939	0.937	0.942
$\sigma = 1.0$	0.871	0.913	0.907	0.921	0.946
$\sigma = 1.5$	0.746	0.854	0.850	0.915	0.944
Singh–Maddala					
$q = 1.7$	0.915	0.931	0.933	0.926	0.928
$q = 1.2$	0.856	0.905	0.899	0.905	0.912
$q = 0.7$	0.647	0.802	0.796	0.871	0.789

the confidence intervals do not intersect. We can thus test if inequality or poverty measures are different between several countries, or over different periods of time, by comparing their confidence intervals. However, the previous results suggest that this approach may be unreliable when comparing inequality measures if the underlying distributions are quite heavy tailed.

Another principal way of performing inference is by carrying out hypothesis tests. Testing the equality of inequality measures with a t-statistic, Dufour et al. (2013) showed that almost exact inference can be obtained with permutation tests, if the samples come from distributions not too far away from each other, even with very heavy-tailed distributions and very small samples. They also showed that this method outperforms other methods when the distributions are far away from each other.

Let us consider two independent samples $X = \{x_1, x_2, \ldots, x_n\}$ and $Y = \{y_1, y_2, \ldots, y_m\}$ assumed to be two sets of n and m independent observations from distributions F_x and F_y. The null hypothesis that an inequality measure W is the same in the two distributions, H_0: $W_x = W_y$, can be tested with a t-statistic,

$$\tau = \left[\hat{W}_x - \hat{W}_y\right] / \left[\widehat{\text{var}}\left(\hat{W}_x\right) + \widehat{\text{var}}\left(\hat{W}_y\right)\right]^{1/2}, \tag{6.113}$$

where τ follows asymptotically the standard Normal distribution. A standard bootstrap approach would be to generate bootstrap samples X^* and Y^* by resampling with replacement, respectively, n observations from X and m observations from Y. The bootstrap samples are drawings from X and Y, from which an inequality measure would provide different numerical results. The null hypothesis tested from the original sample is then not respected in the bootstrap data-generating process. A modified t-statistic has to be computed to test a true null hypothesis from a bootstrap sample (X_b^*, Y_b^*),

$$\tau_b^* = \left[\hat{W}_{x_b^*} - \hat{W}_{y_b^*} - \left(\hat{W}_x - \hat{W}_y\right)\right] / \left[\widehat{\text{var}}\left(\hat{W}_{x_b^*}\right) + \widehat{\text{var}}\left(\hat{W}_{y_b^*}\right)\right]^{1/2}, \tag{6.114}$$

The bootstrap distribution is the EDF of the B bootstrap statistics, τ_b^* for $b = 1, \ldots, B$; it is used as an approximation of the true distribution of the t-statistic τ.[61]

In the permutation approach, we generate samples by permuting the combined sample of N observations,

$$(X, Y) = \{x_1, \ldots, x_n, y_1, \ldots, y_m\}, \tag{6.115}$$

where $N = n + m$. The permutation samples X^* and Y^* are composed, respectively, by the first n and the remaining m observations of the permuted combined sample. Note that the combined sample can be permuted by resampling *without* replacement N observations from (X, Y).

[61] Davidson and Flachaire (2007) considered testing the difference of two inequality measures with independent samples, but no significant improvement of their semiparametric bootstrap method over standard bootstrap method is found.

The permutation samples are drawings from the same set of observations; the null hypothesis tested from the original sample is then respected in the data-generating process. From a permutation sample (X_p^*, Y_p^*), the permutation *t*-statistic is

$$\tau_p^* = \left[\hat{W}_{x_p^*} - \hat{W}_{y_p^*}\right] / \left[\widehat{\text{var}}\left(\hat{W}_{x_p^*}\right) + \widehat{\text{var}}\left(\hat{W}_{y_p^*}\right)\right]^{1/2}. \qquad (6.116)$$

The permutation distribution is the EDF of the P permutation statistics, τ_p^* for $p = 1, \ldots, P$; again it is used as an approximation of the true distribution of the *t*-statistic τ. If the underlying distributions are identical, permutation tests are known to provide *exact* inference in finite samples.[62] Chung and Romano (2013) show that under weak assumptions for comparing estimators, permutation tests are asymptotically valid when $F_x \neq F_y$, while retaining the exact rejection probability in finite samples when $F_x = F_y$.[63] Testing the equality of inequality measures, Dufour et al. (2013) showed that almost exact inference is obtained with permutation tests in very small samples with heavy-tailed distributions, if the samples come from distributions not too far away from each other.

To illustrate, let us consider a simulation experiment concerned with testing the equality of the Gini index, H_0: $I_{\text{Gini}}(F_x) = I_{\text{Gini}}(F_y)$. Data are generated from Singh–Maddala distributions, SM(y; a, b, q), with parameters chosen such that the Gini index is identical in all distributions. The upper tail of a Singh–Maddala distribution behaves like a Pareto distribution with shape parameter $\alpha = aq$.[64] So, the smaller is α, the heavier is the upper tail. The sample size is very small, $n = m = 50$, and the distributions can be very heavy tailed to stress-test the methods employed in testing. The number of replications is equal to 10,000, and the number of bootstrap and permutation samples are $B = P = 999$. We compute the rejection probability, or rejection frequency, as the proportion of p-values less than a nominal level equal to 0.05.[65] Inference is exact if the rejection probability is equal to 0.05.

[62] See Fisher (1935), Dwass (1957), Good (2000), and Dufour (2006).

[63] Estimators have to be asymptotically linear, and the use of a studentized statistic, as defined in (6.113), is crucial for the asymptotic validity of the permutation approach (it would not be valid with the statistic $\tau = \hat{W}_x - \hat{W}_y$).

[64] Singh–Maddala distributions with parameters (a, q) equal to (2.5, 2.640350), (2.6, 2.218091), (2.7, 1.920967), (2.8, 1.7), (3.0, 1.3921126), (3.2, 1.1866026), (3.4, 1.0388049), (3.8, 0.8387663), (4.8, 0.5784599), and (5.8, 0.4473111) share the same (scale-invariant) Gini index, equal to 0.2887138. The tail parameters are, respectively, equal to $\alpha = 6.6$, 5.77, 5.19, 4.76, 4.18, 3.80, 3.53, 3.19, 2.78, and 2.59.

[65] For a two-tailed test, an asymptotic p-value is computed as $p_{as} = 2\min(\Phi(\tau); 1 - \Phi(\tau))$. A bootstrap p-value is similar, but bootstrap distribution replaces the asymptotic one, $p_{\text{boot}} = 2\min\left(\frac{1}{B}\sum_{b=1}^{B} \iota\left(\tau_b^* \leq \tau\right);\ \frac{1}{B}\sum_{b=1}^{B} \iota\left(\tau_b^* > \tau\right)\right)$. A permutation p-value is similar to the bootstrap p-value, p_{boot}, with B and τ_b^* replaced by P and τ_p^*. The null hypothesis is rejected if the p-value is smaller than the nominal level.

Table 6.8 Rejection frequencies of asymptotic, bootstrap, and permutation tests for testing the equality of Gini indices between two samples, when the underlying Singh–Maddala distributions are identical or different, $n=50$

2.59	0.1277	0.0693	0.0513	0.1289	0.0911	0.0800

Table 6.8 shows the empirical rejection frequencies of asymptotic, bootstrap, and permutation tests for testing the equality of Gini indices between two samples, when the underlying distributions are identical and when they are different. As expected, when the distributions are identical, $F_x=F_y$, permutation tests provide exact inference, even in very small samples, with very heavy-tailed distributions (column 4: permut). When the distributions are different, $F_x\neq F_y$, permutation tests provide almost exact inference, except when F_y is much more heavy tailed than F_x (column 7: permut, when $\alpha_x=4.76$ and $\alpha_y\leq 2.78$). Overall, permutation tests outperform asymptotic and bootstrap tests.

Hill plots can be useful for studying the tail behavior in empirical studies. The "tail index" of a heavy-tailed distribution can be estimated by the Hill estimator on the k greatest order statistics of a sample of size n, for $k\leq n$—see Equation (6.109). However, estimation results can be sensitive to the choice of k. Hill plots show the Hill estimate of the tail index as a function of the number k of the greatest order statistics used to compute it. An estimate of the tail index can be selected when the plot becomes stable about a horizontal straight line. For instance, Figure 6.15 shows Hill plots obtained from two samples of 1000 observations drawn from the Singh–Maddala distributions SM(y; 2.8, 0.193, 1.7) and SM(y; 5.8, 0.193, 0.447), with tail parameters, respectively, equal to 4.76 and 2.59, over the range 0.5% to 25% of the largest order statistic used to compute it, with 95% confidence intervals (in gray). It is clear from this figure that the second sample (right plot) comes from a much more heavy-tailed distribution than the first sample (left plot).[66]

[66] The Hill plot is not always revealing. The Hill estimator is designed for the Pareto distribution. But the Hill plot can be very volatile—and thus difficult to interpret—when the upper tail of the underlying distribution is far from a Pareto, see Resnick (1997, 2007).

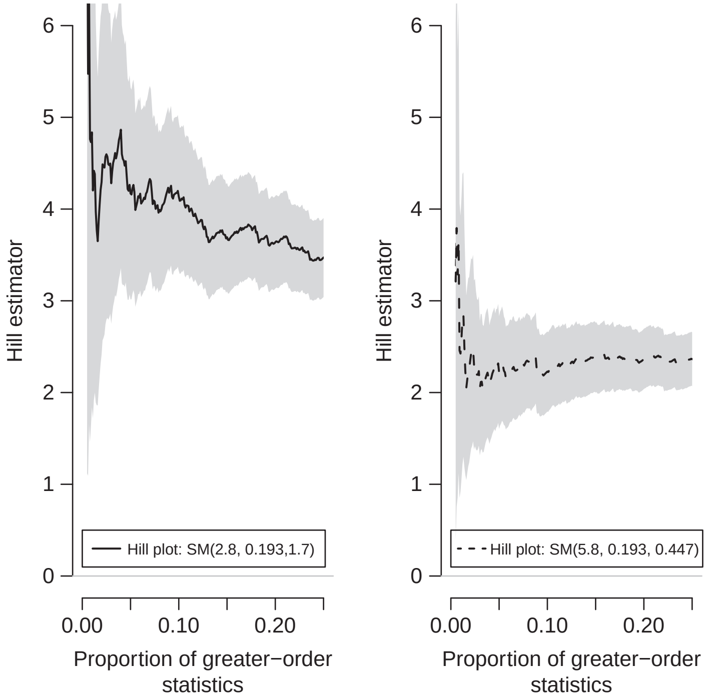

Figure 6.15 Hill plots: plot of the Hill estimate of the tail index (6.109) of two samples of 1000 observations drawn from Singh–Maddala distributions, as a function of the proportion of the greatest order statistics used to compute it.

6.4.6 Parametric Approaches

Sections 6.4.2–6.4.5 deal solely with distribution-free methods; in a sense we are working directly with the sample data. An alternative approach assumes that the distribution is known,[67] up to some parameters, and can be consistently estimated. A preliminary parametric estimation of the distribution is then obtained, and the moments of the parametric distribution are estimated. When the distribution is parametric, inequality indices can be expressed as functions of the distribution parameters. Table 6.9 shows the formulas of the Theil, MLD, and GE measures of inequality for the lognormal and Pareto distributions. They are also given for the Generalized Beta distribution of the second kind (GB2), a four-parameter distribution defined in Equation (6.5) when $c=1$, $\Gamma(\cdot)$ is the gamma function, and $\psi(\cdot):=\Gamma'(\cdot)/\Gamma(\cdot)$ is the digamma function.[68]

The Singh–Maddala distribution is the special case of the GB2 distribution when $p=1$; the Dagum distribution is the special case when $q=1$ (see Figure 6.6). Then, to

[67] See Section 6.3.1 for a discussion of the common functional forms that may be applied.
[68] See Jenkins (2009).

derive the expressions of the Theil, MLD, and GE indices for the Singh–Maddala and Dagum distributions, set $p=1$ and $q=1$ in the equations given in the last column in Table 6.9. An inequality measure can be estimated by replacing the unknown parameters by consistent parameter estimates. Inequality measures are then expressed as nonlinear functions of one or several consistent estimates. From the CLT, they are asymptotically Normal, and their asymptotic variance can be derived using the delta method.[69]

For several of the standard parametric distributions, the Gini index can also be expressed fairly easily as a function of the unknown parameters of the underlying distribution. The Gini index for the lognormal distribution, $\Lambda(y;\mu,\sigma^2)$, and for the Pareto distribution, $\Pi(y;\alpha)$, is equal to

$$I_{\text{Gini}}\left(\Lambda\left(y;\mu,\sigma^2\right)\right)=2\Phi\left(\frac{\sigma}{\sqrt{2}}\right)-1 \tag{6.117}$$

and

$$I_{\text{Gini}}=(\Pi(y;\alpha))=\frac{1}{2\alpha-1}, \tag{6.118}$$

respectively. For the Singh–Maddala distribution and for the Dagum distribution, defined in Equation (6.5) when $c=1$ and when, respectively, $p=1$ and $q=1$, the Gini index is equal to

Table 6.9 Parametric generalized entropy inequality measure for Lognormal (Λ), Pareto (Π), and generalized beta of the second kind (GB2) distributions

	$\Lambda(y;\mu,\sigma^2)$	$\Pi(y;\alpha)$	GB2$(y;a,b,p,q)$
I_{GE}^1	$\frac{\sigma^2}{2}$	$\frac{1}{\alpha-1}-\log\left(\frac{\alpha}{\alpha-1}\right)$	$-\log\left(\frac{\Gamma\left(p+\frac{1}{a}\right)\Gamma\left(q-\frac{1}{a}\right)}{\Gamma(p)\Gamma(q)}\right)+\frac{\psi\left(p+\frac{1}{a}\right)}{a}-\frac{\psi\left(q-\frac{1}{a}\right)}{a}$
I_{GE}^0	$\frac{\sigma^2}{2}$	$\log\left(\frac{\alpha}{\alpha-1}\right)-\frac{1}{\alpha}$	$\log\left(\frac{\Gamma\left(p+\frac{1}{a}\right)\Gamma\left(q-\frac{1}{a}\right)}{\Gamma(p)\Gamma(q)}\right)-\frac{\psi(p)}{a}+\frac{\psi(q)}{a}$
I_{GE}^ξ	$\frac{e^{(\xi^2-\xi)\frac{\sigma^2}{2}}-1}{\xi^2-\xi}$	$\frac{\frac{\alpha}{\alpha-\xi}\left(\frac{\alpha}{\alpha-1}\right)^{-\xi}-1}{\xi^2-\xi}$	$\frac{1}{\xi^2-\xi}\left(\frac{\Gamma\left(p+\frac{\xi}{a}\right)\Gamma\left(q-\frac{\xi}{a}\right)\Gamma^{\xi-1}(p)\Gamma^{\xi-1}(q)}{\Gamma^\xi\left(p+\frac{1}{a}\right)\Gamma^\xi\left(q-\frac{1}{a}\right)}-1\right)$

[69] Software-integrated commands can be used when calculations are cumbersome. Jenkins (2009) used the nlcom command in STATA to compute standard errors of GE indices for the GB2 distribution.

$$I_{\text{Gini}}(\text{SM}(y;a,b,q)) = 1 - \frac{\Gamma(q)\Gamma\left(2q - \frac{1}{a}\right)}{\Gamma\left(q - \frac{1}{a}\right)\Gamma(2q)} \tag{6.119}$$

and

$$I_{\text{Gini}}(\text{D}(y;a,b,p)) = \frac{\Gamma(p)\Gamma\left(2p + \frac{1}{a}\right)}{\Gamma(2p)\Gamma\left(p + \frac{1}{a}\right)} - 1 \tag{6.120}$$

The Singh–Maddala and Dagum distributions are encompassed by the Generalized Beta distribution of the second kind (GB2), defined in Equation (6.5) when $c=1$, for which the formula of the Gini index can also be obtained. However, its expression is lengthy and involves the generalized hypergeometric function, see McDonald (1984) or Kleiber and Kotz (2003) for an explicit formula. Because the Gini index is defined as nonlinear functions of one or several consistent estimates. From the CLT, it is asymptotically Normal, and the asymptotic variance can be derived using the delta method.

6.5. DISTRIBUTIONAL COMPARISONS

Apart from the simple welfare indices discussed in Section 6.4, we also need to be able to implement *ranking tools*. These tools provide the researcher with intuitively appealing methods of making distributional comparisons and are associated with important results in the welfare economics of distributional analysis.

6.5.1 Ranking and Dominance: Principles

The quantile and cumulation functionals Q and C defined in Section 6.4.1 can be used to establish *dominance criteria* for income distribution comparisons in terms of welfare or inequality, and related concepts are available for comparisons in terms of poverty.

6.5.1.1 Dominance and Welfare Indices

6.5.1.1.1 First-Order Dominance

Using (6.23), for a given $F \in \mathbb{F}$, the graph $\{q, Q(F,q) : q \in \mathbb{Q}\}$ describes Pen's parade (Pen, 1974). This is the basis for first-order distributional dominance (or first-order ranking) results. The concept of dominance can be explained as follows: consider two distributions $F, G \in \mathbb{F}$. Then F is said to *first-order dominate* G if the following pair of conditions hold:

$$\left.\begin{array}{l} \forall q \in \mathbb{Q} : Q(F,q) \geq Q(G,q), \\ \exists q \in \mathbb{Q} : Q(F,q) > Q(G,q). \end{array}\right\} \tag{6.121}$$

To see the importance of this concept, suppose we consider the class of all indices expressible in the form $W_{\mathrm{AD}}(F)$[70] additive social welfare functionals giving the aggregate of $\phi(y)$ where $\phi(\cdot)$ is some twice differentiable evaluation function of income. In particular, take the important subclass where welfare respects the monotonicity principle—the evaluation of income is everywhere strictly increasing:

$$\mathbb{W}_1 := \left\{ W | W(F) = \int \phi(y) \mathrm{d}F(y), \phi'(y) > 0 \right\}.$$

Then the statement "$W(F) \geq W(G)$, for any $W \in \mathbb{W}_1$" is equivalent to the statement "F first-order dominates G." If the Parade graph of F lies somewhere above and nowhere below the Parade graph of G, then welfare in F must be higher than in G, for any social welfare function that respects monotonicity (Quirk and Saposnik, 1962).

6.5.1.1.2 Second-Order Dominance

The functional (6.25) can be used to characterize a number of standard concepts associated with second-order dominance.

- For a given $F \in \mathbb{F}$, the graph $\{q, C(F, q) : q \in \mathbb{Q}\}$ describes the *generalized Lorenz curve* (GLC). This is the basis for second-order distributional dominance results (Shorrocks, 1983). The definition of second-order dominance can be derived from (6.121) just by replacing the quantile functional Q by the cumulant functional C. We also focus on a narrower subclass of welfare functions:

  $$\mathbb{W}_2 := \left\{ W | W(F) = \int \phi(y) \mathrm{d}F(y), \phi'(y) > 0, \phi''(y) \leq 0 \right\}.$$

  The concavity restriction $\phi''(y) \leq 0$ implies that a transfer of income from a poorer to a richer individual can never increase social welfare; it is a weak form of the transfer principle (Dalton, 1920). Then the statement "$W(F) \geq W(G)$, for any $W \in \mathbb{W}_2$" is equivalent to the statement "F second-order dominates G." If the GLC of F lies somewhere above and nowhere below the GLC of G, then welfare in F must be higher than in G, for any social welfare function that respects monotonicity and the transfer principle (Hadar and Russell, 1969). However, in distributional analysis attention is focused not only on the basic principle of second-order dominance, as just described, but also on restricted versions of this relationship that incorporate equivalence relationships on the members of $\mathbb{F}$.
- Suppose we want the second-order comparisons to be *scale independent*. This requires that, for any $F \in \mathbb{F}$ and any $\lambda > 0$ the distribution of y and of y/λ are regarded as equivalent for the purposes of distributional comparison; this implies that, when comparing distributions, we may divide incomes by an arbitrary positive constant. A natural

[70] See Equation (6.28)

choice for this constant is the mean of the distribution. The scale normalization of the GLC by the mean (6.26) gives the (*relative*) *Lorenz* functional:[71]

$$L(F;q) := \frac{C(F;q)}{\mu(F)} \tag{6.122}$$

and the graph $\{q, L(F,q) : q \in \mathbb{Q}\}$ gives the *relative Lorenz curve* (RLC).

- As an alternative to scale independence, we might be interested in a form of origin independence for the distributional comparisons, which would require that for any $F \in \mathbb{F}$ and any $\delta \in \mathbb{R}$ the distribution of y and of $y+\delta$ are regarded as equivalent. Instead of the scale normalization used in defining the RLC, we impose a "translational" normalization to define the absolute Lorenz curve. This is the graph $\{q, A(F;q) : q \in \mathbb{Q}\}$, where

$$A(F;q) := C(F;q) - q\mu(F).$$

6.5.1.2 Stochastic Dominance

The first-order and second-order dominance previously defined can be encompassed in a unified method, stochastic dominance, and extended to higher-order dominance.[72] Let us define dominance curves as follows:

$$D_F^s(y) := \frac{1}{(s-1)!}\int_0^y (y-t)^{s-1}\,\mathrm{d}F(t). \tag{6.123}$$

Distribution F is said to dominate distribution G stochastically at order s if the following pair of conditions holds:

$$\left.\begin{array}{l}\forall y \in \mathbb{Y} : D_F^s(y) \le D_G^s(y), \\ \exists y \in \mathbb{Y} : D_F^s(y) < D_G^s(y).\end{array}\right\} \tag{6.124}$$

The case $s=1$ corresponds to first-order dominance based on Pen's parade, previously defined in (6.121). Indeed, first-order stochastic dominance of G by F implies that $F(y) \le G(y)$ for all y, and there exists y over some interval for which the inequality holds strictly. It is similar to (6.121) expressed in terms of the quantile functions rather than CDFs.

The case $s=2$ corresponds to second-order dominance based on the GLC, previously defined. Indeed, from (6.123) and (6.25), we have $D_F^2(y_q) - D_G^2(y_q) = C(G;q) - C(F;q)$. Then, the pair of conditions in (6.124) is similar to that in (6.121) where the quantile functional Q is replaced by the cumulant functional C.

[71] This is equivalent to the income share (6.27).

[72] Fishburn (1980), O'Brien (1984), Stark and Yitzhaki (1988), Thistle (1989), O'Brien and Scarsini (1991), Fishburn and Lavalle (1995), and Davidson (2008).

There is a clear relation between dominance and poverty. From (6.86) and (6.123), we can see that $D_F^s(\zeta_0)$ is equal to the FGT poverty index, up to a scale factor. If, for all $[\zeta_0^-;\zeta_0^+]$, $D_F^s(\zeta_0) < D_G^s(\zeta_0)$, it follows that the FGT poverty index is lower in F than in G for all poverty lines in the interval $[\zeta_0^-;\zeta_0^+]$. The poverty measure can then be viewed as restricted stochastic dominance of G by F over that interval. The stochastic dominance criterion can also be viewed as a generalization of poverty measures when we let the poverty line vary over the whole support of the distribution.[73]

6.5.2 Ranking and Dominance: Implementation

To implement ranking criteria empirically, a standard approach is as follows[74]:

1. Choose a finite collection of population proportions $\Theta \subset \mathbb{Q}$.
2. For each $q \in \Theta$ compute the sample quantiles $\hat{y}_q$ and income cumulations $\hat{c}_q$ required for empirical implementation of first- and second-order rankings. To do this, we replace F in (6.23) and (6.25) by the EDF $F^{(n)}$—see Equation (6.8). Then we have

$$\hat{y}_q := Q\left(F^{(n)}; q\right) = y_{(\kappa(n,\, q))}, \tag{6.125}$$

where

$$\kappa(n, q) := \lfloor nq - q + 1 \rfloor \tag{6.126}$$

and $\lfloor x \rfloor$ denotes the largest integer no greater than x; we also have

$$\hat{c}_q := C\left(F^{(n)}; q\right) = \frac{1}{n} \sum_{i=1}^{\kappa(n,\, q)} y_{(i)} \tag{6.127}$$

3. Compute the variances and covariances of the sample quantiles (first-order) or the income cumulations (second-order).
4. Specify carefully the ranking hypothesis that is to be tested.

Step 1—involves a choice of how many points to select on the Parade or on the Lorenz curve. Step 2 is easy. Step 3 is dealt with in Section 6.5.2.1 and Step 4 in Sections 6.5.2.3 and 6.5.2.4.

6.5.2.1 Asymptotic Distributions

The main results follow from applying Lemmas in Section 6.4.2.2. We also need to define one further functional analogous to (6.23) and (6.25):

$$S(F; q) := \int_{\underline{y}}^{y_q} y^2 \mathrm{d}F(y) =: s_q. \tag{6.128}$$

and its sample counterpart:

[73] See Atkinson (1987) and Foster and Shorrocks (1988).

[74] We consider distribution-free methods. For parametric Lorenz curve comparisons, see Sarabia (2008).

$$\hat{s}_q := S\left(F^{(n)}; q\right) = \frac{1}{n}\sum_{i=1}^{\kappa(n,q)} y_{(i)}^2 \tag{6.129}$$

Then we have the following two theorems:

Theorem 1

For any $q, q' \in \mathbb{Q}$, $\sqrt{n}\hat{y}_q$ and $\sqrt{n}\hat{y}_{q'}$ *are asymptotically normally distributed with covariance*[75]:

$$\frac{q[1-q']}{f(y_q)f(y_{q'})}. \tag{6.130}$$

Proof

Immediate from Lemmas 1 and 2 ▪

Theorem 2

For any $q, q' \in \mathbb{Q}$, $\sqrt{n}\hat{c}_q$ and $\sqrt{n}\hat{c}_{q'}$ *are asymptotically normally distributed with covariance*[76]:

$$\omega_{qq'} := s_q + [qy_q - c_q]\left[y_{q'} - q'y_{q'} + c_{q'}\right] - y_q c_q \ \text{ for } q \leq q'. \tag{6.131}$$

Proof

Using Lemmas 1 and 3, the asymptotic covariance *of* $\sqrt{n}C\left(F^{(n)}; q\right)$ and $\sqrt{n}C\left(F^{(n)}; q'\right)$ is given by

$$\begin{aligned} \omega_{qq'} &= \int \mathrm{IF}(z; C(F;q), F)\mathrm{IF}(z; C(F;q'), F)\mathrm{d}F(z) \\ &= \int [qy_q - c_q + \iota(y_q \geq z)[z - y_q]]\left[q'y_{q'} - c_{q'} + \iota(y_{q'} \geq z)[z - y_{q'}]\right]\mathrm{d}F(z) \end{aligned} \tag{6.132}$$

Given that $\iota(x_{q'} \geq z) = 1$ whenever $\iota(x_q \geq z) = 1$ the right-hand side becomes

$$\begin{aligned} &[qy_q - c_q]\left[q'y_{q'} - c_{q'}\right] + \int_{\underline{y}}^{y_{q'}} [qy_q - c_q]\left[z - y_{q'}\right]\mathrm{d}F(z) \\ &+ \int_{\underline{y}}^{y_q} \left[q'y_{q'} - c_{q'} + z - y_{q'}\right][z - y_q]\mathrm{d}F(z) \end{aligned} \tag{6.133}$$

Using the definitions in (6.23), (6.25), and (6.128), we find that (6.133) becomes (6.131) ▪

We can also rewrite the IF as a random variable minus its expectation. From (6.42) in Lemma 3, we have

$$\mathrm{IF}(z; C(F,q), F) = Z_q - E(Z_q) \ \text{ where } Z_q = [z - y_q]\iota(z \leq y_q). \tag{6.134}$$

[75] See Lemma 1 of Beach and Davidson (1983).

[76] See Theorem 1 of Beach and Davidson (1983).

From (6.132), we can see immediately that the asymptotic covariance of $\sqrt{n}\hat{c}_q$ and $\sqrt{n}\hat{c}_{q'}$ is equal to the covariance of Z_q and $Z_{q'}$

$$\omega_{qq'} = \text{cov}\left(Z_q, Z_{q'}\right). \tag{6.135}$$

From a sample y_i, for $i=1, \ldots, n$, we can then estimate the covariance of the GLC ordinates $\hat{c}_q$ and $\hat{c}_{q'}$ as the empirical covariance of Z_{iq} and $Z_{iq'}$ divided by n

$$\widehat{\text{cov}}\left(\hat{c}_q, \hat{c}_{q'}\right) = \frac{1}{n}\hat{\omega}_{qq'} = \frac{1}{n^2}\sum_{i=1}^{n}\left(Z_{iq} - \overline{Z}_q\right)\left(Z_{iq'} - \overline{Z}_{q'}\right) \tag{6.136}$$

where

$$Z_{iq} = \left[y_i - \hat{y}_q\right]\iota\left(y_i \leq \hat{y}_q\right) \tag{6.137}$$

and $\overline{Z}_q = n^{-1}\sum_{i=1}^{n} Z_{iq}$, $\hat{y}_q$ is given in (6.125).

In a practical implementation one replaces the individual components of the right-hand side of (6.131) by their sample counterparts[77] to obtain the following consistent estimate of $\omega_{qq'}$:

$$\hat{\omega}_{qq'} := \hat{s}_q + \left[q\hat{y}_q - \hat{c}_q\right]\left[\hat{y}_{q'} - q'\hat{y}_{q'} + \hat{c}_{q'}\right] - \hat{y}_q\hat{c}_q. \tag{6.138}$$

These results can also be used for the ordinates of the (relative) Lorenz curve. Using the standard result on limiting distributions of differentiable functions of random variables (Rao, 1973), or using the delta method in (6.60), the asymptotic covariances of $\sqrt{n}\hat{c}_q/\hat{\mu}$ and $\sqrt{n}\hat{c}_{q'}/\hat{\mu}$ are then given by

$$v_{qq'} = \frac{1}{\mu^4}\left[\mu^2\omega_{qq'} + c_q c_{q'}\omega_{11} - \mu c_q \omega_{g'1} - \mu c_{q'}\omega_{q1}\right] \quad \text{for } q \leq q'. \tag{6.139}$$

where $\omega_{q1} := s_q + [qy_q - c_q]\mu - y_q c_q$, $\omega_{11} := s_1 - \mu^2$ and $\mu = \mu(F)$. Again, for practical implementation, the components of the right-hand side of (6.139) are replaced by their sample counterparts. We can also use the IF and express it as a random variable minus its expectation. The IF of the Lorenz curve ordinate (6.122) is given by[78]

$$\text{IF}(z; L(F,q), F) = \frac{1}{\mu}\left[qy_q - \frac{zc_q}{\mu} + \left[z - y_q\right]\iota\left(z \leq y_q\right)\right] \tag{6.140}$$

We can rewrite the IF as $\text{IF}(z; L(F,q), F) = Z_q - E(Z_q)$, where

$$Z_q = \frac{1}{\mu^2}\left[\mu\left[z - y_q\right]\iota\left(z \leq y_q\right) - c_q z\right]. \tag{6.141}$$

[77] $\hat{y}_q$, $\hat{c}_q$, and $\hat{s}_q$ are given by (6.125), (6.127), and (6.129), respectively.

[78] See Cowell and Victoria-Feser (2002) and Donald et al. (2012).

The asymptotic covariance of $\sqrt{n}\hat{c}_q/\hat{\mu}$ and $\sqrt{n}\hat{c}_{q'}/\hat{\mu}$ is equal to the covariance of Z_q and $Z_{q'}$ From a sample y_i, for $i=1, \ldots, n$, *we* can then estimate the covariance of the (relative) Lorenz curve ordinates $\hat{c}_q/\hat{\mu}$ and $\hat{c}_{q'}/\hat{\mu}$ as the empirical covariance of Z_{iq} and $Z_{iq'}$ divided by n,

$$\widehat{\text{cov}}\left(\frac{\hat{c}_q}{\hat{\mu}}, \frac{\hat{c}_{q'}}{\hat{\mu}}\right) = \frac{1}{n}\hat{v}_{qq'} = \frac{1}{n^2}\sum_{i=1}^{n}\left(Z_{iq} - \overline{Z}_q\right)\left(Z_{iq'} - \overline{Z}_{q'}\right) \tag{6.142}$$

where

$$Z_{iq} = \frac{1}{\hat{\mu}^2}\left[\hat{\mu}\left[y_i - \hat{y}_q\right]\iota\left(y_i \le \hat{y}_q\right) - \hat{c}_q y_i\right]. \tag{6.143}$$

and $\overline{Z}_q = n^{-1}\sum_{i=1}^{n} Z_{iq}, \hat{y}_q$ and $\hat{c}_q$ are given by (6.125) and (6.127), respectively.

The case of stochastic dominance can also be considered. For a given value z, a consistent estimator of $D_F^s(z)$ is

$$\hat{D}_F^s(z) = \frac{1}{n(s-1)!}\sum_{i=1}^{n}(z - y_i)^{s-1}\iota(y_i \le z) \tag{6.144}$$

where y_i, $i=1, \ldots, n$ is a random sample of n independent observations. Because it is a sum of IID observations, this estimator is consistent and asymptotically normal. The asymptotic covariance is also easy to calculate.[79]

When we compare two distributions, random samples can be obtained from two independent populations or from two correlated populations. The last case typically occurs when the two samples are independent paired drawings from the same population, as, for instance, with pretax and posttax distributions. In both cases of independent and correlated samples, it can be shown that the difference $\hat{D}_F^s\left(z_q\right) - \hat{D}_G^s\left(z_{q'}\right)$ is asymptotically normal, with asymptotic covariance equal to

$$\frac{1}{((s-1)!)^2}E\left[\left(z_q - y_F\right)_+^{s-1}\left(z_{q'} - y_G\right)_+^{s-1}\right] - D_F^s\left(z_q\right)D_G^s\left(z_{q'}\right) \tag{6.145}$$

where $(x)_+^{s-1} = x^{s-1}\iota(x \ge 0)$. This result comes from the CLT, assuming that population moments of order $2s-2$ for each distribution exist. The asymptotic covariance can be estimated with sample counterparts, with the expectation in (6.145) replaced by

$$\frac{1}{n}\sum_{i=1}^{n}\left(z_q - y_{F^{(n)},i}\right)_+^{s-1}\left(z_{q'} - y_{G^{(n)},i}\right)_+^{s-1} \tag{6.146}$$

[79] It is equal to (6.145) with $F=G$.

and $D^s(x)$ estimated as defined in (6.144). For $s=2$, we find an estimate of the covariance matrix similar to that obtained in (6.136) and (6.137), for the GLC ordinates. More details and explicit expressions for z being stochastic and for poverty measures can be found in the comprehensive approach to inference on stochastic dominance presented in Davidson and Duclos (2000).[80]

6.5.2.2 Dominance: An Intuitive Application

Armed with Theorems 1 and 2, an intuitive approach to dominance can be immediately applied. Using (6.127) we can plot an empirical GLC with confidence bands. Consistent estimates of the variance of the GLC ordinates can be calculated using (6.136) and (6.137) with $q=q'$. Therefore, we can immediately construct an informative graphical presentation for distributional comparisons, $\left(q, \hat{c}_q\right)$, with 95% confidence bands computed as $\left[\hat{c}_q \pm 1.96 \times \widehat{\mathrm{var}}\left(\hat{c}_q\right)\right]$. One could see whether it is reasonable to conclude that the GLC for distribution F lies above that for distribution G (second-order dominance). Clearly the same idea could be pursued with empirical quantiles and parade diagrams (first-order dominance).

Figure 6.16a, to the left, shows two GLCs obtained from two independent samples of 5000 observations drawn from Singh–Maddala distributions F and G, respectively, with confidence bands at 95% evaluated at the percentiles, $q=0.01, 0.02, \ldots, 0.99$. F is the Singh–Maddala distribution with parameters $a=2.8$, $b=0.193$, and $q=1.7$, used in the introduction, and G is the distribution with parameters $a=3.8$, 0.193, and 0.839; the means are, respectively, 0.169 and 0.240. This figure shows that distribution G second-order dominates distribution F. It suggests that poverty measures based on poverty gaps will exhibit more poverty in F than in G (Jenkins and Lambert, 1997). Table 6.10 shows poverty measures computed from the two samples, with 95% confidence intervals (see Section 6.4.4). As expected, poverty indices are significantly greater in F than in G.

We can also plot an empirical (relative) Lorenz curve with confidence bands. Consistent estimates of the variance of the (relative) Lorenz curve ordinates, $\widehat{\mathrm{var}}\left(\hat{c}_q/\hat{\mu}\right)$, can be calculated using (6.142) and (6.143) with $q=q'$. Therefore, we can construct a graphical representation of Lorenz curves, $\left(q, \hat{c}_q/\hat{\mu}\right)$, with 95% confidence bands, $\left[\left(\hat{c}_q/\hat{\mu}\right) \pm 1.96 \times \widehat{\mathrm{var}}\left(\hat{c}_q/\hat{\mu}\right)\right]$. It is often difficult to distinguish between two RLCs by eye; for this reason a plot of the difference between two RLCs is often useful. When the samples are independent, the variance of the difference between the ordinates is the sum of the variances from each sample. In practice, (relative) Lorenz curves often

[80] On dominance with complex sample design, see Beach and Kaliski (1986) and Zheng (1999, 2002). For an alternative approach focusing on crossings in the tails of Lorenz curves, see Schluter and Trede (2002), and for a Bayesian approach, see Hasegawa and Kozumi (2003). On the extension to absolute dominance and deprivation dominance, see Bishop et al. (1988) and Xu and Osberg (1998), and on poverty dominance see also Chen and Duclos (2008) and Thuysbaert (2008).

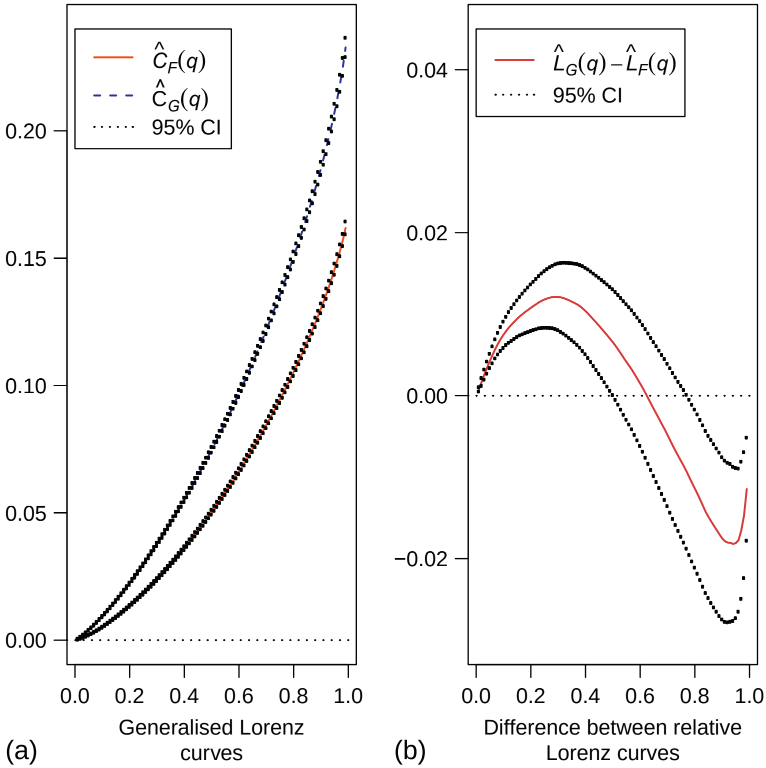

Figure 6.16 Generalized Lorenz curves and difference between Lorenz curves, $n = 5000$.

intersect, and in such cases no unambiguous ranking can be obtained. Nevertheless, useful information on inequality can be drawn from Lorenz curve comparisons.

Figure 6.16b, to the right, shows the difference between two RLCs obtained from the two samples used in Figure 6.16a. The two curves intersect in the upper part. This figure also shows that the empirical Lorenz curve of G lies significantly above the empirical Lorenz curve of F in the bottom part, whereas the reverse is true in the upper part. It suggests that inequality measures sensitive to the bottom part of income distributions would be smaller in G than in F, whereas inequality measures more sensitive to the upper part of income distributions would be smaller in F than in G. Table 6.10 shows inequality measures computed from the two samples, with 95% confidence intervals (see Section 6.4.3) Noting that GE measures, I^{ξ}_{GE}, are more sensitive to the bottom (top) of income distributions with smaller (higher) parameter ξ, we find the results suggested by the previous Lorenz curve comparisons. Indeed, I^{-1}_{GE} is significantly smaller in G than in F, whereas I^{2}_{GE} is significantly smaller in F than in G.

This approach is clearly *ad hoc*, and we need to examine the issues involved more carefully; we do this in Sections 6.5.2.3 and 6.5.2.4. Graphical representation of two

empirical Lorenz curves, with confidence intervals, allows us to make *individual* comparisons. We can test if particular Lorenz curve ordinates are significantly different between two curves. To be able to make conclusions on dominance or nondominance, we need to test simultaneously that all ordinates from one curve are significantly greater or not smaller than the ordinates from the other curve. Appropriate test statistics need to be used to make *multiple* comparisons and to test simultaneously that several inequalities hold. Moreover, Lorenz curve ordinates are typically strongly positively correlated and, thus, test statistics need to take into account the covariance structure between the Lorenz curve ordinates.

6.5.2.3 The Null Hypothesis: Dominance or Nondominance

Performing inference on stochastic dominance is more complex than on a single welfare index. The hypotheses tested are usually based on a set of inequalities. For instance, first-order stochastic dominance requires that,

$$F(y) \leq G(y) \quad \text{for all } y \geq 0, \tag{6.147}$$

to say that distribution F dominates distribution G stochastically at order one. The theoretical literature also include the condition that $F(y) < G(y)$ for some y, as defined in (6.124). However, no statistical test can distinguish between these two forms of weak and strict dominance.[81] Because we are interested in statistical issues hereafter, we make

[81] Under the null of an inequality in one direction, a test cannot reject equality. Indeed, equality is on the frontier of the inequality hypothesis, and a test cannot distinguish statistically between being on the frontier and being very close to the frontier.

no distinction between weak and strict dominance, and we can write all inequalities as weak.

Inference on dominance in the population would be drawn from the corresponding sample properties. From a given sample, we can consistently estimate the two distributions by their EDF counterparts, $F^{(n)}(x)$ and $G^{(n)}(x)$. Sample dominance is then defined as $F^{(n)}(y) \leq G^{(n)}(y)$ for all y. It is clear that dominance in the population cannot be rejected if there is dominance in the sample. It is rejected if sample nondominance is statistically significant only. A similar reasoning applies for nondominance in the population. It follows that, to infer dominance, we should test the null hypothesis of nondominance, and to infer nondominance, we should test the null of dominance.

It can be illustrated with a simple example of two distributions with the same support and three points, $y_1 < y_2 < y_3$.[82] Because $F(y_3) = G(y_3) = 1$, we will say that distribution F dominates distribution G in the population if $d_i = G(y_i) - F(y_i) \geq 0$ for $i = 1, 2$. Figure 6.17 shows two bidimensional plots of $\hat{d}_1$ and $\hat{d}_2$, where the null hypothesis is,

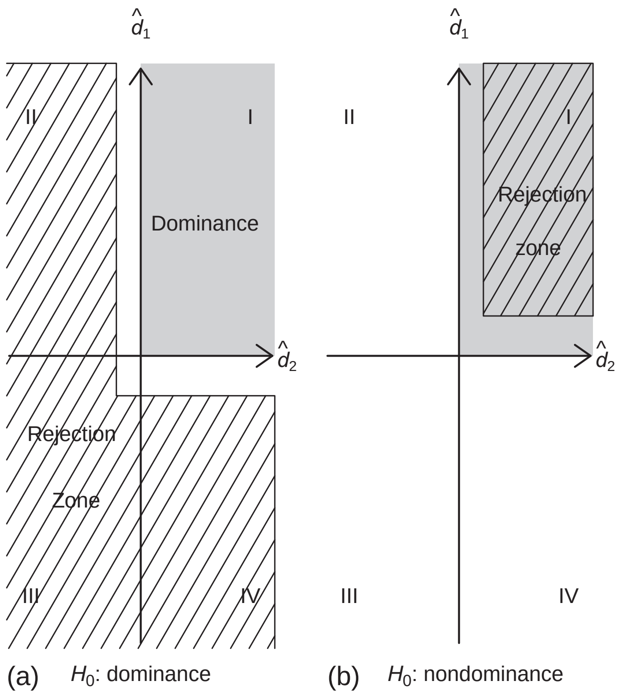

Figure 6.17 Tests of dominance and nondominance. The first quadrant, I, corresponds to dominance of G by F in the sample (gray area). The quadrants II, III, and IV correspond to nondominance.

[82] See Davidson and Duclos (2013).

respectively, dominance and nondominance. Distribution F dominates G in the sample when $\hat{d}_i \geq 0$, for $i=1, 2$. Then, the first quadrant, denoted I (gray area), corresponds to dominance in the sample, whereas quadrants II, III, and IV correspond to nondominance in the sample.

First, let us consider the null hypothesis of dominance, as shown in Figure 6.17a, on the left. To reject dominance in the population, the nondominance in the sample must be statistically significant, that is, the rejection zone has to be far enough from the dominance area, for example, in the cross-hatched area. The rejection zone is exclusively in the area of nondominance, whereas the (remaining) nonrejection zone corresponds to the dominance area plus the white L-shaped band within the nondominance area. Then, rejecting the null hypothesis of dominance corresponds to the case of nondominance, whereas nonrejecting it is inconclusive.

Second, let us consider the null hypothesis of nondominance, as shown in Figure 6.17b, on the right. With a similar reasoning, we can see that the rejection zone is exclusively in the area of dominance, whereas the nonrejection zone is composed of both nondominance and dominance situations (gray L-shaped band). Then, rejecting the null hypothesis of nondominance corresponds to the case of dominance, whereas nonrejecting it is inconclusive.

The previous example illustrates that positing the null of nondominance is the only way to draw a strong conclusion of dominance. However, it comes at a cost: Dominance will be inferred only if there is strong evidence in its favor. From Figure 6.17b, we can see that rejecting the null of nondominance is quite demanding because it requires that both statistics $\hat{d}_1$ and $\hat{d}_2$ are statistically significant. It may be too demanding, especially in the tails where both distributions tend to the same values and where we usually have sparse data and little information. Davidson and Duclos (2013) showed that, with distributions continuous in the tails, it is impossible to reject the null of nondominance over the full support of the distributions. It leads them to develop restricted stochastic dominance, limiting attention to some interval in the middle of the distribution.

The most common approach in the literature has developed tests of stochastic dominance positing the null of dominance.[83] The previous example illustrates the standard feature in statistics that nonrejecting the null does not imply that the null is true, and so selecting the null hypothesis remains allows for the possibility of being wrong at some level.[84] The level at which we may be wrong by accepting the null is unknown

[83] See Beach and Richmond (1985), McFadden (1989), Bishop et al. (1992), Anderson (1996), Schmid and Trede (1996), Davidson and Duclos (2000), Barrett and Donald (2003), Linton et al. (2005), and Maasoumi and Heshmati (2008).

[84] It is usually done when a coefficient is not significant in estimation results and when the analysis that follows is based on the selected regression model without the associated covariate.

(the L-shaped bands in Figure 6.17a and b), but it would be reduced by using statistical tests with greater power properties in a finite sample.

Finally, the two approaches can be seen as complementary. Rejecting the null of dominance or nondominance allows us to infer, respectively, nondominance and dominance when comparing two distributions.

6.5.2.4 Hypothesis Testing

Test statistics have been developed in the literature under the null hypothesis of dominance and nondominance. We distinguish both cases, for which we can interpret them, respectively, as union–intersection and intersection–union tests.

Under the Null of Dominance

Statistical tests can be constructed to test the null hypothesis of dominance against the alternative of nondominance. Under the null hypothesis that F dominates G, we have

$$\begin{aligned} H_0 &: D_F^s(y) \le D_G^s(y), \quad \text{for all } y \in \mathbb{Y}, \\ H_1 &: D_F^s(y) > D_G^s(y), \quad \text{for some } y \in \mathbb{Y}^{\cdot} \end{aligned} \tag{6.148}$$

where $\mathbb{Y}$ denotes a given set contained in the union of the support of the two distributions. An appropriate test statistic could be interpreted as a *union–intersection* test because the null hypothesis is expressed as an intersection of individual hypotheses and the alternative as an union (Roy, 1953). A natural test is based on the supremum of individual differences,

$$\tau = \sup_{y \in \mathbb{Y}} \left(\hat{D}_F^s(y) - \hat{D}_G^s(y) \right). \tag{6.149}$$

It is clear that the null hypothesis is rejected if τ is significant and positive. McFadden (1989) proposed a test based on (6.149) for two independent samples of IID observations. For $s = 1$, it is a variant of the Kolmogorov–Smirnov statistic, with known properties. For $s = 2$, the asymptotic distribution under the null is not tractable. Barrett and Donald (2003) proposed simulation-based methods for estimating critical values, taking into account comparisons at all points of the support (functional approach) rather than at a fixed number of arbitrarily chosen points. Linton et al. (2005) proposed to use subsampling methods, permitting to estimate critical values in general settings, with arbitrary order s, dependent observations, and continuous and discrete supports. For multiple comparisons restricted to a fixed number of points $(y_1, \ldots, y_T)$, a Wald test of inequality restrictions can also be used. Let us note the covariance matrix estimates of $\hat{D}_F^s$ and $\hat{D}_G^s$, respectively, as $\hat{\Omega}_F$ and $\hat{\Omega}_G$, the Wald test statistic is computed by solving

$$\min_{\delta \ge 0} \left(\hat{D}_F^s - \hat{D}_G^s - \delta \right)^\top \left(\hat{\Omega}_F + \hat{\Omega}_G \right) \left(\hat{D}_F^s - \hat{D}_G^s - \delta \right). \tag{6.150}$$

The statistic is obtained by using an algorithm to solve quadratic programming problems. The distribution of the statistic is a mixture of chi-square with weights that require simulation methods to be consistently estimated (Dardanoni and Forcina, 1999).

Lorenz dominance can be tested using similar methods. Bishop et al. (1989) and Davidson and Duclos (1997) proposed a test for a fixed number of points,[85] whereas Donald and Barrett (2004) and Bhattacharya (2007) have considered versions of Lorenz dominance tests in a functional approach, taking into account comparisons at all points of the supports.

Under the Null of Nondominance

Other statistical tests have been developed to test the null hypothesis of nondominance against the alternative of dominance. Under the null that F does not dominate G, we have

$$\begin{aligned} H_0 &: D_F^s(y) \geq D_G^s(y), \quad \text{for some } y \in \mathbb{Y}, \\ H_1 &: D_F^s(y) < D_G^s(y), \quad \text{for all } y \in \mathbb{Y} \end{aligned}. \tag{6.151}$$

An appropriate test could be interpreted as an *intersection–union* test because the null hypothesis is expressed as an union and the alternative as an intersection of individual hypotheses (Gleser, 1973). The idea behind the intersection–union method is that the null is rejected only if each of the individual hypotheses can be rejected. A natural test is based on the infimum of individual differences,

$$\tau' = \inf_{y \in \mathbb{Y}^r} \left(\hat{D}_G^s(y) - \hat{D}_F^s(y) \right). \tag{6.152}$$

It is clear that the null hypothesis is rejected if τ' is significant and positive. The statistic τ' has to be defined over $\mathbb{Y}^r$, some closed interval contained in the interior of the joint support of the two distributions $\mathbb{Y}$. The main reason is that the null hypothesis would never be rejected if we consider the tails of the distributions, where data are sparse and where the differences between the two distributions tend to zero. Specifically, $\mathbb{Y}^r$ should be a restricted interval in $\mathbb{Y}$ that removes the tails of the distributions. Kaur et al. (1994) proposed a test based on (6.152) for $s=2$ with independent samples and continuous distributions F and G. Critical values can be taken from the Normal distribution, making the test easy to implement. However, it can have low power properties (Dardanoni and Forcina, 1999). Davidson and Duclos (2013) and Davidson (2009b) proposed a test for higher order, for correlated samples as well as uncorrelated samples, and for continuous and discrete distributions. They also showed that appropriate bootstrap methods permit researchers to obtain much better finite sample properties.

[85] See also Bishop et al. (1991a,b, 1992).

6.6. OTHER ESTIMATION PROBLEMS

In Sections 6.4 and 6.5, we assumed that data are always drawn from a representative sample of the whole population. For some researchers this state of affairs is something of a luxury. In this section, we discuss a number of common problems that need to be taken into account in practical application and the statistical methods of dealing with them.

6.6.1 Contamination

By data contamination we mean a set of observations that do not "belong" to the sample—see Section 6.2.3. The essentials of the formal approach can be explained using a simple model based on the distribution function (in fact, we have already seen the elements of this model in a different context—see Section 6.4.2). The idea is that, instead of observing a distribution $F \in \mathbb{F}$ directly, one sees it after it has been mixed with another distribution that represents contamination. The elementary model of this is presented in Equation (6.33), where one observes a distribution G given by

$$G = [1 - \delta]F + \delta H^{(z)} \tag{6.153}$$

where δ represents the proportion of contamination in the mixture that we observe and $H^{(z)}$ is the elementary "contamination distribution" (6.32), a single point mass at $z \in \mathbb{Y}$. From this minimalist structure, one can easily develop more interesting specifications of the model of contamination using a mixture of F with a distribution that is richer than $H^{(z)}$. A number of questions immediately arise: Does contamination matter in analyzing income distributions? How does contamination affect distributional comparisons? How may one appropriately estimate models of income distribution if there is reason to believe that contamination is an important issue?

6.6.1.1 The Concept of Robustness

To address the question "how important," we can use the tool introduced in the discussion of asymptotic inference (Section 6.4.2). The IF is precisely designed to gauge the sensitivity of a statistic to contamination. Consider some statistic T (for example, an inequality measure, a poverty index, or a Lorenz ordinate); then IF quantifies the impact of an infinitesimal amount of contamination on the statistic T, namely, $\frac{\partial}{\partial \delta} T(G)|_{\delta \to \infty}$ (assuming that T is differentiable)—see Hampel (1971, 1974) and Hampel et al. (1986). Clearly the size of this differential will depend on the exact specification of the contamination distribution: in the context of the elementary model (6.153) this would mean that it will depend on the exact location in $\mathbb{Y}$ of the point z (where the contamination is concentrated). Of particular interest are cases where this IF is unbounded for some value of z; the interpretation of this is that the statistic T is highly sensitive to an infinitesimal amount of contamination at point z. In the present context this is precisely what we mean by saying that a statistic is *nonrobust*; obviously if the IF for the statistic T is bounded for all values of z then it makes sense to describe T as a *robust* statistic. We will come to some examples of robust and nonrobust statistics in a moment. However, first it is worth making the commonsense point that even if we are only using robust statistics in our analysis, this does not mean that we can ignore the possibility of data contamination; in practice, it may be that the assumption that δ is vanishingly small is just unreasonable.

6.6.1.2 Robustness, Welfare Indices, and Distributional Comparisons

Does contamination matter for the tools that we discussed in Sections 6.4 and 6.5?

Basic cases. First, take two statistics whose properties can be easily deduced, the mean and median. Using the definition of the mixture distribution (6.153) with point-contamination (6.32) and the linearity of the mean functional, we can write the mean of the observed mixture distribution as

$$\mu(G) = \mu\left([1-\delta]F + \delta H^{(z)}\right) = [1-\delta]\mu(F) + \delta\mu\left(H^{(z)}\right) \tag{6.154}$$

Evaluating (6.154) for the elementary point-contamination distribution (6.32), we obtain

$$\mu(G) = [1-\delta]\mu(F) + \delta z. \tag{6.155}$$

The observed mean is a simple weighted sum (with weights $1-\delta$, δ) of the true mean $\mu(F)$ and the value of z where the contamination is concentrated. Now differentiate (6.155) with respect to δ, and we find the IF for the functional μ as follows:

$$\mathrm{IF}(z; \mu, F) = z - \mu(F). \tag{6.156}$$

It is easy to see from (6.156) that $\mathrm{IF}(z; \mu, F)$ is unbounded as z tends to $-\infty$ or $+\infty$: The mean is a nonrobust statistic. So if you want to use the mean as a welfare index, then the introduction of a very small amount of contamination sufficiently far out in one of the tails of the distribution will cause the observed value of the mean to be pulled away from the true value.[86] Now consider the median, as a particular case of the quantile functional (6.23); using the basic result Lemma 2 and setting $q = 0.5$ to obtain the median we have

$$\mathrm{IF}(z; Q(\cdot, 0.5), F) = \frac{q - \iota(q \geq F(z))}{f(Q(F, 0.5))} = \frac{q - \iota(y_{0.5} \geq z)}{f(y_{0.5})}. \tag{6.157}$$

[86] Using (6.42), the same type of reasoning can be used to show that Lorenz ordinates are also nonrobust (Cowell and Victoria-Feser, 2002).

It is clear that, as long as there is positive density at the median $y_{0\cdot 5}$, the IF in (6.157) is bounded (Cowell and Victoria-Feser, 2002). So, in contrast to the mean, the median is robust. The intuition is clear: if you throw a single alien observation into the formula for the mean then, if that observation is large enough, it can have a huge effect when averaged in with the other sample values. But the median simply marks the "halfway" point in the distribution: If you introduce a single alien observation to the right of the median, then the size of that observation (how far it is to the right of the median) has no effect on the observed halfway point.

Inequality. It turns out that most commonly used inequality indices behave in a way that is similar to the mean: they are nonrobust (Cowell and Victoria-Feser, 1996b). To see why, let us check the properties of the W_{QAD} class of welfare indices (6.30) on which many standard inequality measures are based. The IF for a typical member of this class is

$$\varphi(z,\mu(F)) - W_{\text{QAD}}(F) + [z-\mu(F)]\int \varphi_\mu(z,\mu(F))\mathrm{d}F(z) \tag{6.158}$$

where $\varphi(y,\mu(F))$ is the evaluation of each individual income y used in the formula (6.30). It is clear that contamination could have an impact through more than one route—there is the direct effect from the evaluation of z, the first term in (6.158); there is also an indirect route through the effect on the mean, the third term in (6.158). Notice that this indirect route contains the expression, $z-\mu(F)$, as the right-hand side of (6.156). From this we can see that if $\varphi_\mu(z,\mu(F))$ is not everywhere zero, contamination will cause quasi-additive welfare indices to be nonrobust. Now consider the direct route: Clearly if $\varphi(z,\mu(F))$ is unbounded as z approaches infinity or as z approaches zero, the particular index in the W_{QAD} class will be nonrobust; this is precisely what happens with nearly all commonly used inequality measures.[87] Why does this happen? Inequality measures are usually designed to be sensitive to extreme values at one or other end of the distribution, so placing a tiny amount of contamination sufficiently far out in one of the tails is going to have a big impact on measured inequality because of its built-in sensitivity. As an example, take the GE measures. From Equations (6.49)–(6.51) we see that

$$\varphi(z,\mu(F)) = \frac{[z/\mu(F)]^\xi - 1}{\xi^2-\xi}.$$

Clearly this is unbounded for $\xi \geq 0$ as $z\to\infty$ and is unbounded for $\xi \leq 0$ as $z\to 0$, so the inequality indices are nonrobust for contamination among very high incomes in the case

[87] The implication of this is that even with a richer model of contamination than the elementary (6.32) leaves the mean unchanged, quasi-additively decomposable inequality indices will be nonrobust (Cowell and Victoria-Feser, 1996b).

of top-sensitive members of the GE family and for contamination near zero in the case of bottom-sensitive members of the GE family.[88]

Poverty. By contrast, conventional poverty indices such as the FGT class (6.86) and the Sen index (6.93) are robust if the poverty line is exogenous or is a function of a robust statistic such as the median (Cowell and Victoria-Feser, 1996a). Again, the intuition is straightforward. From (6.79), the IF for an additively decomposable poverty measure with a fixed poverty line ζ_0 is

$$\mathrm{IF}(z; P, F) = p(z, \zeta_0) - P(F)$$

where $p(\cdot)$ is the poverty evaluation function. From (6.86), we can see that for the FGT class

$$p(z, \zeta_0) = [\max(1 - z/\zeta_0, 0)]^{\xi}$$

so that $p(0,\zeta_0) = 1, p(z,\zeta_0)$ is nonincreasing in z for $z < \zeta_0$ and $p(z,\zeta_0)$ for $z \geq \zeta_0$. In plain language contamination at the very bottom of the distribution (below the poverty line) has an impact that it is bounded below, but a very high observation has no effect on poverty, whether that observation is a genuine high income or contamination. Poverty measures such as the FGT class are robust under contamination.

6.6.1.3 Model Estimation

If inequality measures are typically nonrobust, what is to be done about the possibility of contamination? A potentially useful approach is to use a parametric functional form $f(y;\theta)$ to model all or part of the income distribution and then compute inequality from the modeled distribution. But of course the robustness property of the inequality index based on the modeled distribution will depend on the way the parameter vector $\theta \in \mathbb{R}^p$ is estimated. If one consider using maximum likelihood estimators (MLEs), for example, the robustness problem remains. Although MLEs are attractive in terms of their efficiency properties, they are usually nonrobust. If we consider the wider class of *M-estimators* characterized by[89]

$$\sum_{i=1}^{n} \psi(y_i; \theta) = 0 \tag{6.159}$$

where ψ is a function $\mathbb{R} \times \mathbb{R}^p \to \mathbb{R}^p$ one can find estimators with suitable robustness properties. These are the bounded-IF M-estimators with minimal asymptotic covariance matrix, known as *Optimal Bias-Robust Estimators* (OBRE)—see Huber (1981) and

[88] The logarithmic variance and the Gini coefficient are also nonrobust—see (6.71), and Cowell and Victoria-Feser (1996b), Cowell and Flachaire (2007).

[89] The MLE belong to the class (6.159); in this case ψ is equal to the score function.

Hampel et al. (1986). One can see OBRE as the solution to a trade-off between efficiency and robustness.

A standard way of specifying the OBRE is as follows. Fix a bound $c \geq \sqrt{p}$ on the IF; then the OBRE are defined as the solution in θ of

$$\sum_{i=1}^{n} \psi(x_i;\theta) = \sum_{i=1}^{n} [s(x_i;\theta) - a(\theta)] \cdot W_c(x_i;\theta) = 0 \tag{6.160}$$

where $s(x;\theta) = \frac{\partial}{\partial\theta} \log f(x;\theta)$, the score function, and

$$W_c(x;\theta) = \min \left\{ 1; \frac{c}{\| A(\theta)[s(x;\theta) - a(\theta)] \|} \right\} \tag{6.161}$$

and $W_c(x;\theta)$ is a weight imputed to each observation according to its influence on the estimator. The $p \times p$ matrix $A(\theta)$ and $a(\theta) \in \mathbb{R}^p$ are defined by

$$E\left[\psi(x;\theta)\psi(x;\theta)^{\mathrm{T}}\right] = \left[A(\theta)^{\mathrm{T}} A(\theta)\right]^{-1} \tag{6.162}$$

and

$$E[\psi(x;\theta) = 0 \tag{6.163}$$

The constant c acts as a regulator between efficiency (high values of c) and robustness (low values of c). The solution of (6.160) must usually be found iteratively.[90]

6.6.2 Incomplete Data

We now turn to the problems of estimation and inference in a situation where, in part of the sample, some information is unavailable. As we noted in Section 6.2.3, this situation is sometimes imposed by data providers, sometimes created by researchers who are attempting to deal with problems of data contamination as discussed in Section 6.6.1.

6.6.2.1 Censored and Truncated Data

Here, we are dealing with the cases summarized in the first row of Table 6.2 in Section 6.2.3 in which we take $\underline{z}$ and $\overline{z}$ as fixed boundaries.

Truncated data. For data represented by Case A in Table 6.2, inference can be approached as for inference in the complete-information case with a redefined population: The limits of the support of the distribution $(\underline{y}, \overline{y})$ are replaced by the narrower truncation limits $(\underline{z}, \overline{z})$. If we wish to say more, it may be possible to use a parametric method to estimate the truncated part of the distribution.

Censoring with minimal information. Now consider Case B in Table 6.2. Clearly if we do not use the observed point masses at $\underline{z}$ and $\overline{z}$, this could be just treated as Case A.

[90] See Victoria-Feser and Ronchetti (1994), Cowell and Victoria-Feser (1996b), and for grouped data, see Victoria-Feser and Ronchetti (1997).

However, if we want to do more, first-order comparisons can be carried out. We need the following statistics: $\overline{n}$ (the full sample size), $\overline{n}$ (the number of observations equal to $\underline{z}$), and $\overline{n}$ (the number of observations equal to $\underline{z}$).

Censoring with rich information. Clearly it is possible to do more in Case C than in the previous two cases: More welfare indices (for the whole population) can be handled. Depending on the richness of information in the censored parts, it may be possible to carry out inference on Lorenz curve ordinates and some welfare indices. First, if, in addition to the information described in the discussion of Case B, the means of the censored parts of the sample are given,[91] then second-order rankings and the Gini coefficient can be estimated. Then it makes sense to define the following:

$$\hat{c}_{\text{low}} := \frac{1}{n}\sum_{i=1}^{\underline{n}} y_{(i)},$$

$$\hat{c}_{\text{high}} := \frac{1}{n}\sum_{i=n-\overline{n}+1}^{n} y_{(i)}.$$

Inference may also be possible using the same methodology as for the complete data case. To do this, we would additionally need the following information

$$\hat{s}_{\text{low}} := \frac{1}{n}\sum_{i=1}^{\underline{n}} y^2{}_{(i)}$$

$$\hat{s}_{\text{high}} := \frac{1}{n}\sum_{i=n-\overline{n}+1}^{n} y^2{}_{(i)}$$

If these variance terms from the excluded portion of the sample are also made available, then the asymptotic variances and covariances for the income cumulations (GLC ordinates) for $q, q' \in (\underline{\beta}, \overline{\beta})$ are found as follows. Replace (6.127) and (6.129) by the following

$$\hat{c}_q := \hat{c}_{\text{low}} + \frac{1}{n}\sum_{i=\kappa(n,\underline{\beta})+1}^{\kappa(n,\,q)} y_{(i)} \tag{6.164}$$

$$\hat{s}_q := \hat{s}_{\text{low}} + \frac{1}{n}\sum_{i=\kappa(n,\underline{\beta})+1}^{\kappa(n,\,q)} y^2{}_{(i)} \tag{6.165}$$

and plug into (6.138). To compute asymptotic variance for the (relative) Lorenz curve and the Gini coefficient, we also need the following:

$$\hat{\mu} = \hat{c}_{\overline{\beta}} + \hat{c}_{\text{high}},\ \hat{s}_1 := \hat{s}_{\overline{\beta}} + \hat{s}_{\text{high}},\ \hat{\omega}_{q1} := \hat{s}_q + \left[q\hat{y}_q - \hat{c}_q\right]\hat{\mu} - y_q\hat{c}_q,\ \hat{\omega}_{11} := \hat{s}_1 - \hat{\mu}^2$$

[91] In some cases means will be available from data providers.

Comparing the outcome from these computations with the full-information case in Section 6.5.2.1, we can draw two important conclusions (Cowell and Victoria-Feser, 2003). First, if the necessary information about the censored part of the distribution is used, the standard errors are the same as in the full information case. Second, when the information about the censored part is not available, the standard errors are smaller.

6.6.2.2 Trimmed Data

In the case of trimmed data, a fixed proportion of the sample is discarded—see the second row of Table 6.2. The trimmed samples for computing welfare indices and making distributional comparisons are usually based on robustness arguments (Cowell and Victoria-Feser, 2006): outliers may seriously bias the point estimates as well as the variances of the distributional statistics that are of interest—see the discussion in Section 6.6.1.

Here, we assume that a given proportion $\underline{\beta}$ has been removed from the bottom of the distribution and $1-\overline{\beta}$ has been removed from the top. If $(y_{\underline{\beta}}, y_{\overline{\beta}})$ denotes the range of the trimmed sample values, then $y_{\underline{\beta}}$ and $y_{\overline{\beta}}$ are *random*. Because of this, and in contrast to the discussion of truncated and censored data (Section 6.6.2.1), case D in Table 6.2 requires more extensive reworking of the full-information analysis in Section 6.5.2.

Inference is carried out on the full distribution[92] conditional on the fact that known proportions have been trimmed from the tails. The *trimmed distribution* $\widetilde{F}_\beta$ is defined as:

$$\widetilde{F}_\beta(y) := \begin{cases} 0 & \text{if } y < Q(F\underline{\beta}) \\ b[F(y)-\beta] & \text{if } Q(F,\underline{\beta}) \le y < Q\left(F,\overline{\beta}\right). \\ 1 & \text{if } y \ge Q\left(F,\overline{\beta}\right) \end{cases} \tag{6.166}$$

where $b := 1/\left[\overline{\beta}-\underline{\beta}\right]$. Using (6.166) the β-trimmed counterparts to (6.25) and (6.128) the income cumulations are given by

$$c_{\beta,q} := C\left(\widetilde{F}_{\beta;q}\right) = b\int_{y_{\underline{\beta}}}^{y_q} y\,\mathrm{d}F(y), \tag{6.167}$$

$$s_{\beta,q} := S\left(\widetilde{F}_{\beta;q}\right) = b\int_{y_{\underline{\beta}}}^{y_q} y^2\,\mathrm{d}F(y) \tag{6.168}$$

[92] Given that the integration of IF. IF$^{\mathrm{T}}$ is required over the full distribution to derive the asymptotic covariance matrix, this might appear to invalidate the applicability of nonparametric techniques because of the lack of information on the structure of the trimmed data. Cowell and Victoria-Feser (2003) show that this supposition is groundless.

and the counterpart of (6.26) is given by $\mu_\beta := \mu(\widetilde{F}_\beta)$. Once again, the sample analogues of (6.166)–(6.168) are obtained by replacing F by the empirical distribution $F^{(n)}$. For example, $c_{\beta,q}$ is estimated by[93]

$$\hat{c}_{\beta,q} := C\left(\widetilde{F}_\beta^{(n)}; q\right) = \frac{b}{n} \sum_{i=1}^{\kappa(n,q)} y_{(i)} \iota\left(i > \kappa\left(n, \underline{\beta}\right) + 1\right), \tag{6.169}$$

where $\{y_{(i)},\ i = 1, \ldots, n\}$ is the ordered sample, and μ_β is estimated by the mean of the trimmed sample

$$\hat{\mu}_\beta := \mu\left(\widetilde{F}_\beta^{(n)}\right) = \frac{b}{n} \sum_{i=1}^{n} y_{(i)} \iota\left(\kappa\left(n, \underline{\beta}\right) + 1 < i < \kappa\left(n, \overline{\beta}\right)\right). \tag{6.170}$$

Lorenz criteria. To apply second-order dominance criteria, we need to know the properties of the income cumulation for the trimmed distribution $\widetilde{F}_\beta$ and its empirical counterpart $\widetilde{F}_\beta^{(n)}$. The income cumulations based on the ordinary and trimmed distributions are related as follows:

$$C(\widetilde{F}_\beta; q) = b\left[C(F; q) - C\left(F; \underline{\beta}\right)\right], \tag{6.171}$$

from which it is clear that plotting Lorenz curves, GLCs, and so on is straightforward.

The estimation of the asymptotic covariance between $\sqrt{n}\hat{c}_{\beta,q}$ and $\sqrt{n}\hat{c}_{\beta,q'}$ follows as before, from an application of the IF. We need to evaluate

$$\int \mathrm{IF}\left(z; C(\cdot; q), \widetilde{F}_\beta\right) \mathrm{IF}\left(z; C(\cdot; q'), \widetilde{F}_\beta\right) \mathrm{d}F(z)$$

and then we may compare the results with those in the complete-information case.[94] Using the definition of the IF then (6.171) implies that IF for the cumulative income functional with trimmed data is[95]

$$\begin{aligned}
\mathrm{IF}\left(z; C(\cdot; q), \widetilde{F}_\beta\right) &= -c_{\beta,q} + b\left[q y_q - \underline{\beta} y_{\underline{\beta}} + \iota\left(y_q \ge z\right)\left[z - y_q\right] - \iota\left(y_{\underline{\beta}} \ge z\right)\left[z - y_{\underline{\beta}}\right]\right] \\
&= -c_{\beta,q} + b\left[q y_q - \underline{\beta} y_{\underline{\beta}} - \iota\left(y_q \ge z\right) y_q + \iota\left(y_{\underline{\beta}} \ge z\right) y_{\underline{\beta}}\right] + b\left[\iota\left(y_q \ge z\right) - \iota\left(y_{\underline{\beta}} \ge z\right)\right] z
\end{aligned} \tag{6.172}$$

Taking the mean of $\mathrm{IF}\left(z; C(\cdot; q), \widetilde{F}_\beta\right) \mathrm{IF}\left(z; C(\cdot; q'), \widetilde{F}_\beta\right)$ for each $z = y_i$ it is clear that no value of $z = y_i < y_{\underline{\beta}}$ or $z = y_i > y_{\overline{\beta}}$ will contribute to the value of (6.172).

[93] Note that at $q = \overline{\beta}$ for $\underline{\beta} = 1 - \overline{\beta}$ one gets the traditional trimmed mean, which generalizes the median as a robust estimator of location.

[94] In Lemma 1 $F(z)$ is estimated by $F^{(n)}$ so that the integral reduces to the mean over the sample.

[95] As before, $c_{\beta,q}$, $c_{\beta,q'}$, y_q, $y_{q'}$ and y_β can be estimated by their sample counterparts.

Assume that the set of population proportions satisfies $\Theta \subset [\underline{\beta}, \overline{\beta}]$. Then Equation (6.172) yields the following result (Cowell and Victoria-Feser, 2003):

Theorem 3

Given an original untrimmed sample of size n and lower and upper trimming proportions $\underline{\beta}, 1-\overline{\beta} \in \mathbb{Q}$, *for any* $q, q' \in \Theta$ *such that* $q \leq q'$ *the asymptotic covariance of* $\sqrt{n}\hat{c}_{\beta,q}$ *and* $\sqrt{n}\hat{c}_{\beta,q'}$ *is given by*

$$\varpi_{qq'} = b^2 \left[\omega_{qq'} + w_{\underline{\beta}\underline{\beta}} + w_{\underline{\beta}} q - \omega_{\underline{\beta}} q' \right]$$

where $\omega_{qq'}$ *is defined in* (6.131).

If we take the set of proportions $\Theta = \{ q_i = \underline{\beta} + i/n : i = 1, \ldots, n/b \}$ then $\varpi_{qq'}$ can be estimated by

$$\begin{aligned} \hat{\varpi}_{q_i q_j} = & \left[q_i y_{(i)} - \underline{\beta} y_{(1)} - \sum_{k=1}^{i} \frac{y_{(k)}}{b n_\beta} \right] \\ & \times \left[\left[1 - q_j\right] y_{(j)} - \left[1 - \underline{\beta}\right] y_{(1)} + \sum_{k=1}^{j} \frac{y_{(k)}}{b n_\beta} \right] \\ & - \sum_{k=1}^{i} \frac{y_{(i)} y_{(k)} - y_{(k)}^2}{b n_\beta} + y_{(1)} \left[q_i y_{(i)} - \underline{\beta} y_{(i)} - \sum_{k=1}^{i} \frac{y_{(i)}}{b n_\beta} \right] \end{aligned} \tag{6.173}$$

In the case of the Lorenz curve ordinates, the asymptotic covariance of $\sqrt{n}\hat{c}_{\beta,q}/\hat{\mu}_\beta$ and $\sqrt{n}\hat{c}_{\beta,q'}/\hat{\mu}_\beta$ is given by

$$v_{qq',\beta} = \frac{b^2}{\mu_\beta^4} \left[\mu_\beta^2 \varpi_{qq'} + c_{\beta,q} c_{\beta,q'} \varpi_{\overline{\beta}\overline{\beta}} - \mu_\beta c_{\beta,q} \varpi_{q'\overline{\beta}} - \mu_\beta c_{\beta,q'} \varpi_{q\overline{\beta}} \right]. \tag{6.174}$$

Compare this with (6.139).

QAD Welfare indices. To evaluate inequality and poverty indices we can again follow the method of Section 6.4, but perform the computations on the trimmed distribution $\widetilde{F}_\beta$ defined in (6.166)—once again ignoring the information on the excluded part of the sample. This means that the trimmed version of (6.30) becomes

$$W_{\mathrm{QAD}}\left(\widetilde{F}_\beta\right) = b \int \varphi\left(x, \mu\left(\widetilde{F}_\beta\right)\right) \mathrm{d}F(x) \tag{6.175}$$

The sample analogs of $W_{\mathrm{QAD}}\left(\widetilde{F}_\beta\right)$ in (6.175) are then given by

$$\hat{w}_{\mathrm{QAD},\beta} := W_{\mathrm{QAD}}\left(\widetilde{F}_\beta^{(n)}\right) := \frac{b}{n} \sum_{i=1}^{n} \varphi\left(y_{(i)}, \hat{\mu}_\beta\right) \iota\left(\kappa\left(n, \underline{\beta}\right) + 1 < i < \kappa\left(n, \overline{\beta}\right)\right) \tag{6.176}$$

which is the counterpart of (6.43) but applied to the trimmed sample. Evaluating the IF we have[96]

$$\begin{aligned}\mathrm{IF}\left(z; W_{\mathrm{QAD}}, \widetilde{F}_\beta\right) = b\varphi\left(\max\left(y_{\underline{\beta}}, \min\left(z, y_{\overline{\beta}}\right)\right), \mu\left(\widetilde{F}_\beta\right)\right) - W_{\mathrm{QAD}}\left(\widetilde{F}_\beta\right) \\ + b\mathrm{IF}\left(z, C\left(\cdot; \overline{\beta}\right), \widetilde{F}_\beta\right)\int_{\mathrm{Q}\left(F, \underline{\beta}\right)}^{\mathrm{Q}\left(F, \overline{\beta}\right)} \varphi_\mu\left(x, \mu\left(\widetilde{F}_\beta\right)\right)\mathrm{d}F(x)\end{aligned} \tag{6.177}$$

Once again, an estimate of the asymptotic variance of $\sqrt{n}W_{\mathrm{QAD}}\left(\widetilde{F}_\beta^{(n)}\right)$ can be easily obtained by computing the mean of squares of $\mathrm{IF}\left(z; W_{\mathrm{QAD}}, \widetilde{F}_\beta\right), z = y_i, i = 1, \ldots, n.$[97] Define the following distribution (corresponding to case E in Table 6.2):

$$F_\beta^*(y) := \begin{cases} 0 & \text{if } y < \mathrm{Q}\left(F, \underline{\beta}\right) \\ F(y) & \text{if } \mathrm{Q}\left(F, \underline{\beta}\right) \leq y < \mathrm{Q}\left(F, \overline{\beta}\right) \\ 1 & \text{if } y \geq \mathrm{Q}\left(F, \overline{\beta}\right) \end{cases}. \tag{6.178}$$

We can then state the following (Cowell and Victoria-Feser, 2003):

Theorem 4

The asymptotic variance of $\sqrt{n}W_{\mathrm{QAD}}\left(\widetilde{F}_\beta^{(n)}\right)$ *for the trimmed distribution* $\widetilde{F}_\beta$ *is*

$$\begin{aligned} & b^2\mathrm{var}\left(\varphi\left(x, \mu\left(\widetilde{F}_\beta\right)\right); F_\beta^*\right) \\ & + 2b^3\mathrm{cov}\left(x, \varphi\left(x, \mu\left(\widetilde{F}_\beta\right)\right); F_\beta^*\right)\int_{\mathrm{Q}(F, \underline{\beta})}^{\mathrm{Q}\left(F, \overline{\beta}\right)} \varphi_\mu\left(x, \mu\left(\widetilde{F}_\beta\right)\right)\mathrm{d}F(x) \\ & + b^4\mathrm{var}\left(x; F_\beta^*\right)\left[\int_{\mathrm{Q}(F, \underline{\beta})}^{\mathrm{Q}\left(F, \overline{\beta}\right)} \varphi_\mu\left(x, \mu\left(\widetilde{F}_\beta\right)\right)\mathrm{d}F(x)\right]^2 \end{aligned} \tag{6.179}$$

Note that in (6.179) the variance and covariance terms for the linear functionals are defined on the distribution F_β^* as opposed to the trimmed distribution (6.166). All the components of (6.179) can be estimated from the trimmed sample.

[96] To see this evaluate the mixture distribution and apply (6.34) to get

$$\begin{aligned} & - W_{\mathrm{QAD}}\left(\widetilde{F}_\beta\right) + b\varphi\left(z, \mu\left(\widetilde{F}_\beta\right)\right)\iota\left(z \leq y_{\overline{\beta}}\right)\iota\left(z \geq y_{\leftarrow\beta}\right) - b\varphi\left(y_{\overline{\beta}}, \mu\left(\widetilde{F}_\beta\right)\right)\iota\left(z \leq y_{\overline{\beta}}\right) \\ & + b\varphi\left(y_{\underline{\beta}}, \mu\left(\widetilde{F}_\beta\right)\right)\iota\left(z \leq y_{\underline{\beta}}\right) + bIF\left(z, C\left(\cdot; \overline{\beta}\right), \widetilde{F}_\beta\right)\int_{\mathrm{Q}\left(F, \underline{\beta}\right)}^{\mathrm{Q}\left(F, \overline{\beta}\right)} \varphi_\mu\left(x, \mu\left(\widetilde{F}_\beta\right)\right)\mathrm{d}F(x) \\ & + b\overline{\beta}\varphi\left(y_{\overline{\beta}}, \mu\left(\widetilde{F}_\beta\right)\right) - b\underline{\beta}\varphi\left(y_{\underline{\beta}}, \mu\left(\widetilde{F}_\beta\right)\right) \end{aligned}$$

where the first two lines follow by analogy with (6.45). The third line is found by considering the way the mixture distribution affects the limits of integration in (6.175) using Lemma 2. Rearranging gives (6.177).

[97] Notice that the contribution of $z = y_i < y_{\underline{\beta}}$ or $z = y_i > y_{\overline{\beta}}$ to (6.177) is nil.

The Gini coefficient. With trimmed data, the Gini coefficient can be expressed as

$$I_{\text{Gini}}\left(\widetilde{F}_\beta\right) = 1 - 2\int_{\underline{\beta}}^{\overline{\beta}} \frac{C\left(\widetilde{F}_\beta, q\right)}{C\left(\widetilde{F}_\beta, \overline{\beta}\right)} \mathrm{d}q. \tag{6.180}$$

Using the same procedure as before, we first evaluate the IF for the Gini coefficient with trimmed data as:

$$\begin{aligned}
\mathrm{IF}\left(z; I_{\text{Gini}}, \widetilde{F}_\beta\right) = {} & \frac{2}{\mu_\beta}\int_{\underline{\beta}}^{\overline{\beta}} c_{\beta,q}\mathrm{d}q - \frac{2b}{\mu_\beta}\left[\int_{\underline{\beta}}^{\overline{\beta}} q y_q \mathrm{d}q + \int_{\underline{\beta}}^{\overline{\beta}} \iota\left(y_q \geq z\right)\left[z - y_q\right]\mathrm{d}q\right] \\
& + \frac{2}{\mu_\beta}\left[\iota\left(y_{\underline{\beta}} \geq z\right)\left[z - y_{\underline{\beta}}\right] + \underline{\beta} y_{\underline{\beta}}\right] \\
& + \frac{2}{\mu_\beta^2}\int_{\underline{\beta}}^{\overline{\beta}} c_{\beta,q}\mathrm{d}q\left(-\mu_\beta + b\left[\overline{\beta} y_{\overline{\beta}} - \underline{\beta} y_{\underline{\beta}} + \iota\left(y_{\overline{\beta}} \geq z\right)\left[z - y_{\overline{\beta}}\right] - \iota\left(y_{\underline{\beta}} \geq z\right)\left[z - y_{\underline{\beta}}\right]\right]\right)
\end{aligned}$$

Using this or the results of Theorem 3, we can obtain[98]

Theorem 5

The asymptotic variance of $\sqrt{n} I_{\text{Gini}}\left(\widetilde{F}_\beta^{(n)}\right)$ *is* $4b^2\vartheta_\beta/\mu_\beta^4$ *where*

$$\vartheta_\beta = \mu_\beta^2 \int_{\underline{\beta}}^{\overline{\beta}} \int_{\underline{\beta}}^{q} \varpi_{q'q}\mathrm{d}q'\mathrm{d}q | \mu_\beta^2 \int_{\underline{\beta}}^{\overline{\beta}} \int_{q}^{\overline{\beta}} \varpi_{qq'}\mathrm{d}q\mathrm{d}q + \varpi_{\overline{\beta}\overline{\beta}}\left[\int_{\underline{\beta}}^{\overline{\beta}} c_{\beta,q}\mathrm{d}q\right]^2 - 2\mu_\beta \int_{\underline{\beta}}^{\overline{\beta}} c_{\beta,q}\mathrm{d}q \int_{\underline{\beta}}^{\overline{\beta}} \varpi_{q\overline{\beta}}\mathrm{d}q \tag{6.181}$$

The estimates of ϑ_β are found by making use of (6.173), with $\hat{\mu}_\beta$ being the trimmed sample mean (6.170).

6.6.3 Semiparametric Methods

The problems that we address here may have arisen from situations where the researcher has concerns about data contamination and robustness (see Section 6.6.1) or where the data provider has truncated or censored the data (see Section 6.6.2).[99]

The type of problem to be analyzed can be simplified if we restrict attention to one leading case. If the support of the income distribution is bounded below, then the problems with contaminated data are going to occur only in the upper tail of the distribution (Cowell and Victoria-Feser, 2002). It may be reasonable to use a parametric model for the upper tail of the distribution (modeled on a proportion $\beta \in \mathbb{Q}$ of upper incomes) and to use the EDF directly for the rest of the distribution (the remaining proportion the $1 - \beta$ of lower incomes). There are four main issues:

[98] For proof of $\mathrm{IF}\left(z; I_{\text{Gini}}, \widetilde{F}_\beta\right)$ and Theorem 5 see Cowell and Victoria-Feser (2003).

[99] This section draws on Cowell and Victoria-Feser (2007).

- What parametric model should be used for the tail?
- How should the model be estimated?
- How should the proportion β be chosen?
- What are the implications for welfare indices and dominance criteria?

6.6.3.1 The Model

The parametric model most commonly used for the upper tail is the Pareto distribution (6.2)—see the discussion in Section 6.3.1.1. In principle the Pareto model has two parameters: We suppose here that the parameter y_0 is determined by the $1-\beta$ quantile $Q(F;\,1-\beta)$ defined in (6.23); the dispersion parameter α is of special of interest and is to be estimated from the data.[100]

The *semiparametric distribution* is then

$$\widetilde{F}(y)=\begin{cases} F(y) & y\leq Q(F;1-\beta) \\ 1-\beta\left(\dfrac{y}{Q(F;1-\beta)}\right)^{-\alpha} & y>Q(F;1-\beta)\end{cases}. \tag{6.182}$$

For $y>Q(F;\,1-\beta)$, the density $\widetilde{f}$ is

$$\widetilde{f}(y;\alpha)=\beta\alpha Q(F;1-\beta)^{\alpha}y^{-\alpha-1}.$$

In particular

$$\widetilde{f}\left(y_{1-\beta};\alpha\right)=\frac{\beta\alpha}{y_{1-\beta}}. \tag{6.183}$$

6.6.3.2 Model Estimation

To estimate the Pareto model for the upper tail of the distribution, one could of course use the MLE but the MLE for the Pareto model is known to be sensitive to data contamination (Victoria-Feser and Ronchetti, 1994). Alternatively one could use OBRE as discussed in Section 6.6.1.3, with $p=1$. Given a sample $\{y_i,\, i=1,\,\ldots,\,n\}$ and a bound $c\geq 1$ on the IF, the OBRE are defined implicitly by the solution $\hat{\alpha}\left(\widetilde{F}\right)$ in

$$\int_{Q(F;1-\beta)}^{\infty}\psi\left(y;\hat{\alpha}\left(\widetilde{F}\right),Q(F;1-\beta)\right)\mathrm{d}\widetilde{F}(y)=0.$$

When ψ is the score function $s(y;\alpha,Q(F;1-\beta))=\frac{1}{\alpha}-\log(y)+\log\left(Q(F;1-\beta)\right)$ we get the MLE. We get the OBRE when

[100] For the results that follow, α is assumed to be >2 for the variance to exist.

$$\psi(y;\alpha)=[s(y;\alpha)-a(\alpha)]W_c(y;\alpha)$$

with

$$W_c(y;\alpha)=\min\left\{1;\frac{c}{||A(\alpha)[s(y;\alpha)-a(\alpha)||}\right\}. \tag{6.184}$$

$A(\alpha)$ and vector $a(\alpha)$ are defined implicitly by

$$\begin{array}{c} E[\psi(y;a)\psi'(y;a)]=\left[A(\alpha)'A(\alpha)\right]^{-1} \\ E[\psi(y;a)]=0 \end{array}.$$

As explained in Section 6.6.1.3, the constant c parameterizes the efficiency-robustness trade-off. A common method for choosing c is to choose an efficiency level (relative to that of MLE) and derive the corresponding value for c: for the Pareto model, a value of $c=2$ leads to an OBRE achieving approximately 85% efficiency.

6.6.3.3 Choice of β

Clearly one could adopt a heuristic approach selecting by eye the amount β of the upper tail to be replaced.

Alternatively one could use the robust approach in Dupuis and Victoria-Feser (2006), who develop a robust prediction error criterion by viewing the Pareto model as a regression model. Rearranging (6.2) or (6.4), one can represent the linear relationship between the log of the y and the log of the inverse CDF:

$$\log\left(\frac{y}{y_0}\right)=-\frac{1}{\alpha}\log(1-F(y;\alpha)).$$

Given a sample of ordered data $y_{(i)}$, the Pareto regression plot of log $(y_{(i)})$ versus $-\log\left(\frac{n+1-i}{n+1}\right)$, $i=1, \ldots, n$ can be used to detect graphically the point above which the plot yields a straight line.

6.6.3.4 Inequality and Dominance

The effect on inequality of semiparametric modeling is easy to see. For example, if we wish to see how the GE indices are affected, one substitutes $\widetilde{F}$—defined in (6.182)—into (6.49)–(6.51) to obtain $I_{GE}^{\xi}\left(\widetilde{F}\right)$. For first-order and second-order dominance results, we need to look once more at the quantile and cumulative income functionals.

The quantile functional obtained using (6.182) is given by

$$Q\left(\widetilde{F},q\right)=\begin{cases} Q(F,q) & q\le 1-\beta \\ Q(F;1-\beta)\left(\frac{1-q}{\beta}\right)^{-1/\hat{\alpha}\left(\widetilde{F}\right)} & q>1-\beta \end{cases} \tag{6.185}$$

The cumulative income functional becomes

$$C\left(\widetilde{F};q\right)=\begin{cases}\displaystyle\int_{\underline{z}}^{Q(F,\,q)} y\mathrm{d}F(y) & q\leq 1-\beta\\ \displaystyle\int_{\underline{z}}^{Q(F,1-\beta)} y\mathrm{d}F(y) & \\ \displaystyle +\beta\frac{\hat{\alpha}\left(\widetilde{F}\right)}{1-\hat{\alpha}\left(\widetilde{F}\right)}Q(F;1-\beta)\left[\left(\frac{1-q}{\beta}\right)^{\frac{\hat{\alpha}\left(\widetilde{F}\right)-1}{\hat{\alpha}\left(\widetilde{F}\right)}}-1\right] & q>1-\beta\end{cases}. \tag{6.186}$$

The graph of (6.186) gives the semiparametric GLC. The mean of the semiparametric distribution is given by (6.186) with $q=1$, namely,

$$\mu\left(\widetilde{F}\right)=\int_{\underline{z}}^{Q(F,1-\beta)} y\mathrm{d}F(y)-\beta Q(F;1-\beta)\frac{\hat{\alpha}\left(\widetilde{F}\right)}{1-\hat{\alpha}\left(\widetilde{F}\right)}=c_{1-\beta}-\beta y_{1-\beta}\frac{\hat{\alpha}}{1-\hat{\alpha}}. \tag{6.187}$$

So, using (6.186) and (6.187), the semiparametric Lorenz curve is just the graph of

$$L\left(\widetilde{F};q\right)=\frac{C\left(\widetilde{F};q\right)}{\mu\left(\widetilde{F}\right)}. \tag{6.188}$$

Estimates of the GLC and the Lorenz curve for the semiparametric model can be found by replacing F with $F^{(n)}$ in (6.182) to obtain

$$\widetilde{F}_{\beta}(y)=\begin{cases}F^{(n)}(y) & y\leq Q(F;1-\beta)\\ 1-\beta\left(\frac{y}{Q(F;1-\beta)}\right)^{-\alpha} & y>Q(F;1-\beta)\end{cases} \tag{6.189}$$

and replacing $\widetilde{F}$ by b $\hat{F}_{\beta}$ in (6.186)–(6.188).

To illustrate, consider the problem of comparing wealth distributions across countries where we are concerned that the upper tail of the distribution may be suffering from some sort of contamination. Table 6.11 shows the results of estimating a Pareto tail for the net-worth distributions of the UK, Sweden, and Canada around the time of the millennium. It employs two different methods of estimating α (OLS and robust) and three different values for the modeled proportion β (top 10%, top 5%, and top 1%).[101] It is clear that the difference between the two methods of estimation in computing $\hat{\alpha}$ can easily be as large as the differences in $\hat{\alpha}$ between countries; in the case where $\beta=0.10$ compare the OLS and robust estimates for the UK with the OLS estimate for Sweden.

Panel (a) of Figure 6.18 shows the two regression methods in detail for the case of the top 10% in the UK using a Pareto plot. It is clear that there are some high net-worth

[101] The data are from the Luxembourg Wealth Study, a harmonized database that facilitates international comparisons—see http://www.lisdatacenter.org/our-data/lws-database/. See Cowell (2013) for more detail of this example.

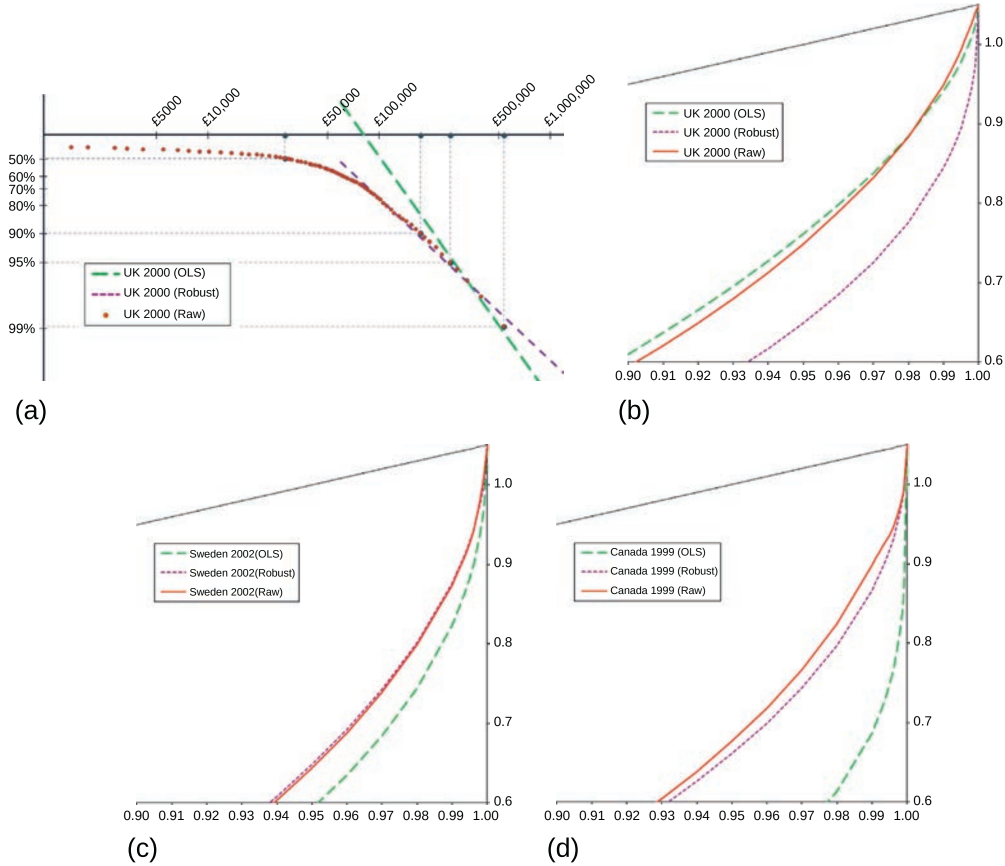

Figure 6.18 Semiparametric modeled Lorenz curves of net worth.

observations that "pull down" the OLS regression line so to speak; if one down-weights these observations, as in the robust regression, one finds a much flatter regression line, corresponding to a lower value of $\hat{\alpha}$ and, consequently, a higher estimate of inequality within the top 10% group. The results of OLS and robust methods used in semiparametric modeling are further illustrated for this case in Figure 6.18b, which shows the Lorenz curves for the raw data and for the semiparametric distributions produced by OLS and robust regression. Notice that if one considers the robust method appropriate, then the Lorenz curve for the whole distribution will lie well outside the Lorenz curve for the raw data and for the OLS semiparametric distribution.

Notice that the contrast between the OLS and robust estimates can differ dramatically between countries. This is evident from a comparison of the UK with Sweden or with Canada in Table 6.11. In the case of Sweden and Canada, the outliers pull the regression line in the opposite direction from that seen in the case of the UK: The robustly

Source: Luxembourg Wealth Study.

computed $\hat{\alpha}$ is accordingly higher than that found under OLS. The consequence for the Lorenz curves is shown in Figure 6.18c and d; it is clear that for Sweden and Canada the robustly estimated semiparametric Lorenz curve is close to the Lorenz curve for the raw data, but the OLS-estimated Lorenz curve is quite far away.

The effect of the different estimation methods on inequality *within* the top $100\beta\%$ is obvious—remember that the Gini coefficient for a Pareto distribution with parameter α is just $1/[2\alpha - 1]$. The resulting effect on Gini in the whole distribution is shown in Table 6.12. Although the effect can be quite large for $\beta = 0.10$, in none of the cases modeled here does it change the conclusion about the ranking by inequality of the three countries.

6.7. CONCLUSIONS

On reaching the end of a lengthy and technical chapter, the authors should confess to an uneasy feeling: A proportion of our potential readership might not have the stamina to work their way through every equation and every footnote. So, we would like to offer time-poor readers three things that may capture the essence of this chapter's contribution:

- A summary of lessons learned that we hope will be useful for practitioners and for other researchers;
- A little worked example that includes an application of many of the tools that we have discussed;
- A quick-reference table of the main formulas that should be useful to data providers as well as to the users of data.

6.7.1 Important Lessons: A Round-Up

Density Estimation, Parametric (Section 6.3.1)

(1) The Generalized Beta distribution encompasses all the standard parametric forms for income distribution. (2) A "good" goodness-of-fit criterion is important: Do use the Anderson–Darling statistic, the Cramér–von Mises statistic, or the Cowell et al. (2014) measure; do not use the χ^2 statistic

Density Estimation, Semi- and Nonparametric (Sections 6.3.2–6.3.4)

Standard kernel-density methods are very sensitive to the choice of the bandwidth. If the concentration of the data is markedly heterogeneous in the sample then the standard approach (the Silverman rule-of-thumb) is known to often oversmooth in parts of the distribution where the data are dense and undersmooth where the data are sparse, although in other cases it works well. However, this standard approach may not be suitable for income distributions, which are typically heavy-tailed: here the use of the adaptive kernel method or mixture model may be more appropriate.

Welfare Measures (Section 6.4)

(1) We propose a global approach to the derivation of variance expressions for all inequality measures. The method uses the IF (see Section 6.4.2.1) to provide a shortcut to the formulas we need. (2) It is necessary to analyze the tails (plot of Hill estimators) and use appropriate methods with heavy-tailed distributions (see Section 6.4.5.3).

Distributional Comparisons (Section 6.5)

(1) As with the welfare measures, we propose an approach to the variance and covariance formulas that again makes use of the IF. (2) A plot of Lorenz curve differences can provide useful information, even where Lorenz curves cross.

Data Problems (Section 6.6)

(1) Careful modeling is essential to understanding what can be done in the case of possible data contamination or incomplete data; again the IF is a valuable tool. (2) If one tries to "patch" an empirical distribution with a parametric model for the upper tail, then special attention needs to be given to the way the parameters of the model are to be estimated.

Figure 6.19—Cont'd (c) Difference of Lorenz curves, and (d) Inequality measures, with bootstrap confidence intervals and permutation p-values for testing equality.

6.7.2 A Worked Example

To illustrate these lessons, let us consider an empirical analysis of inequality measurement on the income distribution in the United Kingdom in 1992 and 1999.[102]

1. As noted in Section 6.7.1, income distributions are usually very skewed and heavy tailed, so fixed-bandwidth kernel density estimation, selected by Silverman's rule-of-thumb, may not be ideal (see Section 6.3.2). Figure 6.19a shows the application of one of the recommended methods, adaptive kernel density estimation (where the bandwidth varies with the degree of concentration of the data) of income distributions in 1992 and 1999.[103] The distribution in 1999 has a smaller mode and is shifted to the right, compared to 1992.
2. Statistical inference on inequality measures may be unreliable, in particular when the underlying distribution is quite heavy-tailed (see Sections 6.4.5.3 and 6.4.5.4). A Hill plot is a useful tool for studying the tail behavior in empirical studies: It represents the Hill estimator of the tail parameter, against the number of k-greatest order statistics used to compute it. An estimate of the tail parameter can be selected when the plot becomes stable about a horizontal straight line. Figure 6.19b shows Hill plots of income distribution in 1992 and 1999, over the range of 0.25% and 25% of order statistics used to compute it, with 95% confidence intervals (in gray). In 1992, the Hill estimate appears to be slightly more than 3, whereas it is very close to 3 in 1999. It suggests that the distribution in 1999 is slightly more heavy tailed than those in 1992, both being quite heavy tailed.[104]
3. Strong results on inequality ranking can be drawn from the comparison of RLCs, if the curves do not intersect (see Section 6.5). However, in empirical studies intersecting RLCs are not unusual, and we find that this is the case in our example, with the difference between the two Lorenz curves plotted in Figure 6.19c. The Lorenz curve for 1999 is above that for 1992 at the bottom of the distribution; the situation is reversed at the top of the distribution. It suggests that inequality measures more sensitive to transfers in the top (bottom) of the distribution would be larger (smaller) in 1999 than in 1992. However, the 95% confidence intervals shows that, at each point, Lorenz curve differences are not clearly statistically significant, and, thus inequality measures may not be statistically different in 1992 and 1999.

[102] The data are from the family expenditure survey, a continuous survey of samples of the UK population living in households. We take disposable household income before housing costs, divide household income by an adult-equivalence scale defined by McClements, and exclude the self-employed. The number of observations in 1992 and 1999 are, respectively, equal to 6597 and 5491.

[103] We obtain a very similar figure with an estimation based on a mixture of lognormal distributions. A kernel density estimation with a fixed bandwidth gives a slightly different picture, the difference being quite similar to that obtained in Figure 6.9.

[104] Note that the variance of a Pareto distribution exists if the Pareto index is >2.

Table 6.13 Formulas for computing coefficient estimates and variances for inequality measures, poverty measures, and (general or relative) Lorenz curve ordinates

Coefficient	Variance: $\widehat{\mathrm{var}}(\mathrm{Coef}) = \frac{1}{n}\mathrm{var}(Z) = \frac{1}{n^2}\sum_{i=1}^{n}(Z_i - \overline{Z})^2$ where Z_i is equal to
Inequality measures	
$\hat{I}_{\mathrm{GE}}^{\xi} = \frac{1}{n(\xi^2-\xi)}\sum_{i=1}^{n}\left[\left(\frac{y_i}{\hat{\mu}}\right)^{\xi} - 1\right]$	$Z_i = \frac{1}{\xi^2-\xi}\left(\frac{y_i}{\hat{\mu}}\right)^{\xi} - \xi\frac{y_i}{\hat{\mu}}\left[\hat{I}_{\mathrm{GE}}^{\xi} + \frac{1}{\xi^2-\xi}\right]$
$\hat{I}_{\mathrm{GE}}^{0} = -\frac{1}{n}\sum_{i=1}^{n}\log\left(\frac{y_i}{\hat{\mu}}\right)$	$Z_i = \frac{y_i}{\hat{\mu}} - \log y_i$
$\hat{I}_{\mathrm{GE}}^{1} = \frac{1}{n}\sum_{i=1}^{n}\left(\frac{y_i}{\hat{\mu}}\right)\log\left(\frac{y_i}{\hat{\mu}}\right)$	$Z_i = \frac{y_i}{\hat{\mu}}\left[\log\left(\frac{y_i}{\hat{\mu}}\right) - \hat{I}_{\mathrm{GE}}^{1} - 1\right]$
$\hat{I}_{\mathrm{MD}} = \frac{1}{n}\sum_{i=1}^{n}\lvert y_i - \hat{\mu}\rvert$	$Z_i = 2(\hat{q}-1)y_i + 2(y_i - \hat{\mu})\iota(y_i \geq \hat{\mu})$
$\hat{I}_{\mathrm{Gini}} = \frac{2\sum_{i=1}^{n} i y_{(i)}}{\hat{\mu}n(n-1)} - \frac{n+1}{n-1}$	$Z_i = \frac{1}{\hat{\mu}}\left[-\left(\hat{I}_{\mathrm{Gini}} + 1\right)y_{(i)} + \frac{2i-1}{n}\,y_{(i)} - \frac{2}{n}\sum_{j=1}^{i} y_{(j)}\right]$
Poverty measures	
$\hat{P}_{\mathrm{FGT}}^{\xi} = \frac{1}{n}\sum_{i=1}^{n} Z_i = \overline{Z}$	$Z_i = \left\lvert 1 - \frac{y}{\zeta_0}\right\rvert^{\xi}\iota(y \leq \zeta_0)$
$\hat{P}_{\mathrm{Sen}} = \frac{2}{nn_p\zeta_0}\sum_{i=1}^{n_p}\left(\zeta_0 - y_{(i)}\right)\left(n_p - i + \frac{1}{2}\right)$	$Z_i = \frac{2n}{\zeta_0 n_p}\left[\frac{\zeta_0}{2}\left(\frac{2n_p}{n} - \hat{P}_{\mathrm{Sen}}\right) - \frac{2n_p - 2i + 1}{2n}\,y_{(i)} - \frac{1}{n}\sum_{j=1}^{i} y_{(j)}\right]\iota\left(y_{(i)} \leq \zeta_0\right)$
$\hat{P}_{\mathrm{SST}} = \frac{2}{\zeta_0 n(n-1)}\sum_{i=1}^{n_p}\left(\zeta_0 - y_{(i)}\right)(n-i)$	$Z_i = \frac{2n}{\zeta_0(n-1)}\left[\zeta_0\left(1 - \frac{n_p}{n}\right) - \frac{2n-2i+1}{2n}\,y_{(i)} + \frac{1}{n}\sum_{j=1}^{n_p} y_{(j)} - \frac{1}{n}\sum_{j=1}^{i} y_{(j)}\right]\iota\left(y_{(i)} \leq \zeta_0\right)$
Lorenz curves	
$\hat{c}_q = \frac{1}{n}\sum_{i=1}^{\kappa(n,\,q)} y_{(i)}$	$Z_{iq} = \left[y_i - \hat{y}_q\right]\iota\left(y_i \leq \hat{y}_q\right)$
$\hat{c}_q/\hat{\mu} = \frac{1}{\hat{\mu}n}\sum_{i=1}^{\kappa(n,\,q)} y_{(i)}$	$Z_{iq} = \frac{1}{\hat{\mu}^2}\left[\hat{\mu}\left(y_i - \hat{y}_q\right)\iota\left(y_i \leq \hat{y}_q\right) - \hat{c}_q y_i\right]$

$Z = \{Z_1, \ldots, Z_n\}$ and $\overline{Z} = \frac{1}{n}\sum_{i=1}^{n} Z_i; \hat{\mu} = \frac{1}{n}\sum_{i=1}^{n} y_i$ is the sample mean; $y_{(i)}$ is the ith order statistic of the sample; $\hat{q} = \frac{1}{n}\sum_{i=1}^{n}\iota(y_i \leq \hat{\mu}); \zeta_0$ is the poverty line; $n_p = \sum_{i=1}^{n}\iota(y_i \leq \zeta_0)$ is the number of poor; q is a sample proportion; $\kappa[n,\ q] = \lfloor nq - q + 1\rfloor$ is the largest integer no greater than $nq - q + 1$, and $\hat{y}_q = y_{(\kappa(n,\,q))}$ is a sample quantile. $\hat{I}_{\mathrm{GE}}^{0}$ and $\hat{I}_{\mathrm{GE}}^{1}$ are, respectively, the mean logarithmic deviation and the Theil inequality indices.

4. Several inequality measures are computed in Figure 6.19d: The Gini index and the GE measures with a sensitivity parameter equals to -0.5, 0, 1, 2. GE inequality measures are known to be more sensitive to transfers in the top (bottom) of the distribution as its parameter increases (decreases). Moreover, GE indices with parameters 0, 1, and 2 are, respectively, the MLD, the Theil and half the square of the coefficient of variation indices. Standard bootstrap confidence intervals are given in brackets. The two distributions are quite heavy tailed, but the tail parameters are not very different. Reliable inference for testing equality of coefficients can then be obtained with permutation tests (see Section 6.4.5.4): the p-values are given in the last column. The results show that the values of inequality measures that are more sensitive to the top (bottom) of the distribution are larger (smaller) in 1999 than in 1992. However, taking into account statistical inference leads us not to reject the hypothesis that the inequality measures are similar in 1992 and in 1999. These results are consistent with the previous analysis drawn from the Lorenz curves comparison.

6.7.3 A Cribsheet

Finally, we offer something for those who are really short of time or patience. In this chapter, we have proposed a unified approach for computing variances and covariances for many inequality and poverty measures, as well as Lorenz curve ordinates. This unified approach involves some quite simple—or at least not very complicated—formulas. Table 6.13 provides a one-page summary of the key formulas for the principal statistical tasks in distributional analysis.

ACKNOWLEDGMENTS

We thank Russell Davidson, Stephen Jenkins, Michel Lubrano, André-Marie Taptue, and the editors, Tony Atkinson and Francois Bourguignon, for helpful comments. Flachaire would like to thank McGill University and CIRANO for their hospitality and the Institut Universitaire de France and the Aix-Marseille School of Economics for financial support.

Abstract

This chapter reviews the long-run developments in the distribution of personal income and wealth. It also discusses suggested explanations for the observed patterns. We try to answer questions such as: What do we know, and how do we know, about the distribution of income and wealth over time? Are there common trends across countries or over the path of development? How do the facts relate to proposed theories about changes in inequality? We present the main inequality trends, in some cases starting as early as in the late eighteenth century, combining previous research with recent findings in the so-called top income literature and new evidence on wealth concentration. The picture that emerges shows that inequality was historically high almost everywhere at the beginning of the twentieth century. In some countries this situation was preceded by increasing concentration, but in most cases inequality seems to have been relatively constant at a high level in the nineteenth century. Over the twentieth century inequality decreased almost everywhere for the first 80 years, largely due to decreasing wealth concentration and decreasing capital incomes in the top of the distribution. Thereafter trends became more divergent across countries and also different across income and wealth distributions. Econometric evidence over the long run suggests that top shares increase in periods of above-average growth, whereas democracy and high marginal tax rates are associated with lower top shares.

7.1. INTRODUCTION

This chapter gives an overview of the evidence on long-run trends in the distribution of personal income and wealth. Our focus will be on empirical estimates of the respective distributions, but we will also cover some ideas that aim to explain the observed patterns. The *long run* refers, at best, to the period from around 1750, that is, the time around the British industrial takeoff, and onward, but in most cases the time span begins in the early twentieth century. As a result of data availability most of the evidence is based on today's developed economies and as a result generalizations will tend to be skewed toward this set of countries. However, this is not to say that the results are relevant for rich countries only. In many cases the data coverage starts at the very beginning of industrialization of today's developed economies, and in addition data is also available for several developing nations.[1]

The kinds of questions we try to answer in this chapter are: What do we know (and how do we know) about the distribution of income and wealth over time? Are there common trends across countries or over the path of development? How do the facts relate to proposed theories about changes in inequality? We will mainly draw on the advances made in the field over the past decade, but before outlining the contents of the chapter and its limitations, we want to recall some points in the development of evidence on long-run inequality leading up to the recent research.[2]

7.1.1 From the Kuznets Series, to Household Surveys, and Back Again

In the very beginning of his famous presidential address to the American Economic Association in 1954, Simon Kuznets outlined some ideals concerning the data required to study long-term changes in inequality (Kuznets, 1955). The "economist's pipe dream" that he described roughly corresponds to what we today would call a detailed, individual panel data set, preferably spanning several generations. He emphasized things such as being able to adjust incomes for household size, to capture "all units in a country rather than a segment either at the upper or lower tail," the importance of being able to control for transitory income fluctuations, being able to calculate individual life time incomes, and so on. He also stressed the importance of the relation between income and wealth (savings) for understanding the distributional dynamics over time.

[1] For a comprehensive treatment of developing countries, see Chapter 9 in this Handbook by Alvaredo and Gasparini (2014).

[2] In the *Handbook of Income Distribution*, Volume 1, two chapters provided a historical perspective; one by Peter Lindert on inequality in Britain and America starting with estimates for England and Wales as far back as 1688 (Lindert, 2000), and one by Christian Morrison on developments in selected European countries with observations as far back as the 18th century for France and Sweden (Morrisson, 2000). We naturally build on their chapters and focus on new findings extending the picture given in their respective chapters.

In many ways the development of inequality data for a long time after Kuznets' well-known speech focused on this "wish list." Even though important advances were, of course, made with respect to historical data, it is fair to say that the focus was on the construction of contemporary national household surveys and individual micropanel data sets.[3] Eventually much effort also went into making such data comparable across countries in projects such as the Luxembourg Income Study (LIS) and its more recent companion the Luxembourg Wealth Study. Building on these and other similar projects, compilations of data such as the World Income Inequality Database (WIID) have also been put together.[4] This development has indeed changed empirical inequality research for the better and made it possible to address a number of new and important questions. But the relative focus on microdata shifted attention away from some issues, and in particular questions regarding long-run developments. Given the relatively recent nature of most household survey data and microdata in general, "the long run" based to these sources naturally becomes quite limited, typically not covering more than the last couple of decades.[5] Such a relatively short time span is unfortunate because several issues concerned with economic development and structural change require a much longer time horizon.

However, recent research has changed things dramatically. Starting with the path-breaking work of Piketty (2001a, 2003), which extends the methods first used in the seminal work by Kuznets (1953) to generate a series of top income shares spanning the entire twentieth century in France using income tax data, similar efforts have followed for many countries. Using similar data and methodology, aiming at making estimates as homogenous as possible, new data are to date available for 26 countries. Most of these were collected in two volumes edited by Atkinson and Piketty (2007, 2010) that also contain chapters on methodological issues and summaries.[6] The full database is available online at http://g-mond.parisschoolofeconomics.eu/topincomes/, and as more studies are conducted, data is added here.

Most of the series span the whole of the twentieth century, sometimes even longer, making the resulting data set unique in its ability to address long-run issues. There are also

[3] Kuznets (1963) updated his series and added data for some more years and countries. Others, like Adelman and Taft Morris (1973), did compile an early data set on the distribution of income as far back as the late nineteenth century, but the reliability of this data was debated (e.g., Paukert, 1973). Contributions on the long-run development of wealth inequality include the comprehensive work by Atkinson and Harrison (1978) and studies by, for example, Lampman (1962), Atkinson et al. (1989), Soltow (1968, 1971), Lindert (1986, 1987), Wolff (1987), and Wolff and Marley (1989). Important contributions to the study of long-run income inequality include Soltow (1968, 1969, 1971), Williamson and Lindert (1980a,b, 1981), and Willliamson (1980). See the introductory chapter in Brenner et al. (1991) for references and an overview. See also further references in Lindert (2000) and Morrison (2000).

[4] Despite such efforts there are many remaining issues when using these data. Atkinson and Brandolini (2001) outline the pitfalls in using compilations of inequality data from different sources.

[5] See the introduction by Thomas Piketty in Atkinson and Piketty (2007).

[6] See also Piketty (2014) for an overview of this and related literatures.

other features of the data such as their relatively high frequency (often yearly), the possibility to decompose income by source, and the possibilities to study changes within the top of the distribution that have proven to be of importance and, as we shall discuss in more detail later, have led to new insights about inequality developments over the long run. This renewed interest in the long run and the reevaluation of historical sources has also led to new studies on the historical trends in the wealth distribution (e.g., Dell et al., 2007; Kopczuk and Saez, 2004; Piketty et al., 2006; see further Section 7.3).

The body of work extending and generalizing Kuznets' pioneering research is often labeled according to its focus on the top of the distribution. The "top income literature" is of course a correct description in the sense that it is based on observing only high-income fractions of the population (typically roughly the top decile and sometimes an even smaller share) and then relating their incomes to estimates of total income. From this it follows that top income shares cannot say anything about changes *within* a large share of the total population. But it does not follow that this data is only about the rich. As we will outline in more detail later, the top income literature is a contribution to both our understanding of long-run changes in overall inequality, as well as a more detailed understanding of developments within the top. Both aspects are important.

Finally, one should remember that it is not always a matter of *choosing* the right inequality measure for the question at hand. In fact, when it comes to the study of long-run inequality, the availability of *any data at all* is often the binding constraint. In such a situation the relationship between different measures becomes important, and we want to know things like: "What are the relationships between different inequality measures?" and "To what extent can this measure serve as a proxy for what we would ideally like to observe?" In the end, the approach to what we know and can know about inequality over the long run will have to be pragmatic. Such an approach calls for cautious interpretation, but not for resignation. We believe, using the words of Kuznets (1955, p. 4), that even "if the trends in the income structure can be discerned but dimly," we should continue to improve on our informed guesses. This is far from saying that the best we can do is to patch together scattered observations over time, using different sources and methods. In fact, many recent insights points exactly to the opposite. In the end we need to combine an understanding about what we are, in fact, observing, how different measures relate to each other, and an understanding of how they relate to the model or theory we wish to test.

7.1.2 Outline of the Chapter

This chapter has three parts in addition to this introduction: one on the trends in long-run income inequality, a second on trends in long-run wealth inequality, and a third on potential explanations of these trends and how they relate to some of the theories about what determines inequality.

7.1.2.1 Top Income Shares and Other Measures of Long-Run Income Inequality

In Section 7.2 we focus mainly on the new evidence on long-run income inequality that has come out of the top incomes project, including some new data points.[7] This means that income inequality is generally in terms of total income, that is, income from all sources, before taxes and most transfers. We briefly discuss the methodology and type of data used in this literature and then give an overview of the most important findings. First, we review the broad trends and to what extent the developments can be described as common for different groups of countries.[8] Second, we stress the importance of studying different parts within the top decile, as it turns out that this is a very heterogeneous group. Here we also present so-called shares-within-shares measures capturing the relative development between various top groups. Third, we emphasize the importance of decomposing income with respect to source of income. This is an aspect that has not received much attention in the past literature on historical inequality, but which can now be studied in more detail thanks to the nature of the income tax-based sources, and which turns out to be of great importance for the interpretation of inequality developments. We also discuss the importance of how to treat realized capital gains.

Thereafter we move on to relating the results based on top income shares with results based on other sources and measures of inequality. We consider both top share measures using somewhat different sources and methods, as well as other estimates of historical inequality based on other measures (wage dispersion across occupations, factor price differentials and differences in life prospects). In particular, we discuss and update the evidence on the issue of how good a proxy top income shares are for other measures of inequality. Putting everything together, we attempt to summarize the overall picture of income inequality developments for the period 1750–2010.

7.1.2.2 Long-Run Trends in the Wealth Distribution

In Section 7.3 we present the evidence on long-run developments of wealth inequality. Similar to the discussion of income inequality trends, we begin by reviewing the different data sources and empirical methods used to estimate the distribution of wealth over time. Much of the methodology used to study wealth distribution resembles the one used to examine trends in the income distribution. In particular, we often rely on top shares of a

[7] Using newly found statistical sources, we have calculated top income shares for Finland in the years 1865, 1871, 1877, and 1881.

[8] Most individual country studies are collected in the two volumes (Atkinson and Piketty, 2007, 2010), and all data are also available in the World Top Income Database (WTID). As new data becomes available for additional countries, this is added to the database together with information about sources and adjustments and so on. Taken together Atkinson and Piketty (2007, 2010) and the WTID provide details about particular aspects of data as well as the main suggested explanations for understanding individual country developments. Here we focus on developments that are joint for groups of countries or, possibly, for all countries.

consistently defined reference total population and their respective shares of an estimate of total wealth as our main measure of inequality. As in the case of top incomes, we also stress the importance of studying fractions within the top.

But there are also some important differences between studying income and wealth concentration. Personal wealth is more difficult both to define and to measure, and the nature of wealth data is also different from income data. Even though information on the distribution of wealth has been collected throughout history (the Doomsday Book from 1086 in England being an early and well-known example), wealth holdings have not typically been taxed directly in a systematic way. Assets have instead mostly been taxed on their transfer and in particular at the time of death. Indeed, most of the information we have on the distribution of distribution comes from inheritance or estate tax data, sometimes complemented by wealth data collected in connection to population surveys. The section describes how researchers have handled these challenges in estimating the wealth distribution and to what extent meaningful cross-country comparisons can be made.

After having discussed methodology, we move on to presenting the broad results emerging from this work covering 10 of today's industrialized economies from their respective eras of industrialization until the present. For a few countries (Finland, the Netherlands, Norway, and Sweden) the chapter also presents some new estimates of wealth concentration.[9]

7.1.2.3 Searching for Explanations

In Section 7.4, we then discuss the possible explanations behind the observed facts. How should we relate the shifts in the income and wealth distributions over time to other developments in society? To what extent are there global forces and events that affect all countries in similar ways (possibly with some time lag between countries)? What theories can shed light on shifts in capital incomes, what theories could explain increasing top wages? How should we think about the development of total income stemming from both wages and capital? What evidence do we have from regression analysis?

We begin by discussing some broad topics often suggested as a cause (and sometimes consequence) of inequality and sketch how the developments of these relate to our evidence. In particular, we will look at how our series correspond to broad global developments such as globalization, technological revolutions, wars and economic shocks, and patterns of economic growth. We then focus on more some specific aspects. First, we look at theories emphasizing capital incomes and also the interactions between earned income and capital as well as the cumulative effects of taxation. These things were all of key importance for the decline of top shares in the first half of the twentieth century and for the lack of recovery after the wars. We then consider some mechanisms that have

[9] We add observations of top wealth shares (to those already presented in previous studies) for Finland during 1987–2005, the Netherlands for 1993–2000 and 2006–2011, Norway in the 2000s, and Sweden in 2007.

been suggested to explain increased top wages such as skill-biased technological change, the rise in executive pay and related so-called super-star theories. These have all been suggested as important factors in the recent rise in top shares in many countries. Finally, we review some insights from econometric studies trying to use the new long-run inequality data to shed light on the developments.

Clearly our coverage of possible theories will be both selective and incomplete. In the end it is based on our subjective reading of which aspects we think are key for understanding the long-run developments of inequality, especially in light of the new evidence produced in the past decade. Furthermore, much of what we write about has been covered in previous overviews and surveys of the top incomes literature (Atkinson and Piketty, 2007, 2010; Atkinson et al., 2010, 2011; Leigh, 2009; Piketty, 2005; Piketty and Saez, 2006), overviews of the changing earnings distribution (Atkinson, 2008a) and in overviews on wealth concentration trends (Atkinson, 2008b; Davies and Shorrocks, 2000; Ohlsson et al., 2008; Wolff, 1996). In general, our aim is to focus on the most recent work in the field building on previous surveys such as Lindert (2000) and Morrison (2000).

7.1.3 What Is This Chapter Not About?

There is a lot of work and several issues regarding inequality over the long run that this chapter does not cover. As we see it, there are four major themes that we do not address but that are still closely related to what we discuss. Two of these omitted themes concern the descriptive scope of our chapter, whereas the other two relate more to the attempts to understand the developments.

First, we will not deal with issues of mobility but instead focus on repeated cross-sections of data.[10] A distribution where individuals constantly move in and out of the top (or bottom) of the distribution and where an individual's position 1 year says nothing of his or her position the next year is clearly very different to one where every individual keeps his or her place over time. Reality is obviously characterized by something in between the two extremes, but importantly the few studies that have been able to directly address this question (or aspects of it) conclude that trends in cross-sectional data are not driven by changes in mobility and do capture actual inequality.[11] In short, even if repeated cross sections of inequality, in theory, could be misleading when discussing changes in inequality over time, this does not seem to be the case in practice.

[10] For an extensive treatment of income mobility, see Chapter 10 by Markus Jäntti and Stephen Jenkins. For a more detailed study of mobility in the top of the income distribution, see Björklund et al. (2012).

[11] A few studies have looked at income mobility over the twentieth century, for example, Kopczuk et al. (2010) on U.S. intragenerational mobility and Björklund et al. (2009) and Lindahl et al. (2012) on Swedish intergenerational income mobility. See also Long and Ferrie (2007) on occupational mobility patterns in the United States and Great Britain since the nineteenth century.

Second, we will restrict our study in time to a period starting roughly at the beginning of the British Industrial Revolution (with data this far back being limited to a few data points for a small number of countries only), and with more comprehensive data starting in the beginning of the twentieth century. Recently there has been a lot of interesting work devising ingenious methods of estimating distributional outcomes in premodern societies.[12] All of this work certainly adds to our understanding of inequality in historical episodes as well as its long-run evolution. However, because these earlier figures are mostly based on occupational groupings or social class, we think one should be cautious when connecting our series to the estimates in earlier periods.

Third, we will not review theories about long-run inequality developments in any detail or with any attempt at fully coverage. We will instead outline some ideas and suggested mechanisms in a highly selective way to outline aspects that can help explain the key developments we find in the data.[13]

Fourth, we primarily discuss inequality as a left-hand side variable in an econometric sense. This means that our discussion will mainly be one about how we can understand the developments of inequality and its determinants and not so much about the consequences of inequality on other developments such as, for example, economic growth, political outcomes, or health.[14] Of course, such a distinction is somewhat artificial in the sense that the distribution of resources at any point forms the basis for economic and political decisions, resulting in outcomes that then create the distribution for the next period.[15] Many questions are, thus, ultimately not about one causing the other, but rather about the dynamic interplay over time. Nevertheless, it is often useful to separate questions in terms of how we think about the causality. In this separation we focus on understanding how and why inequality has changed, not on the consequences of inequality on other developments in society.

7.2. LONG-RUN TRENDS IN INCOME INEQUALITY

In his 1953 book *Shares of Upper Income Groups in Income and Savings*, Simon Kuznets produced the first comparable long-run income distribution series.[16] His main innovation

[12] See, for example, Soltow and van Zanden (1998), Milanovic (2006), Borgerhoff Mulder et al. (2009), Friesen and Scheidel (2009), and Milanovic et al. (2011).

[13] Chapter 5 in the *Handbook of Income Distribution*, Volume 1 (Piketty, 2000) provides an overview of theories of persistent inequality. See also Chapter 14 on inequality in macroeconomic theories and Chapter 15 on the relation between inheritance flows and inequality.

[14] See, for example, Atkinson (1997) and Aghion et al. (1999) for overviews of inequality and growth. Leigh et al. (2011) gives an overview of income and health.

[15] This is, for example, illustrated in the theoretical framework in Acemoglu et al. (2005).

[16] As Thomas Piketty (Piketty, 2007, p. 9) puts it: "These were the first long-run income distribution series ever produced (income distribution had been at the centre of speculative economic thought at least since the time of Ricardo and Marx, but few data were available)."

consisted in using U.S. income tax statistics over the period 1913–1948 and relating the incomes of those who paid taxes (the high-income earners) to an estimate of all personal income.[17] In his words:

> *The basic procedure is to compare the number and income of persons represented on federal income tax returns with the total population and its income receipts.[. . .] Since, except for a few recent years, tax returns cover only a small fraction of the total population—the fraction at the highest income levels—our estimates of income shares are only for a small upper sector. From the same source we can, with certain limitations, carry through the comparison for various types of income.*
>
> ***Kuznets (1953, p. xxix)***

The series for the United States, together with observations from England and Germany,[18] showing a secular decline of top income shares at least since the 1920s, formed the empirical basis of the famous "Kuznets curve" theory.[19]

Kuznets' series were not systematically updated, even if tax data and aggregate income sources of course continued to be available and developed.[20] In recent years, however, there has been what one may call a rediscovery of Kuznets' methodology and with it a significant increase in our knowledge about long-run changes in the distribution of income. Beginning with the influential work on long-run inequality in France by Thomas Piketty (Piketty, 2001a, 2001b, 2003) a number of researchers have created income inequality series using the same methodology for many countries (to date 26), and work is ongoing in many more.[21] For most countries the data spans the full length of the twentieth century, sometimes even longer. As Thomas Piketty phrases it in the introduction to the first of two volumes (Atkinson and Piketty, 2007, 2010) that collects

[17] Tax statistics had been used in several studies before but without relating them to top incomes. For example, see Bowley (1914) and Stamp (1914, 1916) for the United Kingdom and Crum (1935), Johnson (1935, 1937), and Tucker (1938) for the United States. In passing, it can be noted that a few years before Kuznets (1953) made his contributions, South African economists Herbert Frankel and Hans Herzfeld used a similar approach in a study of European income distribution in South Africa (Frankel and Herzfeld, 1943). Similarly, the Swedish economist Ragnar Bentzel independently published a study of the Swedish income distribution in the 1930s and 1940s, using almost the same approach as Kuznets did, that is, relying on historical tax returns data relating them to reference totals computed from national accounts (Bentzel, 1953).

[18] He also compared to some observations from India, Ceylon, Puerto Rico, Kenya, and Rhodesia, but in these cases there was no time series data.

[19] According to this, income inequality follows an inverse U-shape, rising with industrialization, as only a limited number of individuals initially work in the more productive sector, but then eventually declining, as the productive technology gradually spreads to the whole economy. One should note that he developed this idea because he saw his findings of decreasing inequality as a puzzle in face of other aspects that would work in the opposite direction. In particular, he stressed the cumulative effect of the concentration of savings that should increase inequality over time. We will return to this part of Kuznets' article and to the interplay between income and wealth in Section 7.4.

[20] Kuznets (1963) did return to the subject and added data for some more years and countries.

[21] Table 7.3 contains a list of countries and time spans for which we presently have data.

much of this work: "In a sense, all what we are doing in this project is to extend and generalize what Kuznets did in the early 1950s—except that we now have 50 more years of data and over 20 countries instead of one."

This—the long time span covered—is the most obvious advantage of the new data coming out of this project. For most countries the series start in the early 1900s and in some cases even further back. But there are other important aspects as well. First, data are typically high frequency (yearly), which has proven to be important for the interpretation of some historical developments, in particular the dramatic short-run shocks to top incomes in connection to the World Wars and the Great Depression. Second, the data offer a great deal of cross-country comparability as they are based on the same type of primary source across countries, income tax statistics, and there is typically no top coding of these data. Third, and perhaps most important, the data allow for a decomposition according to the source of income (i.e., earnings, capital income), which has proven to be of crucial importance for understanding long-run developments of inequality and, in particular, the interplay between income and wealth.

Naturally, there are important limitations with using these data as well. First of all, data are limited to the development of top income shares and do not reflect what happens in the rest of the distribution. (However, as we shall see in Section 7.2.3, it turns out that top income shares are highly correlated with more general distribution measures such as the Gini coefficient). Second, focus lies on pretax and transfer income. Third, the unit of analysis, as well as the income concept, is determined by the tax code, which differs both across countries and in some cases also over time within individual countries and means that we cannot make any adjustments for household size. It should be noted, however, that considerable effort has gone into adjusting for these changes to make country series at least consistent across time (but leaving some of the cross-country comparability problems unaddressed). Fourth, given the concerns in most countries with tax avoidance and tax evasion, tax statistics are potentially problematic as a source of information on incomes.

7.2.1 Methods and Data in the Top Income Literature

To answer the basic question, "What share of total income is received by some fraction of the population?" one needs to specify three things. First, we need to know what total income is, how it is defined, and how large it is. Second, we need to decide what population we are talking about (all individuals, all adults, all households, etc.). Third, we need information about the incomes of the subset of the population whose income share we want to relate to the total. The innovation of Kuznets (1953)—which was developed in Piketty (2001a) and has been the methodology used in the top-income literature—was to relate the assessed incomes of the taxpaying population to all household sector incomes. Because historically only those with the highest incomes were taxed and thus obliged to hand in personal tax returns, their incomes must be related to reference totals not only for everyone in the taxed population but also for the population as a whole. In other words, the reference total population and income need to also include individuals who did not file a tax return as well as their incomes. To construct these we must use aggregate sources such as population statistics (which is ample), census data (which do exist), and national accounts (which are scarce for historical eras). Top income shares can then be computed by dividing the number of tax units in the top, and their incomes, with the reference tax population and reference total income. Assuming that top incomes are approximately Pareto distributed, standard inter- and extrapolation techniques can be used to calculate the income shares for various top fractiles, such as the top 10% (P90–100) or the top 0.01% (P99.99–100).

In the following section, we will briefly outline the main issues associated with going from basic data to calculating homogenous income shares. This includes thinking about the nature of tax data and the typical adjustments made, the construction of a population total, the construction of an income total, the interpolation techniques used and the relation to shares-within-shares estimates, and finally some other issues such as part-year incomes. For a more detailed discussion on the methodology, see Atkinson (2007).

7.2.1.1 Tax Statistics and the Definition of Income

With the introduction of progressive income tax systems in many countries during the late nineteenth and early twentieth centuries came tabulations published by tax authorities over all income tax returns. These tabulations, often published annually, typically group incomes in different income brackets and, for each bracket, report the number of individuals (or, more generally, tax units) and the total income assessed. Table 7.1 exemplifies the type of information that is typically available in these tables with the case of Sweden in 1951.

As with most other income data sources, the tabulated income statistics does not correspond to any theoretically comprehensive definition of income but a definition determined by tax legislation.[22] And even more important, what is included in this tax income concept has often changed over time, and it varies across countries. To make estimates as comparable as possible, which has been a primary objective in each country study in the top income literature, one therefore needs to fix a definition for the income concept and then make adjustments to the tax data. The concept of income that has been used in almost all country studies of top incomes is some version of *total gross income*, defined as the sum of income from all sources, before taxes and transfers, but net of allowable deductions (mainly interest payments). Total gross income thus consists of factor income (labor earnings and capital income) plus occupational pensions, which equals market income, and in addition taxable transfer income (public pensions and some social

[22] The well-known Haig–Simons definition of income, for example, includes imputed rents, fringe employment benefits, and capital gains. These items are often not included in taxable income.

Table 7.1 Example of grouped income data from tax statistics: Sweden, 1951

Income class (tSEK)	Tax units	Income (tSEK)	Average income (tSEK)	Cumulative tax units	Cumulative tax units (%)	Cumulative income (tSEK)	Cumulative income (%)
0–0.6	154,414	43,002	0.3	3,969,635	100.00	23,274,169	100.00

benefits). Social Security contributions paid by employers and employees are generally excluded, as they are not part of the tax base.[23]

Even if the total gross income concept may seem like a clear enough definition, there are several broad categories of income that may cause problems of comparability both over time and across countries. One example is the tax treatment of transfers (often work-related such as sickness pay, unemployment insurance, and pensions) that are sometimes included in the tax base, for example, in the Nordic countries in recent decades. The reason to include them is that they are not viewed as "pure" transfers but rather part of a collective insurance scheme where you need to work in the first place to get the transfer.[24] Taxable transfers have typically become more important over time but are also very different in size across countries. Roine and Waldenström (2008) calculated top shares both including and excluding such transfers for Sweden. Their conclusion is that for most of the twentieth century the difference is small, but in recent years the increase in top income shares is notably larger for market income than for total income (including taxable transfers). In the year when the effect is the largest, the difference is almost 1 percentage point (about 15% of the income share), but it does not change the main trends though (and considering the importance of these systems in the Swedish context, this is likely to be an upper bound of the effect).

Another area is the inclusion (or exclusion) of capital income and, in particular, realized capital gains. Many countries have moved in the direction of excluding parts of capital income in their tax bases, and to the extent that such incomes accrue to top income groups, this would mean that top shares are underestimated over time. Although the income from interest-bearing bank deposits and corporate dividends are easily observed and included in most countries' taxable income concept, other capital incomes, such as the imputed rent of homeownership and realized capital gains, are more difficult to observe. Imputing income from owner-occupied housing requires information about housing stocks at the household level and has not been generally available over time. However, had it been possible to estimate homeownership rents, we believe that would have reinforced the equalization we observe over the twentieth century, possibly with a more ambiguous effect in the earlier period.[25] As for the impact of capital gains on long-run trends, this issue is discussed further in Section 7.2.2.3.

[23] Conceptually, including Social Security contributions in gross incomes could be motivated because studies have found that they are to a large extent ultimately born by workers through lower wages, which influences not only the estimation of income inequality (which becomes lower) but also the analysis of the redistributive effect of the tax-transfer system (see Bengtsson et al., 2012; Piketty and Saez, 2007).

[24] There may, of course, be other, for example, political economy, reasons for why politicians have decided to make these transfers taxable alongside factor income.

[25] In most developed economies home ownership spread throughout the population during the twentieth century as documented, for example, by Atkinson and Harrison (1978) for the United Kingdom and Waldenström (2014) for Sweden.

In many countries the historical income tax statistics also include information about the different sources of income, such as wage earnings, capital income, and business income, across the income distribution. In these tables, income earners are typically ranked according to total gross income, and then the amount of income from each source is listed within each gross income class. Table 7.2 displays an example of this kind of evidence for Sweden in 1951. Note that as in the case of total gross income, the reported incomes by source may not necessarily follow the theoretically most appropriate concepts but instead reflect definitions in the tax code. This is fairly clear in the Swedish 1951 example. The table consists of three, and perhaps even four, income sources reflecting capital income: interests and dividends (which are called "income from capital" in the tax data), (imputed) property income, realized capital gains, and the part of farm income adhering to imputed income from agricultural property. Also, what we would theoretically think of as labor income is not only contained in what is called "labor income" but also in business (or entrepreneurial) income as well as the part of farm income reflecting labor.

7.2.1.2 Reference Total for the Population

As tax statistics are based on the "tax unit" concept, the natural reference population is the total tax unit population of the country, had everyone filed a tax return. In countries like Australia, Canada, Italy, and Spain, taxes are filed individually, and the natural reference group is then the adult population defined as all residents above some age cutoff. In countries like France, Germany, and the United States, taxes are instead filed per family, which is typically defined as a married couple or a single adult (or an adult child living at home but with own income). In these cases the reference population becomes something like the adult population minus all married women (who file jointly with their husbands), with "adult" again defined as individuals above a certain age. In some countries, such as Finland, Sweden, and the United Kingdom, the definition of the tax unit has changed over time. In the Finnish case, for example, the family was the tax unit before 1935 when separate taxation of married couples was introduced. This was changed back again 1943, and the family was the tax unit again until the reintroduction of individual taxation in 1976. In Sweden the family was the tax unit before 1967 when a *choice* of filing individually was introduced. This was then the rule until individual taxation finally became compulsory in 1971. In the United Kingdom the family was the tax unit before 1991 when the system switched to being individual.[26] In all these cases the population total has to change accordingly. Sometimes there are overlapping periods or legislation that allows family or individual taxation. In these cases judgment has to be used to choose

[26] In addition to these legal changes there are cases where there is a discrepancy between how data are reported and the tax law. In Sweden, for example, data in the period 1951–1966 are reported individually even if couples were taxed jointly.

Table 7.2 Example of income by source: Sweden, 1951

Income class (tSEK)	Income from. . . (million SEK, share of total)						
	Labor	**Interests and dividends**	**Property**	**Realized capital gains**	**Farming**	**Business**	**Total gross income**
0–0.6	33 (75%)	6 (14%)	2 (4%)	1 (1%)	1 (1%)	1 (2%)	43 (100%)
0.6–1	99 (88%)	6 (5%)	2 (1%)	1 (0%)	2 (1%)	4 (3%)	111 (100%)
1–1.5	230 (87%)	15 (5%)	3 (1%)	1 (0%)	7 (2%)	7 (2%)	262 (100%)
1.5–2	339 (86%)	21 (5%)	5 (1%)	1 (0%)	17 (4%)	11 (2%)	393 (100%)
2–2.5	424 (83%)	22 (4%)	6 (1%)	2 (0%)	26 (5%)	25 (4%)	504 (100%)
2.5–3	470 (84%)	20 (3%)	7 (1%)	2 (0%)	36 (6%)	20 (3%)	553 (100%)
3–3.5	483 (81%)	16 (2%)	7 (1%)	2 (0%)	52 (8%)	33 (5%)	591 (100%)
3.5–4	546 (79%)	14 (2%)	4 (0%)	3 (0%)	79 (11%)	41 (5%)	683 (100%)
4–4.5	604 (79%)	13 (1%)	5 (0%)	1 (0%)	95 (12%)	45 (5%)	761 (100%)
4.5–5	750 (81%)	17 (1%)	2 (0%)	2 (0%)	95 (10%)	54 (5%)	917 (100%)
5–6	1772 (82%)	32 (1%)	7 (0%)	3 (0%)	221 (10%)	113 (5%)	2144 (100%)
6–7	2252 (85%)	27 (1%)	5 (0%)	3 (0%)	201 (7%)	150 (5%)	2634 (100%)
7–8	2403 (87%)	31 (1%)	4 (0%)	5 (0%)	181 (6%)	135 (4%)	2754 (100%)
8–10	3470 (84%)	56 (1%)	12 (0%)	10 (0%)	290 (7%)	270 (6%)	4096 (100%)
10–12	1550 (80%)	30 (1%)	13 (0%)	9 (0%)	167 (8%)	167 (8%)	1927 (100%)
12–15	1124 (73%)	31 (2%)	13 (0%)	13 (0%)	164 (10%)	177 (11%)	1508 (100%)
15–20	831 (67%)	53 (4%)	12 (1%)	12 (0%)	132 (10%)	187 (15%)	1216 (100%)
20–30	668 (65%)	48 (4%)	18 (1%)	14 (1%)	92 (9%)	180 (17%)	1005 (100%)
30–50	390 (61%)	40 (6%)	14 (2%)	11 (1%)	36 (5%)	142 (22%)	622 (100%)
50–100	207 (60%)	28 (8%)	12 (3%)	2 (0%)	16 (4%)	79 (22%)	342 (100%)
100	108 (52%)	29 (13%)	8 (3%)	1 (0%)	10 (4%)	53 (25%)	208 (100%)
Sum	18,753 (80%)	552 (2%)	162 (0%)	98 (0%)	1917 (8%)	1893 (8%)	23,274 (100%)

the appropriate reference total. Table 7.3 gives an overview of the key features of the top income data used in all the 26 countries covered in our analysis, including the definition of tax units.

The main question based on these differences in tax unit concepts is, of course: "How important is this administrative setup and variation over time and across countries for the analysis of long run inequality trends?" Does it, for example, matter if we consider the population above 15 as adults or if we set the threshold to 20? Atkinson (2007) answered these questions under reasonable assumptions. The maximum difference between using an age cutoff at 15 instead of 20 (typically the alternative spans are smaller) results in a 6% (not percentage point) difference. If the top 1 percentile share were 10% with an age cutoff at 20, it would thus be 10.6% with a cutoff at 15. With respect to the effect of the tax unit being the individual or the family (or household), the maximum bounds are a little wider. Contrasting the extreme cases where top couples consist of individuals where either both earn the same, or one spouse has zero income, a top 1% share of 10% can be reduced to 8.3%, or increased to 11.8% when moving from joint to individual taxation. In cases where it has been possible to calculate top shares for individuals and couples, the difference is typically smaller. In general, Leigh (2005) showed that unless husbands and wives have equal income, individual-based data tend to (but must not) give rise to a more unequal income distribution than does the household-based data. Overall, the impact of changing tax units and age cutoffs are not likely to be important for the long-run trends we discuss below.

7.2.1.3 Reference Total for Income

When calculating the reference totals for income, there are basically two ways in which to proceed. Either one can start from the sum of all incomes reported on personal tax returns and then add items that are not included in the legal tax base as well as estimated incomes of individuals not filing taxes (not including children). Or one may start from the National Accounts item "Total Personal Sector Income" and from this broad concept deduct (estimates of) all items not included in the preferred definition of income. To the extent that data allow it, a calculation from both directions is of course desirable, as that would give an indication of the size of the potential difference between the respective procedures. In practice, these calculations may be difficult due to lack of data especially concerning early periods. In such cases the reference income total has typically been set to a share of GDP based on calibrations in periods when data are available (see Table 7.3 for an overview).

The following relation between the different parts (taken from Atkinson, 2007; Atkinson et al., 2011) is a useful illustration of the two procedures (starting either from the top and deducting items or from the bottom adding items),

Table 7.3 Key features in top income data

	Main source	Coverage	Tax unit, age cutoff	Income concept	Reference income basis	Capital gains included?
Australia	Atkinson and Leigh (2007a)	1921–2002 (82y)	Ind. 15+	GI	Nat. Acc.	Yes, where taxable
Argentina	Alvaredo (2010)	1932–1973 (39y)	Ind. 20+	GI	Nat. Acc.	No
Canada	Saez and Veall (2005)	1920–2000 (81y)	Ind. 20+	GI	Nat. Acc.	No (but reported after 1971)
China	Piketty and Qian (2009)	1986–2003 (18y)	Ind./Fam.	GI (incl. transfers)	Survey	No

United States	Piketty and Saez (2003)	1913–2007 (96y)	Fam. 20+	GI	Nat. Acc. -1943; Tax stat. 1944-	No

Notes: See also Atkinson and Piketty (2007, 2010), Leigh (2009), Atkinson et al. (2011), and the World Top Income Database for information about the country statistics. Specifically, for several countries there are other studies that have contributed to the series. In column "Coverage," "y" denotes number of year observations. Tax units "Ind." and "Fam." stand for individual and family, respectively. "GI" denotes total income from all sources (labor, capital, business) gross of all deductions, whereas "NI" denotes income net of deductions. All incomes are before taxes and (most) transfers. "Nat. Acc." denotes that the reference income total is based on National Accounts data, typically some share of GDP or the sum of different aggregate income components, whereas "Tax stat." denotes that the reference total is derived from the sum of tax-assessed incomes plus some additional items (e.g., nonassessed income, imputed income from home ownership).

Total "Personal sector total income"
– Nonhousehold income (nonprofit institutions such as charities)
= Household sector total income
– Items not included in the tax base (such as employers' Social Security contributions, and nontaxable transfer payments)
= Household gross income reported to tax authorities
– Taxable income not declared by filers
– Taxable income of those who do not file tax returns
= Declared taxable income of filers

Using different reference totals can potentially have an important impact on the income shares. In their analysis of a number of alternatives for computing reference totals, some based on different National Accounts aggregates, some being fixed shares of GDP, and others departing from tax assessments adding estimated incomes of nonfilers, Roine and Waldenström (2010, Appendix C) show that there are indeed single years or episodes when differences are notable. Overall, however, the main trends in the results are robust to which alternative is chosen.

7.2.1.4 Interpolation Techniques and the Interpretation of the Pareto Coefficient

The historical income tax statistics typically come in the form of grouped observations, where income earners in different income brackets are separated by even income thresholds (see Table 7.2). The estimated top income shares, by contrast, present the share of total income earned by specific top fractions in the income distribution, such as the top 10, 5, 1, and 0.1 percentiles. These even fractions do almost never correspond to the even income thresholds observed in tax data. To get these top shares we therefore need to use interpolation and in some cases even extrapolation when shares of the highest top groups are estimated within the highest, open-ended income interval (see Table 7.2).

The most common interpolation procedure in the top income literature has been to assume that incomes in the top are Pareto distributed. This goes back to Pareto (1897), who was the first to make systematic observations of the size distribution of income. Given the nature of data, his observations were confined to the upper tail, and even though he initially thought that the Pareto function was a correct description of the whole distribution (with a bound at a "physiological minimum" >0), he eventually recognized that the distribution function over the whole population was probably hump-shaped and not Pareto distributed.[27]

[27] See, for example, Lydall (1968) for early references to the discussion of the shape of the top of the distribution and Atkinson (2007) with specific address to the top income literature. Some scholars have questioned the validity of the assertion that top incomes are Pareto distributed and instead applied other interpolation techniques, for example, mean-split histograms, to construct exact top shares (Atkinson, 2007; Atkinson et al., 2011).

The Pareto law says that incomes within the top of the distribution can be characterized by a power function of the form

$$f(y) = ky^{-\alpha}, \tag{7.1}$$

where y denotes income and k and α are constants. The parameter α in (7.1) is called "Pareto's alpha" or the "Pareto–Lorentz coefficient," and it reflects the degree of inequality, or the steepness of the income distribution; the higher α the lower the inequality. To see this, we can express the average income $\tilde{y}$among people earning above a certain "base" income b as a function of the α as

$$\tilde{y}= \left(\frac{\alpha}{\alpha - 1}\right) b. \tag{7.2}$$

That is, at any income level b, the average income above is $\left(\frac{\alpha}{\alpha-1}\right)$ times as large. As $\alpha \to \infty$ the difference between the level b and those above goes to zero, while as $\alpha \to 1$ the distribution moves toward everything being concentrated in the top. This economically more intuitive interpretation of $\left(\frac{\alpha}{\alpha-1}\right)$ has lead to this ratio sometimes being called the "inverted Pareto–Lorentz β coefficient," $\beta = \frac{\alpha}{\alpha-1}$. This coefficient provides a tractable association between a theoretical inequality index and the empirically estimated top income shares.[28]

The assumption of a Pareto distributed upper income tail has been confirmed by several studies using individual microdata for years when such data are available.[29] But again, the results coming out of the top income literature do not hinge on this assumption. Several studies of top income shares have instead of Pareto interpolation estimated top shares using slightly different techniques, primarily mean-split histograms (see table 4 in Atkinson et al., 2011, for details).

7.2.1.5 Tax Avoidance and Tax Evasion

Problems with tax avoidance and evasion are present in all studies of income inequality based on data from personal tax returns.[30] Importantly, though, overall underreporting does not necessarily change income *shares*. If incomes are missing in equal proportion across the distribution and are also missing from the reference total, the shares are unaffected. If, however, income is missing in equal proportions in tax statistics but not from the reference total (as could be the case if we combine tax statistics and National Accounts statistics) then we will underestimate top shares (and overestimate the share of the rest of the population) because we simply allocate the income not observed for the top earners as

[28] The characteristic of the β that it is constant within the income top, that is, it does not depend on the level of base income b, has been shown not to be empirically true for most countries, however.

[29] See Feenberg and Poterba (1993, 2000) for the United States, Piketty, 2001a,b for France, and Atkinson et al. (2011) for further examples.

[30] See Slemrod and Yitzhaki (2002) for an overview of tax evasion and avoidance and Slemrod (2000) for an overview of several issues concerning the economics of taxing the rich. We will not emphasize the distinction between legal tax avoidance and illegal tax evasion, as we are interested in all missing income. Seldon (1979) proposed the term "Tax Avoision" to capture the blurring between the two.

being received by the rest of the population. If avoidance is more important in the top, then we will of course also underestimate their share, whereas the impact of underreporting being more prevalent in the rest of the population typically creates a bias in the opposite direction, but it also depends on the construction of the reference total.

The main potential problem for assessing the trends, however, is the extent to which avoidance and evasion is very different across countries or changes in a systematic way over time. It could, for example, be argued that the increased tax rates seen over the twentieth century have given taxpayers increased incentives to avoid taxation. But this would be ignoring that the same increase in tax rates have given tax authorities increased incentives to collect taxes. Broadly speaking, high tax countries are also better at enforcement.[31] In the recent top income literature virtually all studies include sections on the issue of tax avoidance and evasion. Unsurprisingly, these all point to avoidance and evasion in various forms being present in all countries but the overall picture that emerges is that it is very unlikely that this would have a significant impact on the overall trend (see Atkinson et al., 2011, for details). To illustrate, Italy stands out as a country where evasion is much larger than other OECD countries but Alvaredo and Pisano (2010) still concluded that this does not change the main development of inequality. Dell et al. (2007) looked at the impact of assuming that *all* foreign income in Switzerland goes to French taxpayers and concluded that this would have a marginal effect on French top income shares. Similarly, Roine and Waldenström (2008) estimated the impact of capital flight from Sweden and concluded that even if the absolute numbers are sizable, and the impact on top income shares is nontrivial, the effect does not alter the general conclusions. Under the extreme assumption of attributing all unexplained residual capital flows out of Sweden since the 1980s to the top 1% income group, this increases their share by about 25%. This is significant, but it barely changes Sweden's rank or trajectory in relation to other countries.

The areas where avoidance and evasion responses are most likely to have a significant impact are on short-run fluctuations and when it comes to distinguishing the source of income. When ranking the importance of different behavioral responses to taxation Slemrod (1992, 1996) placed timing of economic transactions at the top as most responsive to tax incentives. Examples of this are clearly visible in the form of spikes in certain years, in particular when including realized capital gains (e.g., in connection to the tax reform act in the United States in 1986, in connection to changes in capital gains taxes in Sweden in 1991 and 1994, the year before the increased tax on dividends in Norway in 2006). As the second most important response to taxation Slemrod identified financial and accounting responses. This could take the form of income shifting between being corporate or personal, but also shifting the reported source of income. There are, for example, clear incentives for individuals to shift earnings to take the form of capital income in dual tax systems

[31] Overall, there is evidence that taxation is a key component of administrative capacity of government (Besley and Persson, 2009, 2013). See also Friedman et al. (2000).

where capital taxes are lower than wage taxes. Such income shifting does not lead to aggregate effects but may be of importance when interpreting shifts across income sources.

The issue of avoidance and evasion is clearly potentially important and should not be dismissed. Still, it is striking that not even in evaluating cases that we have reason to believe are among the more extreme do we see effects that dramatically change the overall trends. Also, as noted by Atkinson et al. (2011), the fact that some incomes (typically from capital) are tax exempt probably has a more important impact on inequality than underreporting.

7.2.1.6 Other Issues

In addition to the preceding, there are many other details in the historical income distribution data that call for attention and possibly correction. For example, in any given year individuals move into and out of the relevant tax unit population, some become "adults" due to age reasons, some die, some move into the country, others move out, some get married, others divorce. This mobility affects the relevant population, and it also creates "part-year incomes" that show up as low incomes in the data. Another potential difficulty is that tax years may not correspond to calendar years. Beside the problem of how to label observations, this may create problems if reference data are collected for calendar years (as is often the case). Fortunately these problems turn out not to be very large in quantitative terms.[32]

7.2.1.7 So Can We Trust the Top Income Data?

How should one deal with the challenges mentioned earlier that are associated with using historical income tax statistics? In past research scholars have suggested different approaches, including calculating theoretical bounds of the size of potential errors and employment of alternative sources that offer external checks of the order of magnitude by which an estimate could be wrong. In the end, however, one must make a number of judgment calls to select a final preferred series, and such calls can of course always be questioned. Having said that, considerable effort has gone into the construction of the series for each individual country with the explicit aim to make the series as homogenous as possible. We actually think that a hallmark of this research has been to take data quality issues very seriously and wherever possible produce estimates under different assumptions to be transparent about the effects of each individual choice made. In most cases where there are alternative ways to proceed, all alternatives have been explored and to the extent that this affects the results this is reported. The end result, we believe, is a data set with robust conclusions about the development of top income shares over time.

[32] For example, Atkinson (2007b) reported that part-year incomes reduced the top 10% income share by 0.3 percentage points in 1975–1976 (out of a total of about 25% in that year).

7.2.2 The Evidence and What We Learn

We identify three main themes in the empirical results. These themes form the basis for the three subsections that follow. The first addresses the overall evolution of income inequality as reflected in top income shares of the 26 countries covered here. The second theme is about the results showing a considerable heterogeneity among groups *within* the income top, especially differences in the top percentile and those in the lower part of the top decile. The third theme considers the role of decomposing total incomes by source, that is, assessing whether the recorded trends are, for example, driven by changes in the earnings distribution or whether they are based on shifts in the returns to personal wealth.

7.2.2.1 Common Trends or Separate Experiences?

Figure 7.1 illustrates the top 1% income share over the period 1870–2010 for all observations we have to date. Clearly this kind of illustration is not meant to be readable in the sense that the development of individual countries is discernible; rather it illustrates the extent to which there are truly common trends globally.[33]

The overall picture that emerges is one where the top 1% income share hovers around a relatively high level up until the First World War (in the few countries for which data exist), and then declines steadily over the twentieth century up until around 1980. After 1980 there seems to be a more scattered pattern. In some countries, in particular the United States and the United Kingdom, and in Anglo-Saxon countries more generally, top shares have increased significantly, whereas developments in other places, in particular in some Continental European countries, are close to flat after 1980.

In the literature on top income shares, much emphasis has been put on the diverging pattern between Anglo-Saxon countries and continental Europe.[34] As a result of the recent additions of new evidence from other countries, however, it is motivated to go beyond this dichotomy and incorporate the experiences of countries in other parts of the world.[35] We extend the division and examine inequality trends across six different country groups:

- Anglo-Saxon countries (Australia, Canada, Ireland, New Zealand, United Kingdom, and the United States)

[33] This question can also be asked in a more systematic way by identifying common trends and structural breaks in the series using econometric techniques; see Roine and Waldenström (2011).

[34] This difference is one of the main findings in the recent research on top incomes. Indeed, the title of the first of two volumes (Atkinson and Piketty 2007, 2010) collecting much of this work is *Top Incomes over the Twentieth Century: A Contrast Between European and English-Speaking Countries*.

[35] Alternatives to geography as a basis for country grouping exist. One is to divide them based on their participation in the Second World War. Another grouping could be based on types of "welfare state regimes," using the terminology of Esping-Andersen (1990). Here Japan fits into the corporatist tradition corresponding roughly to the Continental European countries, although that is perhaps most true for a more recent subperiod than for the whole of the twentieth century.

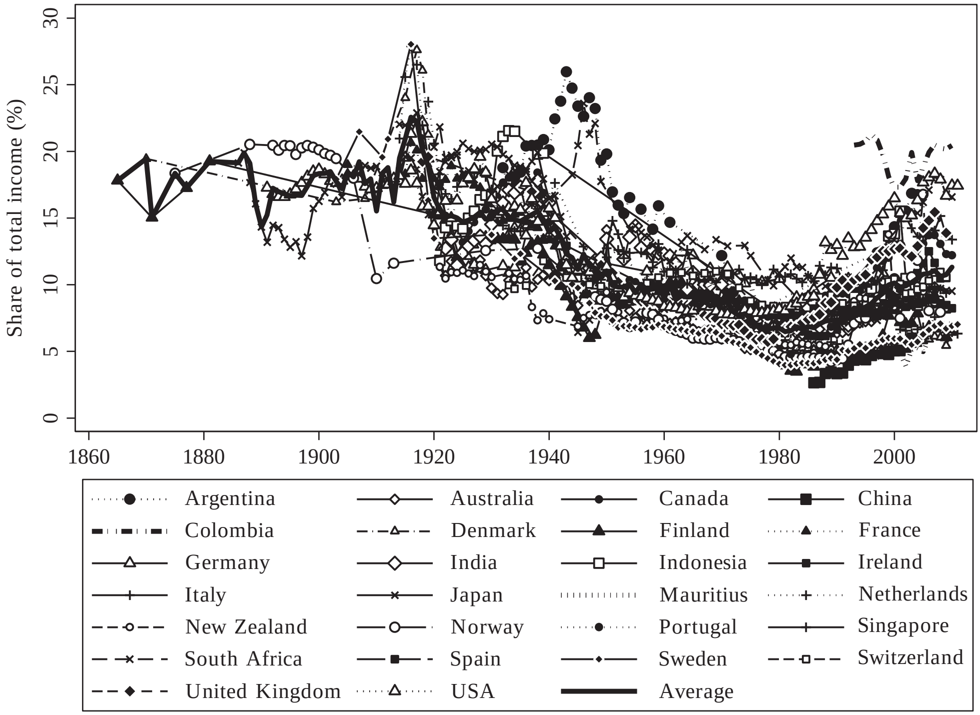

Figure 7.1 Top 1% income share in 26 countries, 1870–2010. *Source: See main text for description of the series and the World Top Income Database for sources.*

- Continental European countries (France, Germany, Italy, the Netherlands, Portugal, Spain, and Switzerland)
- Nordic countries (Denmark, Finland, Norway, and Sweden)
- Asian countries (China, India, Indonesia, Japan, and Singapore)
- African countries (Mauritius and South Africa)
- Latin American countries (Argentina and Colombia)

Figure 7.2 presents the long-run evolution of top income percentile shares in these six country groups.[36] Looking at the overall long-run development, there are clear similarities across the groups. They all exhibit a sharp decline in the top shares over the twentieth century, beginning around the time of the First World War and further reinforced by dramatic drops around the Second World War. Wartime shocks thus appear to have

[36] The creation of geographical country groups is problematic. Some of them are fairly homogenous, for example, whereas the other groups are more diverse, in particular the Asian group. In fact, apart from being Asian countries, it is hard to find a priori reasons for why they should constitute a group. Moreover, the small number of Latin American and African countries also pose problems in terms of representativeness.

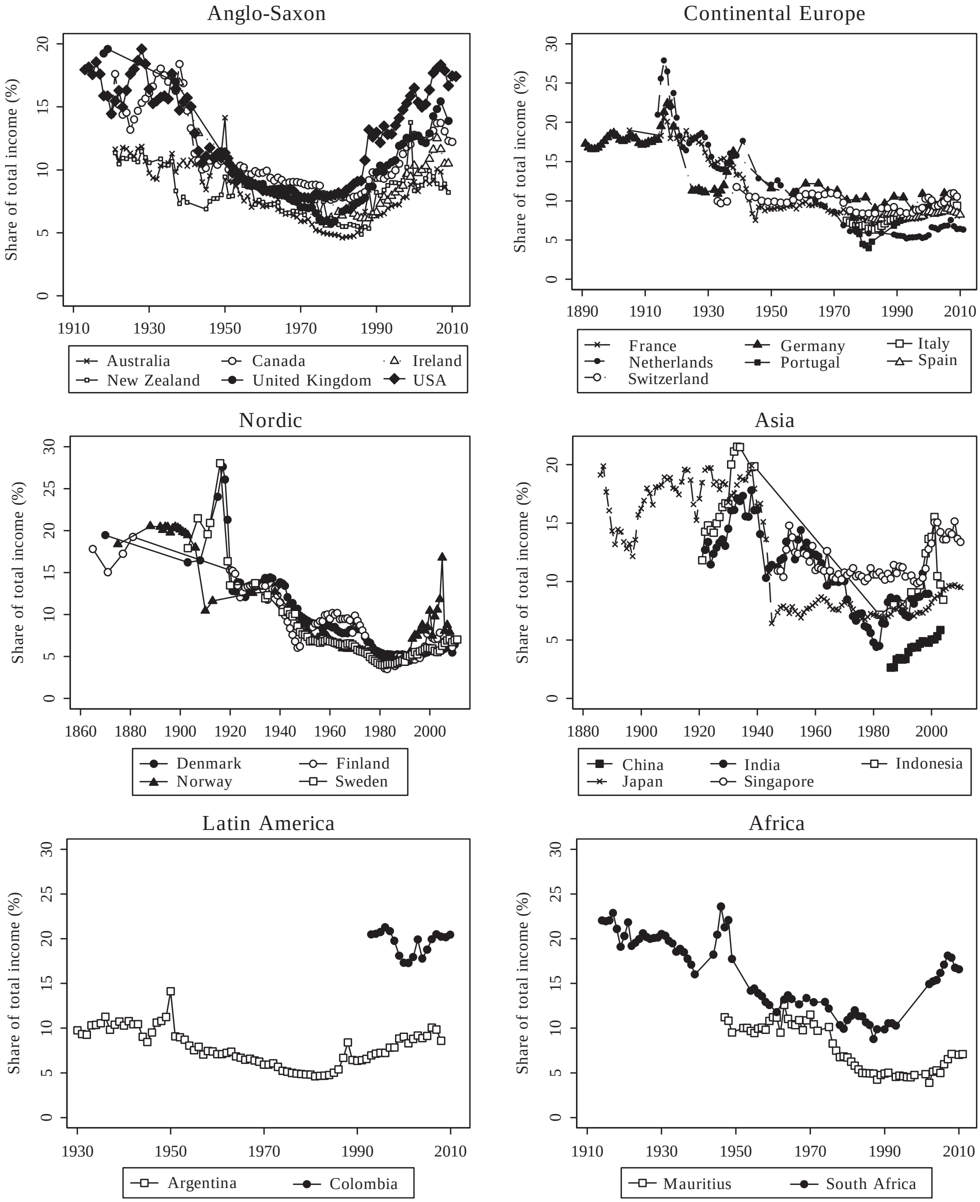

Figure 7.2 Top 1% across country groups. *Source: See Figure 7.1.*

had a large impact on top income shares. Everyone was probably affected by the wartime trade disruptions and new regulations of most goods and labor markets, but when it comes to specific surtaxes on wealth and high incomes or even the bombings of factories and similar capital destroying events, these were probably more important for the incomes of the rich. Having said this, the period 1914–1945 was also associated with periodic booms and asset price bubbles set off by a combination of highly expansionary fiscal policies and the economies being relatively closed. In both Denmark and Sweden, top income shares actually spiked in the midst of the First World War, and this is generally regarded as a consequence of the boom and asset price bubbles (Atkinson and Søgaard, 2013; Roine and Waldenström, 2008).

The twentieth century equalization trend in the top income shares continued up until the 1980s when it either flattened out in some countries or was reversed into increasing top income shares. That these common trends over the past century are in fact statistically significantly joint across countries has been shown recently by Roine and Waldenström (2011) in an analysis of common and country-specific trends and structural breaks in top income shares.

Notwithstanding the similarities, the evidence also indicates variation across countries within the geographical groupings reported earlier. For example, the upward trend in top income shares began in the late 1970s in the United States, Canada, and the United Kingdom, but started about 5–10 years later in Australia, New Zealand, and Ireland (though Ireland had a short-term peak around 1980). Within Continental Europe, most countries have not experienced stark increases in the top percentile share except for Portugal where it more than doubled between 1980 and 2000. The Asian data are not sufficiently complete to allow for conclusions about country differences: Japan and India appear to follow roughly similar patterns over time, with stable inequality levels before and after the dramatic shift in the 1940s when not only war but also profound institutional change hit these two countries. Since 1980 all the five Asian countries have exhibited an increasing top share. In Latin America and Africa, variation is small but so is the sample, and we cannot draw any conclusions from these results until we increase the number of observations.

Altogether, this analysis shows that with respect to the development of inequality, almost all countries display a secular decline in top income shares over the twentieth century up until around 1980. This decline is substantial: top percentile shares drop from around 20% of total personal income at the beginning of the 1900s to between 5% and 10% around 1980. In many countries much of this decline is concentrated around the World Wars and the Great Depression. Around 1980 the decline in top shares stopped, and in most countries they started to increase. This increase is substantial in Western English-speaking countries (Australia, Canada, New Zealand, the United Kingdom, and the United States) as well as in China and India. It is more modest but still clear in both some Nordic countries (Sweden, Finland, and Norway, but less clear in Denmark) and some Southern European countries (Italy and Portugal, but less clear in Spain), whereas finally, the development in some Continental European countries (France, Germany, the Netherlands, and Switzerland) and in Japan is close to flat.

7.2.2.2 The Importance of Developments Within the Top Decile

In income inequality research, top income earners are often defined as everyone in the top decile (P90–100) of the income distribution. However, recent studies following Piketty (2001a) have shown that the top decile is very heterogeneous.[37] For example, the income share of the bottom nine percentiles of the top decile (P90–99) has been remarkably stable over the past century in contrast to the share of the top percentile (P99–100), which fluctuated considerably. Moreover, although relatively high wage earners dominate in the lower group of the top decile, capital incomes are relatively more important to the top percentile. Figure 7.3 shows the development of the P90–99 income share over the period 1870–2010. Whereas the top percent income share fell by roughly a factor between 2 and 4 in the period until 1980 and has thereafter increased by a factor 2 in some countries, the long-run share of the P90–99 group has on average been relatively stable around 20–25% over the whole period.

An alternative way of studying income concentration is to express it in terms of the income share of certain top groups within the income share of another, larger, top group.

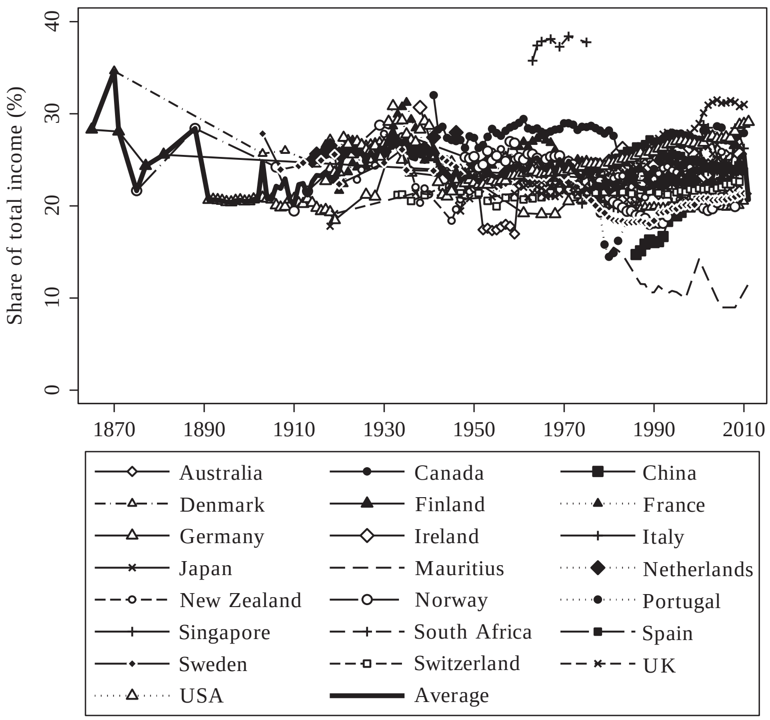

Figure 7.3 Trends in "next 9" percentiles in the top decile (P90–99), 26 countries. *Source: See Figure 7.1.*

[37] See Atkinson and Piketty (2007).

There are at least two merits with this approach. First, it measures the inequality within the top of the distribution, which is different from inequality overall especially when considering theories that predict a widening gap among the rich. Second, the top income shares may contain measurement error through the estimated reference total income held by the full population. By dividing the top income percentile by the top income decile (i.e., P99–100/P90–100), we get a "shares-within-shares" ratio that eliminates the reference total.[38]

Figure 7.4 shows the trend in the shares-within-shares ratio where we divide the top income percentile by the top income decile. It largely resembles the evolution seen in Figure 7.1, with a stable and relatively high level up to the 1910s and then a declining trend up until about 1980, after which an increase can be observed in some countries. This indicates both a degree of robustness of the overall trends in top income shares shown earlier and that concentration within the top has also changed over time.

Taken together, the evidence suggests that there are substantial differences in the long-run development between different groups in the top income decile. In fact, most

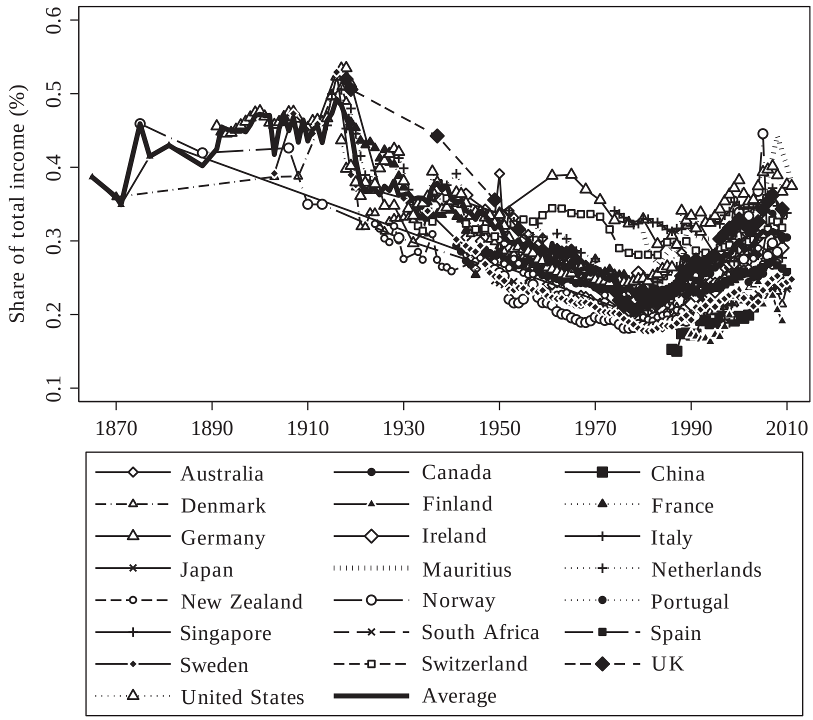

Figure 7.4 Shares-within-shares in top incomes (P99–100/P90–100). *Source: See Figure 7.1.*

[38] To see that this removes the influence of reference totals, note that P99–100 = $Y_{\mathrm{Top1}}/Y_{\mathrm{All}}$ (for income Y) and P90–100 = $Y_{\mathrm{Top10}}/Y_{\mathrm{All}}$. Hence, P99–100/P90–100 = $(Y_{\mathrm{Top1}}/Y_{\mathrm{All}})/(Y_{\mathrm{Top10}}/Y_{\mathrm{All}}) = Y_{\mathrm{Top1}}/Y_{\mathrm{Top10}}$.

of the observed overall changes in inequality are driven by decreasing or increasing shares of income earned by the top percentile group (P99–100), whereas the income share of the rest of the top decile in most countries is remarkably constant over the whole of the twentieth century.[39]

7.2.2.3 The Importance of Capital Incomes and Capital Gains

A major finding of the recent top income literature is that capital incomes are crucial for the development of income inequality over the long run (Atkinson and Piketty, 2007, 2010; Atkinson et al., 2011). Although wage earnings have always comprised the bulk of incomes among the masses, in the top of the distribution incomes have come from both labor and capital. As a consequence, the variation in top income shares can be expected to largely reflect changes in capital income flows. Some of these capital incomes are returns to corporate ownership, some are coupon yields on fixed-interest securities, whereas others come in the form of rental payments from tenants, interest earnings on bank deposit accounts, or as capital gains on financial or nonfinancial assets owned or sold. Our understanding of inequality trends over the long run requires that we closely examine the nature of these capital incomes and, in particular, the association between the distributions of income and personal wealth.

Unfortunately, few countries offer long-run distributional evidence by income source. Figure 7.5 shows the share of capital income (excluding capital gains) in total income since 1920 for the top percentile (P99–100) and the next nine percentiles in the top decile (P90–99) in four countries: Canada, France, Sweden, and the United States. Some notable results stand out. First, the importance of capital income clearly increases in the income level; in all cases capital is a more important source of income for the P99–100 than for the P90–99 group. Second, there was a sharp drop in the share of capital income around the Second World War, with the capital income share dropping by roughly half. This result clearly matches well with the findings of a similar drop in wealth concentration around the time of the war (see the following section for further information), whether due to wartime destruction or increased taxation and regulatory pressures.[40] Third, there is no clear uniform trend in recent decades; in the United States the importance of capital income seems to decrease, in France and Sweden the opposite appears true, while in Canada no clear trend is discernible.

For some countries, such as Sweden, the historical income tax statistics offer a possibility to cross-tabulate taxable wealth and income across both wealth and income distributions for most of the twentieth century (see Roine and Waldenström, 2008, 2009).

[39] This stability is even more marked when looking at the lower half of the top decile (P90–95). For example, this share moves around 9–11% in Sweden and between 10% and 13% in the United States over the entire twentieth century.

[40] It is interesting to note that this change in the role of capital is almost equally important in the case of Sweden, which did not take part in the war as in France and the United States.

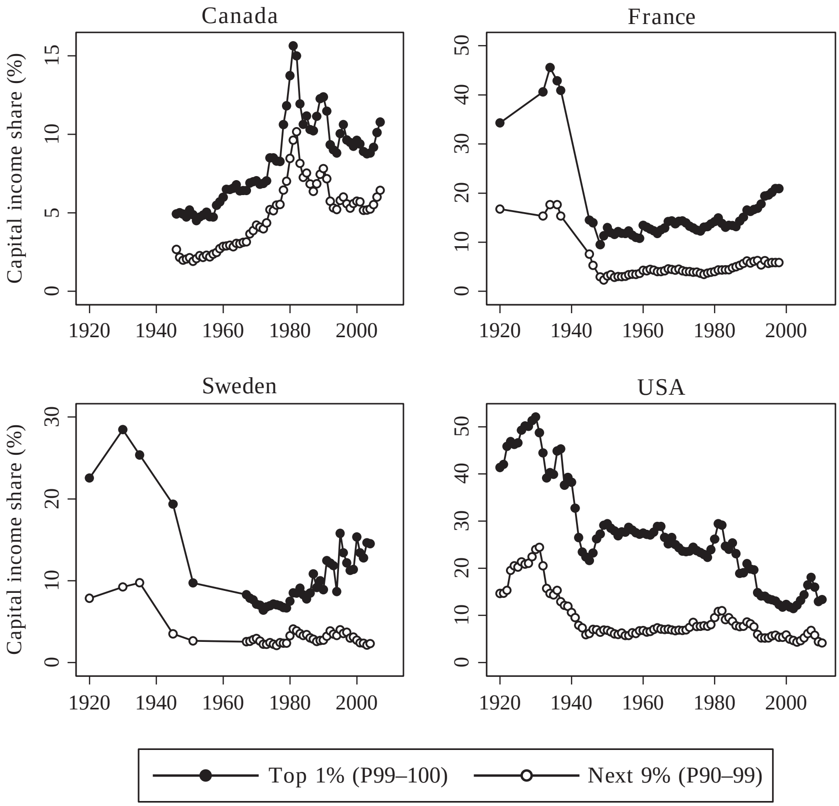

Figure 7.5 Capital income share in total gross income, 1920–2010 (%). *Source: Saez and Veall (2005), Veall (2010) for Canada, Piketty (2001b) for France, Roine and Waldenström (2008, 2010) for Sweden, and Piketty and Saez (2003, and updates) for the united States.*

Although not a complete data source, this allows us to get more insights into the interrelationship between income and wealth and how this matters for the long-run evolution of income inequality. The Swedish evidence indicates that the total wealth share held by people in the top income percentile decreased before 1950, in particular in the interwar period. By contrast, the "high-wage" income earners in the P90–95 income fractile increased their wealth share substantially over the same period, mainly in the 1910s and 1930s. The natural interpretation of these changes is that wealth as a source of income for the very rich declined in this period while, at the same time, moderately rich groups with high incomes accumulated new wealth. However, the drastic drops in Swedish capital income shares between 1930 and 1950 in the entire top decile seen in Figure 7.5 is not mirrored in their relative wealth share. Possibly this could be due to some wealth not being fully covered in taxable wealth because of definitions of the tax code or tax avoidance.

Capital gains turn out to be an additional important and interesting question. Theoretically capital gains, realized and unrealized, are undoubtedly a source of income in the classic Haig–Simons definition.[41] But in practice, capital gains represent a highly complicated income component to include in an individual's income. First, to the extent that they are observable at all, capital gains only appear on tax returns at the point of realization, making it difficult to properly allocate them in time. In many countries' tax codes (e.g., Spain and Sweden up until 1991) parts of the realized capital gains are tax exempt depending on the length of the holding period of the respective assets.[42] Also, if data are grouped in income brackets it is not possible to allocate the capital gains to the right individuals and in the worst case, large one-time realizations may elevate individuals with much lower incomes into a one-time high-income position distorting the true underlying distribution. Finally, the economic interpretation of the capital gain depends on what type of asset transaction it emanates from. For example, if it relates to a house sale, the sale of a closely held firm, or the execution of a work-related options program, the interpretation in terms of labor or capital income differs. Tax data typically lump together all capital gains, but in an effort to disentangle them according to the income characteristics of those realizing capital gains, Roine and Waldenström (2012) divided the top percentile incomes into work-related (earned by "working rich") and capital-related (earned by "rentiers"). They found that the "working rich" are the largest group both in terms of incomes and numbers but that its share has declined since 1980. This, however, does still not answer if realized capital gains stem from work-related activities or if high-income earners also realize capital gains in addition to their incomes.

Problems with observing and accurately dating capital gains have led many inequality researchers to exclude the realized capital gains altogether from inequality data.[43] However, in the top income literature the approach to capital gains has been pragmatic in the sense that, whenever possible, top income shares have been presented both including and excluding realized capital gains (of course making the corresponding adjustments to the reference totals). This has been possible in Canada, Finland, Spain, Sweden, and the United States. In some countries such as Australia, New Zealand, and Norway capital gains are included in the tax base but not reported separately, whereas in other countries (e.g., the United Kingdom, the Netherlands, Switzerland, and Japan), realized capital gains are not taxed under the income tax (with some variation over time) and therefore not included in the reported gross income concept.

The impact on top income shares from adding taxable realized capital gains is shown in Figure 7.6. The figure first illustrates the problem often raised with respect to including

[41] According to Haig (1921) and Simons (1938), income is the value of consumption plus any increase in real net wealth, that is, it should include all capital gains, not just the realized ones.

[42] In Sweden during 1976–1990, for gains from sales of assets held longer than 2 years only 60% was taxable, and before that all the gains from sales of assets held over 5 years were tax exempt.

[43] This is the case for the LIS, for example.

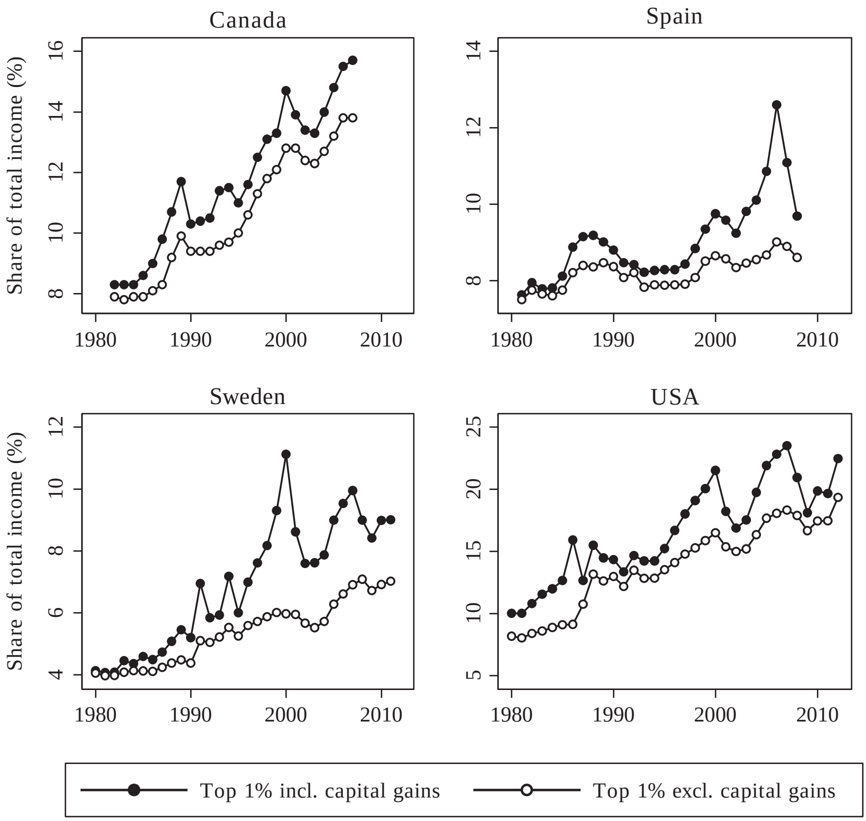

Figure 7.6 Capital gains in top income percentile, four countries. *Note: Income earners are ranked separately according to each income concept.*

realized capital gains, namely, that there are clear visible spikes in years when realizations are attractive for tax reasons. The clearest example of this is the well-known 1986 Tax Reform Act in the United States when the top percentile share was almost twice as high when realized capital gains were included, but the spikes in 1991 and 1994 in the case of Sweden are also driven by similar tax incentives.[44] But, second, even if one disregards these peak years, there seems to be a trendwise increase in the importance of realized capital gains as a source of income in the countries. Roine and Waldenström (2012) study to what extent this, in the case of Sweden, is an artifact of increasing turnover and a reflection of different individuals making occasional appearances in the top group. Using micropanel data they can compute average incomes, excluding and including capital

[44] Auerbach (1989) shows how the one-time spike was created by changed tax incentives. See Saez et al. (2012) for further references. In the case of Sweden, Björklund (1998) noted that "... due to changes in the incentives to sell stock, realized capital gains were unusually high in 1991 and 1994" and goes on to treat the values of inequality in those years as outliers.

gains, of individuals over longer time periods. Their main finding is that it is not mainly different individuals who take turns in appearing in the top group; rather it is mainly top income individuals that earn substantial amounts of capital gains in addition to their other incomes. Armour et al. (2013) and Burkhauser et al. (2013) used survey evidence from household panels in the United States and Australia, respectively, to compute both realized and unrealized capital gains and study their impact on measured income inequality. Comparing their results with those found in the top income literature for these two countries, the authors concluded that capital gains are indeed important drivers of inequality but that only using taxable realized capital gains may confuse the timing of inequality changes and also tend to overstate increases in top income shares.

Taken together, decomposing income inequality trends with respect to income source turns out to be very important for understanding the developments. Whereas earnings have always comprised the bulk of incomes of most individuals, top incomes come from both labor and capital, and variation in top income shares can largely be driven by changes in capital income flows. In the beginning of the twentieth century the highest incomes were dominated by capital income, and most of the decline is caused by decreasing capital incomes, partly due to shocks to wealth holdings during the World Wars and the Great Depression. This clearly explains some of the differences within the top that we observe in the first half of the century. In contrast, the recent upturn in top income shares is mainly due to increasing top wages and salaries, especially in the United States and the United Kingdom, but capital is also making a return in some countries.

7.2.3 The Relation Between Top Income Data and Other Measures of Inequality

As we pointed out in the introduction, the primary motivation for the top income project was a dissatisfaction with inequality data sets in general. It was a lack of comparable, annual time series of inequality over the long run that was the main problem, more than a lack of data on details within the top. As shown earlier, detailed information within the top turns out to be important in its own right and is in fact in many respects crucial for understanding the overall development. But what about the relation between top shares and other measures of inequality that cover the entire population, such as the Gini coefficient? And what about the relationship between top income shares based on tax data and similar top shares based on household surveys? This section seeks to answer these questions.

7.2.3.1 Comparing Tax-Based and Survey-Based Estimates of Top Income Shares

Household surveys are a common source for income inequality analysis. Unlike most tax data, surveys allow for household adjustments and, at times, more comprehensive income concepts. Some recent studies recalculate the U.S. top income shares of Piketty and Saez (2003) using some of the largest U.S. household surveys: the Current Population Survey

(CPS) (Burkhauser et al., 2012) and the Survey of Consumer Finances (SCF; Kennickell, 2009; Wolff and Zacharias, 2009). These studies are only able to compute estimates since the 1970s. Nonetheless, they offer valuable points of comparison for the tax-based top income share series, in particular given the potential problems with tax avoidance and other concerns related with the tax data.

The CPS-based analysis produces lower inequality levels overall and also present a lower trend increase in top shares since the 1970s. Atkinson et al. (2011), however, point out that much of this difference stems from the fact that the CPS data are top-coded, which means that the highest incomes are incompletely observed, which may underestimate the top shares. Similarly, the CPS has a lower coverage of capital gains, and given their importance in the top (as argued earlier in this chapter), this omission may account for a fair share of the difference. The survey evidence based on the SCF suffers less from top-coding and, accordingly, are more in line with the tax-based series of Piketty and Saez. In a similar comparative exercise for Australia, Burkhauser et al. (2013) contrasts the tax-based evidence with top shares calculated from the Household, Income and Labour Dynamics in Australia Survey. The authors find that top income shares are somewhat lower when using a more theoretically appropriate income concept based on the survey evidence. Regarding the overall patterns in terms of time trends and income composition, however, there is a high degree of agreement between the two sets of series. In other words, household surveys in Australia, the United States, or the United Kingdom do not seem to offer a fundamentally divergent picture from the basic evidence of the top income literature.

7.2.3.2 Theoretical and Empirical Relationship Between Top Shares and Overall Inequality Measures

To what extent can top income shares be thought of as a measure of overall income inequality? To answer this question one can refer to desirable properties of inequality measures (see, e.g., Cowell, 2011), the theoretical relationship between top shares and other inequality measures, or to the observed statistical associations between different inequality measures when based on actual observations.

As discussed by Leigh (2007), top income shares meet four basic properties that any measure of inequality should satisfy: they are not affected by any other characteristics of the population than income (anonymity), they remain the same when all incomes are multiplied by the same number (scale independence), top shares remain unchanged if the population is replicated identically (population principle). When it comes to the transfer principle, this is only satisfied in its weak form because a transfer from a high-income individual to a low income never increases the measure, but it may remain unchanged. A transfer from the top group to the rest of the population lowers the top income group share, but transfers within the respective groups leave the measure unchanged. A direct consequence is, of course, that top income shares cannot capture changes that happen *within* the lower part of the distribution.

What is the quantitative impact of a top income share change on the Gini coefficient? Atkinson (2007) suggests a useful approximation. If we assume that the top share is negligible in size but has an income share S, the total Gini coefficient (G) can be approximated as $G = S + (1 - S)G'$, where G' is the Gini coefficient for the population excluding the top group. To use the example given by Atkinson (2007), if the Gini in the rest of the population remains at 0.4 but the top percentile group experiences a 14 percentage point increase in their share (as in the United States between 1976 and 2006) this leads to an 8.4 percentage point increase in the overall Gini.

What about the correlation between top income shares and Gini coefficients in data? Figure 7.7 illustrates the overall, average relationship the 2 for 16 developed countries. The left panel illustrates a positive and high correlation, 0.86, between the *levels* of inequality. The right panel shows that the correlation between average annual inequality *changes* during the period 1985–2005 is lower but still positive and high, 0.57.

Looking at the relationship more systematically, Table 7.4 gives a correlation matrix for the relation between top income shares and broader measures of income inequality. Using data from the LIS, the WIID, and the WTID over the past 30 years, the table shows Pearson correlations between three top income shares (the top percentile, the top decile,

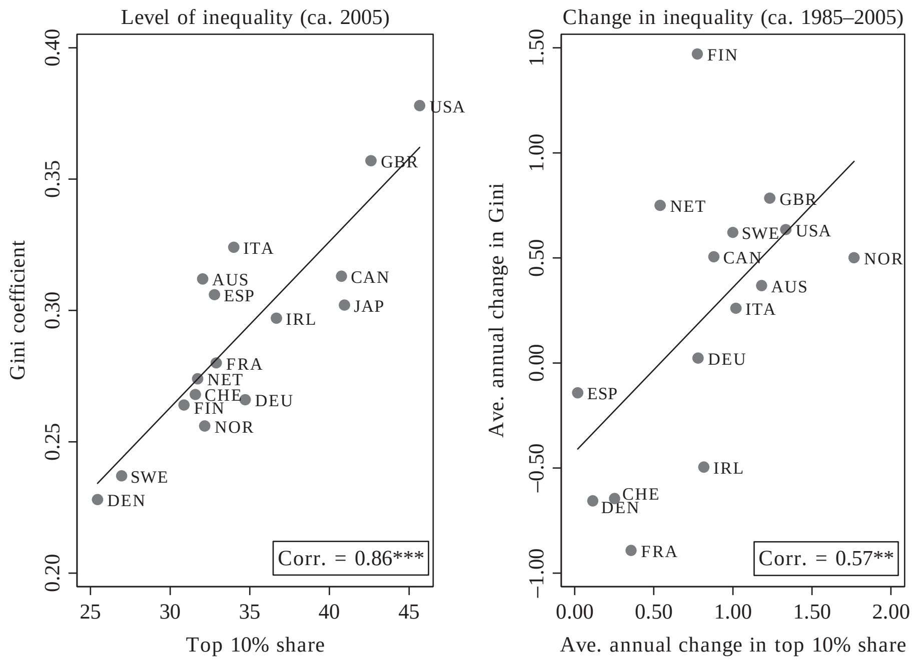

Figure 7.7 Top income decile and the Gini coefficient. *Source: Gini coefficient for disposable incomes of equivalized households are retrieved from the Luxembourg Income Study Datacenter (www.lisdatacenter.org) and top decile gross income shares from the World Top Incomes Database. Pearson correlations are statistically significant at the 1% (***) and 5% levels (**), respectively.*

Table 7.4 Correlations between top income shares and other inequality measures

	Top 1% (P99–100)	Top 10–1% (P90–99)	Top 10% (P90–100)
World Income Inequality Database (WIID)			
Gini coefficient	0.50	0.25	0.42
Luxembourg Income Study (LIS)			
Gini coefficient	0.62	0.69	0.73
Atkinson index ($\varepsilon = 0.5$)	0.61	0.65	0.70
Atkinson index ($\varepsilon = 1$)	0.53	0.61	0.64
P90/10	0.59	0.70	0.72
P90/50	0.57	0.65	0.68

Notes: The correlations are all statistically significant at the 1% level. The number of observations for the WIID variables is 300 for Top 1% and 263 for the Top 10–1% and Top 10%, and 63 for all LIS variables.

and the lower nine percentiles in the top decile) and the Gini coefficient, the Atkinson index using two inequality aversion parameters, and the income ratios between the 90th percentile and 10th percentile (P90/P10) and the median (P90/P50). The correlations are the lowest for the WIID Gini coefficients, 0.25 and 0.42 for two of the top share measures. When using the LIS data, correlations are markedly higher, between 0.53 and 0.57 for the top percentile and between 0.64 and 0.74 for the two other income shares.[45]

Finally, we also examine what the relationship between top income shares and the Gini coefficient looks like over the very long run. We do this by plotting series for two countries, the United Kingdom and the United States, where the Gini coefficient spans the entire period since the beginning of industrialization until present day, whereas the top income percentile only covers the last century. Figure 7.8 shows the results from this exercise. The evidence suggests that the twentieth-century experiences are quite similar across the two indices of inequality. In both countries the documented equalization appears in both measures with only minor deviations in the magnitudes. These observations thus indicate that had we accessed top income data for the eighteenth and nineteenth centuries they may have generated similar long-run trends since the 1700s as those portrayed in Figure 7.8, but of course we cannot make any certain statements without hard evidence.[46]

Altogether, this section shows that top income shares are related to well-known measures of overall income inequality such as the Gini coefficient, the Atkinson index or

[45] We also find strong "conditional correlations" using regression analysis where we account for time trends and country effects, similar to what is done by Leigh (2007) and by Smeeding et al. (2014) in Chapter 8 of this Handbook.

[46] In fact, both Lindert (2000) and van Zanden (1998a,b) seem to find at least some cases of a deviation in inequality trends in the United Kingdom and the Netherlands, respectively, across elite status and population-wide measures. See also the study of U.S. income inequality trends of Lindert and Williamson (2014) for similar evidence.

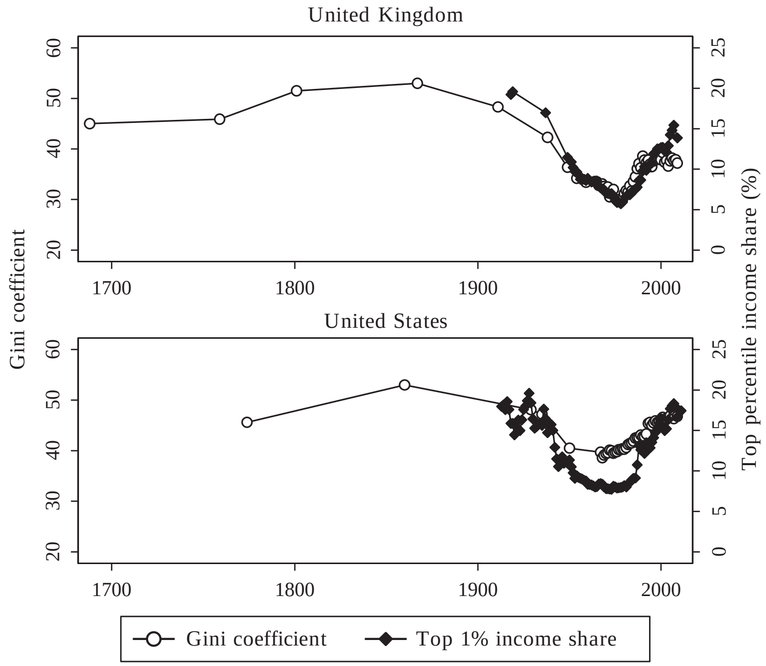

Figure 7.8 Long-run inequality trends using Gini and top income percentile share. *Sources: Gini coefficients for the United Kingdom from Lindert (2000, table 1), Milanovic (2013, table 1), and Office for National Statistics (2011, table 5), and for the United States from the same Lindert and Milanovic sources and U.S. Census Bureau (2011, table A-3). Top income shares from World Top Income Database.*

income ratios, both theoretically and empirically. Top income shares fulfill properties for being sensible inequality measures and quantitatively changes in top shares have a nontrivial impact on the Gini coefficient. They are also significantly correlated with overall measures of inequality although they (by definition) do not capture variation within the lower part of the income distribution. Does this imply that we can uncritically assume that top income shares can serve as a proxy for, say, the Gini coefficient? No, of course it does not. The correlations we present rely on evidence from time periods when we observe both top shares and enough data to calculate the other inequality measures. In practice, this means relying on data starting in the 1970s. In the few cases when we have data for longer periods these confirm the close relationship when going back in time. However, as shown by Smeeding et al. (2014) in Chapter 8 of this Handbook, the relationship is weaker in recent decades as household surveys do not fully capture the developments in the very top of the distribution. In the end, how to use top shares (or any other summary statistic) when aiming to capture overall income inequality, is a question of judgment. Our view is that, based on the evidence we have, and, in particular, given the restrictions in terms of available alternatives, top shares should not be dismissed as being "only about the top" but are also useful as a general measure of inequality in over time.

7.2.3.3 Other Series over Long-Run Inequality: Wages, Factor Prices, and Life Prospects

Much of what we write in this chapter is based on the assertion that the long-run evolution of income inequality is meaningfully reflected in the evolution of top income shares, that is, the shares of income accruing to top fractiles in repeated annual cross-sectional income distributions. Notwithstanding our conclusions in the previous section, there are some important limitations to the top income data, and it is therefore useful to complement these series with alternative measures. One is the poor coverage of period before 1900; top income data only exist in a handful of countries, none earlier than the 1860s and in most cases only in the form of a few scattered year observations. Furthermore, top income data are not ideal to study the dynamics between inequality and economic development in relation to industrialization as characterized by some theories such as the Kuznets hypothesis. Last, the use of repeated annual income distributions prevents conclusions about trends in the distribution of lifetime incomes, that is, whether differences in the quality and length of people's life span has changed in such way that the overall inequality trends are either mitigated or boosted depending whether it is the lives of the poor that has improved the most or the least.

In this section, we present some additional evidence on long-run inequality that have bearing on these issues. We do this by studying trends in some other measures that are popular in the past literature: wage dispersion across occupations (and regions), factor price differentials, and differences in life prospects.

The first measure, wage dispersion, is most often constructed as the wage ratio of rural to urban workers or of professionals (skilled) to blue-collar (unskilled) workers. Besides being available over very long time periods, often well before industrialization, these measures also offer a closer association with the original Kuznets conjecture, which was about changes in wage inequality precisely between urban and rural workers within countries over the path of industrialization. A large number of studies have scrutinized this conjecture using different types of wage ratios, and they offer somewhat contradictory evidence (also see Section 7.4.1). In his review of this extensive literature, Lindert (2000) asserts that, at least concerning the United Kingdom and the United States, historical series are still too incomplete to allow for any firm conclusions. However, at least they do not establish any clear support for strong increasing trends in sectoral or occupational wage differentials as Kuznets' assertion would stipulate.[47] In a study of the evolution of skill premia across occupations during the premodern era up until the early

[47] There are numerous measurement problems that researchers have dealt with. These include how to deal with nonmonetary reimbursement that was particularly common in agricultural professions, or the living conditions and health risks exposing workers differently in cities and on the country side. Specifically, Lindert (2000) points out that whenever costs of living differ between rich and poor, the dispersion of real wages differ from the dispersion of nominal wages. Lindert points to evidence from eighteenth-century England that the cost of living fell slower for the lowest 80% than for the top 20%, indicating that real inequality increased more than nominal inequality.

twentieth century in the entire Western world, van Zanden (2009, ch. 5) also failed to find any evidence of increased wage dispersion during industrialization. Looking instead at the twentieth century, wage ratios decline almost unanimously in Western countries. Not only does this development fit the acclaimed downturn of the Kuznets curve but it also correlates positively with the inequality trends suggested by the declining top income shares. As Lindert (2000) emphasized, however, the twentieth-century drop in pay differentials does not seem to be driven by the forces suggested by Kuznets. Instead the factors compressing wage ratios were rather aligned to institutional developments such as labor market regulations and the expansion of trade unions and to the extension of educational attainment for large masses in the population (Goldin and Katz, 2008).

Sweden has in the past literature been referred to as a "clear example of the Kuznets curve" (Morrison, 2000, p. 227), an assertion based largely on Söderberg's (1991) investigation of sectoral wage dispersion. Swedish wage differentials across skilled and unskilled workers seem to have risen between 1870 and 1930, with exception for a sharp drop during the First World War, and then turned downward until 1950. As Sweden's industrialization can be said to have begun around 1870 and peaked around the turn of the century, the skill differential in wage indeed matches the Kuznets pattern. However, more recent research using new evidence on wage differentials between rural and urban workers (Bohlin et al., 2011) and across occupations (Ljungberg, 2006) cannot replicate these results. They find either no trend at all or even a negative trend beginning already in the nineteenth century, casting doubts about the existence of even a Swedish Kuznets curve.[48]

Relative factor prices, typically expressed as the ratio of land rents to real wages, represent another outcome that bears information about inequality trends, even if it is primarily motivated by trade theory. One basis, the inequality interpretation, is offered by Lindert (1986, 2000), who argued that land ownership during the nineteenth century was highly concentrated and changes in its return relative to real wages can reflect changes in the overall income inequality. According to several studies (Clark, 2008, p. 274; Lindert, 2000; O'Rourke and Williamson, 1999; van Zanden, 2009), the wage–land rental ratio did not decrease (i.e., inequality did not increase) at all during the nineteenth century in the industrializing world. If anything, the wage–rental ratio went up in the decades before the First World War, but whether that reflected a true equalization

[48] Specifically, Bohlin et al. (2011) compared the wage gap between agricultural (rural) workers and engineering (urban) workers between 1860 and 1945, controlling for differences in nonwage reimbursement and costs of living. They find no secular trend in the wage gap before 1950 but a considerable short-term responsiveness to shocks, for example, to local living costs. Ljungberg (2006) compared wages of male manufacturing workers with wages of graduate engineers, college engineers, and secondary school teachers between 1870 and 2000, finding that unadjusted wage gaps trended downward but that the pre-First World War trend largely disappeared when controlling for the growth of human capital in the labor force at large.

in the midst of the second industrial revolution or merely the demise of the rural land owners remains an open question.[49]

Finally, although the dispersion of incomes earned during a single year is often a relevant time frame of analysis, there are dimensions of personal welfare when outcomes over longer time spans are of primary concern. If, for example, industrialization allowed the broad masses to live better, eat healthier, and work safer, and thereby live longer, without affecting the lives of the rich at all, this would result in an equalization of lifetime incomes even if distribution of annual incomes did not change at all. The literature on differential mortality trends over the long run and their implications for lifetime income inequality trends is quite small. In his review article, Lindert (2000) referred to studies of the United Kingdom that seem to reach conflicting conclusions, some finding that the biggest gains in life expectancy materialized among the already rich, whereas others found the opposite. Clark (2008) looked at the differences in life prospects between "rich" and "poor" before and after industrialization, broadly put. He found that the rich–poor difference in terms of male stature decreased from 3% to 1%, in life expectancy from 18% to 9%, in number of surviving children from 99% to −19%, and in literacy from 183% to 14%.[50] However, the most recent research on socioeconomic inequalities in death over the long run presents a more sceptical view of the role of industrialization. Using historical longitudinal microdata from several countries aiming at uncovering the causal impact of industrialization on social mortality differences, scholars have not found any clear trend break along with the industrialization and, in general, no clear impact of income on mortality at all.[51]

Altogether, the evidence put forward in this subsection has broadened the focus on long-term trends to also include other measures of inequality such as occupational wage ratios, factor price differentials, and lifetime-amended income inequality. These other distributional sources offer insights into pre-1900 inequality trends, the economic dynamics more closely related to the Kuznets conjecture, and into the development of the inequality of lifelong well-being, all of which are unsatisfactorily addressed by the top income data (and not addressed at all by other pre-1900 income inequality data sources). The main message from these studies is that there are few indications of an increase in inequality during the nineteenth century, that is, the era when most Western countries experienced their definitive industrial takeoffs. There is hence little empirical support for the first part of the Kuznets inverse-U curve. We would still hesitate to extrapolate our top income shares backward into the nineteenth century based on the

[49] O'Rourke et al. (1996) established the overall trends in the wage–rental ratios, arguing for a crucial role of trade openness as driver of the equalization, whereas Clark (2008, p. 274) emphasized the fact that land owners failed to keep up with productivity booms in the industrial sector.

[50] See Clark (2008, table 14.4, p. 283), based on a number of different sources.

[51] See Bengtsson and van Poppel (2011) and the references therein.

evidence from pay ratios. In terms of lifetime income inequality movements, there is again no clear trend that deviates notably from the one offered by the top income shares. If anything, the twentieth-century equalization may be even stronger if would adjust for changes in longevity differences across the distribution, but this conclusion rests on still quite tentative evidence.

7.2.4 Income Inequality over the Long Run—Taking Stock of What We Know

Combining all the preceding information, it seems that there are three possible permutations of broad overall trends since the beginning of Western industrialization. To continue the letter-analogue to describe shapes, the question is if we (with a bit of imagination) see an N, a U, or an L. The N-shape corresponds to an increase in inequality over industrialization followed by a decrease over the twentieth century and again an increase since around 1980. The U-shape would be a situation where inequality is high before and during the period of industrialization, then declines over the twentieth century, and increases again after around 1980. Finally the L-shape corresponds to the U-shape but without the upturn around 1980.

The question marks, thus, revolve around to what extent there was an increase or not during industrialization and to what extent there has been an increase in recent decades. The answer to the first question is difficult due to lack of clear evidence. There are some signs of increased inequality during industrialization but many studies also point toward high and relatively stable levels before the decrease in the twentieth century.

When it comes to the second question about the increase since around 1980, the evidence is much more solid and clearly indicates that the answer depends on the country in question.[52] In some countries, especially the United States and the United Kingdom, inequality has risen sharply. This increase has taken place from a level that was already high in relation to others before it started. In countries like Sweden and Finland, increases have also been substantial but here from internationally low levels to levels that are much higher, but remain among the lowest. In other words, the increase in percentage terms has been almost as large in Sweden and Finland as in the United States and United Kingdom but the level difference is very significant. In some other countries, for example France, Germany, and Japan, there is no clear upward trend but in absolute terms inequality remains higher than in the Nordic countries.

To what extent is this picture any different than the one we had before the top income literature and other findings that emerged in the past decade? In terms of the broad overall developments, it may actually not be so different. There are some more studies suggesting that the increase in inequality during industrialization is not so clear

[52] For a closer analysis of the post-1970 inequality trends in the industrialized countries, see further Chapter 8 in this Handbook (Smeeding et al., 2014).

and the recent upward trend in inequality has been made even clearer. Of course we have a lot more data on inequality over the long run in the form of top income shares. But overall there is nothing dramatically new in terms of the secular trends over the long run.

What is new, however, is the change in our *understanding* of these trends as a result of a number of features in the top income data. First, the detailed analysis of changes *within* the top of the distribution has shown just how much of the development is driven by the top 1% group of the distribution and, conversely, how surprisingly stable the income share of the lower half of the top decile has been over the long run. Second, the decomposition of income according to source has increased our understanding of the importance of accounting for all sources and how the same broad trend could be driven by entirely different mechanisms depending of the development of capital and wages, respectively. This applies both to the aggregate economy and to different groups across the income distribution. Third, the often yearly observations have shown the importance of sufficiently high frequency data. In particular, this aspect of the new series has been an important part of the focus on the role of shocks and war especially in the first half of the twentieth century, thus creating an at least partly new interpretation of the decline in inequality in the first half of the twentieth century. Finally, the relationship between top incomes and other measures of inequality illustrate how this literature has contributed *both* to our understanding of the importance of developments within the top, and the possibilities to use these measures as proxies for overall inequality.

7.3. LONG-RUN TRENDS IN WEALTH INEQUALITY

It is fair to say that the majority of research on economic inequality has focused on incomes. Much less attention has been given to the role of wealth, which is unfortunate for a number of reasons. As a determinant of people's consumption possibilities, personal wealth is of first-order relevance. The classical Haig–Simons definition of income states that income is what we can consume while keeping our real wealth intact. Wealth can also determine which opportunities individuals have to make investments and pursue different occupations, especially in the presence of credit constraints. The interplay between the distribution of wealth and development is also central to many theories attempting to explain the cross-country differences in long term development.

This section presents and discusses the existing research on the long-run evolution of wealth inequality. The ambition is to harmonize the outline with the previous section on the long-run trends in income inequality. We begin by presenting the core methods and data issues concerning how to measure wealth, wealth inequality, and how to tackle the specific challenges associated with studying historical trends. Thereafter we present ten country case studies for which we have sufficiently good data on wealth concentration for at least a century and in some cases from the beginning of each country's industrialization.

Finally, we bring together the pieces of evidence into cross-country mappings of the trends, searching for common patterns that may help us address the overall questions about the relationship between economic development and inequality.

7.3.1 Data and Measurement

Despite the arguments for studying wealth and its distribution, the empirical literature on wealth inequality is still limited, particularly when it comes to the long-run perspective. Naturally, there are many reasons for this past neglect, but the problem of agreeing on a manageable definition of wealth and then the practical problems associated with measuring it empirically are most likely important.

Sources for studying wealth over time are of different sorts. In their investigation of the analysis of wealth distribution, Davies and Shorrocks (2000) pointed at the five most common sources of wealth data: wealth tax returns, estate tax returns (or probate records), investment income method (using capital income and some assumed or observed net rate of return), household surveys, and journalistic rich list. With respect to investigations of long-run patterns, perhaps the most consistent of these sources is estate records. They have existed for centuries with largely the same basic structure of assets and debts of the deceased individuals. Unfortunately, there are few compilations of estate records in most countries over time, which is why we still lack data on wealth distribution from this source. A few countries have presented tabulated sizes of estate records in relation to estate tax compilations. Wealth tax statistics is another common source, available in a fairly homogenous way in several countries over long periods of time. Here, however, the problems of what components are included in the tax base or how large share of the population that is covered in the statistics are more pressing problems. Surveys, finally, comprise a more recent source for wealth distribution evidence.

Historical evidence on wealth distribution data is primarily based on wealth and estate taxation statistics. These fiscal instruments have been used for centuries and offer consistent source materials. Authorities have often also been interested not only in collecting the revenues but also in calculating the size of each tax base as well as their respective size distribution. Of the historical evidence presented later, series from France, the United Kingdom, and, in part, the United States, all emanate from the estate tax and, specifically, samples of individual estate tax returns. U.S. wealth distribution data from the latter part of the twentieth century and the beginning of the twenty-first century are also available in household surveys. Wealth distribution data from Denmark, the Netherlands, Norway, and Switzerland are all based on wealth tax statistics, in most cases as tabulated distributions published by each country's tax authorities. For Finland and Sweden the bulk of the data come from both wealth tax statistics but there are some complementary observations from estate tax returns. For Australia, finally, observations come from estate tax data, wealth surveys, and even journalistic rich lists.

7.3.1.1 The Wealth Holding Unit

The concept of wealth owner varies across the empirical studies covered in this chapter depending on the nature of the data source used. When wealth tax-based data are used (as in the Netherlands, Switzerland, and the Nordic countries), the most common unit of observation is *households*. For the most part, this means tax households where married couples (and their under-aged children) count as one, as do children 18 years or older living at home. Many of the survey-based wealth records from recent decades, however, define households as cost-based households, the major difference being that adult children living at home are now included in the parents' household. When studying very long time spans, households sometimes also included servants, parents or grandparents, slaves, or unregistered immigrants. Shammas (1993) shows that the U.S. historical wealth concentration is sensitive for the treatment of these different subgroups into the reference tax population.[53] Estate tax data and probate inventories (used in France, the United Kingdom, and the United States) are instead based on (deceased) *individuals*.[54] Most studies focus on adult individuals, thereby imposing a lower age cutoff normally between 15 and 25 years of age.[55]

To define wealth holding units consistently matters for the distributional estimates. As was pointed out earlier in the discussion of the distribution of incomes, individual-based data tend to (but must not) give rise to a more unequal wealth distribution than does the household-based data (Atkinson, 2007). Roine and Waldenström (2009) compared shifts in Swedish top wealth shares using household and individual distributions finding no important differences, and Kopczuk and Saez (2004) reached the same conclusions in their analysis of U.S. wealth distribution trends.

7.3.1.2 The Concept of Wealth

The definition of personal wealth that is most commonly used in studies of wealth distribution is *net wealth*, also called net worth or net marketable wealth. Net wealth consists of the sum of all nonhuman real and financial assets less debt. Real (or nonfinancial) assets primarily consist of housing and land, but they may also include durable consumption goods (see further the discussion later), for example, cars, boats, furniture, and also valuables such as antiquities, jewelry, and art. In the distant past, even items such as clothing and other semidurable consumption goods were often inherited (especially among the less wealthy) and may also be covered among the nonfinancial assets. Financial assets are cash, bank deposits, corporate stocks, bonds and other claims, and insurance savings,

[53] Shammas shows that when including slaves in the population of wealth holders, the top percentile wealth share increased by 15% (Shammas, 1993, table 1).

[54] Some estate reports include joint property if there is a surviving spouse and the property of a deceased spouse that has not previously been transferred to heirs.

[55] Variation in age cutoff across countries and even within countries over time may introduce problems of comparability (Atkinson and Harrison, Chapter 6).

which today also include some parts of funded pension assets. Debts, finally, are the sum of housing mortgages and loans for consumption, investment, or education.

As already stated, our definition of wealth does not include peoples' inherent or acquired skills, or human capital. This is a natural implication of the wealth definition set out at the beginning, which focuses on assets that are *marketable* and thus possible to sell or purchase at a market place.[56] Historically, such market for human wealth has existed, namely in association with slavery. In terms of aggregate wealth the total value of "slave assets" was somewhere between 15% and 30% of total national wealth (Piketty and Zucman, 2014, figure 11; Soltow, 1989, p. 180). According to Soltow (1989, p. 267), slaves were disproportionately held by the wealthy, and the inequality in slave ownership was almost three times as large as the inequality in land and dwellings.

Measuring net wealth is sensitive to the valuation of assets. Ideally assets should be valued at current market prices, net of taxes and transaction costs, the theoretical reason being the possibility to convert wealth to consumption. However, most estimates of historical inequality use data where assets are reported in tax-assessed values rather than in market values. Tax laws are typically designed to strike a balance between the revenue needs of government and tax collectability of tax authorities, and the rules regarding asset coverage or valuation criteria may thus not be aligned with what researchers would ideally like to have. But if the discrepancy across tax and market values is similar across the distribution—and historically we think that this was arguably often the case—the biasing effect of valuation on relative wealth *shares* should be small. Only a few studies have delved into these questions. Examples are the analyses of inequality trends in the United States where Williamson and Lindert (1980a,b) and Wolff and Marley (1989) investigated whether tax-driven avoidance distorts the use of tax data for distributional analysis (and they generally found that it does not). Atkinson and Harrison (1978) examined how the valuation of taxed assets may influence inequality, for example, looking at life policies (table 4.6) and offshore assets (pp. 161f).[57] Roine and Waldenström (2009) studied the effect of valuation by using several alternative estimates of aggregate wealth (based on either tax or market values as well as including items that have not been taxable) and also different assumptions about the distribution of the difference between these alternative reference totals and the baseline specification. They found that there are some differences in the levels of wealth shares over the period, but that the trends in wealth concentration remain unchanged. Altogether, we believe that the comparability of the estimated shares presented in this chapter is good over time.

[56] Some scholars have still tried to quantify the value of individuals' lifetime human capital and its distributional characteristics. Reviewing these estimates and their trends over time, Williamson and Lindert (1980b, p. 71) came to the conclusion that "(w)e have, then, two reasons for believing that trends in conventional wealth distributions understate the true leveling in total wealth distributions." Whether this result is stable across countries and over longer time periods is an open issue worthy of further inquiry.

[57] See also our later subsection on the role of tax avoidance and evasion.

Some components are especially difficult in the analysis of personal wealth. Although some of them appear in the wealth data in several countries and time periods, their presence is associated with uncertainty concerning both valuation and conceptual adequacy. In the following we discuss three of the most important "problematic assets" and how they are typically treated in the historical sources. In the end, they do not, however, affect the main conclusions about the long-run inequality trends reported later.

(i) Pension and Social Security wealth is a composite term for the net present value of individuals' entitlements to future private and public payments for pensions and other social outlays. These assets are for the most part not included in the historical inequality estimates. Conceptually, scholars have shown that expectations about future public pensions reduce the incentive to accumulate private wealth (see, e.g., Berg, 1983; Feldstein, 1976; Gale, 1998), and thus a comparison of private wealth across systems with differing public pension coverage may be misleading unless retirement wealth is accounted for. Researchers therefore sometimes add Social Security wealth to the net marketable wealth of households, yielding a concept often called *augmented wealth*. Studies of the concentration of augmented wealth typically find that it is substantially lower than the concentration of marketable wealth. For example, Wolff (2007) found that the Gini coefficient for the United States in 2001 dropped by a fifth when going from net worth to augmented wealth, and Frick and Grabka (2013) found a similar drop for Germany in 2007. The Inland Revenue in the United Kingdom presented for many years series of the distribution of marketable wealth (Series C) as well as wealth including public and private pension entitlements (Series E), exhibiting Gini coefficients that were about a third lower when including pensions.[58]

However, there are numerous problems associated with defining pension assets, or other "drawing rights" on the Social Security system, as private property, and until questions like those are fully settled we will not see a comprehensive treatment of pension and Social Security wealth alongside net marketable real and financial assets. The main issue is how to judge the fact that, on the one hand, not having the public system would have required an individual to save privately, thus decreasing consumption possibilities, but on the other hand, the "drawing rights" are not marketable wealth and cannot be converted freely into other consumption by the individual.[59]

[58] See Inland Revenue, *Inland Revenue Statistics 1985*, London, HMSO, table 4.8.

[59] For example, pension assets are not fully accessible to their owners on demand at any time (they are not possible to realize before retirement). Furthermore, they are partly defined in collective forms and are hence not well defined for all individuals (or households) even within the system. The calculation of current claims on future pensions necessitates a number of complex assumptions about people's life expectancy, future rates of return on the capital markets, and so forth. There is also a mix of public and private pensions, some being funded and others unfunded. Finally, it is not obvious where to draw the line in terms of valuing the rights of citizens' claims on the public sphere: how valuable is the claim on childcare, elderly care, unemployment insurance, and even the right to freely travel on public roads or be protected by the country's military defense.

(ii) Consumer durables are not always included in the wealth data, and when they are their valuation is difficult. First of all, this asset class is typically completely absent from wealth tax returns or administrative tax registers, primarily for evasion reasons. It is thus not part of the bulk of the distributional estimates examined in this chapter. However, insofar as data are based on probates or estate tax returns or household surveys, durables are more likely to be included because of smaller possibilities (and smaller incentives) to evade.[60] Atkinson and Harrison (1978, p. 43) noted that the valuation of consumer goods is difficult, and they often take too low values in estate data. In general, it is actually an open question whether consumer durables should at all be included in the household balance sheet. According to the System of National Account they should not because all consumed goods are assumed to depreciate within 1 year and therefore cannot contribute to any fixed asset formation.[61] However, many durables (e.g., cars, boats, and some electronic equipment) arguably last more than 1 year, and for this reason some countries (such as the United States) do include durable consumer goods in household balance sheets. Historically, consumption goods like china, furniture, and even clothing were important parts of household inventories and were inherited along with other assets. Waldenström (2014) estimated the household balance sheet of Swedish households since 1810, finding that durables represented between 10% and 20% of nonfinancial assets throughout the period up until today. Interestingly, durables grew more important in the middle of the twentieth century, which is related to the growth in earnings potential of increasingly educated middle-class households (Roine and Waldenström, 2009).

(iii) Foreign wealth holdings have historically been sizeable in many countries, especially colonial powers such as France and the United Kingdom. In a recent investigation, Piketty and Zucman (2014, table A27) found that net foreign wealth represented between a 10th and a quarter of total national wealth in these two countries from the middle of the nineteenth century up to World War I. At the individual level, information about foreign assets such as foreign government stock and bonds and other real estate is most likely completely absent from domestic wealth tax returns, but should in principle be more visible in estate data. As noted by Atkinson and Harrison (1978, p. 161), however, overseas real estate was not taxable before 1962 and therefore not included in wealth inequality estimations before this year. In an attempt to gauge the importance of the acclaimed tax-driven capital flight from Sweden during the period from the 1970s to the 2000s, Roine and Waldenström (2009) used residual flows in the Balance of

[60] An example of this was shown by the Swedish public investigation Kapitalskatteberedningen (SOU, 1969, table 78, p. 276) in a sample of estate tax returns matched with the deceased individuals' last wealth tax returns (from the preceding year). "Other assets" (*Övriga tillgångar*) were four times larger on the estate tax returns, and their largest component, "inner inventories" (*Inre inventarier för personligt bruk*; durable consumer goods, art, antiquities, etc.), was missing altogether from wealth tax returns.

[61] In the realm of corporations, consumption is viewed as firms' running expenses instead of as investments; only the latter results in an accumulation that forms a stock of assets.

Payments and Financial Accounts to estimate the aggregate offshore wealth held by residents. Assuming that this wealth was primarily held by the richest residents, the authors found that the top percentile wealth share rose from about 20% in the 2000s to over 30%, depending on assumptions about interest rates on foreign capital and whether to include the closely held corporations of superrich Swedes.[62] Also, without explicit reference to distributional aspects, Lane and Milesi-Feretti (2001, 2007) constructed estimates of the external wealth of nations since 1970. However, going further back we know very little about the role of offshore wealth in historical eras and can therefore not offer a consistent interpretation of their role for long-run inequality trends.

7.3.1.3 Measuring Historical Wealth Inequality

When we estimate the concentration of wealth, we use a similar methodology as when calculating top income shares. That is, we estimate the *wealth share held by various fractions of the population* by dividing the observed top wealth holdings for specific groups (fractiles) in the top by a reference total for all personal wealth in the economy. Just as in the case of historical income distribution data, the historical wealth distribution data often come in the form of tabulated distributions of grouped data. This means that we observe wealth holders and their net wealth divided into different wealth size classes. To get the exact wealth share accruing to certain fractiles in the top, such as the top percentile or the top decile, we use the Pareto interpolation technique described previously.

Using top wealth shares as measure of inequality has several advantages for our purposes.[63] Most historical sources of wealth data come from wealth and estate tax returns, and the group most consistently represented in these tax listings throughout history is the rich (i.e., where the wealth was), which makes them the most homogenously observed group over time. Moreover, wealth distributions are heavily skewed—much more so than income distributions—and top wealth holders have often held the vast majority of all personal wealth; between 70% and 90% before the Second World War and between 50% and 70% thereafter. Studying the top and its wealth therefore means that almost all personal wealth is being studied. Finally, most of the historical wealth inequality estimates constructed by past researchers come in the form of top wealth shares, especially as top wealth percentiles, and this measure is therefore the most appropriate to use for our purposes.

[62] An alternative approach to estimate the hidden wealth of nations was proposed by Zucman (2013), who instead used balance sheet statements of countries' portfolio investments in the 2000s to detect systematic mismatches that could be interpreted as evaded capital, presumably of the rich. Zucman did, however, not present any distributional implications of his calculations.

[63] Having said this, other measures of wealth inequality may be applicable on the available long-run evidence. In particular, a headcount measure based on the number of wealthy over some cutoff line, which could be defined as a multiple of average incomes, has been proposed by Atkinson (2008b).

A specific challenge associated with estimating top wealth shares is the measuring of the reference total of net wealth of the whole population. Wealth tax data typically only cover the top households that have paid wealth tax, and researchers must therefore limit their observations to years when attempts to measure the corresponding total for the whole population have been made, for example, in censuses or special public investigations. In the case of Sweden, for example, there are years for which tabulated top wealth data exists, but there is no reliable information about the reference total wealth to be found. Estate data also have problems with constructing population measures but they are of a slightly different kind. Researchers here typically try to collect a sample of estates that is representative for the whole population, which thereby enables them to compute the relevant inequality measures using only the sample at hand. However, most of the time the estate data sources are themselves not fully representative for the population, mostly lacking information about people with low levels of personal wealth.[64]

The different wealth data sources also display the wealth distribution for different entities. Whereas wealth tax data and surveys reflect the distribution of the living population, estate tax data and probate inventories reflect the distribution of the deceased. Because those people who die during a year are not a representative sample of the living population (e.g., because the old are heavily overrepresented), these two distributions are not immediately comparable. The usual procedure used by researchers to make them comparable is by applying so-called mortality multipliers, which are inverse mortality rates for different age, sex, or social status groups.[65] In this way, the distribution of estates can be transformed so as to reflect the wealth distribution among the living population.

7.3.1.4 Tax Avoidance and Evasion

As already noted, using data from administrative tax-based statistics to compute measures of wealth distribution gives rise to some problems relating to tax evasion and avoidance. But, as in the case of the income distribution, the extent to which such activities lead to errors in estimated wealth shares is, however, not clear. If noncompliance and tax planning is equally prevalent in all parts of the distribution—it may, of course, take very different forms—this affects the reported wealth levels but not the shares. The same goes for comparisons over time and across countries (see Section 7.2.1.5 for more on this). Unfortunately there is little systematic evidence on this. There are overviews, mainly

[64] The estate tax returns used to calculate U.S. wealth shares over the twentieth century only cover the two richest percentiles in the entire population, and reference total wealth was collected from national balance sheets (Kopczuk and Saez, 2004).

[65] The methodology of using inverse mortality rates, preferably adjusted for sex and social class, was pioneered by the works of Coghlan (1906) and Mallet (1908) and was also implemented around the same time by the Swedish statistician Isidor Flodström (Finansdepartementet, 1910). For a detailed account of the mortality multiplier methodology and theoretical underpinnings, see Atkinson and Harrison (1978, chapter 3).

concerned with personal income taxes, suggesting that, although avoidance and evasion activities are important in size, there are no clear results on the incidence of overall opportunities or on these activities becoming more or less important over time.[66]

Moreover, it is not clear whether to expect more or less avoidance and evasion in countries with higher tax rates. As the incentives to engage in avoidance and evasion become higher when taxes increase, so do the incentives for tax authorities to improve their control.[67] Regarding wealth and estate taxes it may seem plausible to think that estate tax data are more reliable because it is typically in the interest of the heirs to formally establish correct valuations of the estate.[68] At the same time tax planning aimed at avoiding the estate tax is an important industry in the United States and elsewhere. This may affect the reliability of the data. For wealth, tax data problems of underreporting are likely to be similar to those for income data, with items that are double reported being well captured, whereas other items are more difficult.

Finally, the use of tax havens may be a problem, and as we discussed earlier there are indications that substantial amounts have been hidden over the past decades (see for example, Johannessen and Zucman, 2014, and references therein). Given the large fixed costs related to advanced tax planning, it is likely that such activities are limited to the very top of the distribution. If this has become more important over the past decades—something that seems likely—then estimates of wealth concentration for recent periods may understate wealth holdings in the very top and not be directly comparable with estimates produced for earlier years in this century, in particular top wealth shares may be underestimated for recent decades.

7.3.2 Evidence on Long-Run Trends in Wealth Inequality

In this section we present evidence on the evolution of wealth inequality in 10 Western countries. The length and detail of the series vary but in most cases the first observations are from around 1800 and with relatively frequent observations throughout the whole of the twentieth century. The relatively small number of countries for which we have data allows us to delve a little deeper into each country case, examining the specificities associated with national histories as well as the structure of historical wealth distribution evidence. After going through the country cases, we compile the series and study to what extent there are common patterns over time. Note that we focus on the twentieth and twenty-first centuries in the country-specific figures in order to ease inspection of the

[66] See Andreoni et al. (1998) and Slemrod and Yitzhaki (2002).

[67] Friedman et al. (2000) provide evidence supporting the idea that higher taxes also lead to better administration across a broad sample of countries as they find that higher taxes are associated with less unofficial activity.

[68] For 2001, the most recent year for which the IRS has final figures, the tax gap in the United States (i.e., the difference between taxes owed and taxes paid) was around 16%. Out of the 345 billion dollars that make up the tax gap, only about 4 billion were associated with estate and excise taxes.

trends in this era, whereas in the figures compiling several countries (Figures 7.19–7.21) we show the full set of observations stretching back to the nineteenth and eighteenth centuries.[69]

7.3.2.1 *Country-Specific Evidence*

7.3.2.1.1 Australia

A recent investigation of Australian wealth concentration since the beginning of the twentieth century is the one by Katic and Leigh (2013). The authors estimate top wealth shares using three different sources: estate tax returns, household surveys, and journalistic rich lists. The main emphasis is put on the first two, but the very recent trends can also be studied by putting the rich lists into context.

The earliest observation comes from a war wealth survey conducted in 1915 by the Commonwealth Bureau of Census and Statistics. From the 1950s up until the 1970s, tabulated estate tax returns were collected and adjusted by using inverse mortality multipliers adjusted for age, sex, and social status. From the 1980s onward, the authors again used wealth surveys, conducted by different entities, but complemented them by annual observations of wealth share of the superrich Australians published in the Australian magazine *Business Review Weekly*.

A common theme in all these sources is that they are not extensive in terms of coverage of wealth holders. With a few exceptions, only the very richest citizens are covered, and for this reason the only long-run time series coming out of the historical evidence are the wealth share of the top 1 and top 0.5 percentiles.

Figure 7.9 shows the trend in the Australian top wealth percentile share between 1915 and 2008. The share falls from almost 35% of total wealth during the First World War down to less than 15% in the early 1950s. Due to the lack of observations in between these dates, we cannot tell whether the fall came as a consequence of the immediate post-WWI turmoil, the crisis impact during the Great Depression of the 1930s, or the dramatic events during the Second World War and its aftermath. From the 1950s onward, the top percentile share has hovered at around a level of 10–15% of total wealth. Internationally, this is a very low wealth share, actually the lowest of all countries covered in this chapter. At this point, the reasons for the low Australian share have not been studied in detail.

7.3.2.1.2 Denmark

For Denmark, historical wealth concentration data exists from as early as 1789 and then more frequently during the twentieth century. The earliest observation comes from a comprehensive national wealth tax assessment in 1789, from which Soltow (1981a–c) collected a large individual sample of the gross wealth of households.[70] The next observation, however, comes over a century later at the time of the introduction of the modern

[69] This section is built partly on the cross-country analysis in Ohlsson et al. (2008).
[70] See Soltow (1981a–c, table 2).

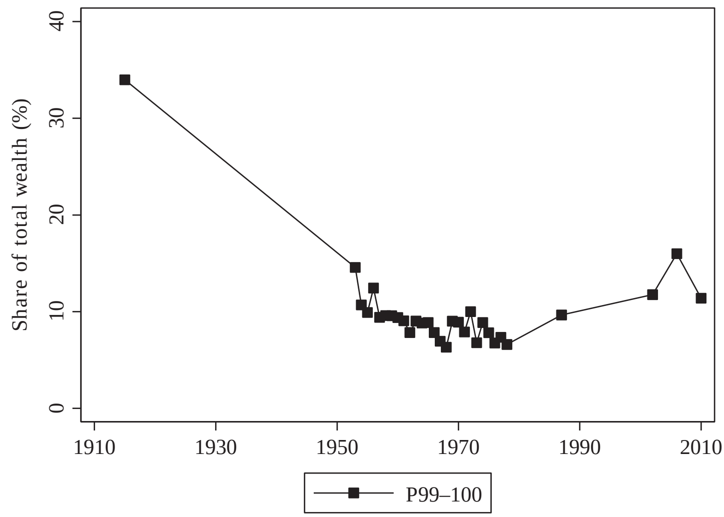

Figure 7.9 Wealth concentration in Australia, 1915–2010. *Source: See the Appendix for details about sources and data.*

wealth tax. For 1908–1925, Zeuthen (1928) lists tabulated wealth distributions (number of households and their wealth sums in different wealth size classes) for Danish households, adjusted to include those households with no taxable wealth. Similar tabulated wealth tax-based data are published in Bjerke (1956) for 1939, 1944, and 1949 and in various official statistical publications of Statistics Denmark for a few years thereafter until the wealth tax was abolished in 1997.[71]

Figure 7.10 shows the wealth shares of groups within the top decile between 1908 and 1996, while Figures 7.19 and 7.20 show the trends back to 1789. The lowest four percentiles (P90–95) exhibit a flat trend up to 1908 and thereafter double their share from 10% to 20% over the twentieth century. The next four percentiles (P95–99) lie constant between 25% and 30% of total wealth over the entire period, whereas the top percentile (P99–100) decreases significantly over the entire period, with particularly marked decreases after the two world wars. When looking at the very top of the distribution, the top 0.1 percentile (P99.9–100), there is no decrease at all up to 1915, but instead there is a dramatic drop by almost two-thirds of the wealth share between 1915 and 1925. Overall, the Danish wealth concentration decreased over the course of industrialization, and this continued throughout the twentieth century, although the development was not uniform at all times and across all groups.

[71] The estimates in 1995 and 1996 were constructed from evidence on only the tabulated number of wealth holders (families) and the total net wealth in the whole country. Supplementary Danish top wealth shares exist for the 1980s in Bentzen and Schmidt-Sørensen (1994), but unfortunately wealth size has been top-coded in their data, and the resulting estimates are not fully comparable with the other tax-based data.

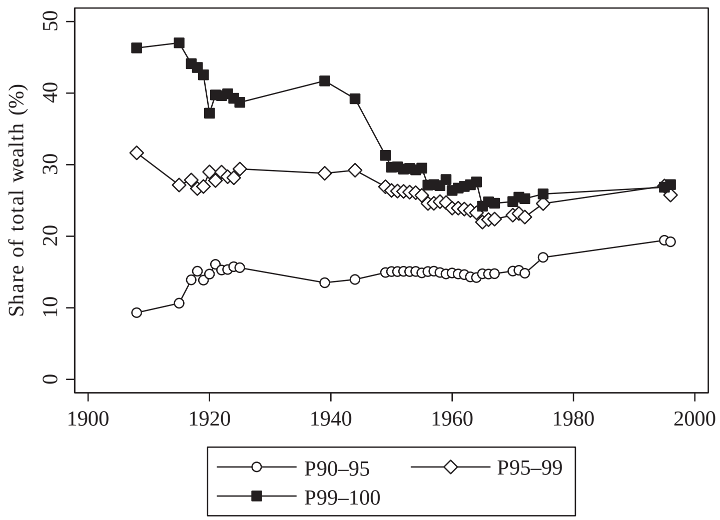

Figure 7.10 Wealth concentration in Denmark, 1908–1996. *Source: See the Appendix for details about sources and data.*

One way to understand the wealth compression of the Danish industrialization is to compare the identities of the Danish top wealth holders before and after the late nineteenth century. The dominant groups in the top of the wealth distribution in 1789 were owners of large agricultural estates. Soltow (1981a–c, p. 126) cited a historical source saying that "some 300 Danish landlords owned about 90 percent of the Danish soil." By contrast, in 1925, the group with the largest private fortunes was the brokers (*Veksellerere*) although landlords (*Godsejere*, *Proprietærer og Storforpagterere*) were still wealthy, both groups having more than 50 times larger average wealth than the country average.[72]

The drops in top wealth shares after the two world wars were partly associated with the sharply progressive wartime wealth taxes.[73] According to Bjerke (1956, p. 140), however, the fall after the Second World War was also largely due to new routines in the collection and valuation of wealth information of the tax authorities, which in particular made middle-class wealth more visible. Toward the end of the century, the wealth concentration continued declining up to the 1980s, largely due to increased share of the relatively equally distributed house-ownership in the total portfolio (Lavindkomstkommissionen, 1979, Chapter 5), but thereafter started to increase up to the mid-1990s.

7.3.2.1.3 Finland

Finland is another Nordic country for which wealth distribution data exist since the agrarian era and during most of the twentieth century. The country's industrialization

[72] The average net personal wealth in 1925 was Danish kronor (DKR) 6826 for all of Denmark, DKR 366,000 for brokers, and DKR 359,000 for large landlords (Zeuthen, 1928: 447).

[73] On the historical development of Danish wealth taxation, see Christensen (2003, pp. 8, 14).

came relatively late, in the interwar period, and even around the Second World War Finland was a predominantly agrarian economy focusing on forest industry and small-scale agriculture. Politically Finland was part of Sweden up until 1809, after which it came under Russian rule until 1917 when Finland ultimately gained independence (Eloranta et al., 2006).

Our estimates of the Finnish historical wealth distribution are essentially based on wealth tax statistics.[74] The earliest known observation of wealth distribution in Finland is 1800, coming from a wealth tax assessment levied in Sweden and Finland. Jutikkala (1953) and Soltow (1980) examined this assessment collecting a representative sample of the gross wealth of almost 2000 male household heads. The taxed households represented about one-third of the population, whereas the other two-thirds were exempt because they lacked a sufficient amount of personal taxable wealth. The next set of estimates comes from estate data in 1907–1909, 1914, and 1915 compiled and published by Statistics Finland.[75] We compute top wealth shares of the deceased but adjust these with respect to the likely difference between top wealth shares of the deceased and living populations using observed differentials in Sweden around the same time.[76] For the early twentieth century, we use Soltow's (1980) estimates from wealth tax assessments in 1922, 1926, and 1967. All these samples include adjustments for the share of the population without wealth on which no wealth tax was levied. Finally, we have wealth tax tabulations for the period 1987–2005 using net marketable wealth data retrieved directly from Statistics Finland.[77]

Figure 7.11 presents the evolution of wealth concentration in Finland from 1908 up to 2005, and Figures 7.19 and 7.20 show the trends back to 1800. The top decile held 46% of domestic net wealth in 1800, and its share peaked at 70% in 1909. Over the period the Finnish top percentile share exhibits an inverse-U shape, setting out at a relatively low share in 1800, which was doubled a century later in the years preceding the First World

[74] There are some previous studies, for example, Tuomala and Vilmunen (1988), who analyzed the distribution of wealth using tax data between 1968 and 1983, and Jäntti (2006) analyzing the developments during the latter 1980s and 1990s using mainly survey evidence. There is also a Finnish wealth survey run by Statistics Finland about twice per decade during the 1980s, but we do not use these data due to comparability issues with tax data as well as concerns about coverage in the wealth top. See Statistics Finland (2006, 2007). For example, the top decile wealth share in 1987 was as low as 35% in the survey, whereas it was 51% in the wealth tax statistics. The latter corresponds to a top percentile share of 16%, which is still in the lower region among Western countries.

[75] Statistics Finland (1911), table "Förmögenhetsförhållanden. A. Kvarlåtenskapsstatistik, 3. Arflåtna bon samt för dem uppburen stämpelskatt år 1909."

[76] In the Swedish investigation Finansdepartementet (1910), detailed calculations of wealth shares were made for both the deceased population (using estate shares) and the living population (using inverse mortality multiplier-adjusted evidence) for the years 1906–1908. It was found that the top wealth share of the deceased exceeded those for the living population by between 10% (for the top decile) and 40% (for the top 0.01 percentile).

[77] Data were submitted as a file by Statistics Finland showing taxable wealth by age and net wealth class in eight brackets from €5000 up to €500,000.

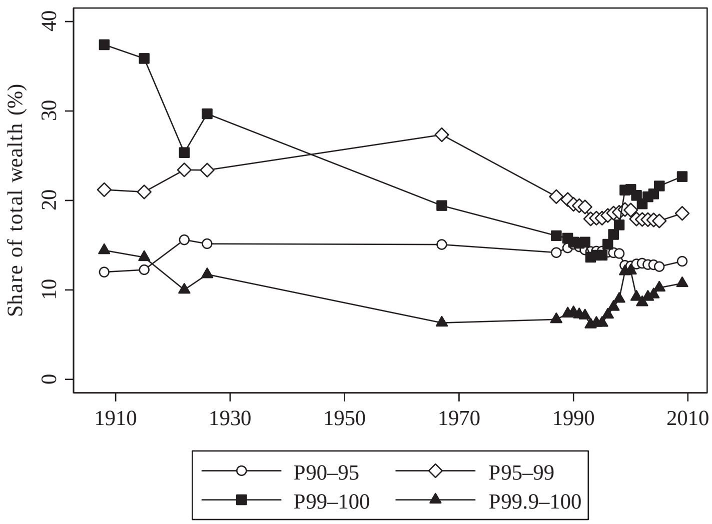

Figure 7.11 Wealth concentration in Finland, 1908–2009. *Source: See the Appendix for details about sources and data.*

War. The 1920s saw a strong reduction in the top percentile share, possibly due to the civil war taking place at this time. Later on during the twentieth century, the top percentile's share decreased further, reaching a global low in around 1990 when its share was less than 14% of total personal wealth. However, after this Finland experienced the IT-boom, led by the immense success of mobile phone producer Nokia, and the top percentile share increased swiftly during the 1990s and 2000s, reaching a level of 22% in 2005 (Eloranta et al., 2006). As for the rest of the top decile, the Finnish pattern is similar to that of most other countries studied here. The next four percentiles (P95–99) also experienced an inverse-U pattern, but peaked later, in the 1960s, after which its share started to decrease. The bottom half of the top decile hovered around 10–15% of total wealth.

Overall, the historical wealth concentration in Finland follows a pattern that looks very much like an inverse-U. The share of total wealth held by the rich (in the top percentile) increased during the nineteenth century and decreased during the twentieth century. The upper middle class (the rest of the top decile), however, did not change their relative position much during the two centuries covered. Also notable is the relatively low level of wealth concentration in Finland, especially in the year 1800 but also during the twentieth century.

7.3.2.1.4 France

The long-run evolution of French wealth inequality is particularly interesting to study given France's important role for Europe's economic and political development. Piketty et al. (2006), and later adjusted by Piketty (2014), presented new data on wealth concentration for Paris and France over almost 200 years from the Napoleonic era up to today. No previous study on any country has produced such long homogenous time series, offering complete coverage of wealth inequality over industrialization. The French wealth data comes from estate sizes collected in relation to an estate tax established in 1791 and maintained for more than two centuries. For every 10th year during 1807–1902, the authors manually collected all estate tax returns recorded in the city of Paris—Paris was chosen both for practical reasons but also because it hosted a disproportionally large share of the wealthy in France. Using summary statistics on the national level for the estate tax returns, the top Paris wealth shares were "extrapolated" to the national level. For the post-1902 period, tabulated estate size distributions published by French tax authorities were used.

Figure 7.12 shows the evolution of the wealth shares for some fractiles within the top wealth decile in France since 1900, while Figures 7.19 and 7.20 show the trends beginning in the early nineteenth century. The estimates are from the population of deceased, that is, directly from the estate tax returns, but comparisons with the equivalent wealth shares for the distribution of the living population (computed using estate multipliers) reveal practically identical trends and levels.[78] The figures show that wealth

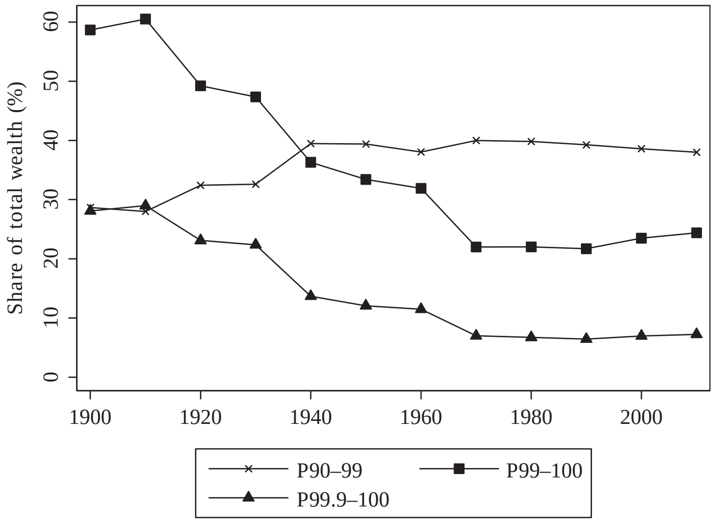

Figure 7.12 Wealth concentration in France, 1900–2010. *Source: See the Appendix for details about sources and data.*

[78] Using data in Piketty et al. (2004: tables A2 and A4) over top wealth shares for both the dead and living populations in Paris and France, it is evident that the trends in wealth shares over time is practically the same for all fractiles, and even the levels do not differ much, on average 0.4% for the top decile and 5.1% for the top percentile.

concentration increased significantly for the top 1 and 0.1 percentiles over the nineteenth century, first slowly up to the 1870s then more quickly until its peak at the eve of the First World War. By contrast, the two lower groups in the top decile are much less volatile during the period. The bottom half (P90–95) held about 9% of total wealth until the First World War when its share started to increase slowly until it had doubled by the 1980s. The next 4% (P95–99) stayed put on a level around 27% of total wealth throughout the period. These patterns suggest that the French industrialization, which took off around midcentury, greatly affected personal wealth. It did so already after a couple of decades, but only in the absolute top. This conclusion is further supported by two other observations. First, the composition of top wealth went from being dominated by real estate assets (mainly land and palaces) in the first half of the century to being dominated by financial assets (cash, stocks, and bonds), which were supposedly held by successful industrialists and their financiers. Second, over the same period the share of aristocrats among top wealth holders decreased from about 40% to about 10%.[79] From the First World War to the end of the Second World War, top wealth shares declined sharply, which according to Piketty (2003) is directly linked to the shocks to top capital holdings that inflation, bankruptcies, and destructions meant. The postwar era was quieter with regard to changes in the wealth concentration, although its decline continued most likely in relation to the increase of progressive taxation (Piketty et al., 2006).

7.3.2.1.5 The Netherlands

The Netherlands represents and interesting point of reference to the analysis of long-run trends in wealth inequality among Western economies. Although the Netherlands did not industrialize in the traditional sense until the middle of the nineteenth century, its economy was already developed due to its role in the expansion of global trade that started already in the sixteenth century. According to van Zanden (1998b), this may explain the apparent lack of increase in inequality following the Industrial Revolution. Although inequality grew during the preindustrial era due to high growth rates but stagnant real incomes, industrialization did not only boost fortunes of the wealthy but there was also an increased demand for all kinds of labor, skilled as well as unskilled.

The previous literature on historical wealth inequality in the Netherlands is relatively rich. Soltow (1998) and Vermaas et al. (1998) present a series of estimates of inherited wealth and housing inequality in different Dutch regions from the beginning of the nineteenth century. Unfortunately, defining a trend over the nineteenth century appears to be difficult. The only comparable information between 1808, 1880, and 1908 comes from inheritance tax records that cover inheritances to distant heirs, that is, not spouses and children. The data indicates a slight increase in inequality.[80]

[79] These facts are shown in Piketty et al. (2006: figures 4–6).
[80] See Vermaas et al. (1998, table 7.11, p. 167).

The most comprehensive longitudinal data are offered by the wealth tax statistics, which allow for an estimation of top wealth shares since 1894. The primary source of these observations is Wilterdink (1984), which presented a detailed account of the top vintile and groups within it for selected years between 1894 and 1974. The estimates stem from wealth tax records, showing the distribution among wealth tax units (mainly individuals), whereas the recent wealth survey data show the distribution among households. For the most recent years, Statistics Netherlands has compiled wealth-tax based distributions for the periods 1993–2000 and 2006–2011.[81]

Figure 7.13 shows the top wealth shares of the Netherlands from this year up to 2011. Wealth concentration was a high and stable around the turn of the century 1900. Thereafter the top percentile wealth share started decreasing. Both Wilterdink (1984) and van Zanden (1998a) highlighted the role of the geopolitical events, and these are clearly seen in the falls in top percentile shares during the two world wars and the depression of the 1930s. However, the researchers also emphasized the role of governmental redistribution, in particular the imposition of heavy wealth taxes after 1946 to finance the reconstruction after the war.

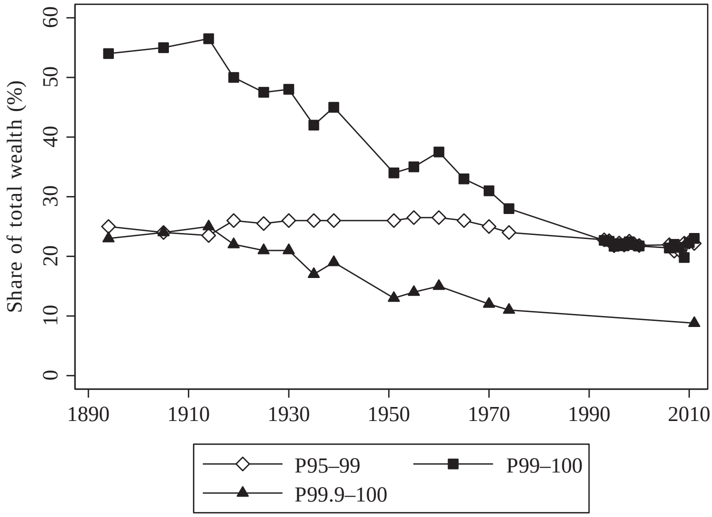

Figure 7.13 Wealth concentration in the Netherlands, 1894–2011. *Sources: See the Appendix for details about sources and data.*

[81] The data come from Statistics Netherlands and were kindly shared to us by Wiemer Salverda (see Salverda et al., 2013, pp. 47ff, and Statistics Netherlands, 2010, for further description of the data). A tax reform in 2001 introduced a slightly different mode of taxing wealth which reduces comparability of data. Furthermore, we only observe the top 5 percentiles in 1993–2003 (and assume their share of the top decile is the same during 2006–2011) and the top 0.1 percentile share in 2011.

7.3.2.1.6 Norway

Data on Norwegian wealth concentration come mostly from various kinds of wealth taxation. Overall, these data are perhaps the most uncertain presented in the entire chapter, and the estimates of top wealth shares presented in this chapter must therefore be interpreted cautiously. The first observation is from 1789, when the wealth tax assessment that also was launched in Denmark came into place (the two countries were in a political union at this time). As in Denmark, both real and financial assets were subject to taxation, including land, houses or farms, factories, livestock, mills, shop inventories, and financial instruments. Debts were not deducted, and hence the wealth concept is gross wealth.[82] Our second observation is from 1868, when the Norwegian government launched a national wealth tax assessment. Mohn (1873) presents totals for wealth and households and a tabulation of the wealth held by the top 0.27% (P99.73–100) of all households, including a detailed listing of the 15 overall largest fortunes.[83] For 1912, we use wealth tax returns from the taxation of 1913–1914 (exempting financial wealth) which are presented in tabulated form in Statistics Norway (1915b).[84] Similarly, for 1930 we use tabulated wealth distributions (number of wealth holders in wealth classes along with totals for wealth and tax units) presented in Statistics Norway (1934).

From 1948 onward, we use the tabulation of wealth holders and wealth sums in classes of net wealth published annually in the *Statistical Yearbook of Statistics Norway*. In the early 1980s the wealth statistics started being reporting for individual taxpayers instead of, as before, for households. To keep our series as consistent as possible, we attempted to convert the post-1982 observations from reflecting the individual distribution to reflect the household distribution using a listing of both types by Statistics Norway for the year of 1979.[85]

[82] We use Soltow's (1980) distributional estimates based on "males or families aged 26 and older," which is not identical to what is used for latter years and probably implies that the 1789 inequality should be adjusted upward to be more comparable.

[83] There is no information about whether it was the gross or net wealth that was taxed.

[84] We use tables of wealth holders in wealth classes in Statistics Norway (1915b: 20–21), corroborated by information about reference wealth and tax unit totals in Statistics Norway (1915a: 13f) and Kiær (1917: 22). The fact that financial assets were exempt in the Norwegian wealth taxation before 1922 is discussed in Statistics Norway (1934: 1).

[85] The *Statistical Yearbook of Norway* of 1981 tabulates the net wealth of both households (table 380: 316) and personal taxpayers (table 368: 306). In the latter case, however, we have no data on the sum of personal wealth of all wealth holders in each wealth class. We therefore insert the sums of wealth observed in household case into the individual case for the exact corresponding wealth classes. The comparison of wealth shares across these two distributions shows that the individual distribution produces shares that are 25%, 21%, 30%, 44%, and 60% higher than the household distribution for the top 10%, 5%, 1%, 0.1%, and 0.01% fractiles, respectively.

For the period since 1993, we use tabulated wealth distributions published on the Statistics Norway's Web site.[86] Somewhat ironically, the uncertainty about these data is perhaps largest because both asset coverage and valuations are highly problematic. For example, tax-assessed values of housing are heavily discounted and represent on average no more than a fifth of their true market value, with the discount being larger for more expensive dwellings (Epland and Kirkeberg, 2012). For this reason, household net tax-assessed wealth is negative for practically every Norwegian household. Furthermore, it is not obvious that the distributional trends in tax-assessed net assets are the same as those in market-valued assets if there are also trends in market-to-tax values of dwellings.

To shed some additional light on these matters, we refer to what we see as the most reliable estimate of the Norwegian net wealth distribution presented by Epland and Kirkeberg (2012). This investigation brings together a rich microdata material for 2009, carefully estimates market-valued assets and liabilities, and computes wealth inequality estimates. The study finds that the top wealth decile held about 53% and the top percentile about 21% of all net wealth (Epland and Kirkeberg, 2012, table 8). Interestingly, although the aforementioned tax-based tabulations of net wealth made no sense, the distribution of gross wealth seems less off the chart, producing for 2009 top shares of 54% for the top decile and 26% for the top percentile. For this reason, we use the time series pattern offered by the tabulated gross wealth of Statistics Norway and scale down the wealth shares to match the Epland–Kirkeberg reference level of 2009.

Altogether, the Norwegian long-run wealth concentration estimates are thus highly problematic in several respects. Looking at the overall trend in wealth concentration, however, it appears to be relatively robust to variations in some of our assumptions, and it does not deviate much from the long-run inequality trends observed in other countries.

Figure 7.14 presents the trends in Norwegian wealth concentration between 1912 and 2002, while the trends back to 1789 are shown in Figures 7.19 and 7.20. The top wealth decile is broken up into the bottom 5% (P90–95) of wealth holders, the next 4% (P95–99), the top percentile, as well as the top 0.1 percentile. Norway's top wealth holders experienced quite different trends in their relative positions over the period. As for the bottom 5% of the top decile, its share decreases between 1789 and 1912 and then jumps up sharply between 1912 and 1930 to land on a fairly stable (though slowly declining) level thereafter. The wealth share of the next 4% exhibits an inverse-U shaped pattern, increasing sometime in the nineteenth century (we do not know exactly when due

[86] See www.ssb.no/statistikkbanken (2013-10-28). For the period 1993–1999, see table "Tabell: 08575: Fordeling av skattepliktig brutto- og nettoformue for busette personar 17 år og eldre, etter talet på personar og gjennomsnitt i kroner (avslutta serie)." For the period 2000–2011, see the table "Tabell: 08532: Fordeling av skattepliktig brutto- og nettoformue for bosatte personer 17 år og eldre, etter antall personer og gjennomsnitt."

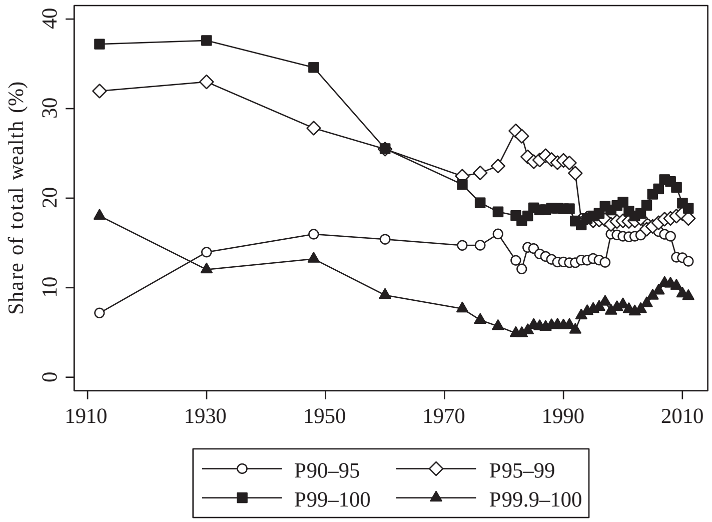

Figure 7.14 Wealth concentration in Norway, 1912–2011. *Sources: See the Appendix for details about sources and data.*

to a lack of data), peaking in 1930 and then declining almost monotonically over the rest of the twentieth century. Finally, the share of the top wealth percentile decreases significantly between 1789 and 1868, both years predating Norway's industrialization period. The share then goes up to slightly in 1912 only to start decreasing again. The most dramatic falls occur in the postwar period, with the top percentile dropping from 34.6% to 17.5% during 1948–1983 and the top 0.1 percentile going from 13.2% to 5.7% over the same period. In the 1990s, there is a rapid recovery, which may be related to the oil fortunes being built up in recent times and to the rise in world stock markets prices that also produced a rise in the top income shares over this period (Aaberge and Atkinson, 2010). The sizeable increase between 1997 and 1998 can also be explained by a change in the Norwegian tax laws specifying an increase in the assessed values of corporate stock on personal tax returns.[87]

Despite the somewhat disparate trends among Norway's top wealth holders and underlying problems with the Norwegian wealth tax-based data series, the evidence presented in Figures 7.14, 7.19, and 7.20 nonetheless corresponds relatively well with what one could expect given the economic and political history of Norway over this period. The Norwegian economy was badly hit by the economic crisis after the Napoleonic wars, and there was a shift in the political power from the great landlords and landed

[87] The tax-assessed values of stocks were raised in 1998 for stocks listed at the Oslo Stock Exchange from 75% to 100% of the market value and for nonlisted stocks from 30% to 65% of a stipulated market value.

nobility to a class of civil servants.[88] When merchant shipping expanded in the world after 1850, Norwegian shipowners and manufacturers experienced a tremendous economic boost. When looking at the average wealth of various occupations in 1868 listed in Mohn (1873: 24), the four richest groups were manufacturers (having 160 times the country average household wealth), merchants (124 times), shipowners (96 times), and civil servants (87 times). Half a century later, in 1930, a similar comparison between the wealth of top occupations groups and the country average was made (Statistics Norway, 1934, p. 6), and only shipowners had kept the distance to the rest of the population (having 119 times the country average wealth), whereas merchants (22 times) and manufacturers (19 times) had lost wealth relative to the average.

7.3.2.1.7 Sweden

In a recent study, Roine and Waldenström (2009) compiled available evidence of historical wealth distribution data for Sweden to construct a homogenous series of top wealth shares from the time of the industrial takeoff in the late nineteenth century up to the early 2000s.[89] The primary basis for these series was wealth tax statistics published in various sources, including censuses and special public investigations by tax authorities or the Ministry of Finance. The concept of wealth in these sources is typically net wealth in tax-assessed values. However, these data were complemented by estate tax material originally presented by Ohlsson et al. (2008) for a few points in time: 1873–1877, 1906–1908, 1954/55, 1967, and 2002–2003. A striking resemblance between wealth tax and estate tax data emerges regarding the patterns over the twentieth century. In addition to these sources, there is also an early observation of Swedish gross wealth inequality in 1800 using evidence collected by Soltow (1985) from a national tax assessment.[90] This observation comes from a wealth census that was carried out in 1800 and describes the gross wealth distribution for the population of males aged 20 and older.[91]

Figure 7.15 shows the evolution of top wealth shares since 1908 while Figures 7.19 and 7.20 depict the trends over the past two centuries. Looking first at the pattern over the nineteenth century, our observations indicate a relatively stable wealth distribution, which by today's standards was very unequal. As there are no observations between 1800 and 1873 (or actually 1908), there is little that can be said about the nineteenth-century

[88] Historical account taken from the section on Norway's history during "The Napoleonic Wars and the 19th Century" in *Encyclopædia Britannica Online*.

[89] Prior to the study by Roine and Waldenström (2009) and series presented in Ohlsson et al. (2008), the long-run evolution of Swedish wealth inequality was also studied by Spånt (1979, 1982).

[90] The observant reader notes that Finland experienced a similar tax in the same year. These taxes were part of the same assessments because Finland still was part of Sweden during this period. Our analysis, however, is confined to Sweden's current borders.

[91] About one-third of the males were wealth holders, and we adjust for the remaining two-thirds when computing the inequality estimates (using data in Soltow, 1985, table 5, p. 18).

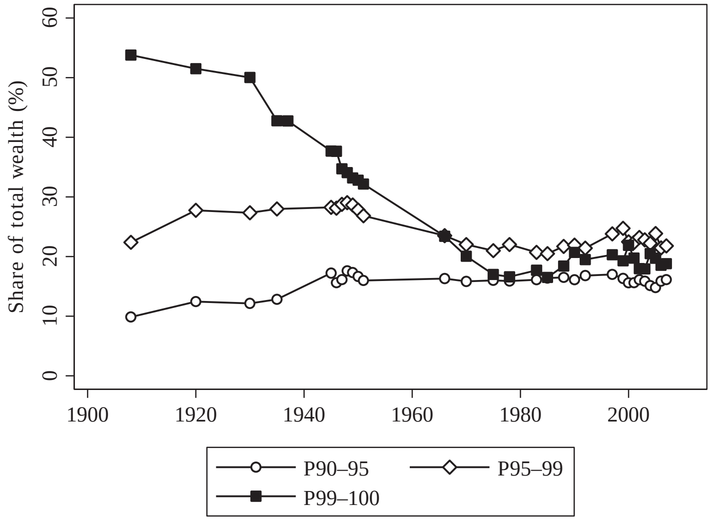

Figure 7.15 Wealth concentration in Sweden, 1908–2007. *Sources: See the Appendix for details about sources and data.*

development. However, Soltow (1989a) made attempt to do so using public reports about the amount of citizens in four specified social classes ("destitute," "poor," "moderately rich," and "rich") between 1805 and 1855 and some other sources of property distribution. His main conclusion regarding the wealth inequality trend is that overall inequality seems to have decreased over this period and all the way up to the twentieth century.[92] Soltow admits, however, that his calculations do not exclude the possibility that the top 1 or 2 wealth percentiles may have actually increased their share of total private wealth.

Over the twentieth century the picture is much clearer. We are able to use multiple sources that overlap in time, and even though there is still uncertainty about the levels over time, the trends seem relatively certain. The long-run trend in wealth concentration in Sweden over the twentieth century is that the top decile has seen its wealth share drop substantially, from around 90% in the early decades of the century, to around 53% around 1980, and then recovering slightly to a level around 60% in recent years. In the bottom half of the Swedish wealth distribution there is a considerable share of households holding negative net wealth, a fact that appears to be partly due to widespread state loans for college studies but partly also because several important assets, for example, condominiums and private and public pension savings, are not fully covered in the official wealth statistics.

[92] See Soltow (1989b, tables 1 and 2, pp. 49–53).

Looking just at this general trend is, however, incomplete if one is to really comprehend the evolution of wealth concentration. Decomposing the top decile as shown in Figure 7.15, we see that the majority of the top decile actually experiences substantial gains in wealth shares over the first half of the century. The overall drop in the top decile share is explained by such dramatic decreases in the top percentile share that this outweighs the increase for the lower groups in the top decile. In the period 1950–1980 the entire top 5 percentile experiences declines in wealth shares, but the decrease is larger for the top percentile, and after 1980 the trend is again the same for both groups but now the gains in wealth shares are somewhat larger for the top percentile.

How can we account for these developments? Focusing first on the decreases in the very top of the distribution over the first half of the century we note that most of the decrease takes place between 1930 and 1950, with the sharpest falls in the early 1930s—a time of financial turbulence and in particular the collapse of the Kreuger company empire—and just after the Second World War.[93] The period after 1945 was a time when many of the reforms discussed in the 1930s, but put on hold by the war, were expected to happen, and politically the Communist Party gained ground forcing the Social Democratic Party to move to the left.[94] In particular, the progressive taxes that had been pushed up during the war remained high and also affected wealth holdings as Sweden had a joint income and wealth tax until 1948.

The main reason for the decreasing share in the very top is, however, likely to be the increasing share for the lower part of the top decile, and this, in turn, is likely to be increased wealth accumulation among relatively well-paid individuals. After 1945 the trend of increased accumulation of wealth continues down the distribution. Over the next 30 years the most important change is the increased share of owner-occupied housing in total wealth, which increases from being 17% of all wealth to 45% in 1975 and remains around that in 1997 when adding owner-occupied apartments and houses and vacations homes (Roine and Waldenström, 2009). Even if this type of wealth was far from evenly accumulated across the distribution, it accrued to relatively large groups in the distribution causing wealth concentration to keep falling. Today about half of all households in Sweden own their homes.[95] Over the past decades fluctuations in wealth shares depend largely on movements in real estate prices and share prices. Increases in the

[93] Although Sweden was not as affected by the Great Depression as many other countries, the so-called Kreuger Crash in 1932, the bankruptcy of Ivar Kruger's industrial empire, led to major loses of wealth in Sweden.

[94] See, for example, Steinmo (1993).

[95] A specific feature of the Swedish wealth distribution in recent decades is the large share of negative net wealth holders, almost a third of the adult population. There are several factors explaining this characteristic, including widespread state loans for higher education and an underreporting of important assets such as condominiums and private and public insurance savings (see further, e.g., Cowell, 2013; Jansson and Johansson, 2000).

former have a tendency to push up the share of the upper half of the distribution at the expense of the very top causing inequality to go down, whereas increases in share prices make the very top share larger due to share ownership still being very concentrated causing inequality to increase.[96] In the year 1997 the top percentile in the wealth distribution owns 62% of all privately held shares, and the top 5% holds 90%.[97]

7.3.2.1.8 Switzerland

Data on the Swiss wealth concentration are based on wealth tax returns compiled by tax authorities for disparate years between 1913 and 1997 and analyzed by Dell et al. (2007). The Swiss wealth tax was levied on a highly irregular basis, and the authors have therefore spliced several different point estimates from local as well as federal estimates to get a roughly continuous series for the whole country.

Figure 7.16 depicts top wealth shares within the Swiss top wealth decile over the twentieth century. In stark contrast to the other countries surveyed in this study, wealth concentration in Switzerland appears to have been basically constant throughout the period. The wealth shares at the top of the distribution have decreased, but the movements are small compared to all other countries studied.[98] This does not only refer to the

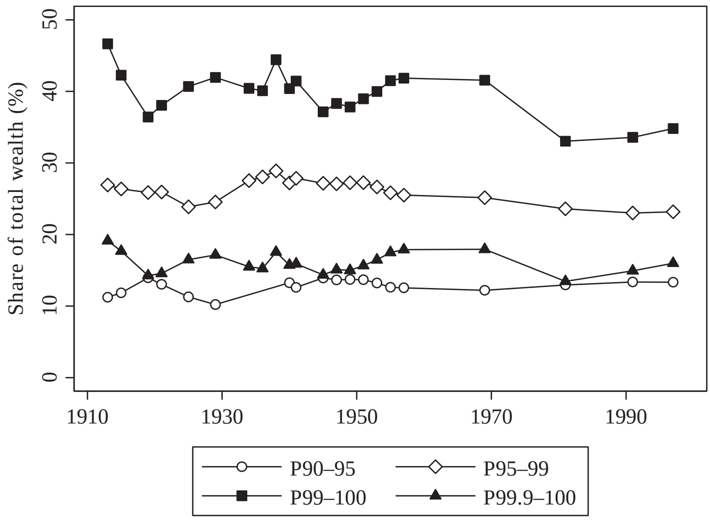

Figure 7.16 Wealth concentration in Switzerland, 1913–1996. *Sources: See the Appendix for details about sources and data.*

96 In their study of the role of capital gains Roine and Waldenström (2012) discussed some aggregate asset developments in Sweden since the 1980s. This indicates that the surge in financial asset values has been much larger than overall real estate values.

97 Jansson and Johansson (2000, pp. 38–40).

98 A simple trend regression yields small but significant negative coefficients.

top decile vis-à-vis the rest of the population, but perhaps most strikingly also to the concentration of wealth within the top. The highest percentile and the top 0.1 percentile have not gained or lost considerably compared the bottom 9% of the top decile, except for some short-run fluctuations.

Accounting for this long-term stability of Swiss wealth inequality is not easy. One possibility is the country's relatively low level of wealth taxation, which suggests a low rate of redistribution and small effects on the incentives to accumulate new wealth. The twentieth-century experience with high taxes on wealth and inheritance appears to have contributed to the low top income and wealth shares in a number of countries, as we discuss elsewhere in this chapter. However, the fact that Switzerland stayed out of both world wars cannot alone account for the stable wealth distribution; Sweden also escaped both world wars does not share the Swiss pattern. In any case, the Swiss top wealth share series seriously questions the hypothesis that significant economic development always lead to a lower level of wealth inequality over time for reasons of either redistribution or simply relatively quicker accumulation of household wealth among the middle class.

7.3.2.1.9 United Kingdom

There are a number of estimates of the wealth concentration in the United Kingdom dating back to the country's industrialization in the middle of the eighteenth century. Prior to 1900, data on wealth distribution are less homogenous and emanate from scattered samples of probate records and occasional tax assessments (see Lindert, 1986, 2000; Soltow, 1981a–c). It was not until the Inland Revenue Statistics started publishing compilations of estate tax returns after the First World War that the series are fully reliable (see Atkinson and Harrison, 1978; Atkinson et al., 1989).[99] Still there are some notable breaks in the series. For example, the geographical unit of analysis changes over time, with pre-Second World War numbers almost always being England and Wales, whereas the post-war ones reflect all of the United Kingdom. Data in Atkinson et al. (1989, table 1) show, however, that the differences between these entities are fairly small. More important, the tax authority changed some of its methods to compute top wealth shares leading to large breaks in the time series around the Second World War, in 1960, and around 1980. Among the important changes were lowered age cutoffs, different treatment of life insurance policies and valuation of consumer durables, and also more careful collection routines of the tax authorities.[100]

[99] The Inland Revenue actually started publishing estate tax data in 1896, but it was not divided by age, which precludes estimation of the wealth distribution using the mortality multiplier method. Note also that the mortality multipliers used by the Inland Revenue were based on age only up until 1923 when they were based on both age and sex.

[100] See further Atkinson and Harrison (1978, Chapter 6) and Atkinson et al. (1989) for an extensive discussion of these breaks.

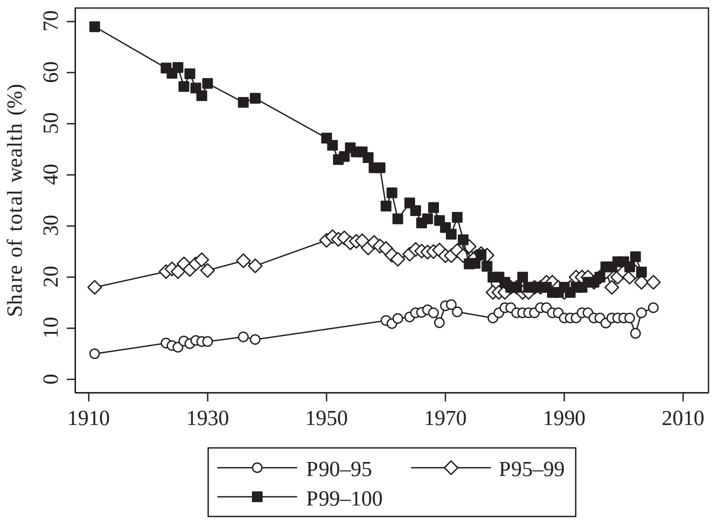

Figure 7.17 Wealth concentration in the United Kingdom, 1911–2005. *Notes and sources: England and Wales up to 1960, Great Britain thereafter. See the Appendix for details about sources and data.*

When England industrialized in the second half of the eighteenth century, the buildup of personal wealth also changed. Looking at the overall wealth concentration since 1911 in Figure 7.17 and Figures 7.19 and 7.20 for the period back to 1740 it is evident that there is great heterogeneity within the top 5 percentiles of the distribution.[101] Apparently, wealth concentration at the very top increased, while, by contrast, the wealth share of the next four percentiles saw its wealth share decline during the same period. Using supplementary evidence on personal wealth, Lindert (1986, 2000) shows that wealth gaps were indeed increasing in the absolute top during the nineteenth century, with large landlords and merchants on the winning side. At the same time, Lindert points out that the middle-class (in this case those between the 60th and 95th wealth percentiles) were also building up a stock of personal wealth, and this is probably what is causing the drop in the share of the next 4% in Figure 7.17.

After the First World War, the pattern was the reversed. While the top percentile wealth share dropped dramatically from almost 70% of total wealth in 1913 to less than 20% in 1980, the share of the next four percentiles remained stable and even gained relative to the rest of the population. Atkinson et al. (1989a,b) argued that this development was driven by several factors, but that the evolution of share prices, the ratio of consumer durables, and owner-occupied housing (so-called popular wealth) to the value of other wealth were the most important ones. According to the most recent statistics from the Inland Revenue, the top percentile's share increased by about one-third between 1990 and 2003, but this increase has not yet been explained by researchers.

[101] The reader should keep in mind that this figure, and several others in this study, contains spliced series coming from different sources, which naturally may impede the degree of homogeneity over time.

Possibly, it reflects the surge in share prices following the financial market deregulation of the 1980s as the financial wealth are most concentrated to the absolute top of the wealth distribution.[102]

7.3.2.1.10 United States

The historical development of wealth concentration in the United States has been extensively studied by economists and historians, and estimates are available back to the time of the American Revolution. In this study, we combine different pieces of evidence to create a long and relatively homogenous series of wealth inequality. As acknowledged by previous scholars, there are several problems concerning consistency over time, which has spurred some controversy over both definitions of data and conclusions drawn. For these reasons, we compare some of the complementary series using different sources and wealth definitions to get an idea of how large these problems may be.

Our focus is the evolution of U.S. top wealth shares from colonial times to the present day. The main series refer to the distribution of net wealth among households, and for these we show wealth shares of fractiles within the entire top decile. Still the figure also presents the top percentile shares in the adult distribution for which there are rich, annual data available over especially the twentieth century. The top wealth shares for the household distribution prior to 1900 are few but important as they determine our notion of the link between industrialization and inequality in the United States. There has been some disagreement over the pre-1900 inequality trends, with some scholars arguing that preindustrial U.S. inequality was high and that inequality was basically stable during the nineteenth century (e.g., Soltow, 1971, 1989), whereas others have argued that U.S. wealth inequality increased markedly between the Revolution and the latter half of the nineteenth century (e.g., Lindert, 2000; Williamson and Lindert, 1980a,b). In this chapter, we use the observations reported by Lindert (2000). These are essentially the estimates from the seminal contributions of Alice Hanson Jones (see, e.g., Jones, 1970, 1972, 1980), which included adjustments to add unfree men and women to the reference total population.

The available evidence for the twentieth century is more unified, with long-run series being based on a combination of estate tax returns and survey data (see, e.g., Lampman, 1962; Smith, 1984; Wolff and Marley, 1989). We use the compilation of those sources by Wolff (1996) for the period up to 1958, and for the period thereafter we use the survey data from the SCF and its forerunners presented by Kennickell (2009, 2011).[103] For the

[102] This is a stylized fact that is true for many developed countries (see, e.g., the overview of "stylized facts" in Davies and Shorrocks, 2000).

[103] Wolff (2012) also used SCF data to compute a series of U.S. wealth concentration since 1962, but his series deviates from those of Kennickell (2009, 2011). Wolff explained this with his exclusion of consumer durables from the wealth concept, motivated by the fact that these are neither easily marketable nor included in the national accounts-based definition of household wealth. In this chapter, we use Kennickell's series as they match the earlier evidence from U.S. surveys and estates, which consistently included consumer durables among household assets.

adult population, our preferred estimate for 1774 is from Lindert (2000).[104] For the nineteenth century, there are unfortunately only gross wealth estimates for the adult population (see Lindert, 2000), and therefore the next evidence is for the years 1916–2000 provided by Kopczuk and Saez (2004) using mortality multiplier-adjusted federal estate tax returns.

Figure 7.18 shows the results for the period since 1916 and Figures 7.19 and 7.20 for the period back to 1774. Beginning with the two top percentile series, they appear to be inversely U-shaped over the period, with wealth shares increasing slowly between the late eighteenth and the mid-nineteenth centuries but then much faster between 1860 and 1929, when they more than doubled. The long-run pattern of the lower 9% of the top wealth decile, however, exhibits stable or even decreasing shares of total wealth (although based on rather few observations). This inequality increase in the absolute top coincides with the industrialization era in the United States around the mid-nineteenth century. Although the few pre-First World War estimates are uncertain, their basic message is supported by researchers using other sources. For example, Rosenbloom and Stutes (2008) also found in their cross-sectional individual analysis of the 1870 census that regions with a relatively high share of its workforce in manufacturing had relatively more unequal wealth distributions (see also Moehling and Steckel, 2001). Another anecdotal piece of evidence in support for a linkage between industrialization and increased

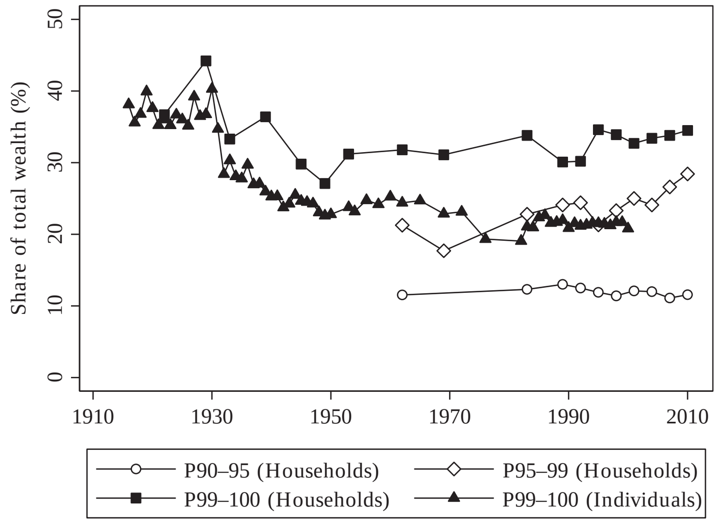

Figure 7.18 Wealth concentration in the United States, 1916–2010. *Sources: "Households" and "Individuals" refer to different wealth holder populations. See the Appendix for details about sources and data.*

[104] As Lindert (2000, footnote to table 3) noted, this estimate deviates slightly from that of Shammas (1993) because the latter also includes the wealth of British residents living in the U.S. colonies.

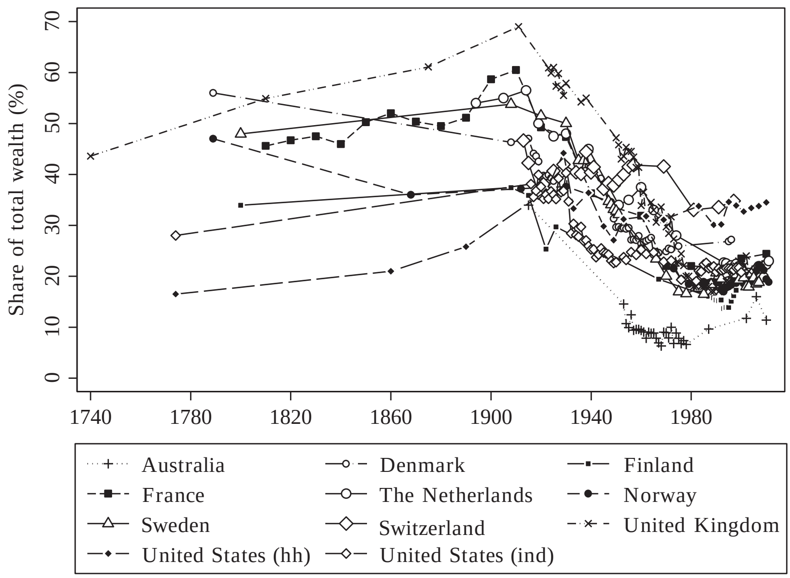

Figure 7.19 Wealth concentration in 10 countries, 1740–2011. *Sources: Graph shows top percentile (P99–100) wealth shares for all countries. See the Appendix for details about sources and data.*

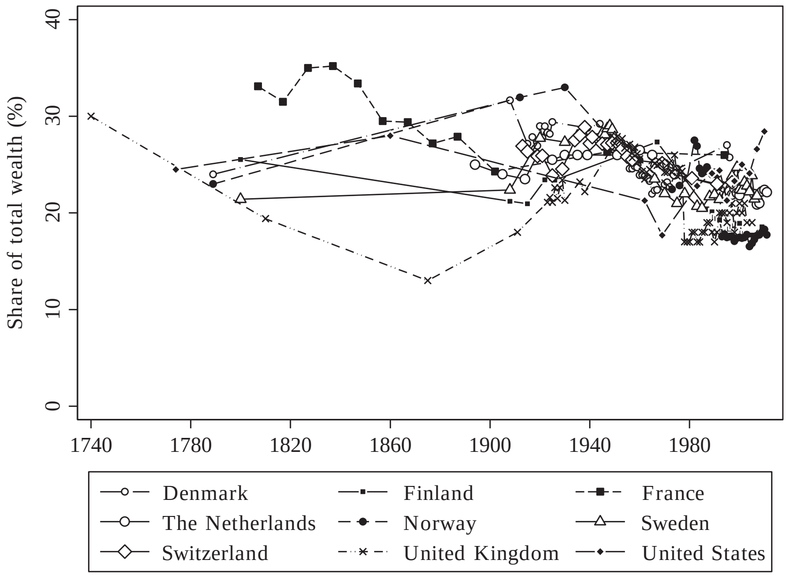

Figure 7.20 Wealth share of the "next four percentiles" (P95–99) in nine countries. *Sources: See the Appendix for details about sources and data.*

inequality is that the 15 richest Americans in 1915 were industrialists from the oil, steel, and railroad industries and their financiers from the financial sector.[105]

The twentieth-century development in Figure 7.18 suggests that wealth concentration peaked just before the Great Depression when the financial holdings of the rich were highly valued on the markets. In the depression years, however, top wealth shares plummeted as stocks lost almost two-thirds of their real values. Kopczuk and Saez (2004) showed that corporate equity represented more than half of the net wealth of the top 0.1 percentile wealth holders in 1929. Another contributing factor to wealth compression was surely the redistributive policies in the New Deal. After the Second World War, the top percentile wealth shares remained low until the 1980s, when the top household percentile's share increased significantly, peaking around mid–late 1990s and then to decline somewhat in 2001. By contrast, the top adult percentile wealth share from the estate series in Kopczuk and Saez (2004) exhibits no such increase, which is surprising given that this period also saw a well-documented surge in U.S. top incomes (Piketty and Saez, 2003). Whether the difference in trends between the household and adult distributions reflects inconsistencies in the data or some deeper dissimilarity in the relation between income and wealth accumulation remains to be examined by future research.

7.3.2.2 Cross-Country Trends in Long-Run Wealth Concentration

Earlier we presented a compilation of recent as well as some new evidence on the long-run evolution of wealth inequality in 10 Western countries: Australia, Denmark, Finland, France, the Netherlands, Norway, Sweden, Switzerland, the United Kingdom, and the United States. As we have already pointed out, the quality of these data differs substantially across countries and in some cases even within single countries over time. Like many previous researchers, we have attempted to adjust the series to make them consistent and comparable over time, but naturally some problems remain. Still, we have tried to classify the series (countries) into different quality levels to run the analysis on more homogenous subsets, and those exercises do not produce any notably different conclusions with respect to the long-run trends in wealth concentration.[106]

Figure 7.19 shows the top wealth percentile in each of these countries for various periods during 1740–2011. Furthermore, Figure 7.20 contrasts the trends in the top

[105] See the listing of the top 20 fortunes in 1915 by De Long (1996).

[106] For example, there are some countries for which the data are quite composite in terms of data sources, coverage of assets, and so on (e.g., Australia, the Netherlands, and Norway), but removing them from the analysis does not change the overall pictures reported. It is more difficult to adjust further for qualitative breaks over time within countries, and both the Norwegian and the U.K. series during the twentieth century contain some important break points in data definitions and quality. However, even if we had acted differently when connecting the segments separated by break points for these countries, we would still have observed a marked long-run trend toward wealth compression in both these countries.

percentile against those in the next four percentiles (P95–99). Even though great caution should be taken when comparing these series, we still believe that some conclusions can be drawn about the developments of wealth inequality in these countries over the past 200 years.

Two broad conclusions can be drawn from the series as summarized in Table 7.5. First, the evidence does not unambiguously support the idea that wealth inequality increases in the early stages of industrialization. Looking at the development of the wealth share of the top percentile among the countries analyzed here, the Nordic observations indicate fairly stable inequality levels over the initial stages of industrialization (i.e., in the late nineteenth century). The U.K. series (England and Wales) exhibits clearly increasing wealth shares for the top percentile in the period of the two industrial revolutions (1740–1911), as do the U.S. and French series over the nineteenth century. For the Netherlands, the evidence is less certain, indicating either a flat or a slightly increasing nineteenth-century trend (van Zanden, 1998b; Vermaas et al., 1998). Overall this suggests that going from a rural to an industrial society, with entirely new stocks and types of wealth being created, may, but does not necessarily, give rise to a large increase in wealth concentration. It also suggests that—just as in the case with income inequality series—carefully studying smaller fractiles of the distribution is necessary to get a more complete picture of the development.

Second, although the series do not suggest a clear common pattern over the nineteenth century when industrialization took place (first in the United Kingdom, later in the United States, France, and the Netherlands and toward the end of the century in the Nordic countries), the development over the twentieth century seems more uniform. Top wealth shares have decreased sharply in just about all countries studied in this

Table 7.5 Wealth inequality trends across eras, 10 Western countries

	From industrial takeoff to the First World War		From the First World War to 2000	
	P99–100 (Top 1%)	**P95–99**	**P99–100 (Top 1%)**	**P95–99**
Australia	–	–	Decrease	–
Denmark	Decrease	Flat	Decrease	Flat
Finland	Flat	Flat	Decrease	Flat
France	Increase	Flat	Decrease	Flat
Netherlands	Flat?	Flat?	Decrease	Flat
Norway	Flat	Increase	Decrease	Decrease
Sweden	Flat	Flat	Decrease	Flat
Switzerland	–	–	Flat	Flat
United Kingdom	Increase	Decrease	Decrease	Flat
United States	Increase	Flat?	Flat/Decrease	Flat?

Notes: The nineteenth century inequality trends for the Netherlands are not observed directly, but various sources indicate that there was little increase in inequality during the Dutch industrialization since the middle of the century (see Section 7.3.2.1.5 on Netherlands).

chapter with the exception of Switzerland and possibly also the United States, where the fall has been small, but where the level also was not as high historically as in most European countries. The magnitude of the decrease seems to be that the top percentile lost its share of total wealth by about a factor of 2 on average (from around 40–50% in the beginning of the century to around 20–25% today). It also seems that the lowest point in most countries was around 1980 and that the top percentile wealth share has increased in most countries after that. Interestingly, the wealth share of the next 4 percentiles (P95–99) does not display any strong indications of a decreasing trend. Indeed, there are periods of notable equalization also affecting this wealth fractile, but over the course of the entire century Table 7.5 clearly highlights that this moderately rich group sustained its share of total wealth. This said, there were likely replacements between economic groups and types of actors over time (as also suggested by the country case studies earlier), indicating that the cross-sectional evidence also needs to be complemented by evidence about mobility within the distribution.[107]

Similar to the analysis of long-run top income shares, we can make a closer examination of the evolution of wealth concentration expressed in terms of wealth shares of the very top groups within the larger top group. This approach results in a slightly different measure of inequality as it looks at the inequality *within the top* of the wealth distribution and not overall inequality. As some theories are especially concerned with widening gap among the rich, investigating inequality among the wealthy can make sense.[108] Furthermore, estimating the reference total wealth held by the full population is associated with potential error. Applying the shares-within-shares measure by dividing the top wealth percentile by the top wealth decile, P99–100/P90–100, we land at a ratio that effectively eliminates the reference total.[109]

Figure 7.21 depicts the evolution of wealth concentration using the shares-within-shares estimate. Two countries drop of out the picture (Australia and the Netherlands) due to a lack of long-run data on the top wealth decile, and there are also fewer observations for the countries still in the comparison. Still the patterns confirm our previous findings. The equalization of the twentieth century is clearly observed except for in the Swiss (and possibly the United States) cases. As for the nineteenth-century development, the picture gets a bit blurry, largely due to a lack of data. The Nordic countries exhibit similar inequality trends as given earlier: rising in Finland and Sweden but falling in Denmark and

[107] See, for example, the study by Edlund and Kopczuk (2009), which found that the share of women in the U.S. wealth top fluctuated and that this indicates changes in the relative importance of dynastic versus entrepreneurial wealth.

[108] There are several theories that in various forms imply an advantage for the very top of the distribution, for example, the superstar model of Rosen (1981). See Section 7.4 in this chapter for more.

[109] Similar to the result found for top incomes, for top wealth percentile P99–100 $= W_{\mathrm{Top1}}/W_{\mathrm{All}}$ (with $W=$ Wealth) and top wealth decile P90–100 $= W_{\mathrm{Top10}}/W_{\mathrm{All}}$, we get P99–100/P90–100 $= (W_{\mathrm{Top1}}/W_{\mathrm{All}})/(W_{\mathrm{Top10}}/W_{\mathrm{All}}) = W_{\mathrm{Top1}}/W_{\mathrm{Top10}}$.

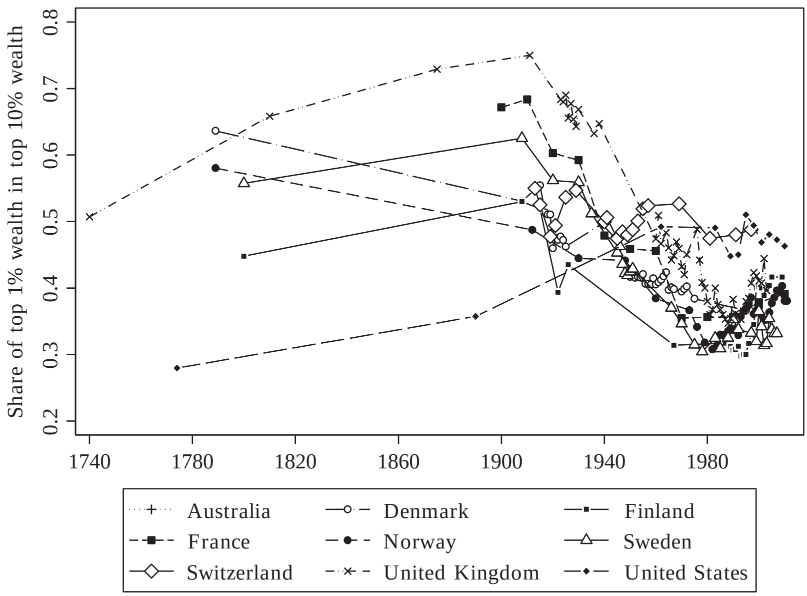

Figure 7.21 Shares-within-shares (P99–100/P90–100), nine countries, 1740–2011. *Notes and sources: The shares-within-shares measure is computed by dividing the top wealth percentile (P99–100) by the top wealth decile (P90–100). The resulting measure eliminates the (often separately constructed) reference wealth total from the equation and thereby offers a robustness check of the overall trends. However, the measure also provides a metric of the wealth inequality within the top. See the Appendix for details about sources and data.*

Norway. France also looks quite similar as when the actual top shares are examined. Overall this implies that, notwithstanding the variations, most of the long-run wealth inequality trends are driven not by the changes of the very top in relation to those just below, but by the change of the entire wealth top in relation to the rest of the population.

7.3.3 The Composition of Wealth

Up until this point, the analysis has dealt primarily with the distribution of total net wealth. However, the composition of wealth across asset types (and debts) also matters to wealth inequality trends just as the composition of labor and capital incomes was shown in the previous sections to matter for the trends in income inequality. Unfortunately, when it comes to the historical evidence about wealth composition across the wealth distribution, we know almost nothing. As for the aggregate composition of private wealth, we know more thanks to both old and more recent evidence.[110] These data show that agricultural assets practically vanished over the course of the two past centuries. Private housing, by contrast, increased its share of total national wealth from one-fifth in

[110] See Chapter 15 by Thomas Piketty and Gabriel Zucman in this Handbook, and the references therein.

the nineteenth and early twentieth centuries to three-fifths today, largely corroborating the previously documented postwar rise in "popular wealth," dwellings, and consumer goods, among the broad layers of the population.[111]

Among the few studies that contain evidence on the wealth composition across different groups of wealth holders, less than a handful offer some kind of historical evidence. One stylized fact that seems to hold regardless of time period, however, is that financial assets in general, and corporate securities in particular, are consistently more important in the portfolios of the rich than of the rest of the population. For example, Kennickell (2009) and Cowell (2013) showed that the share of basically financial assets in the top wealth decile was higher than for the population as a whole (except for savings, which are more important for middle-class households between the median and the 90th wealth percentile). Kopczuk and Saez (2004) showed that the share of corporate stock in the portfolios of top 0.5 percentile U.S. wealth holders (using estate tax data) was between 40% and 60% during 1916–2000 and that this was strictly higher than for the whole population (using national wealth estimates).[112]

In their study of trends in French wealth concentration, Piketty et al. (2006) documented similar patterns for France over the nineteenth century. Specifically, they looked at the share of personal estate, which includes all nonreal assets, in total assets and found that its share was higher among the richest in the top 0.1 percentile than among the intermediately rich in the rest of the top wealth decile. It was, however, also very high among the broad layers population (the bottom nine wealth deciles). The authors explained this U-shaped pattern by the fact "that real estate is a middle class asset: the poor are too poor to own land or buildings; what little they have is in furniture, cash, or other moveables. In contrast, the rich hold most of their wealth in stocks and bonds" (p. 244).

Altogether, the historical evidence on the composition of wealth across the distribution suggests that housing wealth is more important in the portfolios of the broader population, whereas financial assets dominate the portfolios of the rich. Furthermore, the new long-run evidence on aggregate wealth of the private sector shows that housing wealth became more important in total national wealth after the Second World War, and this fact probably explains a large part of the documented wealth compression witnessed in many Western economies during this period.

7.3.4 Concluding Discussion: What Do the Long-Run Wealth Inequality Trends Tell Us?

What then can we say about the relationship between wealth concentration and economic development based on the data reported in this chapter? Can one talk about

[111] See Piketty and Zucman (2013, appendix table A18) and, for an early observation of the postwar rise in popular wealth, Atkinson and Harrison (1978).

[112] The relative difference has varied notably from at least double as high (from the 1930s to the 1980s) to less than 10% (in year 2000).

common patterns across countries over the development path or are there mainly a set of disparate country-specific histories? Have initial wealth inequalities been amplified or reduced? Taking stock of the series shown here suggests that industrialization was not unambiguously accompanied by increasing wealth inequality. Although inequality did indeed increase in the United Kingdom, the United States, and France, it probably did not change much in the Netherlands, Finland, Norway, and Sweden and even decreased a little in Denmark. Noting that the countries in the first group all were large, central economies that were early to industrialize, whereas the Netherlands and the Nordic countries were smaller economies that industrialized later, may hold clues to the different experiences but it does not change the fact that industrialization did not increase wealth concentration everywhere.

The experience over the twentieth century appears to be much more homogenous. As the countries continued to develop, top wealth concentration also dropped substantially. Looking at the details of the pattern by which different fractiles gain wealth shares indicates that this drop was due to a gradual process of wealth spreading in the population—confirming the role of increasing "popular wealth" identified in, for example, Atkinson and Harrison (1978). In a sense this pattern is consistent with a Kuznets-type process in which inequality eventually decreases as the whole economy becomes developed. However, this development was probably not driven by the kind of process suggested by Kuznets, but mainly by other factors such as political interventions and exogenous shocks. Piketty et al. (2006) argued that it primarily was adverse shocks to top wealth during the period 1914–1945 related with wartime shocks that decreased French wealth inequality and that the subsequent introduction of redistributive policies that prevented them from recovering. Piketty (2011) and Piketty and Zucman (2014) emphasized that the wartime shocks to capital were only to a limited extent the consequence of outright destructions of factories, constructions, or infrastructure, instead pointing at the importance of capital taxation and regulation. A similar explanation is given by Kopczuk and Saez (2004) for the United States.[113] This reasoning has been supported by the fact that Switzerland, which did not take part in either of the wars, exhibits rather stable top wealth shares. Our data on Sweden, which also did not participate in any of the world wars, shows an example of equalization taking place without decreases in top wealth shares driven by exogenous shocks. Even though events such as the Kreuger Crash in 1932 hit top wealth holders in Sweden as well, this does not explain the entire drop. Policy may, at least in Sweden, have played a more active role in equalizing wealth than merely holding back the creation of new fortunes after the Second World War. Suggesting that rising taxation and increased redistribution have been important for the decline of wealth inequality is also consistent with the largest drops taking place in the Scandinavian countries as well as with the smaller decline in Switzerland, with its smaller government.

[113] Scheve and Stasavage (2010, 2012) showed the increased taxation of capital and high incomes was indeed political developments associated with wartime events.

Altogether the data presented here suggest that (a) there was a mixed impact of industrialization and (b) in later stages, after countries became industrial, significant wealth holding spread to wider groups, bringing wealth inequality down. In terms of the often discussed inverse U-shape over the path of development, the first upward part does not seem to be present everywhere, whereas the later stage decrease in inequality does fit all countries we have studied. An important addition to this characterization is that this analogy misses an important point that is present in the series. Whereas the inverse U-shape suggests that the distribution of wealth starts at some level in a nonindustrialized society, then rises, and later returns to the same level of inequality, all our series indicate that development has unambiguously lowered wealth concentration. The proper characterization of wealth inequality over the path of development hence seems to be that, so far, it follows an inverse J-shape with wealth being more equally distributed today than before industrialization started. The direction of future inequality remains to be seen.

7.4. DETERMINANTS OF LONG-RUN TRENDS IN INEQUALITY

How can we understand the trends in the distribution of income and wealth outlined in the previous sections? Do the series systematically relate to other developments in society that have been suggested to influence inequality, and if so, in what ways? How can we connect the observed long-run trends to existing theories about inequality? These are questions that we address in this section.

A number of facts that are likely to be important have already been noted in the previous sections along with the characterization of the trends. A first point is that an understanding of the development involves both wage and capital income, and thereby the dynamics are at least in part jointly determined by the distributions of income and wealth. For example, the drop in top shares over the first half of the twentieth century was largely a result of decreased capital incomes in the top, which in turn was largely driven by decreasing wealth shares in this group. High marginal tax rates in the decades after World War II made recovery difficult and caused top shares to decrease even further. We will explicitly look at these explanations in Section 7.4.2.

When it comes to the increase in top income shares since around 1980 this seems to be primarily related to increasing top wages, especially in the United States, but increasing capital incomes in the top also play a role in many countries (such as Sweden), especially after around 1990.[114] The increased earnings dispersion is often attributed to aspects of globalization and technological change. Many have pointed to technological change being skill-biased, usually equated with an increasing education premium, as a possible reason for increasing wage differences. But skill-biased technological change does not

[114] See Chapter 8 for a detailed view of inequality developments since 1970, where the increasing role of capital income in the top is also noted.

automatically lead to increasing wages of the "skilled." The impact on wage dispersion depends on several things, such as the structure of the production function and the change in the supply of educated workers.[115] Unless the dynamics in "the race" between technology and education are made explicit, skill-biased technological change can be consistent with any number of "education premium" profiles over time.[116] Furthermore, even if one were to focus on a version of the model where the increased demand for skills actually lead to increasing wage dispersion, it is difficult to see how this would explain that so much of the increase is concentrated in a relatively small top group. To account for such increases within the top it seems necessary to find something that distinguishes a small fraction of the "skilled" from others who are equally educated (at least in terms of observables). Examples of such explanations include a number of so-called super-star theories, where technology and globalization disproportionately have benefitted those who—for various reasons—are most in demand in their field. Others have emphasized the possible role of changing norms. Some of the theories that have been put forth to understand the rise in top earnings over the past decades will be the subject of Section 7.4.3.

Finally, in Section 7.4.4 we present an overview of some recent econometric evidence on correlations over the long run. These regressions do not constitute tests of any particular theory but nevertheless give some insights as to what relationships seem to be present in the data.

We will begin the current section, however, with offering a broad overview of major events and societal trends that have been suggested to influence the distribution of income and how these correspond to our long-run pattern of top income shares. We will also discuss what the new series imply for our understanding of the Kuznets curve. Our conclusion is that, even if some broad trends are consistent with proposed broad explanations, we cannot distinguish between alternatives just based on looking at how inequality has developed. Instead we need to look more carefully at developments in different parts of the distribution, at the source of income, and in particular on how income and wealth relate to each other and also relate all these aspects to predictions from theory.

[115] A technology that makes skilled workers more productive *decreases* the wage per unit of skill but *increases* relative demand of skilled workers. This alone can drive the wage of skilled workers both up and down. In addition the response (and the speed of it) in the supply of skills will determine the movement in relative wages of the skilled and unskilled.

[116] See Atkinson (2008a) for an explanation of the textbook model and a thorough discussion of other aspects that need to be considered. On the importance of the dynamics, he noted, "Surprisingly, the dynamics of wage differentials seem to have been little discussed in the literature of recent years. Yet, there is good historical precedent. In 1959, Arrow and Capron published a paper on dynamic shortage and price rises, with an application to the then shortage of engineers and scientists—an application that seems of contemporary relevance" (Atkinson, 2008a, p. 10).

7.4.1 A First Look at Inequality Trends, Structural Changes, and Shocks

What is the relationship between top income shares and the broad societal changes that have been hypothesized as affecting distributional outcomes? How well do the basic patterns match? Next we will discuss inequality developments in relation to trends in globalization, technological breakthroughs that have altered production in society (often referred to as general purpose technologies), inequality in relation to wars and shocks to the economy, and finally, inequality in relation to economic growth.

Globalization has been suggested to affect inequality in a number of ways. Classical trade theory in the spirit of Eli F. Heckscher and Bertil Ohlin has a clear prediction for inequality: In countries relatively abundant in skilled labor and capital (developed countries), inequality increases, whereas the reverse is true in (low-skill) labor abundant developing countries, where instead inequality goes down.[117] Modern trade theory is less clear-cut. Although some effects, like the gains to the largest most productive firms (in models like Melitz, 2003; Melitz and Ottaviano, 2008) seem to suggest increasing returns in the top, others have pointed to globalization being most beneficial for the top *and* the bottom, while hurting individuals in the middle of the distribution (e.g., Leamer, 2007; Venables, 2008). Yet others have pointed to the possibilities of efficiency gains from globalization being so large that these effects can compensate losses from, for instance, offshoring (Grossman and Rossi-Hansberg, 2008).

Looking at the inequality developments over what has been labeled as different waves of globalization, the first wave (1870–1914) coincides with flat or increasing inequality, followed by decreasing inequality in the antiglobalization period (1914–1950).[118] As most countries for which we have data belong to the relatively skill and capital abundant, this could be seen as in line with theoretical predictions.[119] The second wave of globalization is harder to reconcile. In 1950–1980 measures of globalization (trade flows/GDP, foreign capital as share of GDP) clearly increase while inequality clearly decreases. There are some obvious counterarguments to this. First, one may argue that the level of globalization was not yet sufficiently high for the predicted effects to show, but second,

[117] These effects remain across the many versions of Heckscher–Ohlin type models. See, for example, Wood (1994) for a summary of the basic arguments.

[118] Clearly the definition of what constitutes a period of globalization is somewhat arbitrary. Most authors seem to agree that there was a globalization period before 1914, though there is disagreement on when it started. It is also commonly accepted that the period between 1914 and 1945 was an era of increased protectionism characterized by drastically smaller economic flows between countries. This was gradually reversed after 1945. To emphasize the difference between the intensity in globalization some refer to the period between 1945 and 1980 as a second wave (with gradually increasing globalization) as different from the period after 1980, when globalization really took off. See Lindert and Williamson (2003) and World Bank (2002) for details on different views on periods of globalization.

[119] Note, however, the important point made by Williamson (2006) that the effects depend on the *relative* abundance more than on a country being rich or poor. Inequality developed in opposite directions in the periphery depending on the labor abundance/scarcity.

one could also point out that this was a period when most of capital flows and trade was between developed countries.[120] If one places the start of the recent era of increased globalization around 1980 instead, the pattern is more promising as the period thereafter is characterized by increasing inequality. A problem is, of course, that during this period inequality has been increasing in developing countries too, counter to the basic Heckscher–Ohlin model.[121]

What about innovations leading to skill-biased technological change? Such shifts play a major role in the large literature trying to explain recent changes in the earnings distribution. Models building on Tinbergen's (1974, 1975) seminal work suggest that the returns to skills are determined by a race between education (creating a supply of skilled workers) and technology (implicitly technology that complements skills). Technological change pushes in the direction of increased wage differences between skilled and unskilled, unless education keeps up and creates an increased supply of skilled workers that keeps down the wage differences. Goldin and Katz (2008) bring much of this work together in a unified framework. Acemoglu and Autor (2012, 2013) give overviews of much of this literature and also claim that these models have been empirically successful in accounting for recent wage dispersion mainly based on U.S. data (e.g., Autor et al., 2006; Katz and Autor, 1999; Katz and Murphy, 1992).

But, as already pointed out, skill-biased technological change does not automatically result in increased wage differences (and even less automatically in increased inequality). Even in the simplest model the outcome depends on the speed of the supply response, and depending on the relative shifts in demand and supply of skills, the resulting wage differential between the groups can look different. In particular, this means that even if countries are affected by the same technological change, the impact on the wage distribution may look very different depending on how responsive countries are in terms of improving the skills in the population. See Atkinson (2008a,b) for more details and additional caveats to the simple model.[122]

Another historical aspect of technological change, noted, for example, by Caselli (1999), is that it has not always been skill biased. Indeed, some of the technological advances in the late eighteenth and early nineteenth centuries replaced, rather than complemented, skilled artisans and increased the productivity of low-skilled workers (Mokyr, 1990). Later advances, such as the electrification of industry in the late nineteenth century, seem to have been more skill biased. Firms using more electricity paid workers higher wages, workers were more educated, and these firms had higher capital ratios (Goldin and Katz, 1998). But soon thereafter the introduction of the assembly line at

[120] This observation is indeed the basis for much of the developments in trade theory since the late 1970s.
[121] See Freeman (2011) for more on the relationship between globalization and inequality.
[122] Also see Atkinson (1999) for an early critique of overly simplified versions of skill-biased explanations.

Ford's Highland Park facility in 1913 seems to be another technology shift that increased the relative productivity of unskilled workers.

If (and this is a potentially big "if") one accepts that technology shifts that are skill biased always lead to increasing inequality, and vice versa for deskilling technological change, then the basic historical pattern looks promising. The skill-biased electrification coincides with increasing or at least unchanged inequality, the introduction of the assembly line coincides with the start of the long decline in inequality, and the recent ICT revolution starting in the 1970s and 1980s also happens at the time when inequality turns up again. But obviously this does not mean that we can conclude anything about the relationships. In addition to the many assumptions needed, there are some other factors that are potentially problematic for a simplistic story of technological change driving common patterns of inequality. One is that technological changes do not take place everywhere at the same time. Comin and Mestieri (2013) give an overview of technology adoption lags and show that these can be very long. Second, given what we know about the role of capital in explaining the declining inequality in the first half of the twentieth century this seems separate from an explanation emphasizing returns to skills and an increasing earnings dispersion. Third, and perhaps most important, an explanation that focuses on the returns to higher education surely includes everyone in at least the top decile group. As such it cannot explain the large changes *within* the top and the fact that much of the recent increase has been limited to the income growth in the top percentile rather than a broader top group.

Shocks in the form of wars and major financial crises constitute yet another broad category of explanations. As already noted in previous sections, these events certainly seem to have had an impact on top shares, especially in some countries, and in particular on capital incomes. The exact degree to which the equalizations following after the wars were due to outright destruction of capital owned by the wealthy or whether taxes and regulations redistributed wealth and increased overall socioeconomic mobility seem to have varied across countries. We discuss this issue further later.

Another broad topic concerns the relationship between inequality and economic growth. The crudest possible illustration of this could be done by dividing history since 1870 into four broad periods based on the overall inequality trends and calculating the average yearly growth rate over these. Starting in 1870 the average growth rate until today is 1.82% for the countries in the sample. Dividing this period into four subperiods—1870–1914, characterized by increasing (or unchanged) inequality; 1914–1950 characterized by rapidly decreasing inequality; 1950–1980, when inequality continued to decline but at a slower rate; and finally the period 1980–today, when inequality has been increasing—we can examine the average growth rate in each of these periods. It turns out that only one of these subperiods has an average growth rate higher than the long-run average 1.82%, namely 1950–1980, when average growth was 3.18%. This period is characterized by falling top income shares. The lowest growth rates are in the late 1800s and early 1900s when inequality was relatively flat (or rising), and growth rates in-between can be found both in the past 30 years 1980–2010 when inequality has increased, and in the period 1920–1950, when top shares declined. Based on this, it is certainly hard to see any clear secular (bivariate) relationship between inequality and growth.

7.4.1.1 What About the Kuznets Curve?

Despite Lindert's (2000, p. 173) urge to the profession to "move onto explorations that proceed directly to the task of explaining any episodic movement, without bothering to relate it to the Kuznets curve," we find it difficult to avoid discussing the Kuznets curve in this chapter. In the end we will, however, perhaps even more clearly thanks to the new evidence we have, come to the same conclusion.[123]

In its crudest interpretation, equating the Kuznets curve with the question, "Is it true that inequality first increases and then decreases as a country develops?" the answer must clearly be "No." The fact that the broad pattern of decreasing inequality up until around 1980 has been followed by a sharp increase in some countries (but not all) clearly shows a pattern that is not consistent with inequality following an inverse U-shape, nor is it consistent with changes in inequality being the same across countries at similar levels of development. When testing the hypothesis on broad cross-country samples and in particular on developing countries, the evidence is mixed and inconclusive (Kanbur, 2000). With a broader interpretation it could be argued that increasing inequality in recent decades is, in fact, the start of a new Kuznets curve. The technological development starting in the 1970s constitutes the start of a shift, not from agriculture to industry as in Kuznets' original story, but from traditional industry to an ICT-intensive sector that initially rewards a small part of the population, but eventually will spread, bringing inequality down. This idea would, under a number of assumptions, fit the general pattern better.

But even in its broader interpretation, a number of aspects do not fit the Kuznets curve hypothesis. First, when it comes to the first half of the twentieth century, a main finding of the recent top income literature is that most of the decline is a capital income phenomenon. Even if there was a continuous decline in the share of workers in agriculture and a large rural–urban migration, their impact on wage inequality was small; low-wage rural workers were mostly replaced by low-wage urban workers (see the discussion in Section 7.2.3.3 and also Piketty, 2006, 2007). The inequality decline was, as evidenced by the timing of the fall, the source of income, and the concentration of the fall to the top percent group, due to shocks to wealth holders from the wars, the depression, and anticapital policies.[124] Second, the recent increase since around 1980 has the problem that it

[123] Also see Piketty (2006, 2007) for an account of how the recent top income literature impacts the view of the Kuznets curve.

[124] As Piketty (2011, p. 10) put it: "In effect, the 1914–1945 political and military shocks generated an unprecedented wave of anti-capital policies, which had a much larger impact on private wealth than the wars themselves."

does not fit the predicted earnings dynamics within the distribution. As an increasing number become skilled, the difference within the top should decrease, not increase as seems to be the case.[125]

Taken together the preceding suggests that there is no mechanical relationship between inequality and industrialization or technological change. It is no more unavoidable that inequality increases at early stages of introducing new technology, than it is automatic that inequality eventually goes down. The Kuznets curve conjecture has indeed played an enormous role in shaping the research on long-run changes of inequality, but the recent research has made it even clearer that it is time to follow Lindert's (2000) suggestion to look at long-run changes "without bothering to relate it to the Kuznets curve." In a way, part of the evidence suggests that other aspects also pointed to by Kuznets (1955) deserve more attention. After all, he formulated the famous Kuznets curve as a suggestion of how to explain what he saw as a puzzle of decreasing inequality. It was a puzzle because what he saw as the more obvious forces at play suggested that inequality be *increasing* in the countries he looked at: "There are at least two groups of forces in the long-term operation of developed countries that make for increasing inequality in the distribution of income..." (Kuznets, 1955, p. 7). The first of these forces had to do with the interplay between the concentration of savings, the impact this would have over time on capital incomes, and income inequality. In forces that could counter such a mechanical increase of concentration he pointed to political decisions and taxation. These are all features that play a major role in potential explanations that we will look at in the next section.

7.4.2 Combining Wage Earnings and Wealth

The relationship between savings, income, and wealth discussed by Kuznets (1955) pointed to the need for a theory where individuals both work and receive income from capital, in different proportions. Such a theory was developed by Meade (1964). In his framework individual wealth holdings grow along with savings, s, and returns to capital, r, but diminishes across generations as the wealth is divided among a growing population that is $1+n$ times larger in every period. If $sr \geq n$ wealth grows without limit but if $sr < n$ then the division of wealth exceeds the growth of wealth, and wealth holdings converge to being a multiple of earnings.

Stiglitz (1969) embedded Meade's framework in a general equilibrium model. Assuming that individual output is $f(k)$, with k being capital per worker, a competitive rate of return, r, being the same for everyone and equal to $f'(k)$, and population grows at rate n, aggregate capital converges to a steady-state level where $sf(k)/k = n$. This in turn implies that $sr < n$ so that in equilibrium division dominates growth of capital, and eventually the only thing determining wealth inequality is differences in earned income. This result, however, hinges on estates being divided equally. If one instead assumes that

[125] See Atkinson (2008a,b, p. 13) for more on this point.

wealth is inherited by one child (as with primogeniture), so that wealth is not divided, long-run wealth inequality is compatible with the $sr < n$.

Furthermore, the resulting distribution will have a Pareto upper tail with Pareto coefficient $\alpha = \frac{\ln(1+n)}{\ln(1+sr(1+t))}$, where $sr(1-t)$ is rate of accumulation out of wealth net of taxes, t (see Atkinson and Harrison, 1978, Chapter 8). This also suggests an empirical specification where we regress $1/\alpha$ on $sr(1-t)/n$.[126] However, even if primogeniture has been applied in the past (and still exists) the assumption of inheritance not being divided is implausible. In fact, today it is not even legal in most European countries. But there are several other assumptions that can be changed with the result that wealth inequality remains in equilibrium even if earnings are the same. Bourguignon (1981) shows that with a convex savings function there can be multiple locally stable equilibria, and with imperfect capital markets individuals with initially low wealth can be stuck in a "poverty trap." Introducing stochastic elements allows for the possibility of escaping such a trap, but also introduces a new source of wealth inequality. Benhabib and Bisin (2007) showed how introducing an idiosyncratic rate of return results in a Pareto distribution for wealth that depends on capital income as well as inheritance taxes.[127]

Besides providing the first model to treat individual incomes as jointly determined by income and wealth, Meade (1964) also provided a basis for studying the joint impact of changes in wealth concentration and changing factor shares on the income distribution. To illustrate using the top percentile group, their share of total income can be broken down into one part based on earnings and one part originating from wealth holdings in the following manner:

Share of top percentile = (proportion of earned income) × (share of top wage earnings percentile) × (alignment coefficient for earnings) + (proportion of capital income) × (share of top capital income percentile) × (alignment coefficient for capital income).

The alignment coefficient for earnings is the share in earnings of top percentile of income recipients divided by share of top percentile of wage earners and defined correspondingly for capital income. This captures the extent to which top wage earners and capital income recipients are also in the top of the total income distribution. In a class model where workers and capitalists are totally separate groups, there is zero alignment; workers have only earnings and capitalists only capital income. In a life cycle savings model with no inheritance, on the other hand, the same individuals inhabit the top of both earnings and capital income distributions, and the alignment is unity.

[126] Approximating $\ln(1+n)$ by n, and $\ln(1+sr(1-t))$ by $sr(1-t)$; see Atkinson et al. (2011), p. 58. See also Atkinson (2007).

[127] Piketty (2000) provided an overview of models of persistent wealth inequality. Recently, much important work has also been done on optimal taxation in models where income stems not only from individual actions over a lifetime but also from bequest flows from previous generations. In general, this changes many of the standard results in important ways. See Piketty and Saez (2013a,b). See also Chapter 15 by Thomas Piketty and Gabriel Zucman in this Handbook, and the references therein.

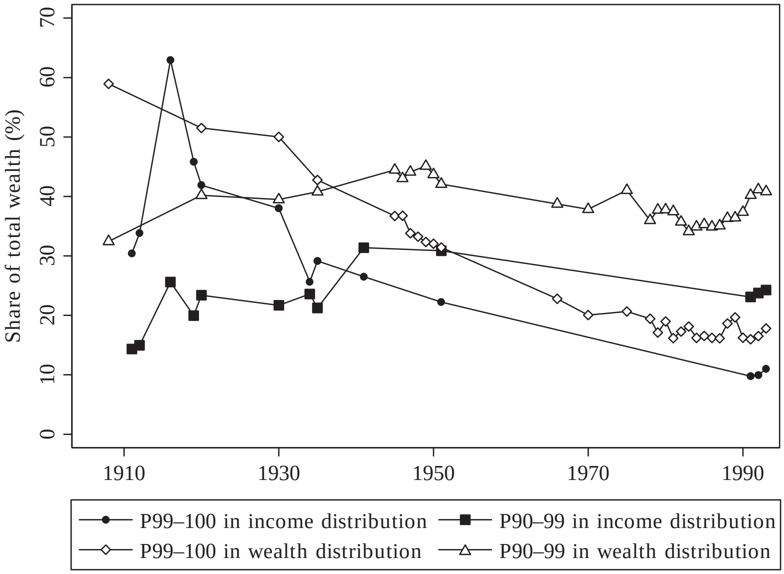

Figure 7.22 Wealth in top income and wealth fractiles in Sweden, 1908–2004. *Notes and sources: See main text and Roine and Waldenström (2008) for further details.*

Using this labor–capital decomposition it is, in principle, possible to attribute shifts in top income shares to shifts in top earnings shares, top capital income shares, and factor shares. A practical empirical problem, however, is that in most cases we lack data on the cross distributions over long periods of time. Roine and Waldenström (2008), studying Sweden, is an exception. Thanks to a particular form of combined income and wealth tax it is possible to calculate the distribution of wealth ranked both by wealth and total income.[128] Figure 7.22 shows that the share of total wealth when ranked by total income is somewhat lower than when ranked by wealth, but the two series are highly correlated, suggesting that there is significant overlap between the two distributions.

7.4.2.1 Explaining the Drop over the First Half of the Twentieth Century: Wealth Shocks and the Cumulative Effects of Taxes

Even if it is in most cases not possible to get a complete picture of the alignment of the distribution of earnings, capital income, and total income, a key feature of the top income data is the possibility to decompose income according to source. And, as already discussed in Section 7.2, it is clear that the drop in inequality in the first half of the twentieth century is mainly a capital income phenomenon. Combining what we know about the

[128] Between 1910 and 1948 Sweden had a form of wealth tax according to which a share of individual wealth holdings (initially 1/60, later 1/100) was added onto other incomes. The tabulations of incomes therefore also contain wealth amounts by income groups. In addition, for a few years wealth and income tax data can be matched on an individual level.

composition of the drop according to income source (almost entirely capital income driven), the timing (in most countries concentrated to wartime and the Great Depression periods), and the development of wealth concentration (large decreases in wealth concentration), declining capital incomes among top earners constitute the main explanation for declining top shares.

It is interesting to note that this development came about even in counties not immediately exposed to all of the great shocks of the twentieth century. Sweden is a case in point. The world wars did affect the Swedish economy, but the country never participated directly in either of them, and looking at details in and around these periods it is clear that they did not constitute immediate shocks to Swedish wealth holders. If single events are to be pointed out, the economic crises in the early 1920s, the indirect effects of the Great Depression, which hit Sweden in 1931, and, in particular, the dramatic collapse of the industrial empire controlled by the Swedish industrialist Ivar Kreuger (the "Kreuger Crash") in 1932, stand out as being most important. These are, however, not sufficient to explain the drop in top shares in Sweden. Instead, a trend of decreasing share of capital in value added corresponds well to the declining top income shares. Policy, especially sharp increases in top tax rates, also stand out as important for explaining especially the drop just after the Second World War.

The general picture thus seems to be that macroshocks explain most of the drop, but there is also a role for a shift in policy and probably also in an economy-wide shift in the balance between returns to capital and labor.[129]

Assuming that we are satisfied with the explanation of why top shares dropped, we then face the challenge to explain why they did not recover in the decades after the Second World War, but rather continued to decline. Here a key factor seems to be the high rates of marginal taxation facing the top. The long-run evolution of statutory top marginal taxes is shown in Figure 7.23. As a broad generalization, top rates started to increase rapidly in the 1930s and reached high levels in many countries during and just after the Second World War.[130] As shown in Piketty (2001a,b, 2003), the combined effect of

[129] The fact that macroshocks and financial crises led to decreased top shares in this period is not the same as saying that this is the expected outcome of financial crises in general. When wealth concentration is high, a sharp decline in its value translates to decreasing incomes from it. But if top incomes are primarily based on earnings (as in many countries in recent decades) the effect need not be large. Furthermore, it is also possible that in developed financial markets rich wealth holders can protect themselves against shocks using various instruments, or even by altering the rules of the game in their favor (as argued by, e.g., Reich, 2010). See Jenkins et al. (2013) for an overview of the recent financial crises pointing to varying effects on inequality across countries.

[130] Note, however, that statutory taxes and actual taxes paid by top income earners are not the same. In particular, during the 1950s and 1960s available evidence suggests that top rates were only paid well above the P99 level (see Roine et al., 2009 and references therein). Scheve and Stasavage (2010, 2012) argued that the increased wartime taxation of the rich can be related to a political process of equal sacrifices, where the wars forced the masses to put up with their poverty and in return the rich were forced to put up with their wealth.

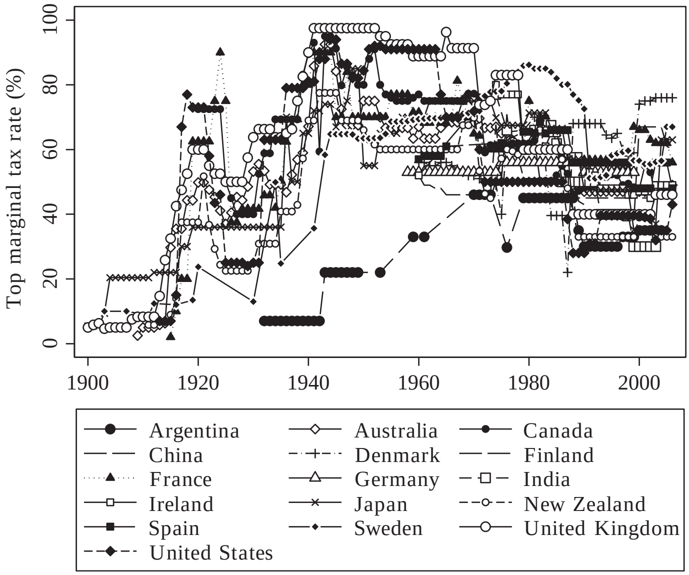

Figure 7.23 Trends in top marginal tax rates, 1900–2006. Sources*: See main text.*

shocks to capital holdings and high marginal tax rates is that recovery takes long. Unless adjustments to consumption are not made, current consumption levels can be sustained for some time by running down wealth holdings even further, but this decreases future income from wealth even more. An important point to note is that in these processes the short-run effect from taxes looks small. It is the cumulative effect over time that is important.[131]

How much do taxes impede capital accumulation and the recovery of top income shares? Just to illustrate the order of magnitude, assume a simple case with two groups of income earners; a top group that derives half their income from capital (the rate of return is assumed to be 5%) and the other half from wages, whereas the rest only have a wage income. Initially the income share of the top group is 15% of all income, and their consumption is such that their capital stock remains unchanged. These assumptions are, of course, not calibrated to fit any particular economy, but the numbers fit an approximate representation of the relationship between the top percentile and the rest of the population, both in terms of the importance of capital (with a broad interpretation) and the income share around World War II.

The combined effect of a tax increases from 30% to 60% and a shock that leaves the top group with 0.7 times initial wealth causes a gradual decline of both the capital income share (from 50% to 37% in 5 years and to 30% in 10 years) and total income share for the

[131] Roine et al. (2009) also showed that the cumulative effects of the relatively small short-run impact of taxes found in their econometric analysis are consistent with much larger effects over time.

top group (from 15 to 12.3 in 5 years, down to 11.1 in 10 years) with wages and consumption being unchanged. Despite the stylized nature of the setup, these magnitudes are reasonable when looking at data from the 1930s and following the Second World War. In the scenario with no changes to consumption wealth is eventually used up, and capital income goes to zero. Altering consumption too little makes the process longer but in the end the result is the same, whereas a sufficient adjustment allows for accumulation over time.[132]

7.4.3 Explaining Increasing Top Wages: Executive Compensation, Superstar Effects, and the Possibility of Changing Norms

Although shocks to capital income combined with the cumulative impact of high marginal taxes are important in explaining the development between the First World War and around 1980, something else is needed to account for the increasing inequality since. This is especially true for understanding changes in top earnings, most visible in the United States, but also clear in many other countries (see Atkinson, 2008a, Chapter 4).[133] As discussed in Section 7.4.1, it has been argued that increasing wage dispersion can be explained by theories of skill-biased technological change (Acemoglu and Autor, 2012, 2013) but also that these theories have some problems. In particular, it is hard to see how an increased advantage of the skilled, typically equated with the well-educated, squares with increased inequality not just in general but also increased inequality *within* the top group.

There are several strands of literature that give insights into why the top of the earnings distribution may behave differently from the rest and what factors may govern compensation of top performers. This includes theories of determination of earnings in hierarchical organizations, tournament theory, and superstar effects. Research based on these ideas, and sometimes combinations of them, has tried to account for the sharp increase in top wages in recent decades.

In models first developed by Simon (1957) and Lydall (1968) pay is related to the number of individuals supervised and to a (constant) pay increase at each step in the hierarchy. They assume that, first, at every level of the organization individuals supervise a constant number of people at the level below and, second, that the salary of these "managers" at every level is a constant proportion of the aggregate salaries of the people they directly supervise. More precisely, if at every level i of the organization there are y_i employed, then the number of employed at the level below is $y_{i-1} = sy_i$. Furthermore, the

[132] See Section 4.4, pp. 20–24 in Piketty (2001a,b) and Appendix A in Roine et al. (2009).

[133] It is important to recall that in some countries the recent rise in top shares is not primarily driven by increased wage dispersion but by a return of capital in the top. This may be due partly to work-related remuneration taking the form of capital income for tax reasons, but also due to capital actually becoming more important. In this section, we will focus on theories that aim to explain increased concentration of earnings in the top.

wage w_i at any level i is related to the aggregate of those below by a fixed proportion, p, such that $w_i = nw_{i-1}p$. Under these assumptions the upper tail of the earnings distribution will be approximately Pareto distributed with exponent $\alpha = \frac{\log s}{\log(1+p)}$.[134] At any level in the organization the people above will earn on average a constant of the wage at that level, the multiple being $\alpha/(\alpha - 1)$.

How much pay increases as one moves up in such an organization is determined by the number of individuals supervised and by the pay increase at every level, but also by the size of the organization. If firms become larger in terms of the total number of employees, the salaries of the top management can be expected to increase. This basic insight, that large firms pay their top managers more than small firms, was noted by Mayer (1960) and is also a prominent fact in the data on the distribution of CEO pay (see, e.g., the overview by Murphy, 1999). But the hierarchical models have other problems empirically, in particular when it comes to explaining the very top. As noted already by Phelps Brown (1977, p. 309) plausible values of the span of control (the number of direct subordinates at each level in the hierarchy) and the pay raise at each step of the hierarchy do not match observed Pareto exponents (see Atkinson, 2008a, p. 77). Individuals high up in organizations simply earn more than what the model would predict.

In hierarchical models individuals are not paid based on "ability" but based on "responsibility."[135] But if "ability" determines the growth of a firm and the size of operations, then "responsibility" is endogenous, and the matching of ability and position becomes important.[136] In Rosen (1981) the distributions of firm size, span of control, and managerial incomes are modeled as the joint outcome of market assignments of personnel to hierarchical positions. Assuming the process assigns the most able individuals to the highest positions and that the talent of these individuals also multiplies throughout the organization, this results in firms of more capable managers being larger and also justifies high rewards to these managers.[137] In particular, it suggests that both the size distribution of firms and pay are skewed relative to the underlying ability distribution. Focusing on

[134] See Lydall (1968, pp. 127ff) and also Section 7.2.1.4 for more details.

[135] However, the relationship between the success of a firm, its growth, and consequently the size of the firm (both in sales and individuals employed) was in this way indirectly related to ability of the management, see Lydall (1968, Chapter 4). Also Baumol (1959, p. 46) at the time made the observation that "executive salaries appear to be far more closely correlated with the scale of the operations of the firm than with its profitability."

[136] This problem is the focus of many so-called assignment models, that in general study matching in perfectly competitive markets focusing on the combined effect of indivisibilities and heterogeneity on both sides of the market. In labor markets these features are important when there are complementarities between types of jobs and types of workers (e.g., Sattinger, 1979). See Sattinger (1993) for a review.

[137] The assumption that the process allocates the highest talent to the highest position is a contested one, and there is a large literature on executive compensation where many note that executive pay is not always based on performance, for example, Bertrand and Mullainathan (2001) and Bebchuk and Fried (2004).

CEO pay across different firms, Terviö (2008) built on this kind of assignment model for managerial talent to a distribution of firms, where firm size may be different not just due to managerial ability but for other reasons as well. Under the assumption that the larger firms will have most to benefit from hiring the best managers, the pay levels of these individuals across firms will be determined by distributions of firm size and managerial talent. In such a context the value of the highest talent may be significant for the largest firm. In similar spirit, Gabaix and Landier (2008) suggested that even very small ability differences can have large impacts on firm value. They found the sixfold increase of U.S. CEO pay between 1980 and 2003 can be fully attributed to the sixfold increase in market capitalization of large companies during that period.

A common feature in these (and many other) models is the idea that something (exogenous or endogenous) transforms small differences in the underlying ability to large differences in outcomes. Lazear and Rosen (1981) showed how compensation based on the outcome of a tournament where only the winner receives compensation can induce the highest effort under certain assumptions.[138] In general, attempts to implement payment schemes that give efforts to perform well has created a growth of performance-based pay in many fields. These schemes typically have the effect that the increase the individual returns to "top performers." However, it is not clear that the effect is positive for the economy as a whole or even for the implementing firm.[139] In models following Rosen (1981) a combination of technological change (production that makes replication easier such as printing, recording) and the size of the market gives the "most talented" disproportionately large rewards.[140] As the market reach of a so-called "superstar" increases, the returns to the highest talent also goes up, and at the same time the returns to those just below in the ability distribution goes down. The "global leader" drives out individuals or firms that used to be competitive at a more local level leading to increased concentration in top rewards. Frank and Cook (1995) argued that an increasing number of markets have developed features that fit the superstar model; they have become what they call "winner-take-all-markets." The examples range from activities

[138] This is, however, for example not true if the differences between the competitors is too large; see, for example, Freeman and Gelber (2010).

[139] See Fahlenbrach and Stulz (2009) and Bebchuck and Spamann (2010) for overviews of performance-based pay in the financial sector. Cahuc and Challe (2009) showed how performance pay can attract individual talent to a certain sector but also to possible misallocation of this talent in the economy. Agarwal and Wang (2009) showed how a shift to performance-based pay results in an increase in earnings dispersion but also to an increase in the amount of risk-taking with negative effects on aggregate performance.

[140] As Rosen noted in his paper, the basic idea was clear already to Marshall (1890/1920). Another early observer of the phenomenon, Watkins (1907) wrote: "The opportunity of the business man in any line to profit by value increase is multiplied by the increase in the breadth and in the number of exchanges" (pp. 62–63), and he went on to note that: "Even very slight changes in price, under modern conditions of a world-wide market and an unprecedented scale of individual transactions, may mean enormous gain or loss" (p. 63).

where broadcasting in a wide sense enlarges the market (such as markets for sports stars, artists, writers), to those where hiring a "superstar" may become more important as the amounts that hinges on their performance grows (lawyers, investment bankers, and CEOs), to more standard product markets where decreasing transportation and other trading costs make increases the potential market.[141]

So to what extent is the top of the distribution composed by such superstars? Kaplan and Rauh (2010) studied the representation of four sectors, top executives in nonfinancial firms, top employees in the financial sector (investment banks, hedge funds, and private equity), lawyers, and professional athletes and celebrities, in the top of the U.S. income distribution. They found that financial sector employees comprise a larger share than top executives from other sectors, and also that their share has grown in the past decades.[142] Athletes and celebrities as well as lawyers are certainly represented in the top but play a comparatively small role. Most striking perhaps is that the aggregate of these four groups account for less than 25% of the top income earners. This is due both to missing high-earning individuals in these four groups but also to the top of the income distribution consisting of much more than representatives of these groups.

Overall, theories focusing on various ways in which the underlying ability distribution may be magnified in terms of top earnings certainly contribute to our understanding of the recent increase in top income shares. There are also a number of areas where it seems clear these effects have grown over the past decades. But also some developments suggest that these theories are unlikely to be the full explanation, especially if one looks at the longer run developments. Frydman and Saks (2007) studied the ratio of CEO to worker pay in the United States over the period 1936–2005. They showed that this ratio was falling between the 1930s and the 1970s even though firms certainly grew in size over this period. Over this longer period they concluded that relationship between pay and firm growth is weak. In Figure 7.24, we complement their U.S. data with corresponding data from Sweden for the period 1950–2011. The long-run picture is very similar with falling ratios until around 1980 and then clear upturns thereafter. The level difference between the countries is marked, however, as is the fact that the recent increase has been much larger in the United States than in Sweden.

Another study that has looked at the long-run development of wages in a field with features that have been suggested to magnify small differences in ability, namely the financial sector, is Phillippon and Reshef (2012). They found that deregulation of financial markets is closely tied to compensation levels, as well as education levels and innovation, but also that the sector in the 1930s and since the 1990s seems to pay wages that are

[141] Gersbach and Schmutzler (2007) and Manasse and Turrini (2001) study how increased market size can drive increasing wage inequality within the top of the distribution.

[142] Bell and van Reenen (2010) also found that the financial sector is clearly overrepresented in the top of the U.K. income distribution.

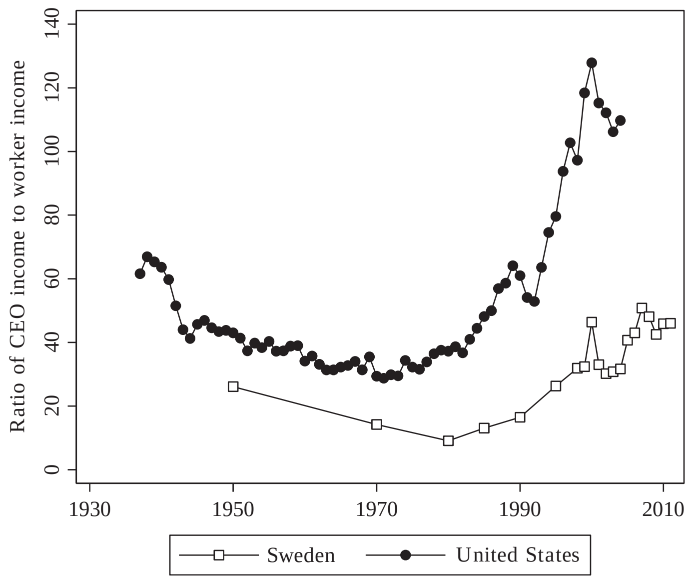

Figure 7.24 CEO and worker incomes in Sweden and the United States, 1936–2011. *Note and sources: Ratios are based on the following series. U.S. CEO incomes in 2005 U.S. dollars refer to CEOs in the largest 500 corporations in the ExecuComp database, from Frydman and Saks (2007) (including salary, bonus, long-term payments, and options granted). This series was generously shared by Carola Frydman. Average income refers to workers in the Social Security Administration database, collected from Kopczuk et al. (2007, table A2, downloaded at http://www.columbia.edu/~wk2110/uncovering/, 2013-12). Swedish incomes refer to CEOs in the 50 largest Swedish corporations, and male industrial workers, data coming from LO (2013, bilaga 2, "Näringslivet").*

substantially higher than what can be accounted for by observable factors (such as increased complexity of tasks and education levels). Interestingly, when comparing the relative pay in the financial sector with the top percentile income share in the entire United States, as is done in Figure 7.25, the resemblance is striking. The post-Depression drop in the 1930s is close to contemporaneous, and this is also true for the strong increase beginning in the late 1970s.

Finally, some scholars have pointed to the possibility of changing social norms as the most likely explanation for why top earnings have increased so much in recent decades (e.g., Levy and Temin, 2007; Piketty and Saez, 2003). Atkinson (2008a, Chapter 8) illustrates how, in a setting where individual utility depends on income as well as conforming to a social norm about fair pay (which operates both on the employer and employee sides of the market), there can be multiple equilibria for a given distribution of underlying ability.[143] The loss of utility when not adhering to the norm depends on how many others do the same. As a consequence, market forces alone do not uniquely determine the

[143] Similar to the model in Akerlof (1980).

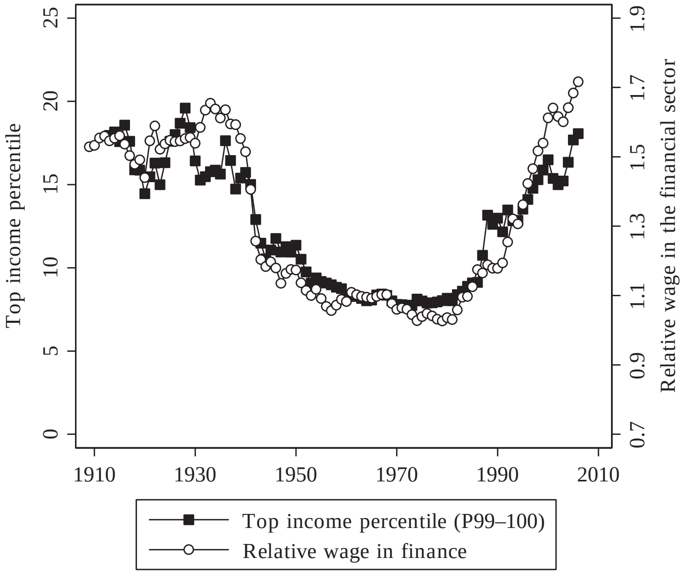

Figure 7.25 Relative wage in the financial sector versus the top income percentile in the United States, 1909–2006. *Note and sources: Ratio of financial sector wages to wages in agricultural and industrial sectors is from Phillippon and Reshef (2012) and U.S. top income share (excluding realized capital gains) are from Piketty and Saez (2003 and updates).*

outcome. There can be a situation where most individuals adhere to a norm, according to which pay is determined by a combination of ability and a fixed amount, as well as a situation where few individuals adhere to the norm, and pay is determined by individual productivity. Depending on initial conditions, different countries can converge on different pay norms, and "exogenous shocks" to the economy may cause a shift from one equilibrium to another.

7.4.4 Econometric Evidence on Determinants of Top Income Shares

A key objective in the top income project has been to create a sufficiently rich cross-country panel to enable an econometric testing of questions about what determines inequality.[144] In this subsection we will report on the results from a number of such studies.

7.4.4.1 Determinants of Inequality: Correlations over the Long Run

Roine et al. (2009) combined top income shares with data on a number of variables that have been suggested to affect inequality. The approach is not to test a particular theory

[144] As mentioned earlier, we focus on questions about what determines inequality, but obviously the top income data set has a large number of applications for questions regarding the consequences of inequality as well.

but rather to draw on a large number of models to produce a list of variables of interest in an exploratory fashion (see Atkinson and Brandolini, 2006, for a discussion of the clear limitations with such an approach). Econometrically the adopted method is to analyze first differences (using both first differenced generalized least squares and dynamic (with lagged dependent variable) first differences), assuming a linear relationship at least in this specification. Panel estimations make it possible to account for all unobservable time-invariant factors as well as common and country-specific trends. The potential that the relationships change over time is dealt with indirectly by allowing effects to differ over the level of development and for different country groups, and so on. This is clearly not the same as testing for the long-run effects of various variables on inequality but rather a way of testing what the short-run effects look like over the long run.

The main variables included in the analysis are the following. Financial development is measured as the sum of stock market capitalization and total amount of bank deposits divided by GDP. Trade openness is measured either *de facto* as the trade share in GDP (i.e., sum of exports and imports over GDP) or *de jure* as the average tariff rate (total tariffs paid divided by traded volume). Public sector influence is proxied by the share of central government spending in GDP and as the top marginal tax rates. Finally, we also include GDP per capita and population.[145] Given the importance of changes within the top, the income shares of three groups are analyzed: the rich (P99–100), the upper middle class (P90–99), and the rest of the population (P0–P90).[146]

Table 7.6 reports the regression results, and some basic relationships stand out as constantly robust across all specifications.[147] First, economic growth, that is, change in GDP per capita, seems to have been pro-rich over the twentieth century. In periods of faster than average growth, top income earners have benefited more than proportionally.[148] A likely reason for this result is simply that top incomes are (and have been) more closely related to performance than other incomes. This result is similar at different levels of

[145] There are also a number of additional variables, such as measures of democracy (Polity) and proxies for technological development (share of agriculture in GDP, number of patents) that are used in a robustness section. See Roine et al. (2009) for details.

[146] Clearly, any such division is arbitrary, but the results are not sensitive to the exact definitions of these top groups. Running the regressions defining the top 0.5% or the top 1.5% does not have any qualitative impact on the results. A threshold around top 1% can be justified by looking at the details of income compositions indicating that (approximately) the top 1% as a whole is very different from the rest of the top decile, especially with regard to capital income share. Also a similar classification, but with respect to wealth, is made in Hoffman et al. (2007).

[147] In Roine et al. (2009), the number of countries ranged between 12 and 14. Since then top income data has become available for more countries, and we have rerun the regressions. The results largely go through with the number of countries now ranging between 15 and 20. Here we also report results for some additional variables, such as Polity, that were not included in the results in Roine et al. (2009).

[148] See also Dew-Becker and Gordon (2005), who found that high productivity growth mainly benefitted the rich in the U.S. postwar era.

Notes: The regression method and underlying data are described in Section 7.4.4.1 and Roine et al. (2009). "Δ" denotes log change between 5-year periods, "GDPpc" is real per capita GDP, "Pop" is population, "Govspend" is central government spending as share of GDP, "Findev" is the sum of banking deposits and stock market capitalization as share of GDP, "Openness" is trade share in GDP, "Marginaltax" is the statutory top marginal income tax rate, "Democracy" is the autocracy score in the Polity IV index, and "Bank crisis" and "Currency crisis" are dummy variables for years when such crises occurred. Robust standard errors in parentheses. $^{*}p<0.1$, $^{**}p<0.05$, $^{***}p<0.01$.

development and is not different between Anglo-Saxon and other countries. However, the relation between economic growth and income share for the "upper middle class" (P90–99) seems to be the reverse. In high growth periods this group loses out in relative terms. This, again, highlights the importance of distinguishing between groups in the top decile. Second, financial development seems to have been pro-rich over the twentieth century, both in Anglo-Saxon countries and elsewhere and regardless of whether it is approximated using bank deposits or stock market capitalization (often said to be a difference between Continental Europe and Anglo-Saxon countries).[149] High marginal tax rates also have a consistent negative effect on top income, whereas government spending seems associated with a larger income share for the P0–P90 group. Somewhat surprisingly perhaps, there is little evidence of any clear effects of trade openness on top shares over the long run. Democracy, as measured by the commonly used Polity IV score, turns out to be negatively related to top shares, and this effect is larger as countries become richer, suggesting that democracy and development have an equalizing effect. The subsections that follow look at some of these relations in more detail.

7.4.4.2 The Effect of Top Tax Rates on Top Incomes

The theoretical effects of taxes on top incomes are not obvious. Recently much progress has been made in the field of optimal taxation both with respect to optimal labor income focusing on top income responses (Piketty et al., 2013) and in dynamic settings where income is determined by labor and capital and also influenced by bequests across generations (Piketty and Saez, 2013a,b).[150] Taken together the expected effect of higher top rates is to lower top income shares. This also appears to be the consistent finding in recent empirical work. Saez (2004) showed that changes in marginal tax rates over the period 1960–2000 can explain variation in top income shares in the United States, but also that the effect only seems to hold for the top percentile group. Saez and Veall (2005) showed that Canadian top income shares are negatively correlated with top marginal income tax rates. Using a similar specification, Roine and Waldenström (2008) concluded that changes in top rates in Sweden also had a significant effect on the Swedish development over the twentieth century, and Jäntti et al. (2010) concluded that the drop in top rates was a key determinant in the increase of Finnish top shares. Atkinson and Leigh (2013) found that top income shares are highly correlated across Anglo-Saxon countries and that top shares are very responsive to changes in marginal tax rates. Over the period 1970–2000 they estimated that reductions in tax rates could explain between one-third and one-half of the rise in the income share of the top percentile group. Atkinson and

[149] The finding that finance is pro-rich does not preclude that it can also be pro-poor, as has been found in previous research (e.g., Beck et al., 2007), but that it is the groups in the middle that seem to benefit the least from financial development.

[150] Persson and Sandmo (2005) however studied a tournament setting and showed that under some conditions increased taxation lead to increased inequality.

Leigh (2013) also tried to estimate the cumulative effect and found that a fall in the marginal tax rate on investment income (based on a lagged moving average) is associated with a rise in the share of the top 1%. Finally, Piketty et al. (2013) showed that there is a strong negative correlation between top tax rates and top 1% income shares in 18 OECD countries since 1960, and also that there is no evidence of high top shares corresponding to higher growth.

7.4.4.3 Political and Institutional Factors and the Impact of Crises

One potential advantage with the new top income data is that it spans a sufficiently long period for there to be sufficient variation in the degree of democracy and other institutional variables.[151] The long time period also makes it possible to potentially capture sufficiently many crises episodes to test effects of these econometrically.

The results in Table 7.6 include the role of democracy as captured by the well-known Polity IV measure. The results suggest that democracy indeed has an equalizing effect, but that it appears to be confined to reducing the top percentile's income share leaving the share of the rest of the top decile largely unchanged. Scheve and Stasavage (2009) looked at the effect of institutional differences in centralized wage bargaining and partisanship in 13 countries over the twentieth century but do not find any clear effects.

The effects of financial crises is also addressed in Table 7.6 and originally by Roine et al. (2009) using data from Bordo et al. (2001) and Laeven and Valencia (2008), indicating a negative effect of banking crises, but not currency crises, on the top percentile's income shares.[152] Atkinson and Morelli (2011), however, noted that when looking closer at how one might characterize the development after crises episodes, it is difficult to find a clear pattern. In many cases data are insufficient to give a clear picture of the direction of development.[153]

7.4.5 What Do We Learn?

The long-run development of wealth and income inequality is clearly a result of the joint effect of changes in both distributions. From any starting point, economic, social, and technological developments interact with shocks, crises, and policy to determine the evolution of both. The dynamics can go in both directions with effects over different time horizons. Exogenous events or policy can lead to wealth concentration going up or down, resulting in capital incomes becoming more or less important in explaining income inequality. But periods where high-income earners, due to exogenous factors or policy, receive a larger share of the total can also lead to increased wealth

[151] See Chapter 21 in this Handbook (Acemoglu et al., 2013) for an overview on the relation between democracy and inequality.

[152] However, currency crises and banking crises do not seem to have any clear effects.

[153] Bordo and Meissner (2012) used top income data to study if inequality has been related to credit expansion which in turn has been argued to be a good predictor of crises. They found no evidence of such a relationship.

concentration. Over time this leads to a return of capital incomes, and unless individuals consume all their earnings over their lifetime, inheritance also becomes a factor across generations.

In terms of understanding inequality developments over the past century in the countries studied in this chapter, some main themes are worth recapitulating. The drop in inequality over the first half of the century is mainly due to decreased wealth shares of top wealth holders, resulting in declining capital incomes. The wage share of high earners, however, typically looks very stable. The drop in wealth holdings and subsequently in capital incomes seems to be the result of both macroshocks such as the World Wars and financial crises but also to policies pursued in many countries. After these shocks high top marginal tax rates made it difficult to rapidly accumulate new fortunes, and inequality leveled out or continued to decline. Such a development can be accounted for in a simple model that combines capital and earnings and uses it to study the effects of exogenous shocks to the capital stock and the effects of taxation.

The recent increase in inequality, observable in many countries but not all, seems to be mainly due to increased top wages. Explaining this turns the focus to a different set of explanations emphasizing higher returns on the labor market for some groups (based on higher ability, skill, effort, education, etc.). Two key facts seem important in guiding efforts to understand this change. First, much of the increase is concentrated to a small fraction at the top of the population. This means that theories focusing on changes for broader groups (such as "skilled" and "unskilled") at least need to be complemented by a mechanism explaining the increase within the top. Second, the degree to which top earnings have increased relative to the average is very different across countries. Thus, a theory based on a common global shift of some kind at least needs to be complemented with mechanisms that can account for the cross-country difference.

Finally, the preliminary econometric evidence points to taxation being important in explaining the developments. Even though magnitudes in the short run may seem small, it is important to take the long-run dynamic effects into account. Financial development and economic growth being pro-rich also stand out as clear and robust correlates over the whole of the twentieth century, but so far we have only begun to use the data for systematic cross-country analysis.

7.5. SUMMARY AND CONCLUDING REMARKS

In this chapter we have outlined the broad facts about long-run trends in the distribution of income and wealth. The focus has been on findings primarily stemming from the top income literature and recent studies of wealth concentration, using historical tax and estate data. However, we have also tried to relate the new results to previous observations in the economic growth and economic history literatures. The end result is always going to be subjective, and we have therefore tried to be as clear as possible on where in the development there is disagreement.

When it comes to *describing* the overall developments of income inequality across the 26 countries studied in Section 7.2, there are three possible broad eras that can usefully be distinguished. The first is the period before the First World War, the second is the period from around 1914 until 1980, and the third consists of the time thereafter. In the first period evidence is relatively clear on the fact that inequality was historically high in the beginning of the twentieth century. To what extent this high level was present throughout the nineteenth century or if it gradually increased is, however, still less clear due to the lack of data. There are some signs of increased inequality but many studies also point toward high and relatively stable levels before the twentieth century.

The period from around 1914 to 1980 is characterized by substantial drops in top income shares in almost all countries for which we have data. The top percentile share falls from around 20% before 1914 to between 5% and 10% around 1980. The decreasing income share for the lower parts of the top decile group are much more modest. In fact, in some countries the income share of lower half of the top decile group (P90–95) remains almost constant throughout the twentieth century. Thus, distinguishing developments within the top group seem important. Large parts of the decreases seem to happen in connection to shocks such as the World Wars or the Great Depression, but it is worth noting that decreases also take place in countries that did not take part in the war, such as Sweden. Also the drop continues after the Second World War throughout the high-growth periods in the 1950s and 1960s. In terms of income composition, most of the drop seems related to decreasing capital income.

The development after 1980 is less homogenous. In some countries, especially the United States and the United Kingdom, inequality has risen sharply. This increase has taken place from a level that was already high in relation to others before it started. In countries like Sweden and Finland, increases have also been substantial but here from internationally low levels to levels that are much higher but remain among the lowest. In, for example, France, Germany, and Japan, there is no clear upward trend but in absolute terms inequality remains higher than in the Nordic countries.

Turning to the development of the wealth distribution in the 10 countries for which we have long-run data, studied in Section 7.3, a picture similar to that of income emerges. In most places (the United States being the notable exception) wealth concentration was relatively constant and historically high before the twentieth century. Even if cross-country comparisons should be made with caution, there seems to have been important level differences. Estimated top wealth shares at the beginning of the twentieth century were clearly higher in the United Kingdom and in France than, for example, in the United States and in Switzerland, Finland, and Norway, with Denmark, Sweden, and the Netherlands in between. Starting around the First World War, the top percentile group wealth shares decreased substantially until around 1980. Thereafter the development is again more diverse but also much more uncertain and debated than for income

In terms of *understanding* these developments, we have, in Section 7.4, discussed a number of suggested theories and empirical regularities that aim at explaining various aspects. The developments over the first half of the twentieth century points to the importance of understanding the joint developments of wealth and income as much of the decrease is related to sharp drops in capital incomes in the top. The cumulative impact of taxation over time also seems important, especially for understanding the lack of recovery of top income shares in the decades after the Second World War. With respect to the different developments after 1980, it seems likely that many factors interact. There are probably important changes in terms of technological change and globalization that affect inequality, but the differences across countries also suggest that the impact depends on individual country characteristics (such as the functioning of the labor market, the education systems, and other policies). In most countries much of the inequality increase is driven by changes *within* the top, suggesting that an explanation must include a mechanism that gives an increasing income advantage to the very top groups, rather than only accounting for differences between broad groups such as, for example, skilled and unskilled. In addition, the recent increase is not homogenous in terms of income composition. In some countries (the United States) an increased earnings dispersion explains most of the recent increase, whereas in other countries (Sweden) capital seems more important. Finally, we also note that there are cases where data and explanations seem to fit what we observe since the 1980s, but when one applies a long-run perspective the same theory seems less successful (an example being executive pay as explained by the growth of firms). This need not imply that the account for the post-1980 period is incorrect, but it does suggest that most explanations are likely too sensitive to interaction with aspects that change both over time and across countries.

7.5.1 Going Forward

When looking ahead a number of areas seem promising in terms of future research. First, the ongoing work of extending the top income database is obviously important, both in terms increasing the number of countries, but also in terms of adding new dimensions. In at least some countries it could, for example, be possible to distinguish income for men and women over much of the twentieth century. Constructing similar data sets on long-run wealth inequality trends would also represent important contributions.

Second, making use of the top income database seems important. Numerous aspects of long-run developments can now be studied over a time span previously void of systematic inequality data. In doing so it is, as emphasized by Atkinson and Brandolini (2006), it is important to take an integrated approach to theory and estimation and to use proper econometric techniques to address deficiencies in the data.

Third, results on the importance of changes within the top illustrate how development can be missed or misinterpreted if one focuses solely on overall inequality. These findings also pose challenges for theories trying to explain the recent surge in income inequality. It is in general quite likely that different explanations apply to different parts of the distribution.

Fourth, a number of the recent findings illustrate the importance of the interplay between wealth and work in determining total income. Also, when income is determined not just by actions over an individual's lifetime, inheritance also becomes important. This has important effects on a wide range of issues such as optimal taxation (Piketty and Saez, 2013b) and the future development of inheritance flows (Piketty, 2011).

These are some of the research areas that will surely be important for our understanding of long-run inequality trends, their causes, and their consequences.

ACKNOWLEDGMENTS

We have received valuable comments from Anthony Atkinson and seminar participants at the conference "Recent Advances in the Economics of Income Distribution" held at the Paris School of Economics, April 2013. We thank Wiemer Salverda for sharing wealth distribution data on the Netherlands. Data underlying all graphs and tables in the chapter are available on the authors' Web sites or on request.

Note: List of sources and data definitions of the wealth distribution data used in the chapter. See text for further descriptions of the data. The definition of household used here is not exactly identical across (and sometimes even within) country samples. The basic concept is one where individuals (aged 18 or above) and married couples count as one household (see Section 7.3.2.1.7 on Sweden for details). The asterisk denotes the way that pages are numbered/indexed in the original publications.

2007					22.0	22.1	18.8			33.8	
2008					21.5	21.9					
2009			22.7		19.8	21.2					
2010	11.4			24.4	22.3	19.4				34.5	
2011					23.0	18.9					

Note: Note that many series contain several breaks in data definitions that may severely affect comparability both over time and across countries. See Table 7.A1 for sources and Section 7.3 for details. "USA (hh)" denotes top wealth shares in the U.S. distribution of households (with some exception) and "USA (ind)" top wealth shares in the U.S. distribution of adult individuals.

Abstract

Like the other chapters in this volume of the *Handbook of Income Distribution* (and its predecessor), the aim of this chapter is to provide a comprehensive review of a particular area of research. We examine the literature on post-1970 trends in poverty and income inequality, up to 2010 or 2011 in most countries. We provide measures of the levels and trends in each of these areas, as well as an integrated discussion of empirical choices made in the measurement of poverty, overall income inequality, and inequality among those with top incomes.

Trends in income inequality, Poverty, Gini, Top income shares, Inequality

8.1. INTRODUCTION

The chapter on "Post-1970 Trends in Within-Country Inequality and Poverty" was rather sketchy 13 years ago when the first volume of the *Handbook of Income Distribution* was published (Gottschalk and Smeeding, 2000). A separate chapter was devoted to poverty measurement (Jäntti and Danziger, 2000). The first Canberra Report (2001) on international standards for income distribution, much less the second report (2011), had not yet been published, and the Luxembourg Income Study (LIS) database had less than 15 years of comparable data on poverty and inequality for fewer than 20 rich nations, for which only trend data from 1980–1995 were available. The Organization for Economic Cooperation and Development's (OECD) method for collecting comparable income distribution data was in its infancy, and the top incomes database was even younger still; Piketty (2001) was just publishing his paper on the long-term distribution of top incomes in France.

The data world has come a long way in 14 years; now available are multiple sources of comparable (harmonized) household income data (overall and top incomes), wealth data, and poverty data. Even heeding warnings to take caution with harmonization of secondary data (Atkinson and Brandolini, 2001), the world now has a substantial number of more comparable data series, both across nations and over time. Still, there are limits to what can be accomplished in terms of comparisons. Here we rely on high-quality comparable level and trend data for income and income poverty from the 1970s on. While our measures dwell heavily on OECD countries, using both the LIS and the most recently available OECD data, particularly for the richest of these nations, improved availability has allowed us to add some data for "developing" nations and middle-income countries (MICs).[1]

Two other chapters in this volume cover longer-term trends in inequality and developing country inequality (Chapters 7 and 9, respectively). Chapter 23 focuses on the effects of policy on poverty. We overlap to a small degree with these chapters. As argued below, our income and poverty measures are based on commonly defined and measured disposable income as well as pretax income for tax records. Consumption data are not yet comparable enough to use in cross-national analysis; wealth data comparability has begun but not yet flowered. There are only scattered cross-national studies of wealth or asset poverty. While the European Union (EU) and some OECD studies consider indices of material deprivation, such measures are not standardized enough in the rest of the world to be examined here, as elaborated in the next section, where we select yardsticks.

Next we turn to income poverty measures, mainly those based on data from the LIS and the OECD, where we examine levels, trends, and both anchored and relative poverty. We then turn to the topic of overall income inequality levels and trends, based on these same sources, before turning to top-end inequality measures. In so doing we attempt to bridge the divide between household income distribution data, from surveys and registers, and top income data based on taxable income and income tax units, highlighting the extent of complementarity and substitutability between the two. The final section summarizes our review and the conclusions we draw.

8.2. CHOOSING A YARDSTICK AND ITS COMPONENTS

Multiple perspectives can be used to evaluate the distribution of living standards in a society. These focal points, as labeled by Sen (1992, p. 20), include monetary indicators such as expenditure, income, and wealth, as well as nonmonetary indicators such as multidimensional measures of material standard of living, happiness and life satisfaction, functioning, and capabilities. Here disposable income is taken as the focal variable for overall inequality and poverty trends, and taxable income records for tax filing units which permit long-term and accurate investigations of the incomes of the top strata of society.

The distribution of income among persons, or households, has attracted the attention of social scientists at least since Gregory King's 1688 social tables, "which offer unique quantitative views of social structure and income distribution during a statistical Dark Age" (Lindert and Williamson, 1982). Pareto's analysis of the revenue curve in 1897

[1] We include Brazil, Bulgaria, China, Chile, India, Hungary, Romania, South Africa, Turkey, and additional nations in some of the analysis, based on LIS data (http://www.lisdatacenter.org/) or OECD data (www.oecd.org/social/income-distribution-database.htm).

is a more recent formalization of this interest. Income is still the most common indicator of economic resources in rich countries. While consumption expenditure is often used in developing countries, the Hicks–Hansen identity for income (or potential consumption), which is equal to actual consumption plus the change in net worth[2] over a given period, ideally ties income and consumption neatly together. But no one data set contains fully comparable measures of all three ingredients in any nation, mainly because change in net worth is difficult to measure (see also Brandolini and Smeeding, 2009; Fisher et al., 2012).

8.2.1 Consumption or Income?

The nearest alternative to disposable income is consumption or consumption expenditure, a variable that is often preferred in less developed countries because it is more easily measured in such localities. Consumption can be smoothed over time and therefore is less volatile and less reliant on seasonal variation than is income, especially in agricultural societies (Deaton and Grosh, 2000). Apart from this practical reason, many economists view consumption as a better proxy of well-being than income (Fisher et al., 2012). One argument is that well-being (utility) is a function of the goods and services actually consumed, not those merely owned (Slesnick, 1994). However, focusing on the means available to purchase commodities (income) rather than the commodities actually purchased (expenditure) makes the assessment of well-being independent of the purchase choice. Sen (1992) offers the example "... of the person with means who fasts out of choice, as opposed to another who has to starve because of lack of means" (pp. 111–112), whereas Hagenaars and colleagues (1994, p. 8) argue that using income helps us avoid the trap of confusing voluntarily low levels of consumption with material deprivation.

A second argument in favor of consumption is that it is more closely related to permanent income or lifetime resources than current income. As described by Friedman (1957, p. 209), the distributions of current income "... reflect the influence of differences among individual units both in ... the permanent component of income and ... the transitory component. Yet these two types of differences do not have the same significance; the one is an indication of deep-seated long-run inequality, the other, of dynamic variation and mobility." If one is interested in "deep-seated long-run inequality," permanent income and, hence, consumption are what matter. However, the simple proportionality between consumption and permanent income in the baseline intertemporal consumer's optimization problem does not hold if some of its basic hypotheses are relaxed and simple forms of personal heterogeneity are introduced (effects of accumulated or inherited wealth, the degree of intergenerational altruism, the variability of uncertain labor incomes, and capacity to borrow, to name just a few). Therefore, current

[2] Change in net worth can be positive (net income saved) or negative (net debt incurred).

consumption may not be a very good, and not even the best available, proxy of permanent income. Moreover, it is far from obvious that "deep-seated long-run inequality" should be our major concern. The concept has some natural appeal: an undergraduate may have a current income below that of a manual worker of the same age, but she is likely to be better off within a few years and for most of her lifetime. But "the promise of resources in the future may do little to pay the bills today" (Deaton and Grosh, 2000, p. 93). In the real world, capital markets are imperfect, and units face borrowing constraints that render the actual standard of living dependent on currently available resources. Conversely, "... the fact that an old person had a high income thirty years ago does not make up for his having a pension that is below his needs today" (Atkinson, 1983, p. 44).

Finally, there is the problem of measuring "true" consumption in rich societies. Consumption expenditure data are collected mainly to provide weights and prices for measuring the Consumer Price Index, not for measuring consumption. Few surveys actually try to measure actual consumption because purchases of durables such as major appliances, automobiles, and especially housing must all be spread out over the useful life of the good, which is bought in one period but consumed in another. Indeed, measures of consumption may differ greatly from consumer expenditures for such persons as older individuals living in an owned but mortgage-free house (Fisher et al., 2012; Johnson et al., 2005; Meyer and Sullivan, 2012a,b).

In brief, there is *a priori* no cogent or practical reason to prefer consumption to income or permanent income to current income. Indeed Haig (1921) and Simons (1938) recognized that income represents the possibility to consume and therefore established their famous identity that income equals consumption plus or minus changes in net worth. Most often, the choice is driven by available information, and there is a clear preference among rich nations to rely on income and not consumption. MICs also are increasingly likely to have living standards better measured by incomes, especially in their rapidly growing urban areas. Indeed, if the value of informal labor is captured (including production for personal consumption) then income and consumption differ only by changes in net worth, which may be small in the less modern regions of MICs. Our income data on MICs, presented below, are based on such a definition of income. Current income, therefore, seems to be a satisfactory measure of people's (material) living standard.

After settling on income as the focal variable, however, a number of important conceptual issues and data concerns remain. In addition to the issues of data availability over time and comparability across countries, the analysis of distributional measures requires decisions and assumptions regarding the income concept, the income-sharing unit, the accounting period, and statistics for measuring poverty, material hardship, or the distribution of income (Johnson and Smeeding, 2013; Smeeding and Weinberg, 2001).

8.2.2 The Definition of Income and Other Essentials

The most basic income concepts collected by national statistical agencies and used by researchers are market (factor) or pretax and transfer income and disposable income. On the basis of the recommendations of the reports of the Expert Group on Household Income Statistics—The Canberra Group (2001, 2011), market income should include all types of earnings gross of employees' social insurance contributions; net self-employment income[3]; all types of capital income, including interest, rent, or dividends received (but not accrued); and subtracting interest paid and adding private pensions.

Disposable income takes market income and subtracts direct taxes (including an employee's contributions to social insurance) but ignores other "indirect" taxes (property, wealth, and value-added taxes); then it adds back in regular interhousehold cash transfers received net of those made, as well as all forms of cash and near-cash public income transfers including social insurance benefits (for social retirement, disability, and unemployment); universal social assistance benefits; and targeted income transfer programs such as social maintenance. Near-cash benefits in the form of housing allowances or food stamps are included, as are negative taxes (for instance, in-work benefits now popular in many rich nations).[4]

However broad these definitions might be, they exclude imputed rents, capital gains and losses, and other unrealized types of capital income, home production, and in-kind transfer benefits such as education and health insurance. Because these items may account for an important share of the economic resources at the household's disposal, their inclusion in the income definition may affect measured inequality. Indeed, research on the United States suggests that uncounted realized and unrealized income from capital increases measured incomes by over 40% at the mean and more than 20% at the median (Smeeding and Thompson, 2011).

Imputed rent for owner-occupied dwellings tends to benefit a wide range of low- to high-income units, especially the elderly, but their overall effect may vary across countries, depending on the level of housing prices and the diffusion of home ownership (Frick and Grabka, 2003). Unrealized appreciation and untaxed income from capital, as well as capital gains, mainly benefit higher-income units. Indirect taxes have a relatively

[3] All surveys net out the costs of producing self-employment income, but none also deduct the costs of earning wage income, such as child care. More generally, traditional household income data cannot account for the cost of foregone home production, especially when parents switch their work from household income to market earnings, as has taken place widely in rich countries since the 1970s. Because of the change in modes of production, and the failure to account for the direct and opportunity costs of earning incomes, the rise in secondary earners among partners with children probably overstates their net income gain when both partners work.

[4] In practice, many surveys also exclude various elements of market incomes, such as interest paid or private transfers made to other households, and therefore these are often ignored.

larger impact on the budget of lower-income units (Newman and O'Brien, 2011), but the opposite happens with the imputation of in-kind public benefits for health care, housing, and education valued at their cost of provision. Because the value of these benefits is spread more or less evenly among beneficiaries ("potential" beneficiaries in the case of health insurance), the typical approach is to augment income by a fixed amount, which accounts for a larger fraction of income at lower-income levels (Burkhauser et al., 2012b). In general, elder households and households with children are net gainers from the imputation through health insurance and education benefits, respectively, whereas middle-aged childless units are net losers (Garfinkel et al., 2006, 2010). These results are very sensitive to the imputation assumptions: both valuing benefits according to willingness to pay and accounting for the quality of services provided would reduce benefits to the poor (Smeeding, 1982).

As stressed in the first Canberra Group Report (2001, pp. 62–67), the undercoverage of property and self-employment income, own account production, imputed rent for owner-occupied dwellings, in-kind social transfers, capital gains, and other unrealized income from wealth are major issues to be addressed in expanding internationally comparable income measures. But the analysis of these augmented notions of income is also scarce at the national level. Despite these omissions and shortcomings, market income and disposable household income (DHI) remain the standard concepts measured and published by national statistical agencies and research institutions.

8.2.2.1 Reference Period, Income Units, and Resource Sharing

Income is a flow of resources received by people over a given period. To have a coherent concept of income that can be used to compare distributions across countries and analyze trends over time requires common units to describe the period over which income is received and the groups of people who are sharing the income.

The statistics and trends analyzed in this section are all based on annual data, in part because of convention and data availability. The choice of the reference period does, however, have implications for the degree of inequality in the distribution measured at any given point in time. In the presence of fluctuations in income, where some households experience positive or negative shocks or lumpy income streams, the distribution of income will seem more unequal the shorter the reference period (Atkinson, 1983; Atkinson et al., 1995). At intra-annual frequencies, income may fluctuate because of seasonal factors (e.g., in agriculture), movement of workers into or out of jobs, or the timing of payments (e.g., interest on financial assets or liabilities, dividends on stocks). Aggregating over the year implies averaging out these differences, although the overall impact on measured inequality may be small (Böheim and Jenkins, 2006). By the same token, lengthening the reference period beyond the year reduces measured inequality by smoothing the variability due to the business cycle or the life cycle (e.g., Björklund, 1993; Björklund and Palme, 2002). Longer periods of time may come closer to approximating the "lifetime income" concept preferred by some economists, but in practice these data are quite rare. Using Swedish data, Björklund (1993) found that the dispersion of four decades' worth of cumulative income data for individuals was up to 40% lower than dispersion measured from a standard cross section.

Income is typically shared across family or household units. Analysis of the distribution of income across countries and over time requires both adjustments for the economies of scale associated with income sharing and the use of comparable income units. The typical income-receiving unit is the household, but some data sources report income for individuals, families, or tax-paying units, which potentially include individuals, families, and subfamily units. The broader the definition of household, the more measured inequality tends to decrease, because the dispersion of individual incomes is abated by their aggregation and supposedly egalitarian distribution among all members of the unit (Redmond, 1998). The poverty trends discussed below in Section 8.3 and the distributional measures for the entire population discussed in Section 8.4.1 are based on household income surveys and use the household as the income unit. The trends in high-income shares discussed in Section 8.4.2 are typically based on tax-paying units; they are commonly based on national income tax statistics, and multiple tax units may be included in one household.

It is widely accepted that there are greater costs associated with larger households and economies of scale in consumption that are generated by cohabitation. A family with two children faces greater costs than a family with one child, with greater expenses for food, clothing, education, transportation, and housing. As a result, the same level of after-tax income implies a lower material standard of living for the larger family. With economies of scale in a household, though, providing for the second child will not be as costly as providing for the first. Similarly, a couple living together will spend more on housing, utilities, food, and transportation than a single person, but the couple does not need to spend twice as much to obtain the same standard of living, all else being the same.

To account for costs associated with household size and the related economies of scale, researchers have developed different "equivalence scales" to create comparable incomes of different household sizes and compositions. The most commonly used equivalence scale, taken from Buhmann et al. (1988), further described by Atkinson et al. (1995), and recommended by the Canberra Group, divides household income by the square root of the household size. Using the square root scale, costs increase with the household size, but at a declining rate. The square root scale, though, does not explicitly acknowledge differences in the cost of living between adults and children. The LIS project uses the square root scale, and the OECD has used it in its publications since 1995. The EU uses an alternative scale when calculating distributional statistics with the Statistics on Income and Living Conditions (SILC) data (Atkinson et al., 2010a,b). The scale used by the EU divides household income by the weighted number of household members; different weights are applied to adults and children. The household head is given a weight of 1, each additional adult household member a weight of 0.5, and each child a weight of 0.3.[5] The U.S. Census Bureau adopted a three-parameter equivalence scale that further differentiates between children in different household types. The census scale, discussed by Short (2001), reflects the idea that children in single-parent families represent a greater increase in costs than do children in two-parent families.

The choice of the equivalence scale affects inequality comparisons. It also affects poverty comparisons, especially between those who typically live in small units (elderly) or larger units (families with children or multigenerational units) (Buhmann et al., 1988; Coulter et al., 1992).

Finally, the welfare weighting of the single observations may vary. Each observation may receive a weight of 1 (household weight) or may be weighted according to its size (person weight) or its size and composition (equivalent adult weight), again bringing differences in poverty and inequality outcomes (Danziger and Taussig, 1979; Ebert, 1997).

8.2.3 Data Source Comparability: Surveys, Tax Records, and the Rich

The last cause of limited comparability may be attributable to differences in the source of data. Income data are available both from national household surveys and from administrative archives. Of the latter, the most important are income tax records, which have historically provided long runs of continuous data and have been exploited in the literature on top incomes (Atkinson and Piketty, 2007). Income tax records suffer from potentially serious problems, including the incomplete coverage of those with incomes below the tax threshold, inability to adjust for household size, and the tendency to underreport certain types of income. These and other methodological issues related to tax records and calculation of top income shares are discussed in greater detail in Section 8.4.2.

Household surveys are also subject to problems, including sampling errors, which depend on the size and structure of the sample, and nonsampling errors caused by nonresponse and underreporting (see Chapter 2 of Atkinson et al., 1995). For these reasons, the upper tail of the income distribution tends to be unsatisfactorily covered in sample surveys, unless the rich are oversampled and reporting errors are minimized. The survey-based evidence discussed later in this chapter may be seen as being about the incomes of the bottom 95–99% of the population, and it is thus complementary but not always fully comparable to the results of high incomes based on tax records reported

[5] The equivalence scale used in the Eurostat figures is sometimes referred to as the "modified" OECD equivalence scale because it supersedes another scale previously used by the OECD (see http://www.oecd.org/els/soc/OECD-Note-EquivalenceScales.pdf).

in the final section of this chapter.[6] The specific statistics used in the calculation of poverty and income inequality using household survey data are discussed below in Sections 8.3 and 8.4.1.

All these factors need to be kept in mind in the analysis of the national trends in income inequality or in cross-national comparisons. While the data include a great deal of "noise" or possibly unknown errors, the important assumption is that the signal derived from the analysis exceeds the noise for most careful analyses, which also include sensitivity tests of assumptions (Atkinson et al., 1995; Gottschalk and Smeeding, 2000). In examining trends, we are aided by the fact that errors may be more consistent across multiple rounds of the same survey, and therefore trends may be more cross-nationally reliable and comparable than levels of inequality (Gottschalk and Smeeding, 1997). But even then, almost all surveys undergo often substantial changes over multiple decades, producing artificial changes in results due to changes in sampling, survey mode, or other changes in procedures.

Finally, full comparability is an impossible goal. Surveys within countries as well as across countries are subject to changes in methods and are characterized by differences in sampling and nonsampling errors. Comparability is vastly increased when the researcher can access the individual observations on household incomes available in a national archive or in international databases, where the original databases are harmonized, such as the LIS and the EU-SILC. Here, both levels and trends are more comparable than using other methods. Ex ante instructions to compute a series of harmonized data also are available from the OECD (2008, 2011, 2013).

Since 1983, the LIS Cross-National Data Center has been creating "harmonized" income data sets for a growing number of countries. LIS works with the existing income surveys of different countries and converts them to a format with consistent definitions and concepts that make cross-national comparisons possible. By way of nondisclosure agreements and secure remote access servers, LIS also makes possible for research access to income surveys from a number of countries that traditionally do not share their underlying data. By 2012, LIS included eight different waves of harmonized data covering roughly equivalent points in time between 1967 and 2010 across countries. The initial LIS wave included 7 countries, but the number has grown steadily, reaching nearly 40 countries in the most recent waves.

The EU's statistical agency, Eurostat, provides comparable income survey statistics for the EU member countries. Eurostat initially used a common survey instrument across the European counties but has since switched to an "ex-ante harmonized" framework (Atkinson et al., 2010a,b). The European Community Household Panel Survey covered 15 different countries from 1994 to 2001 and was replaced by the SILC. SILC works

[6] Data may be bottom and top coded, either in the course of data collection, as in the U.S. Current Population Survey (Ryscavage, 1995), or as a decision of the researcher to reduce the noise that is typically concentrated in the tails of the distribution (Burkhauser et al., 2009; Cowell and Victoria-Feser, 1996).

through the statistical agencies of the different EU member countries and achieves cross-national comparability through adoption of common definitions and concepts key to cross-national comparability of income and other policy-relevant matters in the EU.[7] In 1995 there were 13 countries initially represented, but the number of countries expanded to 22 by 2000 and 30 by 2005. The income distribution measures produced by Eurostat now cover 32 different countries. In contrast to LIS, the Eurostat distribution statistics are produced annually; covering the years between 1995 and 2011 there are 380 year-country observations for the different distributional measures.

The OECD also regularly releases income distribution and poverty measures for its member countries. These releases have been highlighted in major publications, including *Growing Unequal?* (2008), *Divided We Stand* (2011), and *Crisis Squeezes Income and Puts Pressure on Inequality and Poverty* (2013), and are also available in the organization's Household Income Distribution and Poverty online databases (www.oecd.org/social/inequality.htm). The OECD figures are based on the national statistical agency household surveys and are created by a network of country specialists using common measures.[8] Since the figures are calculated from country-specific surveys in different years, the data are not always based on the same years. In several of these publications, the OECD data compare fairly well with the LIS data observed in the same year, but then the OECD methods add more up-to-date data than those available from the LIS. In the mid-1970s, 8 countries were represented in the distributional statistics, but by the late 2000s the number of countries had grown to 34. Because these data tend to be more immediate and can be updated with less ex-post harmonization than, say,

[7] Even within this common framework, there are important differences in the approaches the different EU countries use in their SILC income surveys. See Iacovou et al. (2012) for a detailed discussion of some of the weaknesses of the EU-SILC data and potential problems for using these data for cross-national analysis. Several EU countries (Finland, the Netherlands, Norway, Slovenia, and Sweden) use administrative records supplemented with interviews of representative household members. Most of the countries use rotational panel household surveys, but there is considerable variation in the number of rotation groups and length of time in the panel. In most of the countries the length of the panel is 4 years, with one rotation group dropped every year, but Norway and France have 8- and 9-year panels, respectively, and Luxembourg uses a traditional panel. Spain and Ireland use substitutes for nonresponders in their household survey. Before 2008 Germany used a combined quota and random sample for its survey.

[8] At least some of the surveys used by both OECD and LIS are household surveys combined with samples drawn from administrative registers in the Nordic nations, Austria, France, and Denmark. These data suffer from less item nonresponse and reporting error than most household surveys, and they include a full random sample of all households, including the top 1%, thus also improving nonresponse and data quality. Because so much of the income gain in the past two decades has been at the top end of the distribution, these national register data might have become systematically different from the normal survey data in these databases. See OECD (2012) for a list of their surveys based on registers compared with other types of sample surveys. See also Chapter 2 of Atkinson et al. (1995) for a more general discussion.

LIS, we use OECD (2013) poverty data to capture the effects of the Great Recession (GR) on poverty below.

8.3. POVERTY MEASUREMENT AND TRENDS

In this section we examine the complexities of poverty measurement from its origins to current practice. We rely mainly on the LIS and OECD data to examine levels and trends in overall poverty, but we also refer to the literature on child and elder poverty. In our empirical examinations we look at both rich countries and MICs, comparisons of trends in relative poverty over different time periods, comparisons of relative and anchored poverty across the GR, and finally the correlation between levels of relative poverty and inequality as an introduction to Section 8.4 on overall income inequality.

8.3.1 Origins and Development of Poverty Measurement

The fundamental concept of poverty concerns itself with having too few resources or capabilities to participate fully in a society. As Blank (2008) reminds us, "poverty is an inherently vague concept and developing a poverty measure involves a number of relatively arbitrary assumptions." Ultimately, social scientists first need to establish the breadth and depth of this social phenomenon called "poverty" before they can meaningfully analyze it and explore its ultimate causes and remedies. Thus, we turn to measures and comparisons of poverty used by economists and other social scientists within and across nations.

Our discussion is framed by Figure 8.1, which reviews most of the possibilities of poverty concepts and measures. Here we are mostly interested in the concept of objective poverty measures, according to some standard definitions of means versus resources.[9]

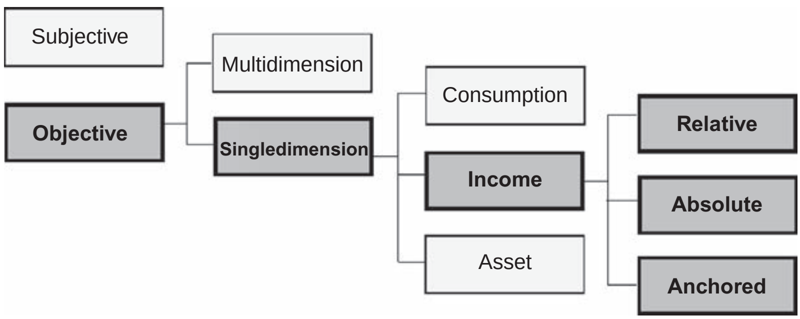

Figure 8.1 Conceptualizing poverty and its measurement. *Source: Adapted from Dhongde (2013).*

[9] See also Chapter 22, "The Idea of Antipoverty Policy" by Ravallion (2014) on the origins of poverty in economic thought and the role of antipoverty policy and social protection in meeting basic human needs.

In this chapter we are mostly interested in objective poverty measurement using a single dimension of "resources," income, and several notions of "needs" standards: those that are relative, absolute, and closely related anchored poverty lines. We chose income poverty because of its domination in modern (post-1960s) poverty studies and because of its linkages to the income inequality literature that follows. Other measures and concepts of poverty also are mentioned but not empirically investigated.

Income or living standards poverty measurement began in the Anglo-Saxon countries and dates back at least to Rowntree (1901), who was the first to use the concept of a poverty line in his empirical work on York, England. Thanks to his enterprise, and that of Booth (1903), who invented the idea of a poverty line for London, we have a meaningful social indicator of basic needs (see, for instance, Piachaud, 1987; Ravallion, 2014; Ringen, 1985; Townsend, 1979, 1993). We also note that official poverty measurement began as an Anglo-American social indicator. Since then, "official" measures of poverty (or measures of "low income") now exist in over 100 countries and for Europe as a whole (Eurostat, 2005). The United States (DeNavas-Walt et al., 2012) and the United Kingdom (Department for Work and Pensions, 2012) have long-standing "official" poverty series. Statistics Canada publishes on an irregular basis the number of households with incomes below a "low-income cutoff", as does the Australian government with those below the "Henderson line." In Northern Europe and Scandinavia the debate centers instead on the level of income at which minimum benefits for social programs should be set. In other words, their concept of insufficient "low income" is directly fed into programmatic responses to social needs (Björklund and Freeman, 1997; Marx and Nelson, 2013; Ravallion, 2014).[10]

While poverty measurement is an exercise that is particularly popular in English-speaking countries, most rich nations share the Anglo-Saxon concern over distributional outcomes and the well-being of the low-income population. There is no international consensus on guidelines for measuring poverty, but international bodies such as the United Nations Children's Fund (UNICEF, 2000), the United Nations Development Programme (UNDP, 1999), the Organization for Economic Cooperation and Development (OECD, 2008, 2013), and the European Statistical Office (Eurostat, 1998, 2005) have published several cross-national studies of the incidence of poverty in rich countries. The large majority of these studies have been based on the LIS database, which can be accessed at www.lisdatacenter.org. Some examples of these studies include Förster (1993), Jäntti and Danziger (2000), Smeeding et al. (2000), Kenworthy (1998),

[10] In addition to these objective poverty measures, several economists have used subjective measures of poverty and well-being, including income sufficiency (Groedhart et al., 1977; Hagenaars and van Praag, 1985; Ravallion, 2012; van Praag, 1968).While we do not cover these types of measures here, they are much akin to the chapter on subjective well-being and inequality later in this volume (Clark and D'Ambrosio, 2014).

Smeeding et al. (1990), and Smeeding (2006). More recently the European Union and the OECD have regularized measurement of poverty but using different standards and data sources. Today one can find poverty measures in over 100 countries, as well as some harmonized measures from the World Bank that use both secondary (published) data- and microdata-based measures of consumption and income to determine those living below some particular amount of income per person day, from $1.25 to $2.00 (Chen and Ravallion, 2012; Ravallion and Chen, 2011b).

8.3.2 Measuring Poverty

Most broadly, the measurement of poverty in rich nations involves the comparison of some index of household well-being with household needs. When command over economic resources falls short of needs, a household (or person or family) is classified as poor. Well-being refers to the material resources available to a household. Among most social scientists, the concern with these resources is generally not with material consumption *per se*, but rather with the capabilities such resources give to household members so they can participate fully in society (Brandolini and Smeeding, 2009; Sen, 1983, 1992). These capabilities are inputs to social activities, and participation in social activities gives rise to a particular level of well-being (Coleman and Rainwater, 1978; Rainwater, 1990). Methods for measuring a person's or household's capabilities differ according to the context in which one assesses them, either over time or across nations or among subpopulations within a nation, for example, rural versus urban China.

All advanced societies are highly stratified; hence, some individuals have more resources than others. The opportunities for social participation are affected by the resources that a household disposes, particularly in nations such as the United States, where there is heavy reliance on the market to provide such essential services as health care, postsecondary education, and child care. Monetary income is therefore a crucial resource. Of course, there are other important kinds of resources, such as social capital, wealth, noncash benefits, primary education, and access to basic health care, all of which add to human capabilities (Coleman, 1988). These resources may be available more or less equally to all people in some societies, regardless of their monetary incomes. There are many forces in rich societies that reduce well-being by limiting capabilities for full participation in society, including inadequacies in neighborhoods where people live, racial and ethnic discrimination, neighborhood violence, low-quality public schools and other social services, lack of good jobs, and job instability, all of which increase economic insecurity, reduce human capabilities, and increase poverty.

Because there is no single commonly accepted way to measure poverty among social scientists, there is a desire to go beyond the popularly used income poverty definition used below. So there exists a wide variety of additional poverty measures that substitute for or complement the preponderance of income-based measures used by quantitative sociologists and economists (see, e.g., Boltvinik, 2000; Haveman, 2009; Ruggles, 1990). In principle, poverty is a multidimensional concept and should reflect several aspects of personal well-being, as shown in Figure 8.1. Forms of deprivation other than economic hardship can certainly be relevant to poverty measurement and to antipoverty policymaking. A number of authors have suggested that separate measures of needs ought to be developed for different goods and services (Aaron, 1985). Housing and health care often are mentioned in this context, although the latter is particularly of interest in medically unequal nations such as the United States, whereas the former is of much greater interest in the United Kingdom (United Kingdom Department of Social Security, 1993).

The concept of multidimensional poverty is also flourishing. Official measures of social exclusion, material deprivation, and material hardship exist mainly in Europe, although they are beyond the empirical bounds of this chapter. Europe adopted the official Laeken set of social indicators in 1995, including the at-risk-of-poverty indicator, with an explicit objective of reducing poverty and social exclusion (Marlier et al., 2007). Indeed, indicators of material deprivation now form part of the Europe 2020 target of poverty reduction (Atkinson and Marlier, 2010, Chapter 6).

Both consumption poverty and asset poverty have been proposed as an alternative to income poverty in rich nations (Brandolini et al., 2010; Meyer and Sullivan, 2012a,b). In a few nations, asset and income poverty can be combined into a joint measure (Gornick et al., 2009), as can consumption and income poverty (Meyer and Sullivan, 2012a,b). But consumption and asset poverty measures are not yet ready for widespread use on a cross-national basis, despite their usefulness for some types of poverty measurement (e.g., many income-poor elderly consume more than their incomes because of dissaving and spending from assets).

In summary, we are interested primarily in comparative cross-national poverty measured in terms of income, not only because income-based poverty measures are more comparable across nations but also because income-based poverty allows us to connect our empirical work to overall inequality *per se* in the rich nations and MICs observed in this chapter. As mentioned above, income is generally a better measure of resources than consumption in rich countries. In the rapidly growing MICs, the differences in living standards between rural and urban populations cause the most angst over consumption versus income poverty. The richer the country, however, the more income becomes a better and more comparable measure. At the frontier of such comparisons, work by the LIS on "production for own consumption" and "informal labor" income help ease the comparisons across diverse areas within nations.

8.3.3 Measuring Absolute, Relative, and Anchored Poverty in Rich and Selected MICs

An absolute poverty standard is defined in terms of a level of purchasing power that is sufficient to buy a fixed bundle of basic necessities at a specific point in time. A relative standard, on the other hand, is defined relative to the typical income or consumption level in the wider society. The purchasing power of a relative poverty standard changes over time as society-wide income or consumption levels change, whereas an absolute poverty standard changes only with the prices of commodities it can buy. Most cross-national comparisons use the relative definition of poverty, especially because purchasing power parities to convert any absolute measure to country currency are subject to fluctuation and sometimes severe measurement error (Jäntti and Danziger, 2000).

In the broadest sense, all measures of poverty or economic need are relative because context is important to the definition of needs. The World Bank uses poverty measures of \$1.25–2 per person per day—or \$1095–2190 per year for a family of three—for the developing nations of Africa, Central Asia, or Latin America (Chen and Ravallion, 2012). In contrast, the 2011 United States "absolute" poverty threshold was about \$18,000 for a family of three—8–17 times the World Bank's poverty line; one-half of median income, the preferred relative poverty standard in the United States, is another 25% above this poverty line, or 10–21 times the poverty standard in poor countries. Moreover, as economic inequality has increased in most rich societies over the past 20 years, the study of relative deprivation and poverty has taken on new life (Gornick and Jäntti, 2013; Gottschalk and Smeeding, 2000; OECD, 2011, 2013).

Cross-national comparisons of poverty in rich countries therefore rely heavily on relative concepts of poverty, which are a reflection of the fact that a poverty standard or a minimum income standard ought to reflect the overall standard of living in society. One early source of this formalization (Abel-Smith and Townsend, 1965) came about in arguing that the officially defined minimum level of income in the United Kingdom, as represented by the National Assistance scale, should increase with the rising standard of living, and not just with consumer prices. It was Townsend's work in the early 1960s, culminating in his famous 1979 book, that really launched the relative poverty approach on a much wider scale.

As Townsend (1979, p. 31) wrote:

> *Individuals, families and groups in the population can be said to be in poverty when they lack the resources to obtain the type of diet, participate in the activities and have the living conditions and the amenities which are customary, or at least widely encouraged or approved in the societies to which they belong.*

The measurement of relative poverty has more recently been generally operationalized with a definition of the poverty line as a fraction of median income. Cross-national studies typically compare the percentage of people living with income below some fraction of the family-size-adjusted national median income.

Measurement of relative poverty in the United States also began in the 1960s and was pioneered by Fuchs (1967), who followed the thinking of Townsend and Abel-Smith and linked relative and absolute income poverty measurement. When Fuchs began his study, the absolute poverty measure in the United States begun by Lampman (1964) and then Orshansky (1965) was based on a poverty line of about $3000 for four persons. Fuchs pointed out that this was half of the median income at that time and that one could think differently about relative poverty compared with absolute poverty (Gilbert, 2008, p. 136).[11]

A relative poverty measure comparison is also consistent with a well-established theoretical perspective on poverty (Sen, 1983, 1992; Townsend, 1979). However, the fraction of income at which the poverty line ought to be set is open to debate. Most cross-national studies (LIS, OECD) focus on half of the median income, following Fuchs and others. But many feel that a 50% of the median standard is too low. It implies a poverty cutoff well below half the mean in unequal societies,[12] and it also affects the country rankings.[13] The European Statistical Office Working Group on Poverty Measurement has used 60% of the national median income as the common poverty threshold for European Community poverty studies in the new millennium (Eurostat, 2005, 2011).

A fully relative measure of poverty changes in lock step with median income, whereas an absolute measure changes only with prices. The income elasticity of the poverty line is therefore between 0 for the absolute measure and 1 for the fully relative measure. In some countries, such as the United States, the measure of poverty has become "semi-relative" as the poverty line advances only with the living standards of the bottom part of the distribution and not the whole distribution (Short, 2012). Ravallion and Chen (2011a) refer to "weakly relative measures," which have the feature that the poverty line will not rise proportionately to the median or mean, but will have income elasticity less than unity. These are also-called quasi-relative poverty standards in the new "Supplemental Poverty Measure" for the United States, which varies by considering expenses on basic needs for a low-income family and how they change over time (Short, 2012).

Understanding both absolute and relative poverty measures is worthwhile because they tell different things about living standards as well as deprivation. Increasingly, the idea of "anchored" poverty measures have become important and can be used to indicate both relative (or weakly relative) and absolute poverty trends within a given nation.

[11] Lampman's chapter, "The Problem of Poverty in America" (part of the 1964 Economic Report of the President), preceded President Johnson's declaration of the "War on Poverty" in his 1964 State of the Union Address. But while Lampman used $3000 of monetary income for his measure, it was not adjusted for family size. Orshansky (1965) produced a measure that had a similar poverty count and a similar poverty line for a four-person family but that differed by family size. In the late 1960s, Orshansky's measure became the official measure of poverty in the United States.

[12] Most relative poverty or deprivation measures rely on the median, not the mean income, especially in cross-national studies, because the latter may be affected by sampling and nonsampling error in different surveys. Moreover, the reference to the standard of living enjoyed by the middle or average family means the median family. See Smeeding et al. (1990).

[13] See LIS key figures for country poverty rates at 40, 50, and 60% of the median at http://www.lisdatacenter.org/data-access/key-figures/search/) and compare rankings there with the European Community rates in 2012 as taken from the Eurostat web data explorer.

Anchored poverty measures begin with the same fully or weakly relative measure in 1 year (t) and then compare relative poverty in some future year (say year $t+10$) with poverty measures against a poverty line that has been changed only for prices between year t and year $t+10$. These measures are especially useful in periods of rapid expansion or contraction in an economy, where relative poverty may not change by a lot, but where absolute poverty does change because of economic growth or contraction (see Atkinson et al., 2002; Johnson and Smeeding, 2012; OECD, 2013; Smeeding, 2006). Any absolute poverty line is also, therefore, an anchored poverty line. The difference is that an anchored poverty line can be updated to any period that is relevant to policy, given the analysis. As suggested above, the absolute (or anchored) U.S. Orshansky poverty line for the 1960s was about the same as a fully relative half-median income measure at that time. The United States has anchored its "official" poverty measure at this same point since that date. Now, 60 years later, the U.S. poverty line is only at about 30% of median income, not the 50% it was at its inception. Hence, analysts prefer to anchor their U.S. poverty studies at a semi-relative line (Johnson and Smeeding, 2012).

Here, for simplicity and breadth, we focus exclusively on the "headcount" measure of poverty, the share of people who fall below some definable point that indexes poverty. This approach does not measure the depth of economic need, the poverty gap, or the severity of poverty. People who are poor could become richer or poorer, with no change in a headcount measure of poverty. A pragmatic reason for using the poverty gap is that the headcount may be quite sensitive where there are spikes in the distribution because of the payment of flat-rate social transfers such as minimum social retirement level (or changes to the minimum wage).[14] Others (see especially Foster et al., 1984; Sen, 1976) focus on poverty measures that examine the distribution of poverty among the poor, taking account of both the depth of poverty and its severity. Because headcount measures are more easily understood, compared, and implemented than other more complex measures, we rely on them below.

The data we use are taken from LIS and sometimes OECD and are limited mainly to rich countries and MICs. The OECD includes a large number of rich nations, as well as Chile, Mexico, and Turkey. Both LIS and OECD have been interested in the BRICS countries (Brazil, Russia, India, China, and South Africa). LIS also has expanded to include other Latin American nations and Mexico. To establish trends in income poverty, however, one must have at least a decade or two of data, and here the number of MICs we can examine is severely limited.[15]

[14] A pragmatic reason for not using the poverty gap, especially in cross-national studies, is that underreporting of incomes, the definition of incomes, and editing for item nonresponse may differentially affect the lowest incomes and overstate the poverty gap.

[15] Indeed, we do not use the Eurostat (2012) poverty measures for two reasons. First, both the LIS and OECD measures rely on the same EU-SILC data for most of the EU nations and, second, because the EU-SILC data are very recent, starting only in 2005.

8.3.4 Level of and Trends in Poverty

We examine the level of and trends in poverty in a set of graphs and one table, all based on the LIS key figures data set, plus some special tabulations, to determine the level of anchored poverty using both LIS and OECD data. The percentage of people living below the half-median poverty line can now be examined for 38 nations using the LIS data (Figure 8.2). The 28 nations with light gray bars are the richest Anglo-Saxon, EU, and OECD nations; the 10 darker gray bars are for the MICs, including Russia, the BRICS nations, and several South American nations.[16]

If a "less poor" country is one with a single-digit poverty rate (where between 5% and 10% of its population are poor), 17 countries hit that target in the mid- to late 2000s, as

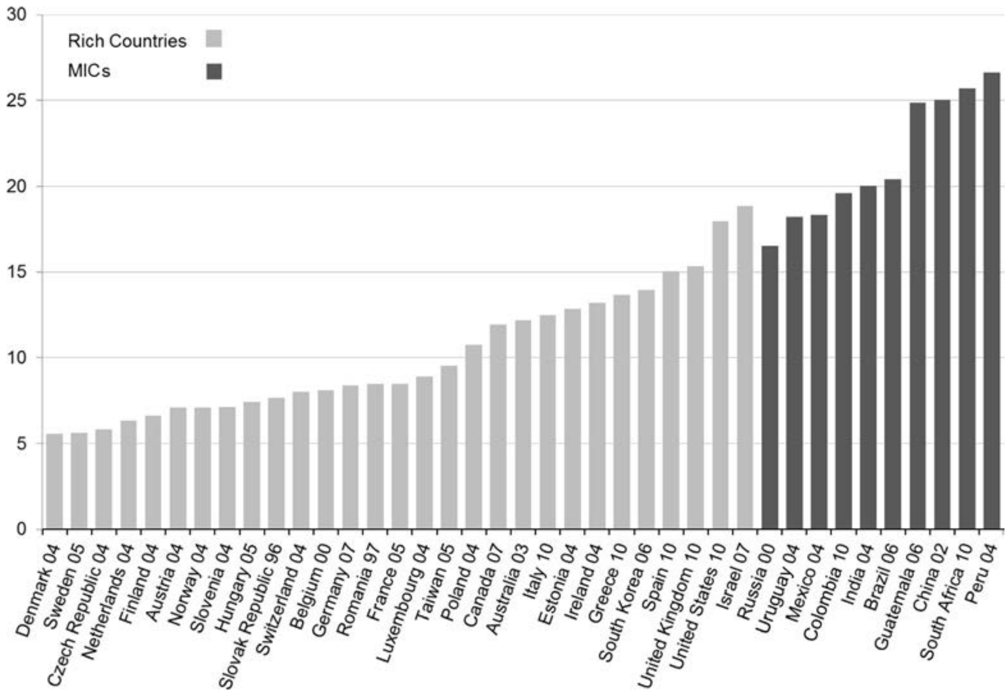

Figure 8.2 Relative poverty rates for total population (mid- to late 2000s) using LIS data. Poverty is measured by the percentage of people living in households with income (adjusted for family size) below half the median national income. *Source: Luxembourg Income Study, Key Figures: http://www.lisdatacenter.org/lis-ikf-webapp/app/search-ikf-figures*.

[16] The Eurostat (2005) produces poverty measures for all 27 EU nations now, including some which are not captured in either OECD or LIS data, and measures of poverty depth and severity as well. But their figures are at the 60% of poverty level and are not comparable to the half median figures in LIS and OECD.

shown in Figure 8.2. The Scandinavian and Nordic nations are generally lowest, along with a number of "middle" western, central, and eastern European nations who have joined the 27 in the EU (from Belgium and the Netherlands west to Luxembourg, Germany, France, and Austria, plus Switzerland, the Czech Republic, Slovakia, Hungary, Slovenia, and Romania). This pattern has been more or less the same since the first LIS measures appeared 20–25 years ago (Atkinson et al., 1995; Smeeding et al., 1990), although the number of nations has now expanded considerably. Taiwan weighs in with the 17th lowest poverty rate—about 9.5%. Another nine nations have relative poverty rates from 10% to 15%, including Italy, Spain, Greece, Poland, Estonia, Canada, Australia, Ireland, and South Korea. Three rich nations are between 15% and 19%: the United Kingdom (15%), the United States (18%), and Israel (19%). Moving to the MICs, six countries overlap the three rich nations in the 15–20% range; Russia has a poverty rate below the United States and Israel, and Uruguay and Mexico more or less even with the United States. Finally, Colombia, India, and Brazil were all at 20% poverty. Poverty rates are 25% and above in Guatemala, China, South Africa, and Peru. In short, the range of comparable relative poverty rates from the most comparable source extant varies by a factor of 5.

The OECD data in Figure 8.3 provide essentially the same picture but measuring all nations in 2010 compared with 2002–2010, as shown in Figure 8.2. The OECD data also

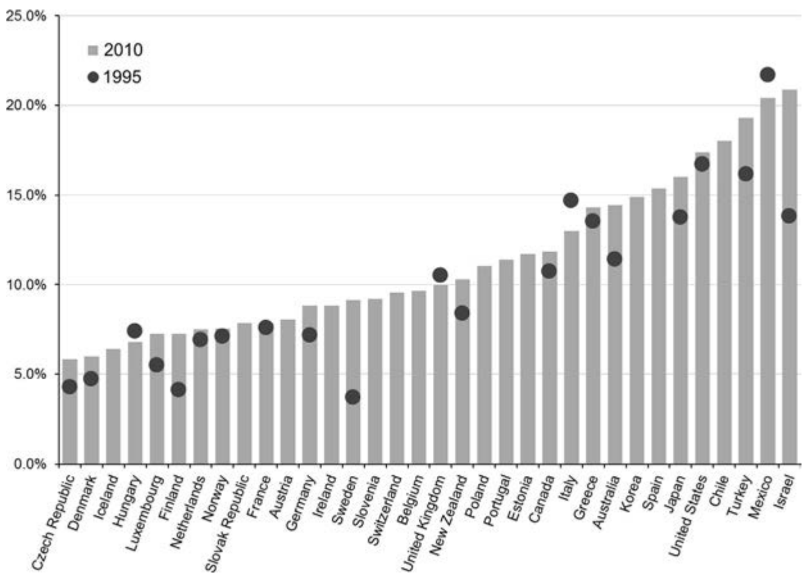

Figure 8.3 Levels and trends in relative poverty in OECD nations: 1995–2010. Poverty is measured by the percentage of people living in households with income (adjusted for family size) below half the median national income. *Source: OECD Income Distribution Database (www.oecd.org/social/income-distribution-database.htm).*

add a few nations (Iceland, Chile, and Turkey) to those in Figure 8.2 and also presents some data on 15-year trends in poverty, where available. Here, Israel leads the league in the table of poverty, with headcount rates surpassing 20%. The advantage of the OECD data is its rapidity of observation, and with 15-year trends, it is clear that relative poverty rates may change substantially over short periods of time.

Poverty in LIS is typically somewhat higher among children (Figure 8.4). Poverty averaged 13.5% among the countries for the total population but 16.5% for children. The correlation between child poverty and poverty in the total population is, however, quite high at 0.91, as reflected in Figure 8.4. The slope of the regression line in Figure 8.4 is 1.32, suggesting that child poverty rises about one-third faster than does overall poverty in these nations. The same sets of countries that are high, middle, and low poverty countries in Figures 8.2 and 8.3 also fall in the same relative positions for child poverty, but in some nations, such as Uruguay and Brazil, child poverty is disproportionately higher than overall poverty. In South Korea, child poverty is substantially lower than overall

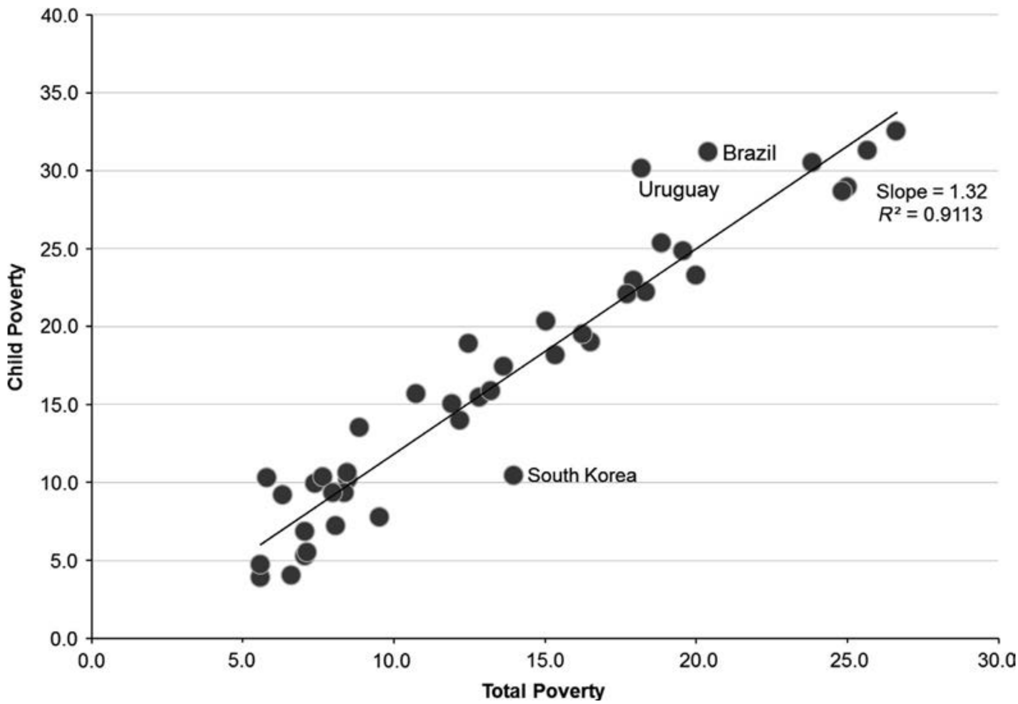

Figure 8.4 Correlation between total population poverty and child poverty in 38 rich and middle-income countries (late 2000s) using LIS data. Poverty is measured by the percentage of people living in households with income (adjusted for family size) below half the median national income. *Source: Luxembourg Income Study, Key Figures: http://www.lisdatacenter.org/lis-ikf-webapp/app/search-ikf-figures.*

poverty. In the others, child poverty and overall poverty track each other closely. In general, poverty among the elderly is both lower and falling compared with that among children, which is higher and rising in most nations (LIS key figures, and OECD, 2013, Figure 8).

Trends in poverty can be evaluated using the same data and allow us to break the countries into several different groups based the range of years over which data are available and geographic/institutional comparability. The panels in Figure 8.5 show longer-term (since 1979) trends for the 14 different countries that have been in the LIS data for the longest period. All of these figures include data up through 2010 (or the latest year available). The trends from 1995 to 2010 are best illustrated using the OECD data in Figure 8.3, where we have such data for 21 nations.

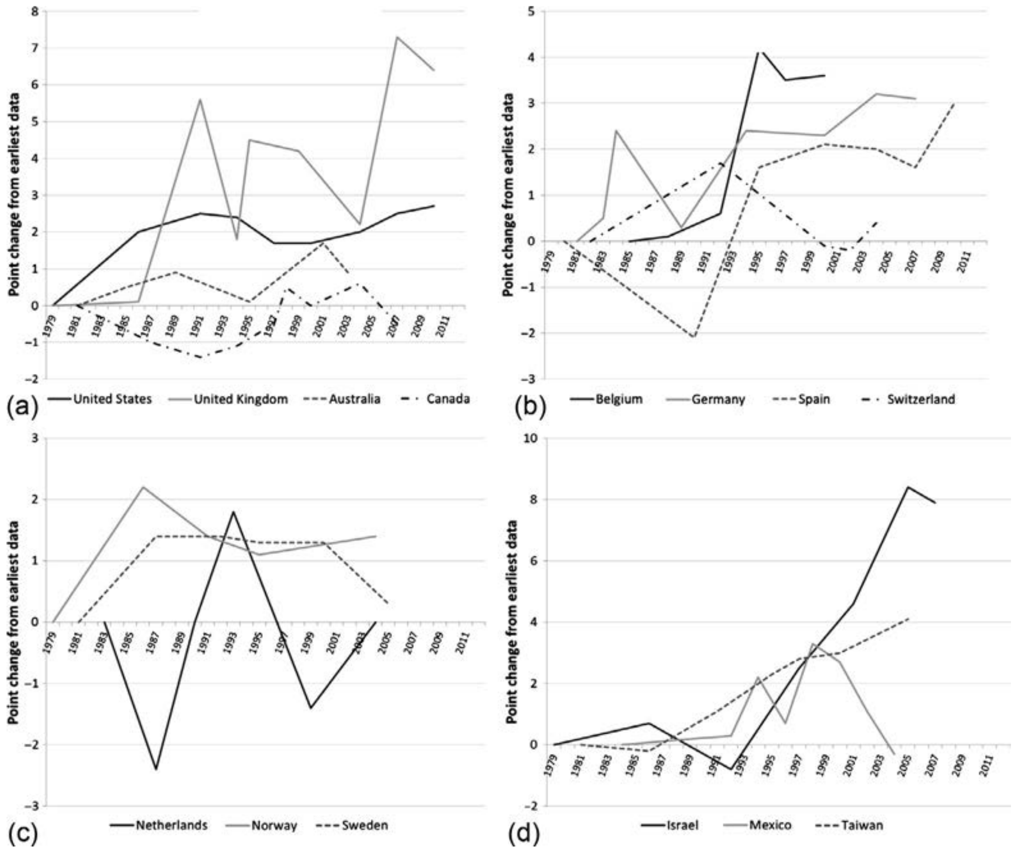

Figure 8.5 Trends in half-median poverty for 14 rich/middle-income nations, 1979–2010: (a) English-speaking countries, (b) continental/southern Europe, (c) Nordic countries, and (d) other countries. Poverty is measured by the percentage of people living in households with income (adjusted for family size) below half the median national income.

In analyzing trends in poverty, we are interested in both the direction of change and its magnitude. One finding is that none of the countries in Figure 8.5 (those countries with the longest series of data) have poverty that is appreciably (3 percentage points) lower in the most recent year than in the initial year of data from the late 1970s or early 1980s.[17] Canada (panel a) and Mexico (panel d) do have a bit lower poverty, but the difference for each country is very small (−0.5 and −0.3 points, respectively, with both series extending up through the mid-2000s—2007 and 2004, respectively). The trend data from the OECD (1995–2010 in Figure 8.3) suggest that relative poverty decreased only in Italy and Mexico over that period, although both by less than 3 percentage points.

Each of the other countries with long trends in Figure 8.5 has seen poverty increase or remain flat. Two countries stand out for particularly large increases, including Israel (panel d) and the United Kingdom (panel a), whereas the Nordic countries stand out as a cluster for seeing very little change in poverty (panel c) based on the LIS data. In contrast, the OECD data in Figure 8.3 show a massive increase in Swedish poverty, coming mostly after 2005 (compare with the LIS trend for Sweden in Figure 8.5c) and almost no change from 1995 to 2010 in the United Kingdom.[18] While relative poverty more than doubled in Sweden, appreciable increases can also be found in Australia, Finland, Israel, and Turkey over the 1995–2010 period (Figure 8.3).

Returning to Figure 8.5, in some nations, such as the Netherlands and Spain, poverty fell in the 1980s but returned to former levels (Netherlands) or went on to new heights (Spain) based on the LIS data. Poverty in Mexico rose though 1997, but then plummeted back to near its origin in 2004. Israel and the United Kingdom each had poverty rates more than 6 points above their origins by the late 2000s. Poverty rose steadily in the United States and Germany, increasing by about 3 percentage points in each, and by 4 points in Taiwan and more than 3 points in Belgium, from origin until the late 2000s. The rest generally stayed within ±3 percentage point bands from the origin until the final year.

While lessons about the importance of the start and end dates in term of volatility can be drawn, as well as differences across data sources in Figures 8.3 and 8.4, some other lessons emerge. These trends suggest that progress against relative poverty was uneven

[17] *Appreciably* here means more than a 3 percentage point change. Atkinson and Morelli (2012) discuss the definition of a salient change in the poverty percentage, explaining that there are both supply (sampling error and other design elements) and demand considerations (use of the figures). They end up applying a 2 percentage point change criterion. The period examined here is a much longer one, so we choose 3 percentage points as the cutoff. The lines in Figure 8.5 show the 3 percentage point bounds in each panel.

[18] Interestingly, the increase in Swedish relative poverty coincides with a rapid increase in income inequality (see Section 8.3.5). Because Sweden is one of the few nations that use register data that contain the full range of top incomes, the rapid increase in the Swedish median income may in part be driving this trend.

Table 8.1 Trends in relative and anchored poverty

		Poverty rates				
		Initial year	End year		Percentage point change from initial year	
	Years	Relative	Relative	Anchored	Relative	Anchored
Czech Republic	1996–2004	5.1	5.8	3.4	0.7	−1.7
Germany	1994–2007	7.7	8.4	7.3	0.7	−0.4
France	1994–2005	8.0	8.5	7.2	0.5	−0.8
Netherlands	1993–2004	8.1	6.3	4.4	−1.8	−3.7
Hungary	1994–2005	9.9	7.4	4.8	−2.5	−5.1
United Kingdom	**1994–2010**	**10.8**	**15.4**	**7.2**	**4.6**	**−3.6**
Canada	1994–2007	11.3	11.9	7.6	0.6	−3.7
Australia	1995–2003	11.4	12.2	7.8	0.8	−3.6
Italy	**1995–2010**	**14.1**	**12.5**	**9.5**	**−1.6**	**−4.6**
Greece	**1995–2010**	**15.4**	**13.6**	**6.4**	**−1.8**	**−9.0**
United States	**1994–2010**	**17.6**	**17.9**	**14.5**	**0.3**	**−3.1**
Mexico	1994–2004	20.8	18.3	16.5	−2.5	−4.3
Average		11.7	11.5	8.0	−0.2	−3.6

Data are based on the authors' calculations from LIS microdata files, http://www.lisdatacenter.org/.
Note: Poverty is measured by the percentage of people living in households with income (adjusted for family size) below half of the median national income.

and rare in rich nations over the past 20–30 years. Other than Mexico, poverty rates did not consistently decrease over the past 25 years in any of the nations we examine here.[19]

8.3.5 Relative Versus Anchored Poverty and the GR

A different way to examine progress against poverty is to take a set of OECD nations and examine changes in both relative and anchored poverty in 12 nations over an 8–15-year period using LIS (Table 8.1) or across the shorter period of the GR, from 2005 or 2007 to 2010 (Figure 8.6). On average, relative poverty did not change much in the LIS, but anchored poverty fell by about a third from 11.7% to 8.0% between the mid-1990s and the year of the most recent observation (Table 8.1), suggesting rising living standards for people with incomes that would have been considered poor in the initial period. Indeed, anchored poverty decreased in every nation, reflecting rising living standards in Europe and elsewhere in the rich countries and MICs up until the GR. In contrast,

[19] Ferreira de Souza (2012) also suggests that both poverty and inequality decreased in Brazil over the 1995–2009 period.

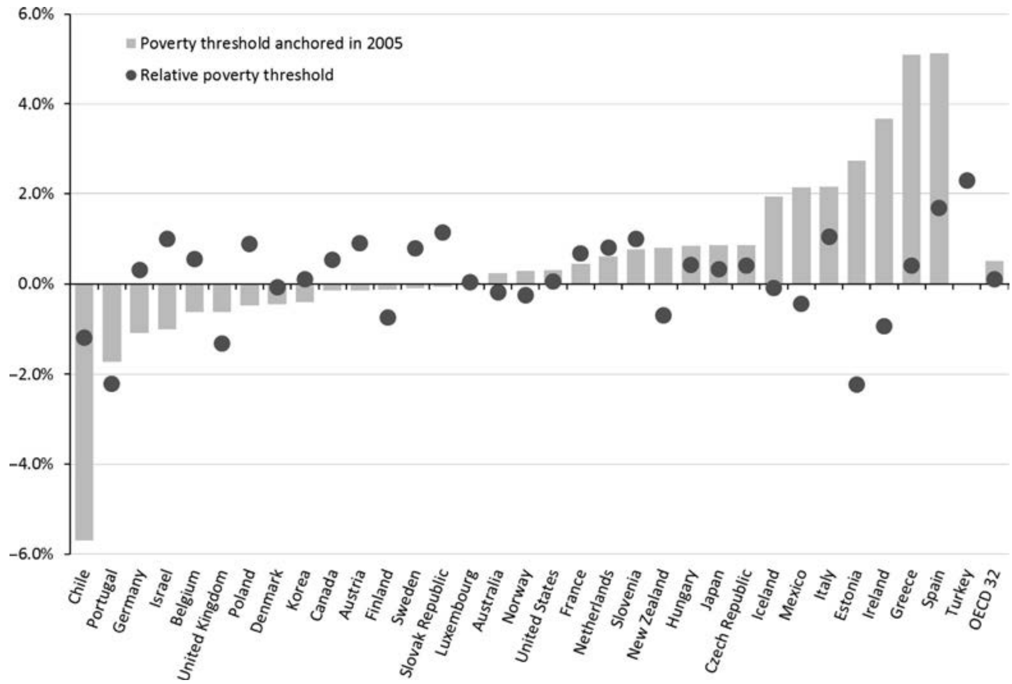

Figure 8.6 Anchored poverty in OECD countries: 2007–2010. *Source: OECD Income Distribution Database (www.oecd.org/social/income-distribution-database.htm).*

the changes in relative poverty over this same period were small, on average, in the LIS data but ranged from an increase of 4.6 percentage points in the United Kingdom to a decrease of 2.5 percentage points in Hungary and Mexico. All other relative poverty rates changed by less than 2 percentage points over this period.

The effects of the GR are included in the four LIS data sets in bold for the United States, United Kingdom, Italy, and Greece in Table 8.1. In each nation a data point is also available for 2007 (or 2008 for Italy only). In each nation, relative poverty rose by 0.2–2.2 percentage points through 2010, suggesting greater relative income losses for the poor than the rich in each nation during the GR. Despite the overall trends in each nation, anchored poverty increased between 2007/2008 and 2010. It increased by 1.2 points in the United States, 1.9 points in Italy, 2.6 points in Greece, and 3.0 percentage points in the United Kingdom. Hence, in each nation, despite the overall reductions in anchored poverty shown in Table 8.1, the poor lost ground in both relative and real terms over the course of the GR.

The OECD data (Figure 8.6) suggest much the same pattern in these four nations but add many others as well. Iceland, Mexico, Spain, Estonia, and Ireland join the list above, where living standards fell during the GR and anchored poverty increased much faster than relative poverty. Indeed, relative poverty did not increase much at all during the GR (and even decreased in Estonia and Ireland). In Poland, Belgium, and Germany, anchored poverty decreased but relative poverty did not change much. In Portugal and Chile, both anchored and relative poverty decreased during the GR. The changes in other nations were smaller.

We conclude that there was little progress in reducing relative poverty in almost all the rich nations examined here over the past two or three decades. Anchored poverty did decline in almost all rich nations from the 1990s up until the GR in 2007. Since the onset of the GR, however, anchored poverty has trended upward, with increases in anchored poverty in a majority of nations reducing some of the progress in real living standards for low-income households over the past 20 years, especially in the nations hardest hit by the GR. Relative poverty rates changed much less during the GR.

Finally, Figure 8.7 shows the correlation between relative poverty and inequality (using the LIS project Gini coefficient for DHI) across 38 nations. The correlation is astoundingly high: over 91%. The slope is 0.63, suggesting that a 10-point difference in the Gini, say from 0.20 to 0.30, is associated with a more than 6 percentage point increase in relative poverty. Still, at inequality levels of about 0.27 and 0.32, poverty rates can vary as much as 4 percentage points across nations with the same level of overall

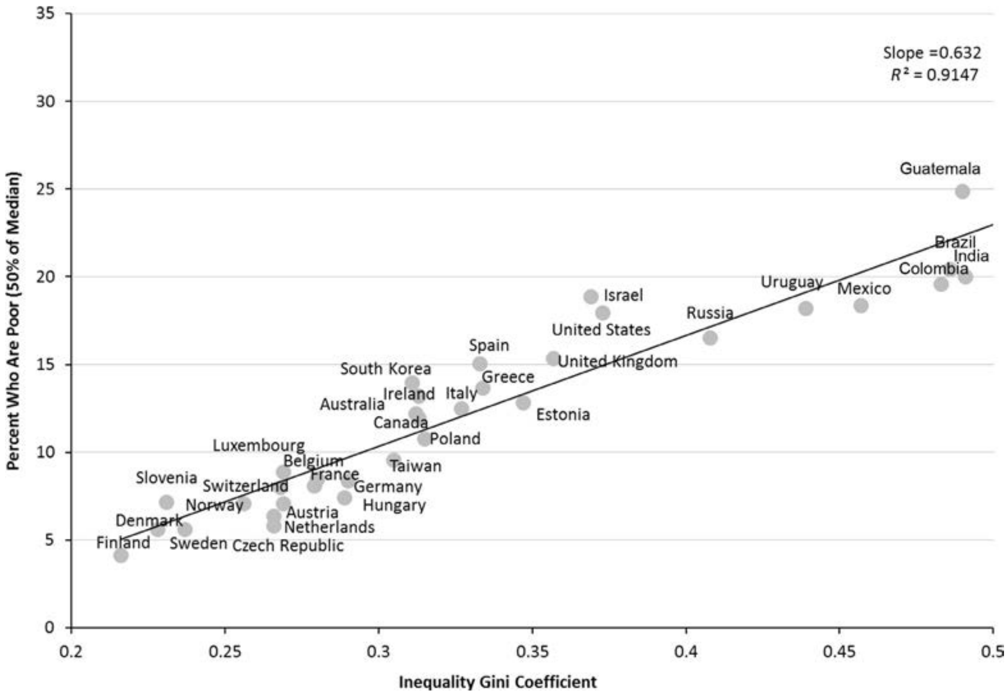

Figure 8.7 Relationship of relative poverty and income inequality in 38 nations (LIS). *Source: Luxembourg Income Study, Key Figures: http://www.lisdatacenter.org/lis-ikf-webapp/app/search-ikf-figures.*

inequality. Four nations stand out as having above-average poverty for their inequality level: Guatemala, Israel, South Korea, and the United States. Relative poverty levels are notably lower than inequality in the Czech Republic, Netherlands, Austria, and Hungary.

8.4. INEQUALITY IN INCOME

8.4.1 Measures of Inequality from the Overall Distribution

8.4.1.1 Introduction

This section focuses on measures of the overall distribution of income in high-income and some middle-income and developing countries. In contrast with the next section, which focuses narrowly on the top of the pretax income distribution, this section considers a variety of statistics that either explicitly exclude the very top (and bottom) of the distribution or that use the full distribution but are calculated with data that are not necessarily representative of incomes at the very top. Most of this section describes trends since 1970, but some attention is also paid to data series that are available over shorter periods and to a single-year analysis of the most current available income data, which allow us to discuss a broader range of inequality metrics and a greater number of countries.

Overall conclusions about the broad distribution of household income include:

* The countries with the least unequal distributions are the Nordic (Sweden, Norway, Denmark, and Finland) and "Benelux" (Belgium, Netherlands, and Luxembourg) countries as well as Austria and some eastern European nations.
* Across MICs and high-income countries there is a wide range in levels of inequality. By most measures the income distribution in the United States is among the most unequal, and when compared with the narrower set of the richest nations, the distribution in the United States is the most unequal. A number of MICs and developing nations, including Brazil, China, Turkey, and South Africa, though, have income distributions that are more unequal than in the United States.
* Taxes and transfers reduce the degree of inequality in every country, but there is dramatic variation in the extent of redistribution. The impact of taxes and transfers is very small in some highly unequal countries (Russia) and some less unequal ones (South Korea). In some countries, taxes and transfers have a dramatic impact on the distribution of income; Finland has among the most unequal distributions of market income but one of the most equal distributions of DHI because of the extensive distribution in its welfare state. The United States combines relatively high levels of inequality in market income with very low levels of tax and transfer redistribution to achieve the highest level of DHI inequality among rich nations.
* The distribution of income has become more unequal in most countries since the 1970s. The only rich country to buck the long-term trends toward greater

inequality is France. Even France, though, has experienced increases in inequality since the early 2000s.

* The income distribution in a number of countries has followed a U-shaped pattern (Sweden, Finland, and Canada), falling in the 1970s or the 1980s before rising in the 1990s.
* Two of the most unequal of the rich nations—the United States and the United Kingdom—experienced large increases in inequality in the late 1970s and 1980s and modest increases in the second half of the 1990s, but in both countries the level of inequality in 2010 was not very different from levels experienced in the early 1990s.
* The distribution of market income in Germany, Italy, Japan, and some of the Nordic countries grew steadily more unequal between the mid-1980s and the mid-2000s, and the distribution of pretax/transfer income in those countries is now almost as unequal as in the United States, Israel, or the United Kingdom.
* In almost all countries the long-term trends in inequality are more pronounced among the working-age population.

8.4.1.2 Distributional Statistics

A variety of statistics have been developed for the analysis of the distribution of income. The most commonly used statistic is the Gini coefficient, but a number of other measures have been applied to a wide range of countries using data covering the most recent decades. The statistics discussed below include Lorenz curves, the Gini coefficient, Atkinson Index (ATK), percentile ratios (P90/P50 and P90/P10), quintile shares (S80/S20), and the Palma Index. (See Allison, 1978; Atkinson, 1970; Cowell, 2000; Heshmati, 2004; among others, for overviews of the various summary statistics to describe distributional inequality.)

Not a statistic *per se*, the Lorenz curve is a graphical representation of the cumulative distribution of income. The Lorenz curve uses ordered income data and shows the cumulative share of income held at each point in the distribution of households.

To reduce the information contained in the Lorenz curve to a single number, a variety of summary statistics have been proposed. One that has a direct link to the Lorenz curve is the Gini coefficient. The Gini coefficient can be calculated in a number of ways and visually can be represented as a ratio of the area between the Lorenz curve and the perfect equality line divided by the total area below the perfect equality line. In ordered data for household share of total income, the 45-degree line represents perfect equality; each household has the same income and each point in the distribution of total households matches the same point in the distribution of total household income (e.g., the bottom 45% of households receive 45% of total income). The Gini coefficient ranges from 0 (perfect equality) to 1 (the most extreme inequality) if all income is held by a single household.

Using unordered data, the Gini coefficient for household income can be calculated as the relative mean difference, or the average absolute difference between incomes for all pairs of households divided by twice the mean income (Allison, 1978):

$$\text{Gini} = \frac{\sum_{i=1}^{N}\sum_{j=1}^{N}\left|x_i - x_j\right|}{2N^2\overline{x}}, \tag{8.1}$$

where N represents the total number of households, i and j index each household in all possible pairings of household, x is household income, and $\overline{x}$ is mean income over the sample.

The Gini coefficient is one of many statistics representing the entire distribution. Other commonly used measures of inequality focus on specific points or regions of the distribution. Below we discuss inequality measures from the most recently available data using the P90/P10 and P90/P50 interdecile ratios, which represent "high" income levels (from the 90th percentile of the distribution in this case) as some multiple of "low" income (the 10th percentile of the distribution) or "middle" income (the median). A similar measure, the S80/S20, represents a ratio of the shares of total household income received by those in the top quintile of the distribution and those in the bottom quintile. The Palma Index, popularized by Palma (2011), is a slight modification of the more common S80/S20 and divides the share of income held by the highest 10% of the distribution by the share of income received by the lowest-income 40% of the distribution.

The final measure discussed in this section is the ATK.[20] Similar to the Gini coefficient, the ATK summarizes the entire distribution. Unlike the Gini, though, the ATK can be decomposed to identify different groups or income sources making different contributions to inequality. The ATK differs from the previous measures by explicitly incorporating a weighting variable that can be selected to place more weight on incomes at the top or the bottom of the distribution

$$\text{ATK}(\varepsilon) = 1 - \frac{1}{x}\left(\frac{1}{N}\sum_{i=1}^{N} x_i^{1-\varepsilon}\right)^{\frac{1}{(1-\varepsilon)}}. \tag{8.2}$$

The weighting variable (ε) is typically selected from values between 0 and 2, although any positive value can be used. Higher values for the weight, called a measure of inequality

[20] The mean log deviation (MLD) is another statistic that uses the entire distribution but tends to produce results very similar to the Gini coefficient. MLD statistics are not included here because of limited space, but they have been calculated by the OECD in the past, including in Divided We Stand (2011). Also, the squared coefficient of variation (SCV) has been used in some analyses of income distribution, including OECD (2011), but rankings developed using this measure are very sensitive. Deding and Dall Schmidt (2002) showed that, compared to the Gini coefficient, the SCV produces substantially larger year-to-year shifts in inequality and is particularly sensitive to tax and transfer payments at the upper tail of the distribution. For these reasons we do not include SCV measures in this review.

aversion, reflect greater sensitivity to incomes at the lower end of the distribution. The ATK falls between 0 and 1, equaling 0 under perfect equality and with higher values when dispersion is greater.

8.4.1.3 Levels of Inequality in High- and Middle-Income Countries in the Late 2000s

With expanded interest in the distribution of income, there are more data available from recent years to compare incomes across countries than at any point in history. This section reviews evidence from a broad array of rich countries and MICs using all of the distribution statistics described above. The following section focuses on a narrower set of countries and examines trends in the distribution of income using a more limited set of statistics. All of the analyses in these sections rely heavily on the data produced and made available by LIS, Eurostat, the OECD, and the national statistical agencies of a handful of rich countries.

8.4.1.3.1 Lorenz Curves

Unlike most summary statistics used in the analysis of inequality, Lorenz curves visually represent the entire distribution. Analyzing these plotted cumulative distribution functions allows us to see whether pairs of countries can be ranked by standard dominance criteria.[21] Figure 8.8 includes a series of Lorenz curves for different geographically or institutionally coherent clusters of countries. Each graph also includes the Lorenz curve for the United States to aid in comparability across the different graphs. The figure uses data from the most recent LIS wave for each country (identified in the individual graphs) and represents equivalized DHI.[22]

The distribution of income in the continental European countries (including Austria, Belgium, France, Germany, Luxembourg, and Switzerland), as well as Japan (shown in Figure 8.8a), and the Nordic countries (Denmark, Finland, Norway, and Sweden, shown in Figure 8.8b) is much less unequal than in the United States. Because the Lorenz curves do not cross at any point, we can say that each of these countries has a "superior" Lorenz curve to the United States. Any differences between these countries—which are slightly more evident among the Nordic counties—are small compared with their differences with the United States.

The U.S. distribution is more unequal than most of the rest of the European countries, but not to such a great extent. In the case of the Anglo-Saxon countries (Figure 8.8c), Australia, Canada, and Ireland have Lorenz curves that are superior to that of the United States, but the Lorenz curves for the United States and the

[21] See Cowell, 2000 (*The Handbook of Income Distribution*, Chapter 1) for a discussion of the properties of Lorenz curves and dominance criteria.

[22] The Lorenz curves displayed here are based on income that is bottom coded at 1% of average income and top coded at 10 times the median household income.

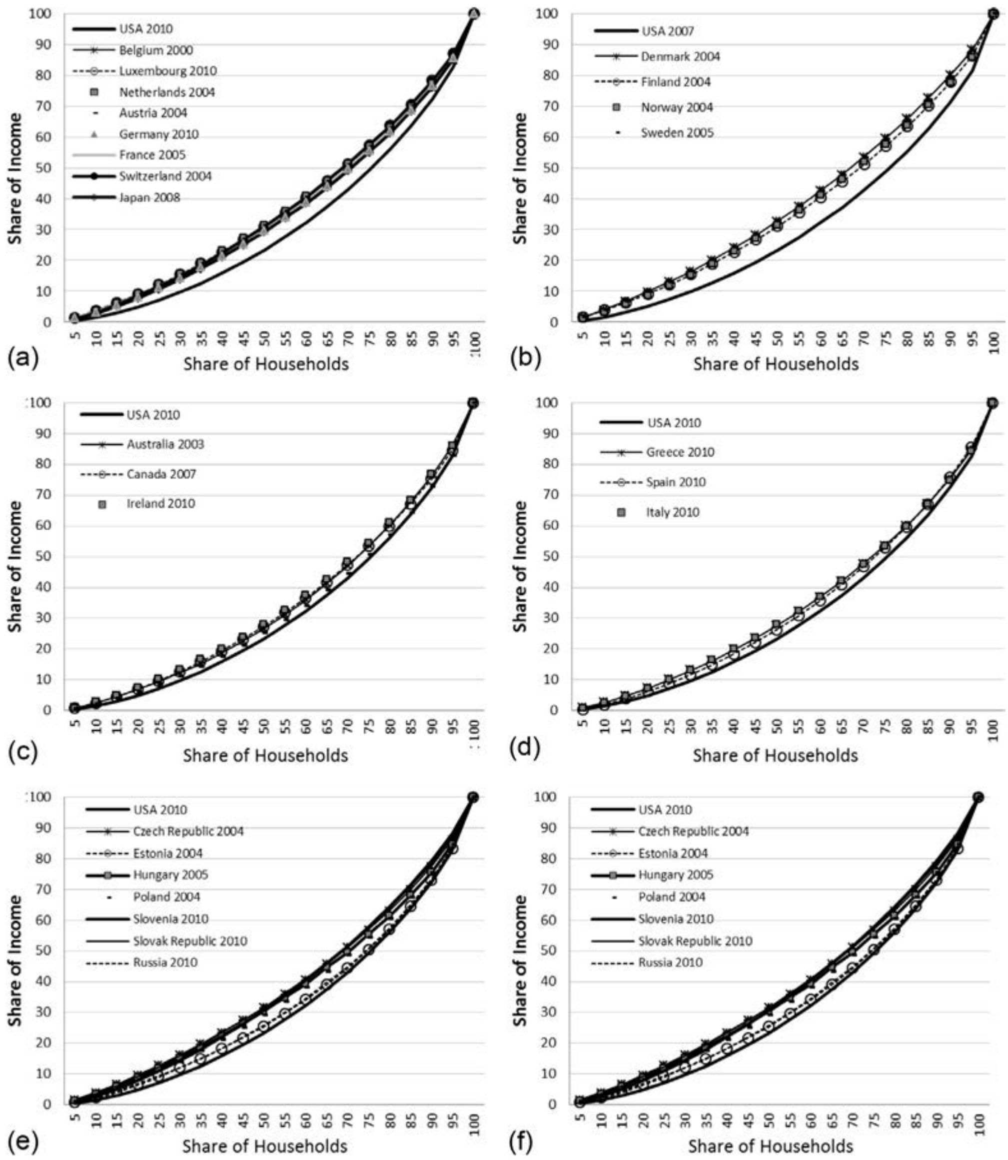

Figure 8.8 Lorenz curves of equivalized DHI (LIS) in the mid- and late 2000s: (a) continental European countries (and Japan), (b) Nordic countries, (c) Anglo-Saxon countries, (d) Southern European countries, (e) Eastern European countries, and (f) other countries. *Data are based on the authors' analysis of LIS data.*

United Kingdom are virtually indistinguishable, although they do not cross. The United States also has an inferior Lorenz curve relative to the countries in Southern Europe (Spain, Italy, and Greece, shown in Figure 8.8d), but the gaps are less dramatic than for the Nordic or continental European countries. None of the southern European countries has a distribution that is superior to the others, as the Lorenz curves cross at the top and the bottom of the distributions.

Even in Eastern Europe (Figure 8.8e), each country has a Lorenz curve superior to that of the United States. In the case of Estonia (2004) and the Russian Federation, the distribution is very similar, especially in the upper third, but at no point do the Lorenz curves cross. In the Slovak Republic, Slovenia, and the Czech Republic (2004) the distributions look more similar to those of continental European countries than those of their Eastern European neighbors.

Only when we expand the set of countries beyond Europe and include MICs and developing counties do we find distributions of income that are more unequal than that of the United States ("Other Countries" include South Korea, India, China, Brazil, and Israel, shown in Figure 8.8f). The most recent LIS data for Brazil, India, China, and South Africa show that the Lorenz curves for those countries are inferior to that of the United States. Among those four nations, South Africa stands out with the most unequal distribution. Israel and the United States have virtually indistinguishable Lorenz curves, both of which are inferior to the Lorenz curves for South Korea and Taiwan.

8.4.1.3.2 EU and OECD Country Summary Statistics and Rankings

In recent years the EU and the OECD have calculated timely summary distributional statistics for their member countries. These figures are based on DHI data from 2010 to 2011 for the EU and "around 2010" for the non-EU OECD countries.[23] Statistics from both entities are adjusted for household size using slightly different equivalence scales.

Figure 8.9 includes three different summary statistics for the 23 richest nations that are EU or OECD members and is sorted based on rankings for the Gini coefficient (shown in Figure 8.9a).[24] With a Gini coefficient of 0.38, the United States has the highest level of inequality among the rich nations. At the other extreme, with Gini coefficients between 0.23 and 0.28, the Nordic and Benelux (Belgium, Netherlands, and Luxembourg) countries and Austria had the most equal distribution of income, led by Norway. The large continental economies and the Anglo-Saxon countries fall in the middle, with Gini coefficients ranging from 0.28 and 0.31 in Germany and France, respectively, to between 0.32 and 0.33 in Australia, Canada, and the United Kingdom.

While they are based on smaller ranges of the distribution, the S80/S20 interquartile share ratio (Figure 8.9b) and the P90/P10 interdecile ratio (Figure 8.9c) each produce rankings similar to that of the Gini coefficient. In the rich nations with the highest

[23] All figures are reported based on the income year, not the survey year. Eurostat figures are originally published by survey year, but we report them according to the year in which the income was received. Details on the timing for the data are contained in Table 8.2 and Figure 8.9.

[24] These nations all have gross domestic product per capita of more than $29,000 (PPP) in 2012 and account for 23 of the world's 31 richest countries (International Monetary Fund, 2013).

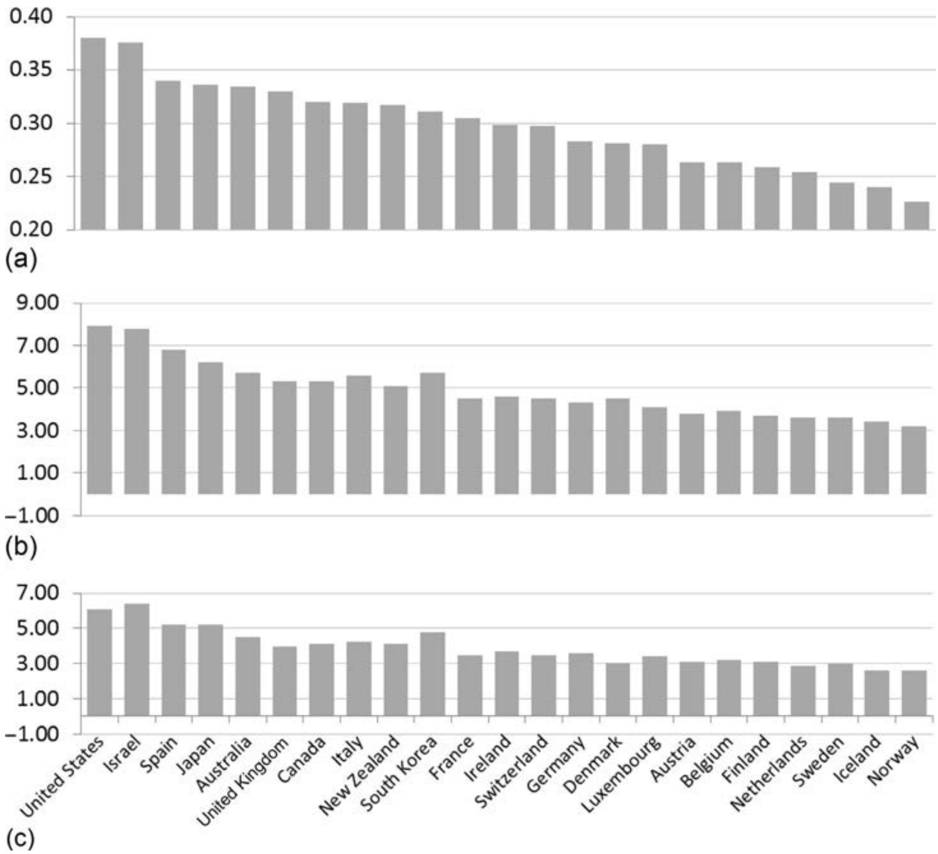

Figure 8.9 Summary distribution statistics for equivalized DHI for the richest EU and OECD nations for 2010–2011: (a) Gini coefficient, (b) interquartile share ratio (S80/S20), and (c) interdecile ratio (P90/P120). EU member country data are mainly from 2011 or 2010; non-EU OECD member country data are primarily from 2010. Gini coefficient, S80/S20 ratio, and P90/P10 ratio figures for EU member countries are based on Eurostat data and are mostly from 2010. A number of EU countries have data from 2011, including Denmark, Finland, France, Germany, Iceland, Luxembourg, the Netherlands, and Norway. Non-EU OECD member county figures for Gini, S80/S20, and P90/P10 are mainly from 2010, with some exceptions: South Korea, 2011; Japan, New Zealand, and Switzerland, 2009. *Sources: Eurostat and OECD.*

S80/S20 ratios, the United States and Israel, the average income among the highest-income fifth of households is 7.8 times the average income in the bottom fifth. In the less unequal Nordic and Benelux nations, the ratio ranged from 3.2 to 3.9. The P90/P10 ratio was 6.4 in Israel, followed closely by the United States at 6.1. Most of the ranking using the P90/P10 is similar to the S80/S20 ranking and, in turn, the Gini coefficient ranking, but the rich Asian nations stand out somewhat. In the Gini coefficient rankings, Japan and South Korea were similar to, and somewhat less unequal than,

Table 8.2 Summary distributional statistics for equivalized disposable household income—EU and OECD measures for 2010–2011 and the late 2000s

	Gini	Interquintile share ratio (S80/S20)	Interdecile ratio (P90/P10)

Sources: Eurostat and OECD.
Note: Eurostat data are used for EU countries that are also OECD members. EU member country data mainly from 2011 or 2010; non-EU OECD member country data are primarily from 2010. Gini Coefficient, S80/S20 ratios, and P90/P10 ratio figures for EU member countries are based on Eurostat data and are mostly from 2010. A number of EU countries have data from 2011, including Bulgaria, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Iceland, Luxembourg, the Netherlands, Norway, Poland, Portugal, and Slovenia. Non-EU OECD member country figures for Gini, S80/S20 ratios, and P90/P10 ratios are mainly for 2010, with some exceptions: South Korea figures are from 2011; Japan, New Zealand, and Switzerland are from 2009; and Russian Federation are from 2008.
SCV for all countries is from the OECD's "Divided We Stand" and are primarily for 2008, except for Hungary and Turkey (2007) and Japan (2006). These statistics are no longer collected by the OECD.

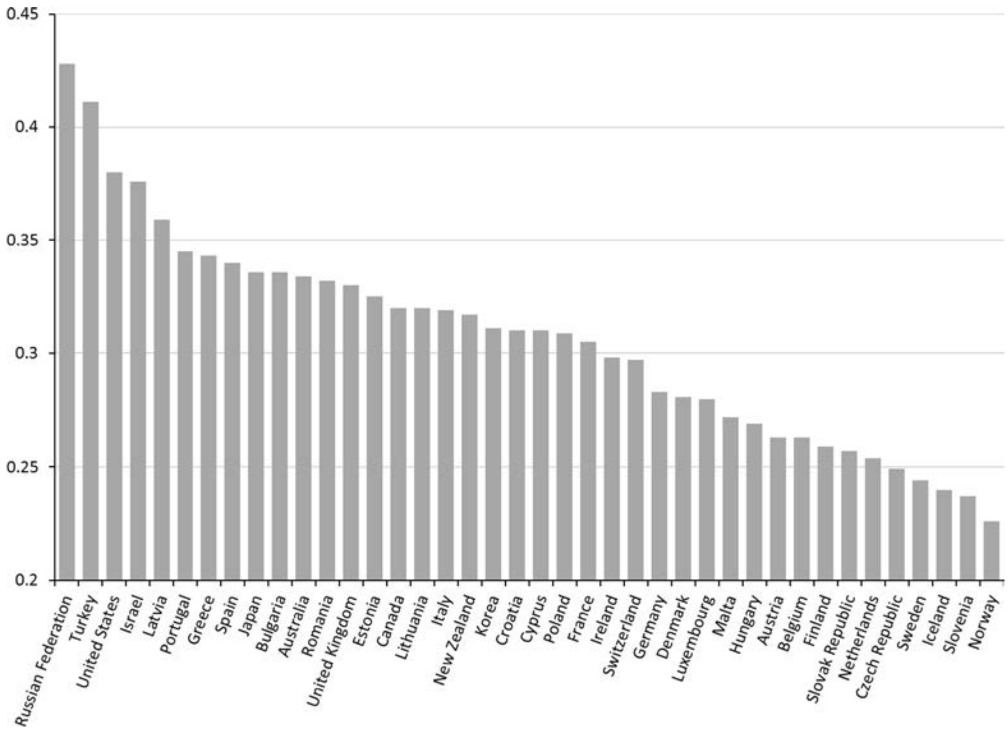

Figure 8.10 Gini coefficients for equivalized DHI for 2010–2011, including middle-income and developing EU and OECD nations. *Source: EU-SILC, Eurostat data (figures for 2010/2011 for EU member countries). OECD data are mainly from 2010; exceptions include South Korea (2011) and New Zealand and Turkey (2009).*

many of the Anglo-Saxon and southern European nations. Using the P90/P10, Japan and Korea appear more unequal and rank third and sixth, at 5.2 and 4.8, respectively. Among the less unequal Nordic and Benelux countries, the P90/P10 lies between 2.6 and 3.2.

The list of countries regarded as the "most unequal" or "least unequal" is, of course, somewhat dependent on the set of countries included. Figure 8.10 represents the ordered Gini coefficients for a set of countries that includes the 23 rich nations already shown in Figure 8.9 with 17 additional high-income countries, with gross domestic product per capita above $12,500 (International Monetary Fund (IMF), 2013), that are also part of EU or the OECD. In Figure 8.10, the United States is supplanted by the Russian Federation and Turkey as having the most unequal distributions using the Gini coefficient. The list of countries with less unequal distributions is similarly bolstered as the Nordic and Benelux countries are joined by several central European nations, including Slovenia and the Czech Republic. All of the summary statistics from Figures 8.9 and 8.10 are in included in Table 8.2.

8.4.1.3.3 LIS Country Summary Statistics and Rankings

As seen in the Lorenz curves above, the LIS project includes data from a number of countries that are not part of the EU or the OECD. LIS also regularly calculates several distribution statistics not typically reported by the OECD or the EU. Figure 8.11 includes two different ATK measures ($\varepsilon = 0.5$, 1), the P90/P50 interdecile ratio and the Palma Index (Figure 8.11d), for 34 countries with values reported in any of the three most recent LIS waves (covering the decade of the 2000s). The data used in these figures also are included in Table 8.3.

The alternative summary statistics in Figure 8.11 maintain the same basic rank ordering among the rich countries shown in Figure 8.9, with the least unequal distributions found in the Benelux and Nordic countries and the most unequal found in the United States, Israel, and the United Kingdom. Including the MICs and developing countries that are part of the LIS project, though, alters the ranking considerably. South Africa stands out as the most unequal country by far among the 34, with an ATK of 0.29, 38% higher than second-ranked China. Using a somewhat larger inequality aversion parameter ($\varepsilon = 1$) results in higher measured ATK numbers but by and large preserves the rank ordering across nations (Figure 8.11a). With greater sensitivity to incomes at the bottom of the distribution, the Czech Republic's rank (from most unequal to least unequal) falls three spots, and Switzerland's rises five spots, but overall our understanding of which countries have more- or less-equal distributions of income is essentially unchanged by modest changes in the inequality aversion parameter.

Analysis of the P90/P50 interdecile ratio (Figure 8.11c) demonstrates the dramatic differences in the distributions of the rich EU and OECD countries from those of the MICs and developing countries in the LIS project. Israel is the rich nation with the highest P90/P50, with an equivalized DHI at the 90th percentile 2.3 times that at the median. Four LIS lower-income countries (Brazil, China, India, and South Africa) have P90/P50 ratios at least 40% higher than Israel.

Proponents of adopting the Palma Index have argued that it isolates the portions of the income distribution that are most volatile over time and across countries (Cobham and Sumner, 2013). Compared to the Gini Index (and the ATK) the Palma Index is also transparent as to which portions of the distribution are determining the measure of inequality. This feature is shared by the P90/P10, P90/P50, and S80/S20 measures. Country rankings based on the Palma Index, calculated using LIS data, are very similar to those obtained using more common measures. The Nordic countries have the least unequal distributions, with values ranging from 0.98 (Norway) to 0.82 (Denmark), whereas South Africa has the most unequal, with a Palma Index of 7.8. The United States has the highest Palma Index (1.75) among rich nations.

Figure 8.11 indicates that the country rankings are similar across all four inequality measures. South Africa is the most unequal among the 34 nations in the LIS data using all of the measures, whereas Denmark is the least unequal. The United States ranks fifth most unequal using three of the measures and seventh most unequal using the other (P90/P50).

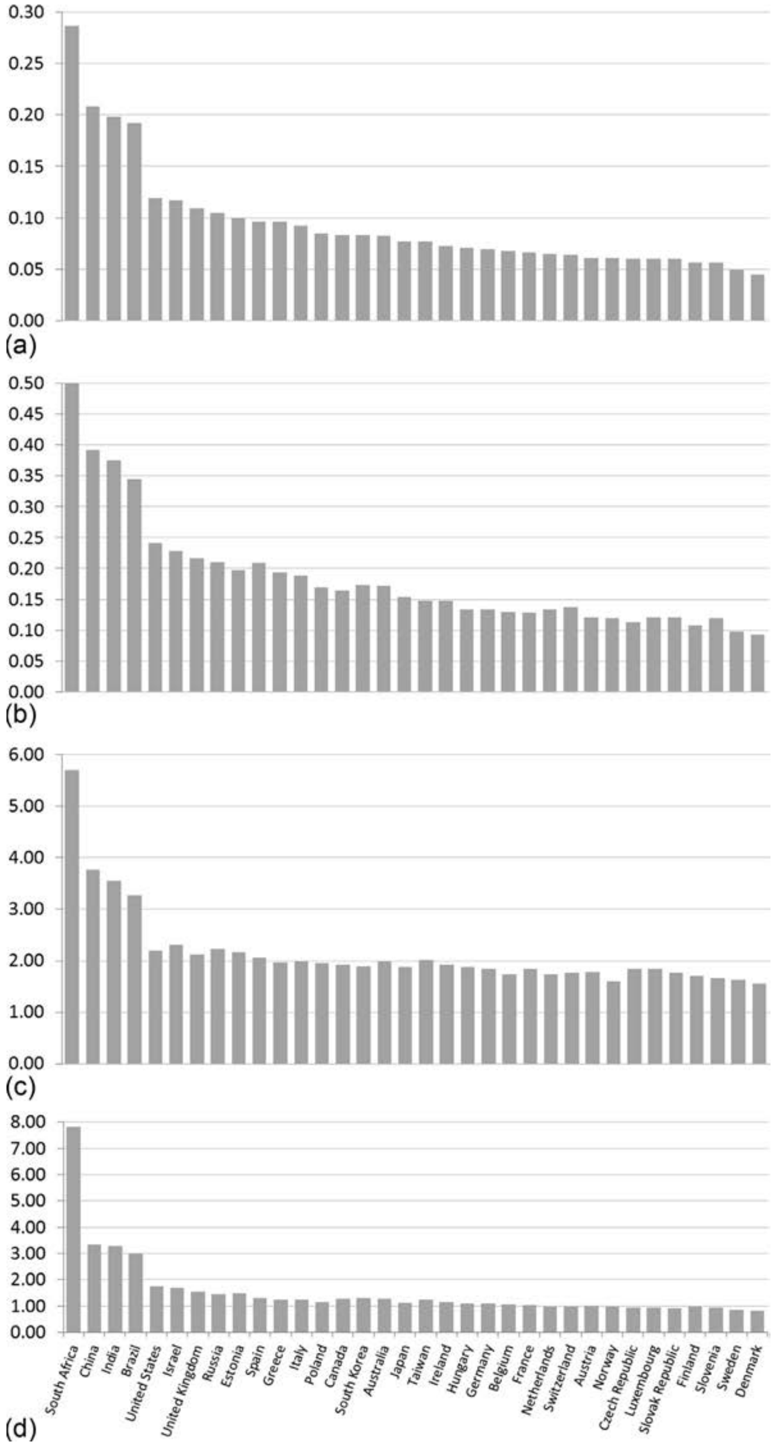

Figure 8.11 Distributional summary statistics from LIS countries using equivalized household income in the 2000s (LIS waves VI, VII, and VIII): (a) Atkinson coefficient ($\varepsilon = 0.5$), (b) Atkinson coefficient ($\varepsilon = 1$), (c) P90/P50 ratio, and (d) Palma Index (S10/S40 ratio). The sample years range from 2002 to 2010. *Data are from the authors' analysis of LIS data. (a)–(c) are from LIS published "key figures." (d) is based on the authors' analysis of LIS data.*

Slovenia, 2010	0.056	0.119	1.66	0.95
South Africa, 2010	0.287	0.505	5.70	7.81
South Korea	0.083	0.173	1.895	1.31
Spain, 2010	0.096	0.209	2.06	1.32
Sweden, 2005	0.049	0.097	1.63	0.85
Switzerland, 2004	0.064	0.137	1.76	0.97
Taiwan, 2005	0.077	0.147	2.02	1.26
United Kingdom, 2010	0.109	0.216	2.13	1.56
United States, 2010	0.119	0.241	2.19	1.75

Data are based on the authors' analysis of LIS project data. The Palma Index was calculated by the authors using LIS project data, the Atkinson coefficient, and P90/P50 from LIS published "key figures."

8.4.1.3.4 Comparing Current Distributions of Pretax and Transfer Income and DHI

In almost every nation, and particularly among rich nations, the tax and transfer systems reduce the disparity of income. Whether taxes are paid at higher rates among upper-income households, benefits and transfer payments are directed disproportionately toward lower-income households, or both, measures of inequality are lower for DHI than for market income. The extent to which the tax and transfer systems reduce measured inequality varies substantially across countries. The distributions of DHI and pretax and transfer income, and the extent to which taxes and transfers reduce inequality, are shown in Figure 8.12 for a set of 31 OECD countries. The figure shows Gini coefficients for DHI and pretax and transfer income (sorted on the latter) for all age levels (panel a) and for working-age (18–65 years old) individuals (panel b).

The rank ordering of countries based on inequality of pretax and transfer income for all ages (Figure 8.12a) is very different from the previously described rankings based on DHI. The United States does not have the most unequal distribution of pretax and transfer income, even among rich countries—it is ninth behind Ireland, Israel, the United Kingdom, and the southern European countries. The pretax and transfer income Gini for Italy is 0.50, 47% greater than South Korea, which has the lowest Gini among this set of countries. Also, instead of being clustered at the bottom, the Benelux countries are spread across the rankings based on the Gini coefficient for pretax and transfer income, and at least one Nordic country—Finland—rises to the middle.

Another important feature highlighted in Figure 8.12 is the substantial cross-national variation in the extent to which the tax and transfer systems reduce inequality. In several countries—notably the Russian Federation and South Korea—the tax and transfer systems have little impact on the distribution of income, and the Gini coefficient for DHI is only slightly smaller than the Gini for pretax and transfer income. In the case of Russia, low levels of redistribution leave the country with very high levels of inequality in DHI compared with other countries. In South Korea there is relatively little redistribution, but pretax and transfer income is distributed more evenly than in most countries, leaving a Gini for DHI that falls in the middle of the rankings.

In other countries, the tax and transfer system has a considerably larger impact on the distribution of income. In 11 countries the Gini coefficient is at least 40% lower for DHI than it is for market income. This is true for several of the Nordic and Benelux countries, as well as Ireland, Germany, and a number of eastern European countries. Substantial tax and transfer redistribution in these countries leaves them with the most equal distributions of DHI. In the case of the United States and Israel, above-average inequality in the distribution of market income combined with below-average levels of tax and transfer redistribution leave them with the highest Gini coefficients for DHI among the rich nations.

In this section we describe the difference between the Gini coefficients for pretax and transfer income and DHI as a measure of the extent of redistribution in a country. This measure of redistribution, however, has important limitations and warrants some caveats. One such caveat is that the gap between these two Gini coefficients is a distorted measure of "redistribution" because the tax and transfer policies carrying out said redistribution can be expected to cause some changes in household and firm economic behavior that

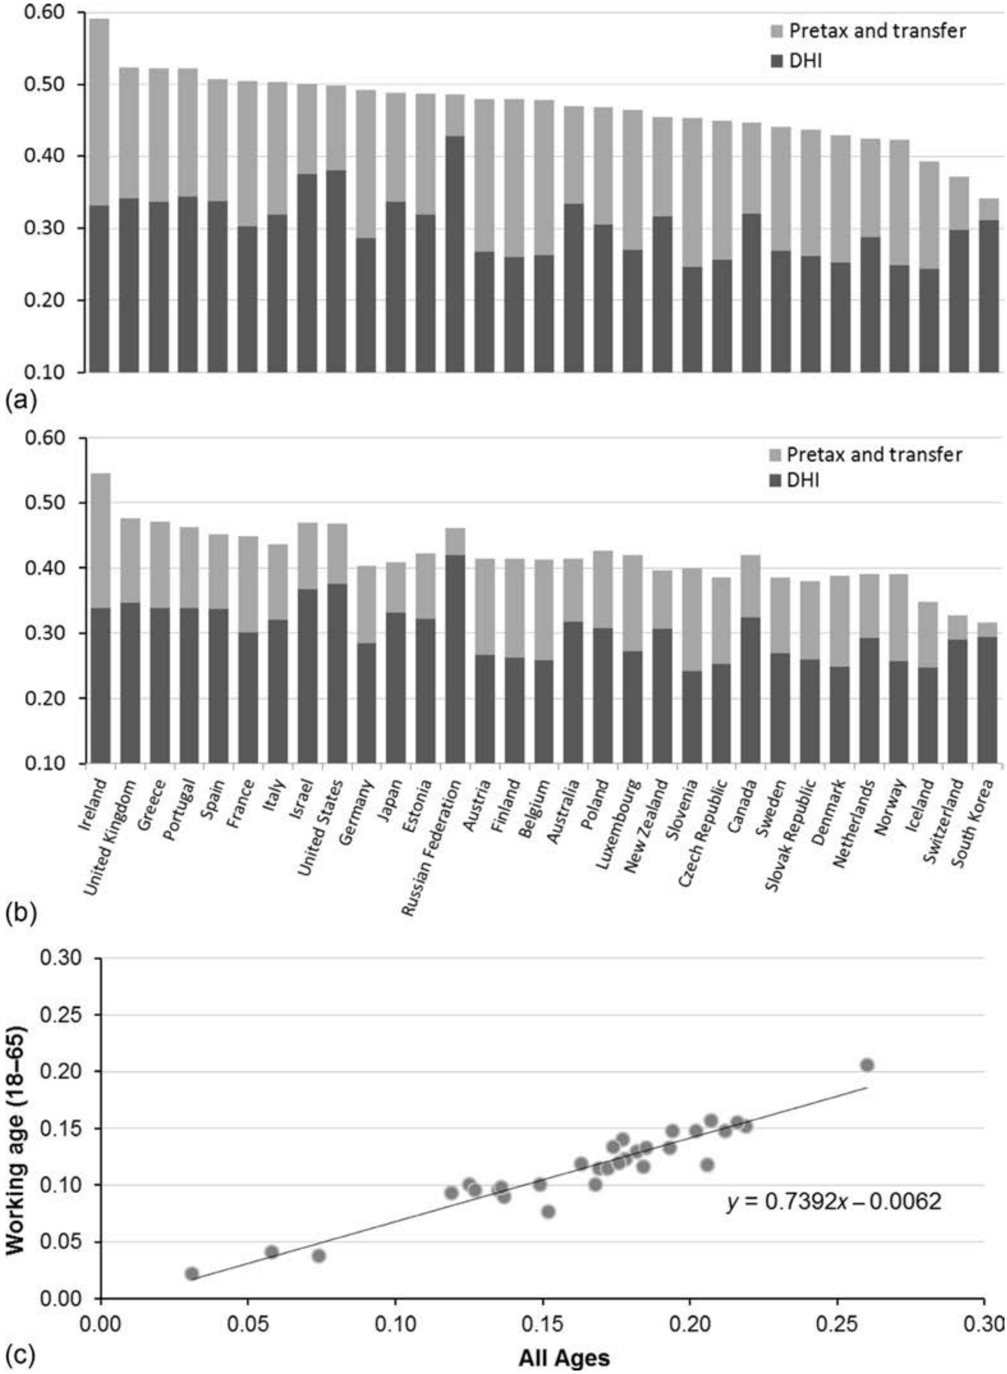

Figure 8.12 Gini coefficients around 2010 for pretax and transfer income and DHI for all ages (a), working age (18–65 years old) (b), and correlation between "redistribution" (pretax and transfer income Gini less DHI Gini) for all ages and the working-age populations (c). OECD member country data are primarily from 2010 with some exceptions: South Korea data are from 2011; Japan, New Zealand, and Switzerland data are from 2009; and the Russian Federation data are from 2008.

will be reflected in pretax and transfer income. Another limitation of this measure of redistribution is that similar types of income are classified as transfers in some countries but not in others, according to different institutional arrangements and policy choices. Retirement income systems are particularly relevant here. Countries with greater reliance on pensions provided directly by the public sector will seem to have greater redistribution than countries that finance retirement schemes through employers and private accounts (supported by tax incentives and potentially regulations).[25] A corollary is that countries with older populations (and otherwise equivalent pension systems) will seem to have greater redistribution by this measure.

We can compare the extent of redistribution across countries in a way that avoids some of these classification issues, at least in part, by using incomes from the working-age population (Figure 8.12b). Excluding retirees, who overwhelmingly rely on pension income, does not dramatically alter the rank ordering of countries based on the Gini coefficient for pretax and transfer income or the extent of redistribution observed across countries. The United States and the Anglo-Saxon and southern European countries remain the most unequal, whereas the Nordic and Benelux countries remain the least unequal. In a few countries, however, the cross-national ranking for inequality of pretax and transfer income jumps when elderly individuals are excluded; countries with notable increases include the United States, Canada, Israel, and the Russian Federation.

This extent of redistribution is greater among the total population than it is for the working-age population in every country. In the typical country the measure of redistribution for the working age is almost three quarters as large as it is for the total population (Figure 8.12c). The correlation between redistribution for all ages and for the working-age population is quite high. The simple correlation coefficient between the measures of redistribution for these two different age groups is 0.95. Countries that engage in relatively high levels of redistribution among the total population (including the elderly) also tend to engage in relatively high levels of redistribution among the working-age population. Table 8.4 contains all of the figures used in Figure 8.12.

8.4.1.4 Trends in the Distribution of Income Since 1970

Because income distribution data and statistics for some countries are only available for recent years, we are able to analyze trends in the distribution of income since the 1970s for a more limited set of countries than was discussed in the previous section. Here we first describe trends in the Gini coefficient for equivalized DHI since the mid-1970s for 10 rich nations. Then we turn to trends in the S80/S20 and P90/P10 measures, which are available for a somewhat larger number of OECD countries starting mostly in the

[25] This will be true even if the level of pension benefits is identical and the level of savings to finance the private pension scheme is equal to the taxes to finance the public pension scheme.

Source: OECD Inequality Database, accessed October 23, 2013. Data for most OECD countries are for 2010; exceptions include South Korea (from 2011); Ireland, Japan, New Zealand, and Switzerland (from 2009); and the Russian Federation (from 2008).

mid-1980s, but with data going back to the 1970s for a few.[26] Then we discuss trends in the Gini coefficient for pretax and transfer income and the extent to which taxes and transfers lower the Gini coefficient in a broader range of OECD countries. Finally, we compare trends in inequality since the mid-1980s using all three distributional statistics for working-age population and for all ages.

8.4.1.4.1 Trends in Equivalized DHI Gini Coefficients for 10 Rich Nations

Most of the rich nations that have collected comparable, mostly annual, data since the early 1970s have experienced sizeable increases in the Gini coefficient[27] (Figure 8.13). For some countries those increases came in the 1980s (United States, United Kingdom, and the Netherlands), whereas for others they came in the 1990s and early 2000s (Canada, the Nordic countries, and Germany). Inequality trends in these countries can be thought of as following a J or U shape to varying degrees (see Gottschalk and Smeeding, 2000, for further discussion).

In Italy and France, inequality decreased in the 1980s, and since the mid-1990s the Gini coefficient has changed little in either country. Italy's early 1980s declines were, however, offset by increases in the early 1990s (Brandolini and Vecchi, 2011). Most of the rich nations included in Figure 8.6 have experienced relatively small changes in their DHI inequality over the last 10 or 20 years, but many have witnessed marked cyclical fluctuations, particularly the United States, the United Kingdom, and the Nordic countries.

In most cases the rank ordering of countries remains unchanged after nearly 40 years of mostly rising inequality. The most dramatic shifts were undertaken by France, which had the most unequal distribution (among these rich nations) in the mid-1970s and now has a Gini coefficient only modestly higher than that of the Nordic countries. Also, the United Kingdom had among the least unequal distributions in the mid-1970s and has been among the most unequal since the early 1990s. The United States has had the most unequal distribution of income among rich nations since the early 1980s.

Rising inequality in the Nordic countries has produced relative but notable shifts as well. Through the early 1990s, the distribution of income in the Nordic countries was substantially less unequal than it was in other countries; since that time rising inequality in the Nordic countries and stable (France and the Netherlands) or modestly rising

[26] There are 14 OECD countries with S80/S20 and P90/P10 statistics available starting in or before the mid-1980s. For five of those countries there are some data for some years in the 1970s. For several of these countries there is a single year of data for these indicators available for the 1970s.

[27] Data for these countries are collected by the OECD (described in their income distribution database) and by national statistical agencies in some countries. Data for the United Kingdom, Finland, Norway, France, and Germany are from national statistical agencies and are published in Atkinson and Morelli (2012, 2014) (updated by the authors), which provides further detail on the sources. Data for Italy were published in Brandolini and Smeeding (2008, 2009) and since updated by Brandolini (personal communication).

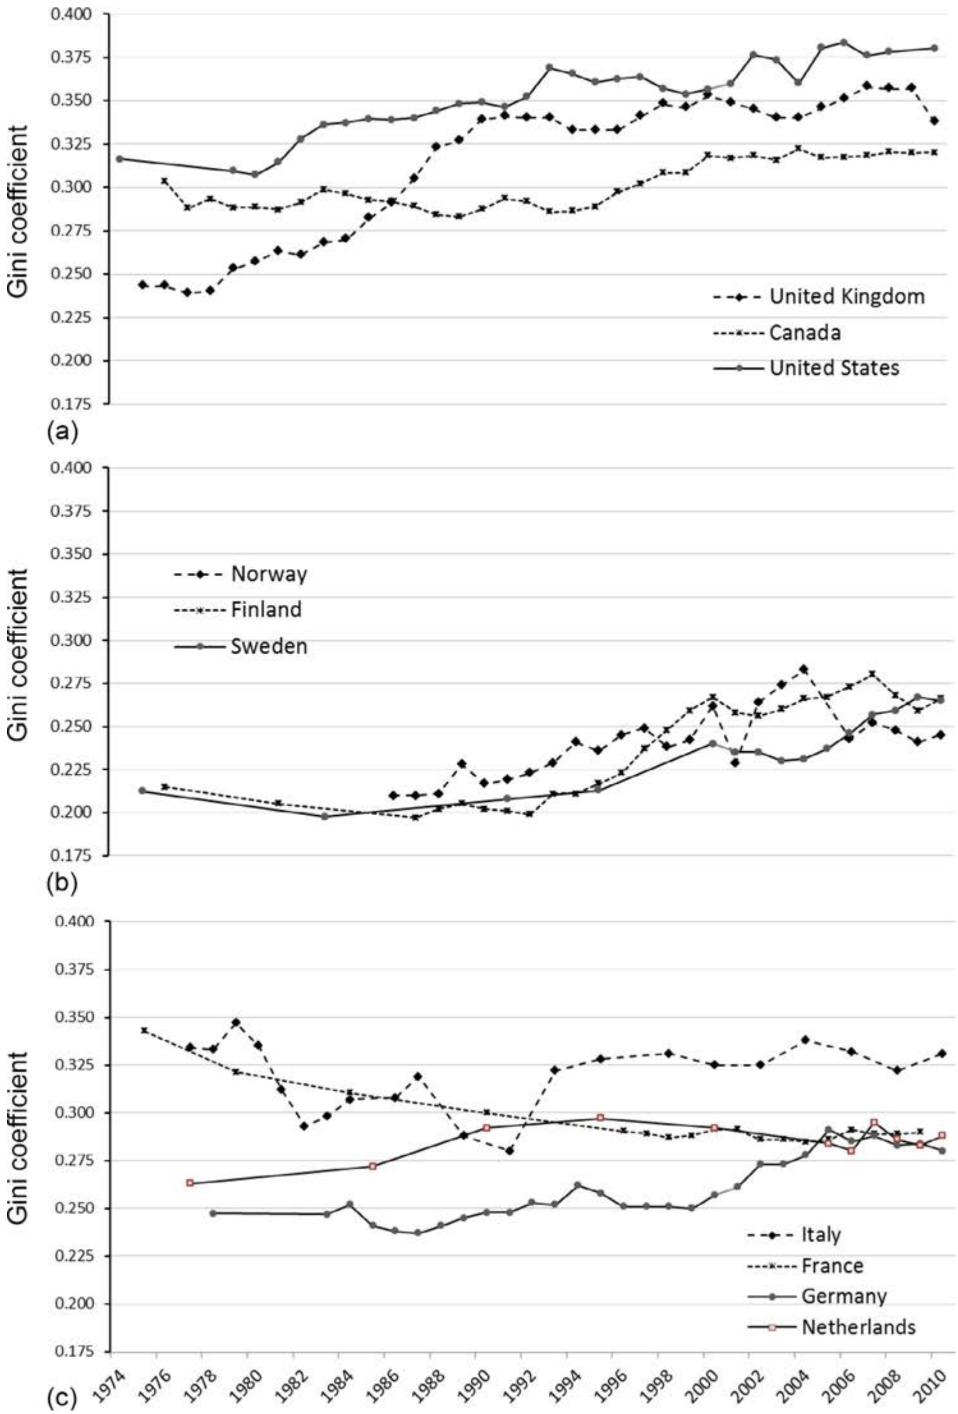

Figure 8.13 Trends in equivalized DHI Gini coefficient in rich countries by country group, OECD, and statistical agency data: Anglo-Saxon countries and the United States (a), Nordic countries (b), and Continental and Southern Europe (c). *Source: OECD income distribution data for Canada, Sweden, and United States.* Inequality Chartbook *(Atkinson and Morelli, 2012, 2014) based on figures published by statistical agencies for remaining countries and updated by authors. Data for Italy from Smeeding and Brandolini (2009), updated by Brandolini.*

inequality (Germany) in other countries has produced some convergence in the inequality levels in continental Europe and the Nordic countries. In Germany, the Gini of DHI rose 14% (from 0.25 to 0.28) over the period.[28] Although the distribution of income was less unequal in the Lander of the former East Germany (EDHI Gini of 0.20 in East Germany and 0.25 in West Germany in 1991), reunification had little impact on the inequality trends for Germany (Fuchs-Schündeln and Schündeln, 2009; Grabka and Kuhn, 2012).

Compared with the early 1980s, the range of inequality measures of these 10 rich countries has become somewhat more compressed. The two nations that previously had the most equal distributions—Sweden and Finland—experienced some of the largest increases in inequality. Around 1980, this set of 10 rich countries had a mean DHI Gini of 0.265 with a variance of 0.0022; around 2010 the mean had increased to 0.30, while the variance had decreased to 0.0017.

8.4.1.4.2 Trends in the S80/S20 and P90/P10 Measures for Equivalized DHI for 14 OECD Countries

A somewhat larger group of countries has been collecting comparable income data at least since the early 1980s (with Denmark, Israel, Japan, Luxembourg, and New Zealand augmenting the 10 rich nations discussed in the previous section).[29] The OECD has analyzed the income surveys from those countries and calculated S80/S20 and P90/P10 ratios. Both of these alternative measures yield largely similar trends in income inequality to what we saw for the Gini coefficient in Figure 8.13.

The share of income received by the top quintile divided by the share of income received by the bottom quintile (S80/S20) has increased in each of these countries since the early 1980s, but some countries experienced larger increases in inequality, and the rank ordering changed somewhat (Figure 8.14). Israel experienced the largest absolute change over this period, with its S80/S20 rising by 2.5, basically matching the United States for top spot with the top fifth of households receiving 7.8 times as much income as those in the bottom fifth. Israel's inequality surge occurred in the late 1990s and early 2000s. Sweden experienced the largest relative increase over the same period—its S80/S20 increased 48%. Canada experienced the smallest increase among these countries: its S80/S20 increased less than 10% higher than its lowest point in the 1980s.

Shifting to an inequality measure that further sharpens the contrast between the top and bottom of income distribution, the P90/P10 interdecile ratio does little to change the trends (Figure 8.15). Similar to the S80/S20 measure, income inequality did increase in each of the countries over this period. For Israel and Japan, the distribution seems to have

[28] For further analysis of trends in German inequality see Grabka and Kuhn (2012), Faik (2012), and Goebel et al. (2010).

[29] France is not included in the OECD series that are available to calculate S80/S20 and P90/P10 ratios.

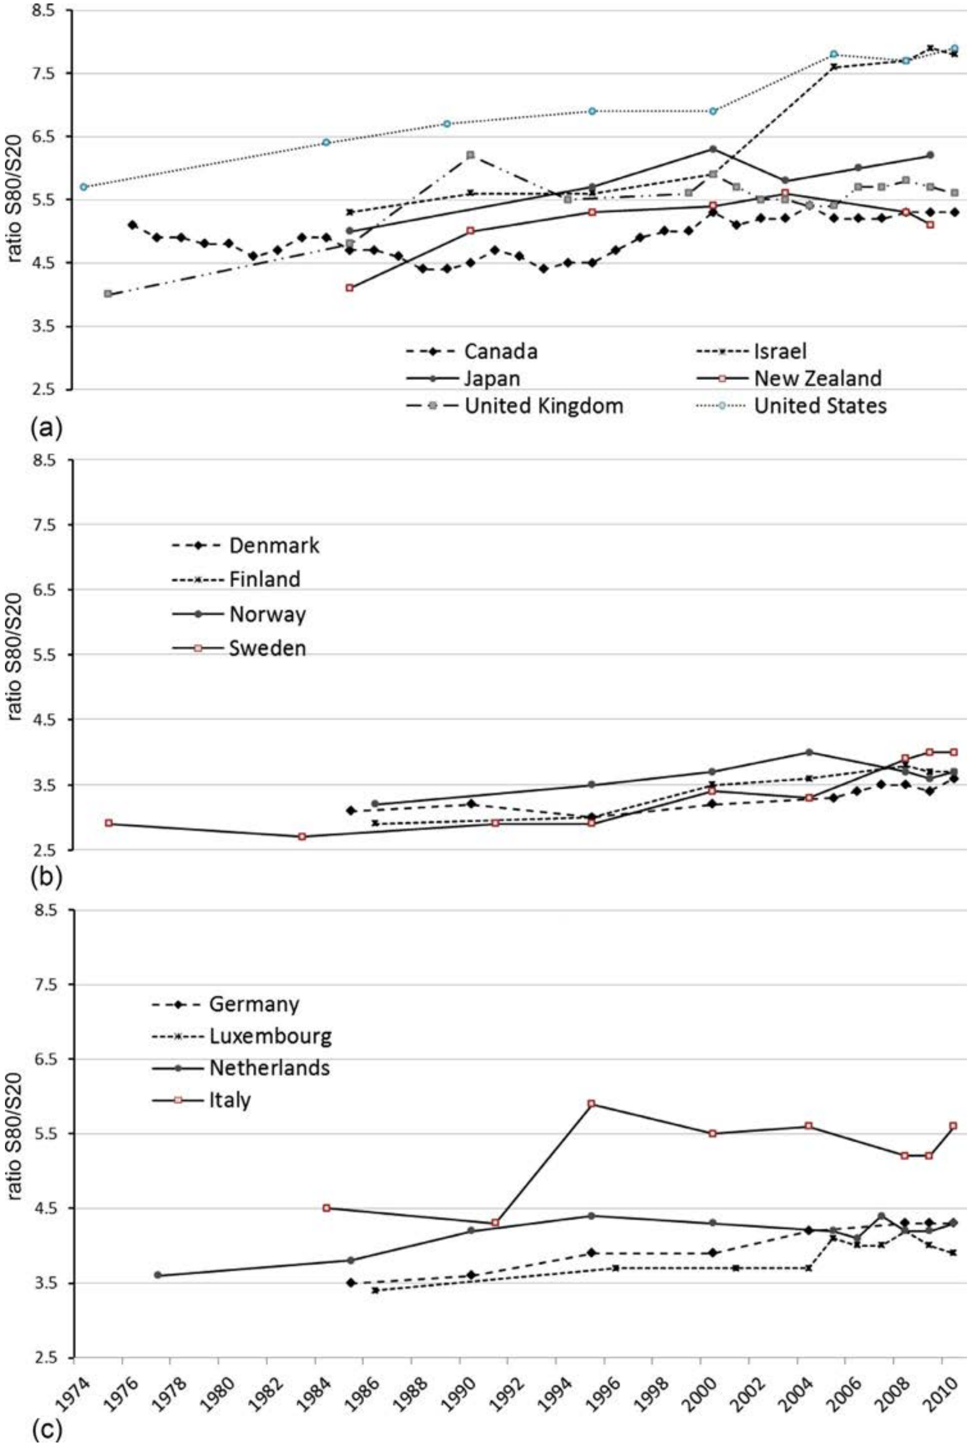

Figure 8.14 Trends in S80/S20 ratio for equivalized DHI by country group based on OECD data: Anglo-Saxon countries, the United States, and others (a); Nordic countries (b); and Continental and Southern Europe (c). *Source: OECD income distribution data.*

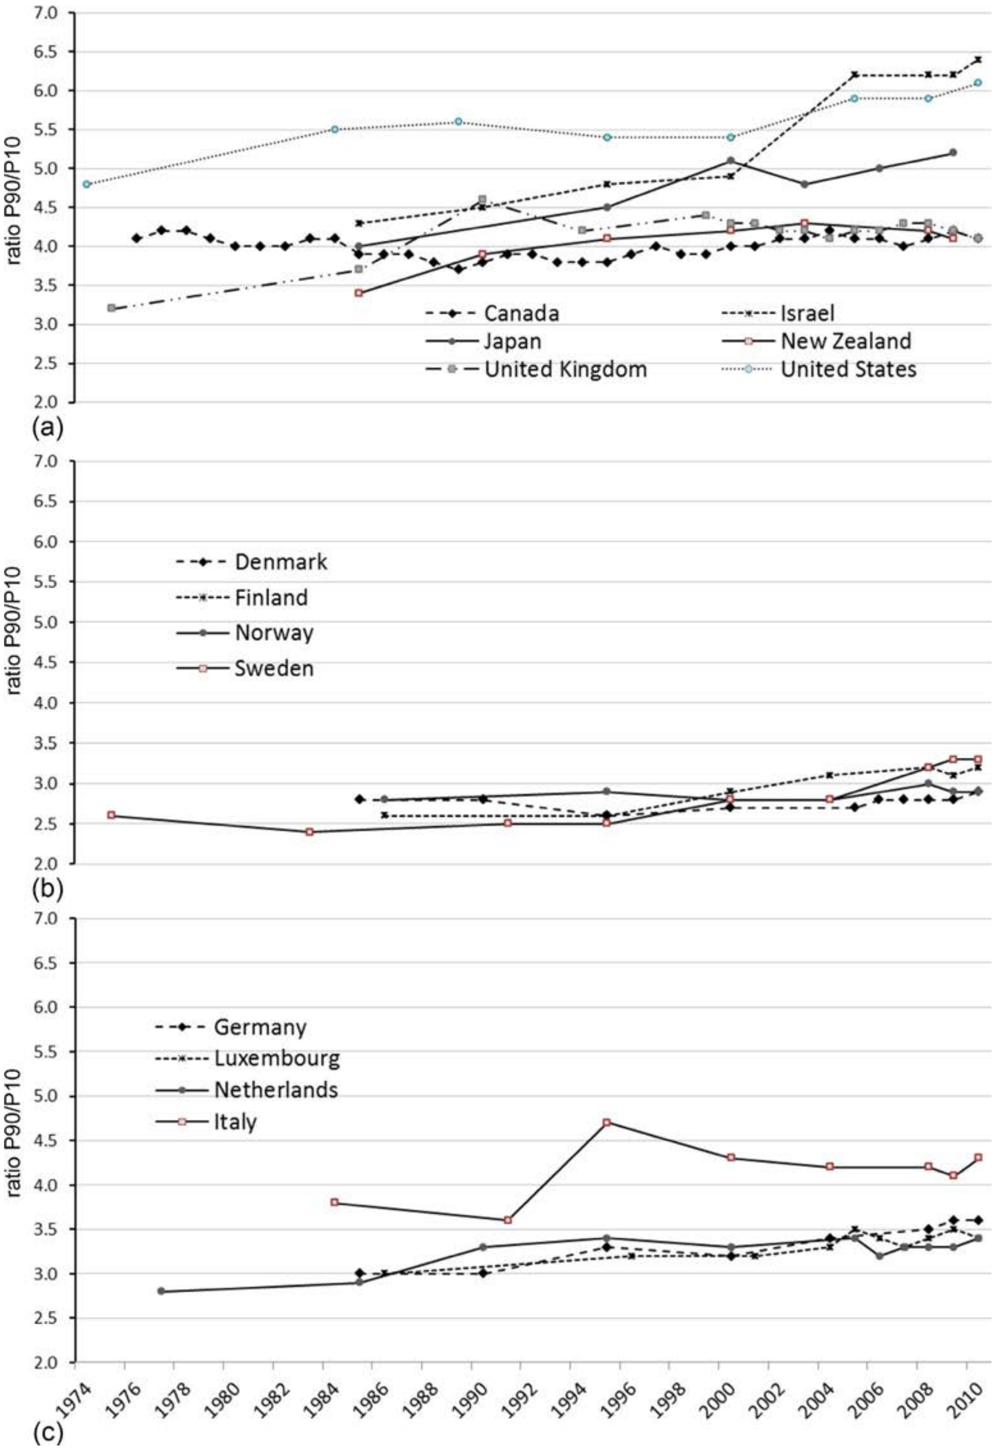

Figure 8.15 Trends in P90/P10 ratios for equivalized DHI by country group based on OECD data: Anglo-Saxon countries, the United States, and others (a); Nordic countries (b); and Continental and Southern Europe (c). *Source: OECD income distribution data.*

grown even more unequal using the P90/10 ratio. By the mid-2000s Israel had supplanted the United States as the most unequal rich nation, with households at the 90th percentile receiving DHIs 6.4 times greater than those at the 10th percentile. In Japan the P90/P10 ratio rose 30% over these three decades.

In most cases, though, the increase in inequality since the early 1980s is equivalent to or somewhat smaller than what is indicated by trends in the S80/S20. In the case of Canada, the 2010 value for the P90/P10 ratio was equal to its 1983 value but 0.4 above its low point in the 1980s. In all of the Nordic and continental European countries (except the Netherlands), the P90/P10 ratio increased less in percentage terms than the S80/S20 did over the same period.

8.4.1.4.3 Trends in Pretax and Transfer Gini Coefficients and the Extent of Redistribution for OECD Countries

Trends in the distribution of pretax and transfer income (using the Gini coefficient) and the extent of redistribution can be explored using the same data, which are available for an expanded set of OECD countries, though for some only since the mid-1990s.

Japan is the country with the largest increase in pretax and transfer inequality among these high-income countries, increasing more than 40% and going from the least unequal distribution in the mid-1980s to one of the most unequal in 2010 (Figure 8.16a). (Figures 8.16 and 8.17 include only countries with data available for the mid-1980s and show the percentage change relative to the mid-1980s base.) Italy also experienced relatively large increases in inequality over this period, with its pretax and transfer Gini increasing 30% (Figure 8.16c). Pretax and transfer inequality increased in most of these countries. In the Anglo-Saxon countries and the United States, the increases were concentrated in the 1980s and early 1990s; in the Nordic and continental European countries Gini coefficients increased most in the early 1990s. The only country that seemed to avoid increased pretax and transfer inequality was the Netherlands. The pretax and transfer Gini actually fell more than 10% in Finland in the late 1990s. For the US, the Netherlands, and Finland, however, data are only available since the mid-1990s. In the Netherlands, increases in the pretax and transfer Gini coefficient in the 1980s were offset by decreases in the late 1990s. New Zealand also experienced declining inequality in the 2000s. A number of countries (including Finland, Israel, and Sweden) have witnessed very little change in pretax inequality over the past 15 years; Gini coefficients have fluctuated only slightly between the mid-1990s and 2010.[30]

Incorporating the influence of taxes and transfers can produce inequality trends that seem quite different, in some cases, than what we see in market or pretax and transfer

[30] For some countries, at least, this finding only holds in income excluding capital gains. In Sweden, for example, inclusion of capital gains income results in sizable increases in pretax and transfer Gini coefficients over this period (Atkinson and Morelli, 2012).

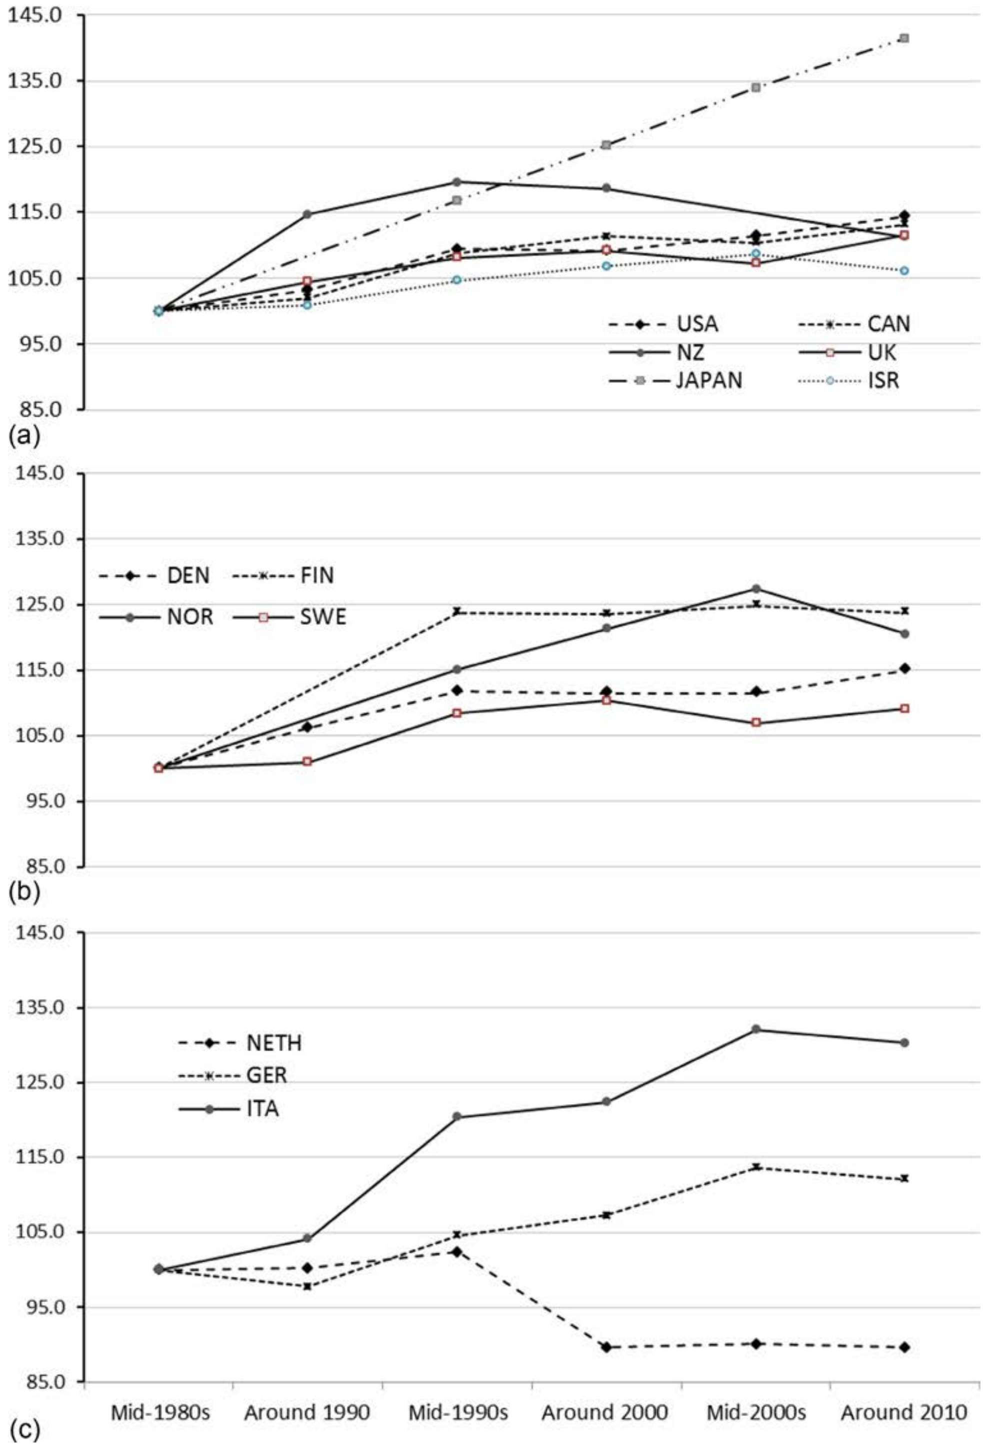

Figure 8.16 Change in pretax and transfer income Gini (mid-1890s = 100) for OECD countries, by country group: Anglo-Saxon countries, the United States, and others (a); Nordic countries (b); and Continental and Southern Europe (c). *Source: OECD Inequality Database, accessed October 23, 2013.*

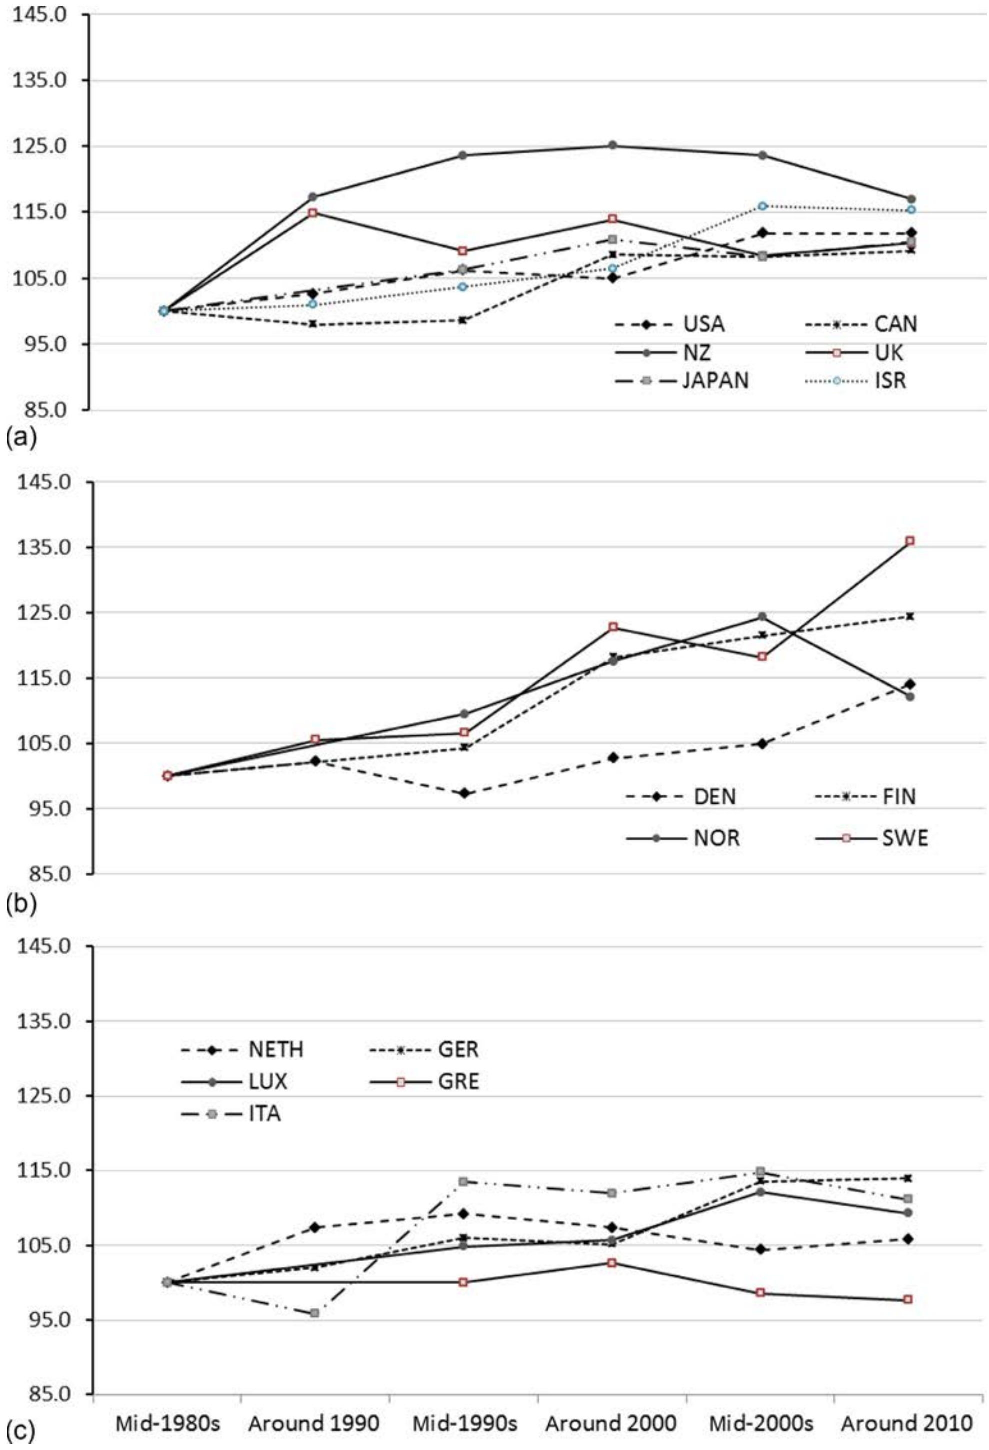

Figure 8.17 Change in disposable household income Gini (mid-1980s = 100) for OECD countries, by country group: Anglo-Saxon countries, the United States, and others (a); Nordic countries (b); and Continental and Southern Europe (c). *Source: OECD Inequality Database, accessed October 23, 2013.*

income. (See Deding and Dall Schmidt, 2002 for an earlier analysis of this issue during the 1990s.) Trends in the Gini coefficients using equalized DHI for the same countries over the same period are shown in Figure 8.17. For some countries trends for the DHI and pretax and transfer Gini coefficients are very similar. The United States, for example, saw the pretax and transfer Gini coefficient increase 14% between the mid-1980s and 2010, while its DHI Gini coefficient increased 12%. The United States is one of the countries for which excluding trends for the 1970s substantially understates its increase in inequality; between the mid-1970s and 2010 the U.S. pretax and transfer Gini increased 23% and its DHI Gini increased 20%.

Denmark, Finland (Figure 8.17b), and Germany (Figure 8.17c) also saw similar increases in the Gini coefficient before and after the inclusion of taxes and transfers. For a number of countries, though, the inclusion of taxes and transfers produces markedly different trends in inequality. For Canada, Japan, Italy, Norway, and the United Kingdom, rising inequality in the distribution of income is blunted once taxes and transfers are included. Japan and Italy, the countries with the largest increases in pretax and transfer inequality in Figure 8.16, experienced increases in their DHI inequality only one-quarter and one-third as large, respectively. The opposite is the case for Sweden, the Netherlands, Israel, and New Zealand, which experienced larger increases in inequality after including taxes and transfers. In the case of Sweden, the Gini for pretax and transfer income increased 9% (from 0.40 to 0.44) between the mid-1980s and 2010, while the Gini for DHI increased 36% (from 0.19 to 0.27).

The differences in the trends illustrated in Figures 8.16 and 8.17 are partly a result of the evolution of the tax and transfer systems in these countries. (As mentioned previously, changes in the age of the population and other demographic and policy factors can influence these trends as well.) Figure 8.18 shows how the extent to which tax and transfers reduce the Gini coefficients for pretax and transfer incomes has changed over this period. The most striking pattern in Figure 8.18 is the dramatic and sustained increase in tax and transfer "redistribution" in most rich nations from the mid-1970s through the mid-1990s, which was followed by steady declines in the decade and a half since. The Anglo-Saxon (Figure 8.18a) and Nordic countries (Figure 8.18b) in particular followed an inverse U-shaped pattern, with redistributive efforts increasing between the mid-1970s and mid-1990s but declining after that point. Since around 2000, taxes and transfers also have played a smaller role in reducing market income inequality in Israel.

In some countries the redistributive impact did not subside in the 1990s. Japan (Figure 8.18a) and Italy (Figure 8.18c) both experienced steady increases in redistribution from the 1990s through the late 2000s. The impact of redistribution has fluctuated less in the United States than in most other high-income countries. Increased redistribution in Canada and Japan, though, has shifted the United States from having one of the lowest levels of redistribution to having the lowest among rich nations. (See Caminada et al., 2012; Immervoll and Richardson, 2011; Wang and Caminada, 2011, for more detailed

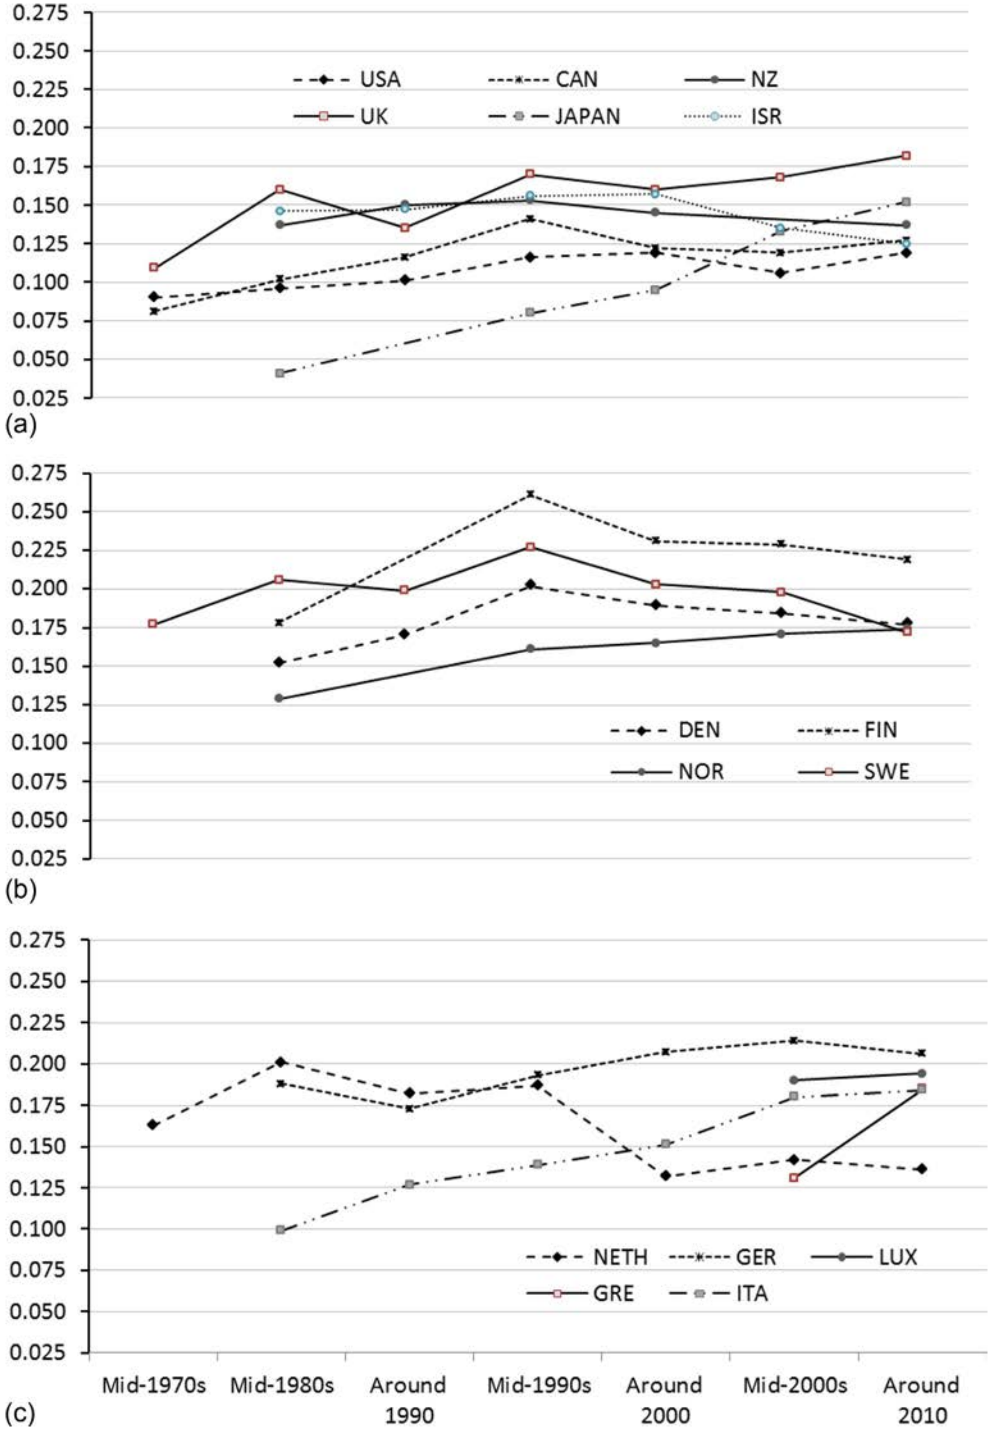

Figure 8.18 Reduction in Gini coefficient due to taxes and transfers trends for OECD countries, by country group: Anglo-Saxon countries, the United States, and others (a); Nordic countries (b); and Continental, Southern, and Eastern Europe (c). *Source: OECD Inequality Database, accessed October 23, 2013.*

discussion of the specific policies and their contribution to reducing market inequality in OECD and LIS countries.) Gini coefficients for pretax and transfer income, DHI, and the difference between the two for the OECD countries are shown in Table 8.5.

8.4.1.4.4 Comparing Trends in DHI Inequality for All Ages and the Working-Age Population

We previously described how age composition is important in understanding how taxes and transfers affect cross-national rankings of income inequality. We can use the same OECD data to evaluate trends in income distribution statistics for the working-age population and contrast them with trends for the overall population. Table 8.6 includes S80/S20 and P90/P10 ratios, as well as Gini coefficients using equivalized DHI for a selection of years between the mid-1980s and 2010 for high-income OECD countries.

Over the entire 25-year period, the distribution of income grew even more unequal among the working-age population in almost every country. The largest differences can be seen among the Nordic countries. In Norway and Sweden, the P90/P10 ratio increased 20% and 15% more among the working-age than for the overall population, respectively, between the mid-1980s and 2010 (panel A). Smaller differences can be seen for the United States, United Kingdom, and Canada, which saw inequality increase between 4% and 8% more among the working-age than among all ages combined. Israel is the only country to see larger increases among the overall population than the working-age, although New Zealand also saw larger increases among the overall population after the mid-1990s. For some of the countries, though, there is no notable difference in the inequality trends between the working-age and the overall population at any point, or at least in more recent years.

The S80/S20 ratio measure yields a strikingly similar pattern of results (panel B) as the P90/P10 ratio, but differences in Gini coefficient trends between the age groups (panel C) are more muted. Norway and Denmark saw DHI Gini coefficients increase 10% and 5% more, respectively, among the working-age than the overall population between 1985 and 2010. In most countries, however, trends in the Gini coefficient were only modestly greater among the working-age population. The tails of the distribution have a greater impact on the S80/S20 and P90/P10 measures than they do on the Gini coefficient and seem to be particularly relevant to understanding any differences in inequality trends for different age groups.

8.4.2 Top Incomes

8.4.2.1 Introduction

The first empirical section of this chapter focused on incomes at the bottom of the distribution relative to the poverty line. The previous section discussed trends in the overall distribution of income (e.g., Gini coefficients), suggesting that the distribution of income has become more unequal in most countries since the 1970s. This section shifts attention to the top of the distribution. Top incomes deserve a separate discussion because top

Note: For most OECD countries, "Around 2010" is for the year 2010, with some exceptions: for South Korea, data are for 2011; for Hungary, Ireland, Japan, New Zealand, Switzerland, and Turkey, data are for 2009; and for the Russian Federation, data are for 2008.

income measures taken from household surveys are typically less accurate because of both sampling and nonsampling errors.

The main objective of this section is to discuss the trends of the so-called top income shares as computed from administrative tax statistics. Different from Chapter 7, we focus here on the investigation of the four decades since 1970. Moreover, we mainly describe here the trends in top shares, leaving out a discussion of what may have driven such trends (see Part III of this volume). The methodological issues affecting the comparison of trends over time and across countries also define a substantial part of this section. Indeed, we start

Source: OECD Income Distribution Database, accessed November 8, 2013. Some data for some countries are from the following years: Finland, 1986, 2004; Greece, 1986, 1994; Italy, 1984, 2004; Japan, 2006, 2009; Luxembourg, 1986, 1996; New Zealand, 2003, 2009; Norway, 1986, 2004; Sweden, 1983, 2004; United Kingdom, 1994; United States, 1984.

here with an overview of the main features and limitations of the data with the objective of highlighting how the latter can affect the comparability of the top shares over time and across countries. Where possible, we illustrate how income at the top can be decomposed by different sources, highlighting the role of capital and wage incomes. Similarly, we provide a brief description of the impact of fiscal policy on the top income shares after taxes. Differences in tax systems can affect differently the level as well the trend of top shares across countries. Finally, we discuss how we can complement the two sources of information (tax and survey statistics) to improve our understanding of the evolution of income inequality.

The analysis in this section uses data on total income of the families, tax units, and individuals above the 99th percentile of the distribution. Therefore, unlike Chapter 7, this chapter does not focus on different income groups within the top decile. The data are collected and assembled from tax statistics, available from the World Top Incomes Database (WTID) by Alvaredo et al. (2012). The database is the result of years of work in a line of research initiated by Frankel and Herzfeld (1943)[31] and Kuznets (1953), revived by Piketty (2001), and carried on in subsequent collective works directed by Atkinson and Piketty (2007, 2010), who pulled together a number of contributions from different authors.[32]

Motivations for the surge of interest in incomes at the top of the distribution vary. On one hand, the WTID database constitutes a unique source of information covering most of the twentieth century (and in a few cases the beginning of the twenty-first century as well). As shown in great detail in Chapter 7, this is a crucial advantage for studies of income distribution, which are usually plagued by data limitations.

On the other hand, the analysis of top income shares helps to offer a better understanding of the post-1970 dynamics of income distribution and its determinants. First, the share of total income captured by a tiny minority of the population in many advanced countries has been increasing continuously since the 1980s, and this has fueled concerns about the social inclusiveness of economic growth. In the United States, "the top 1 percent captured 58 percent of real economic growth per family" during the 1976–2007 period (Atkinson et al., 2011, p. 8). Findings such as these likely motivated the managing director of the IMF, Christine Lagarde, to refer to inequality and the inclusiveness of growth as one of the three future challenges of the global economy that the IMF aims to address.[33]

[31] Although Kuznets is often considered to be the pioneer of this stream of literature, Alvaredo and Atkinson (2010) noted that "Frankel and Herzfeld (1943) published estimates of the European income distribution in South Africa based on the income tax returns, but making use of control totals from the census of population and from the national accounts. Their use of external information to complement income tax data pre-dated by ten years the study of upper income groups in the United States by Kuznets (1953)."

[32] The reader is directed to the WTID Web site at http://topincomes.g-mond.parisschoolofeconomics.eu/ for a complete list of the sources of data.

[33] "A better financial system" and overcoming economic and financial crisis are the two other points. This refers to the Annual Meetings Speech in Tokyo on October 12, 2012 (http://www.imf.org/external/np/speeches/2012/101212a.htm).

Second, understanding the dynamics of the share of total income of the upper-income brackets may be crucial to understanding changes in the overall income distribution. This has been shown empirically by Leigh (2007) and Smeeding and Thompson (2011) and discussed more formally by Atkinson (2007) and Alvaredo (2011). As in Chapter 7, we recognize here that the relationship between top shares and other income inequality measures may well be changing over time. In particular, we exploit disaggregated evidence for different decades to show that such a relationship has weakened since the 1990s. This differentiates our conclusions from those of Chapter 7, calling for extra prudence in using top shares as a proxy for the overall income distribution as obtained from household surveys. Furthermore, academic research has shown that the information contained within standard surveys hardly captures incomes above the 99th percentile so that top income shares can be potentially used to adjust available measures of overall inequality such as the Gini coefficient, discussed in the previous section.

Third, top income shares have been particularly useful to studies of important issues in public economics, such as the elasticity of reported income to tax changes, the extent of income shifting and tax avoidance, and, more generally, behavioral responses to changes in taxation. Finally, the new empirical evidence on top shares gave the economic profession a new challenge: conventional explanations of rising income inequality since the end of Bretton Woods system, such as the skill-biased technological change and globalization forces, are no longer sufficient to explain the evolution of top income shares across different developed countries.

8.4.2.2 Data and Methodology

As mentioned above, our analysis makes use of the WTID for 21 countries since 1970.[34] In general, the series are constructed using tax statistics, and they make use of gross types of income (e.g., in the United States, the gross market income is defined before deductions, individual income taxes, payroll taxes, and all kinds of government transfers).

Top income shares are mostly calculated from detailed, historically tabulated income tax statistics. Alternatively, tax administration microdata are also increasingly used, especially for the last decades of the twentieth century. Information contained within the tax statistics then is combined with control totals for population and income. Essentially, tax statistics provide the total income and the total number of tax units for given income ranges and allow us to compare these values with the totals in the economy.[35] It is important to note that when using group tabulations data, the precise share of income accruing

[34] The countries are Australia, Canada, China, Denmark, Finland, France, Germany, India, Ireland, Italy, Japan, the Netherlands, New Zealand, Norway, Portugal, South Africa, Spain, Sweden, Switzerland, the United Kingdom, and the United States.

[35] This refers exclusively to those who file taxes, which can be quite a small portion of the population, especially in earlier years of the twentieth century. The assumption is that the top of the distribution is always sufficiently covered.

to a specific percentile within the top decile is obtained through interpolation techniques because the ranges of tax units within tabulations do not necessarily coincide with the percentage of the population for which we would like to assemble data. Interpolation is commonly applied using distributional assumptions about the top tail of income distribution (e.g., Pareto distribution) or, alternatively, by computing lower and upper bounds for every share (e.g., the actual share can be obtained using the mean-split histogram, as used by Atkinson, 2005).

Broadly speaking, the choice between these two different interpolation techniques does not affect the substance of the results, and interpolation errors have been generally proven to be negligible. This is particularly true when the information within the grouped tabulations is detailed and of high quality.[36] While choice of interpolation technique does not seem to be crucial, other factors may substantially influence the accuracy of estimates of top income shares and the comparability of levels and trends across countries.[37]

8.4.2.2.1 Caveats and Limitations to the Data

Although top shares are calculated with similar methodologies across countries, there are a number of caveats that are important to consider.[38] This section summarizes and extends the discussion of the methodology for the derivation of top shares data found in previous publications. Differences and changes in methodology may (or may not) affect the comparability of data across countries as well as over time, even within individual country-specific series. Understanding the relevance of these issues is the focus of the following subsections.

Reliance on tax statistics raises a number of important questions and concerns about the construction of top income shares. First, the income definition is tailored to follow administrative requirements, implying that the definitions of income, income unit, and so on, do not necessarily coincide with the preferred definitions used for research purposes.[39] Administrative criteria may also differ across countries or change over time (e.g., changes to tax legislation such as income sources subjected to taxation, tax units), generating comparability issues.

Calculating comparable top share series also requires consistency between the numerator (total top income) and the denominator (total income in the economy). However, the control total for income is calculated in different ways across countries and over time, in turn affecting the comparability of data. In addition, economic agents have incentives

[36] See Atkinson (2005) for a detailed discussion.

[37] Atkinson et al. cover these issues extensively in their 2011 paper in the *Journal of Economic Literature*.

[38] The limitations of income tax data have been discussed extensively by Leigh (2009), Atkinson et al. (2009, 2011), and Burkhauser et al. (2012b).

[39] Ideally, the Haig-Simons definition of income is preferred. This includes accruing capital gains and losses (not only realized), imputed rents, and fringe employment benefits.

to change their behavior to minimize their tax liabilities and most probably understate their true income (e.g., tax avoidance, tax evasion, income shifting), and these incentives may vary with income and across tax systems.

Finally, the series are largely concerned with gross income before taxes so that the effective change in income inequality after taxes is dependent on changes in the effective tax rate of top income brackets. This has certainly changed dramatically over time and might not have followed a similar pattern in all countries. This is an issue of crucial importance, although it is much less debated because of data limitations. This section addresses these issues separately.

Despite these concerns, it is worth noting that the literature on top income shares also has highlighted the potential and the strength of these data, generally concluding that these problems can be attenuated. The country-specific series are usually obtained from the same sources over time, and we can easily identify breaks that may affect the measurement as well as indicate the direction and magnitude of the potential change. In addition, our focus on the post-1970 period allows us to have both better data and better documentation to deal with these issues to a satisfactory level. For an analysis on the very long run (since approximately 1750), we direct the reader to Chapter 7.

8.4.2.2.2 Definition of the Control Total for Income

Every top share is a fraction between the incomes accruing to a specific top income group with respect to the total income in the economy. The two definitions of income have to be consistent, and there are different ways to come up with an estimate of the total pretax income in the economy.

As detailed by Atkinson et al. (2011), and illustrated within the previous chapter as well, one possible approach is to subtract specific categories of income from the total personal income within the national accounts. This is done to come as close as possible to the income definition reported in the tax statistics (occasionally proportionally adjusted). This is the original approach pioneered by Frankel and Herzfeld (1943), then by Kuznets in 1953, and later adopted by Piketty in 2001 and used by most of the countries in the WTID.[40] The alternative approach is to inflate the total income that is reported in the tax statistics to correct the missing income of individuals who do not file a tax return (as done for the series for the United Kingdom, Finland, the Netherlands, Sweden after 1942, Switzerland after 1971, and the United States after 1944). Whereas the first approach makes use of external control of income from national accounts sources, the second approach deals with sources of income that are mainly internal to the tax statistics.[41]

[40] Australia, Canada, Germany, India, Ireland, Italy, Japan, New Zealand, Norway, South Africa, and Sweden before 1942; Switzerland before 1971; and the United States before 1944.

[41] It is worth noting that additional information (external from tax sources) can also be used to estimate the income of nonfilers (this is, for example, the case of the United Kingdom, as described by Atkinson, 2005).

In a few cases where national accounts are not available (this is especially true for earlier years), total income is estimated from the full population households survey (this was done for China) or as a share of gross domestic product (this is the case for initial observations of Spanish and Portuguese top incomes).

As should be expected, these methodological differences may affect the level of the series as well as the trend. In particular, the comparison of cross-country trends can be affected when different methodologies are systematically applied by different countries. For the case of the United Kingdom, Atkinson (2007) documents how the ratio between total income based on tax statistics and total income from national accounts[42] has declined over time, falling from 0.9 at the beginning of the century to 0.85 in the last years of the century. Assuming that the ratio decreased at a constant rate, we could obtain a rough estimate of the dynamics of the top income shares based on the control totals using national accounts. Despite the documented minor change, the impact on the trend of top shares can be seen over time. The gap between the top shares reported in the WTID (using control total estimated from the tax statistics) and the ones we estimate based on a different control total rises from 1 percentage point in 1970 to 2 percentage points in 2000. In the case of the United Kingdom, the two different approaches yield very similar trends over time, but the magnitude of the increase—whether the top 1% share rose 5 or 6 percentage points—is sensitive to the definition of control total. The differences could potentially influence comparisons of top income shares within and across countries at a point in time as well over time.[43]

8.4.2.2.3 Definition of Top Income

As discussed above, the income definition follows the administrative requirements for tax statistics, which vary over time and across countries. In particular, the income definition used within the WTID attempts to be as close as possible to the definition of gross total market income (net of government transfers, taxes, and deductions). Changes in tax legislation may allow the inclusion or the exclusion of particular income sources within the reported income (e.g., capital gains, dividends, income deductions). In other words, these changes may bring about an expansion or a reduction of the tax base. We discuss below three specific types of changes and structural breaks in taxation regimes that can create severe problems for the consistency of top shares estimates over time. Nonetheless,

[42] Personal income minus transfers.

[43] There are, however, ways of avoiding the problem of control total altogether. The phenomenon of increasing inequality can be explained on one hand with the redistribution of resources toward the top 1% from the rest of the population (increase in top shares). On the other hand, this has proceeded together with a redistribution of income in favor of the very rich within the top percentile. The latter increase in inequality within the top is described by the Pareto coefficients or by the so-called shares within shares. These variables are, by construction, independent from the external control total.

we also point out that these changes do not always result in actual breaks (in levels or trends) for the top income shares series.

The first type of change in taxation discussed here deals with the treatment of deductions within the tax statistics. Starting from 1976, the income of the U.K. series, for instance, is grossed to include deductions that were previously subtracted from income[44]: "(i) allowable interest payments such as those for house purchase, (ii) alimony and maintenance payments, (iii) retirement annuity premiums, and (iv) other allowable annual payments" (Atkinson and Salverda, 2005). Such a change did not, however, cause a substantial change in the top income share: "the share of the top 1% was shown as rising from 5.6 to 5.7%, and that of the top 10% from 25.8% to 26.2%" (Atkinson and Salverda, 2005).

The second relevant type of taxation change concerns the treatment of capital income within the tax base. This problem is listed by Atkinson et al. (2011) as probably the "main shortcoming" of the WTID data, undermining the comparability of the top income series. Indeed, the estimation of top income shares is based on the observation of reported income for taxation purposes, and the restriction or the expansion of the tax base may be misleading representation of the real changes of total income held by top income groups.

On one hand, many sources of income from capital (interest income, returns on pension funds, imputed rents, etc.) have disappeared from the income tax base over time because they have been either fully exempted from taxation or are taxed separately. As reported by Iwamoto et al. (1995) and Moriguchi and Saez (2008), a substantial share of capital income, for example, was missing from the Japanese self-assessed income tax starting from 1947 "because almost all interest income has been either tax exempted or taxed separately and withheld at source . . . and so was a large part of dividends since 1965." However, as suggested by Moriguchi and Saez (2008), interests and dividends constitute only approximately 3% of total personal income in Japan, and even assuming that top groups absorb the whole income from these sources, the top 1% would still be far below the pre-1945 levels and below top 1% share in the United States. Similarly, the French tax base shrank with the exclusion of imputed rents of homeowners, as documented by Piketty (2001, 2003), who also provides some conservative estimates showing that the reduction of French top income shares was robust to the full imputation of tax-exempted capital income to reported income at the top.

On the other hand, the tax base may be expanding, generating a problem similar to, but the reverse of, the one discussed above. This is, for instance, described by Burkhauser et al. (2013) for the case of Australia, where the tax reform proposed in 1985 (and formally approved by 1987) aimed at broadening the tax base "in order to improve equity and efficiency."

[44] The income can be adjusted at the source for those countries where the information on deductions is available for income level. This is the case for the United States, as shown by Piketty and Saez (2006).

Most important, the tax reform included realized capital gains within the personal income tax base because "prior to 1985, Australia had no general tax on capital gains" and reduced substantially the marginal tax rates on dividends by introducing the so-called full-imputation system, which no longer allowed dividends to be subjected to both corporate and income taxation.[45] More specifically, both tax interventions (approved in 1987 and 1986, respectively), on the one hand, allowed the inclusion within the income tax base "most realized capital gains regardless of how long the asset was held. But to soften its effect, the reform applied only to assets purchased after September 19, 1985. Certain types of assets continued to be exempt, most importantly owner-occupied housing" (p. 8). On the other hand, the switch to a full-imputation system increases enormously, although artificially, the reported dividends income.[46] However, Burkhauser et al. (2013) further note that whereas the change in the tax law on dividends may have had an impact on the level of the share, the change in capital gains taxation had instead an impact that "grows over time with the stock of assets purchased after September 19, 1985 and the share of realized capital gains that enter the tax base" (p. 9). As reported by Burkhauser et al. (2013), these issues were not directly addressed by Atkinson and Leigh (2007) and led them to overstate the real increasing trend of Australian top shares.[47]

Finally, the third type of taxation change relates to the treatment of capital gains within the income definition. This can be more problematic because this source of income is particularly important for the very top income brackets—and is increasingly so because capital gains have been receiving advantageous tax treatment with respect to dividend-type income in most advanced countries. As distributed, corporate profits became less advantageous (dividends often are taxed at the income tax rate and subject to double taxation at the corporate level and individual level). Thus, including capital gains becomes fundamental "to assess the impact of retained profits of corporations on top individual incomes" (Atkinson et al., 2011). Moreover, because of favorable taxation, investors may be more willing to hold stocks with an underlying low payout ratio to cash in capital gains rather than dividends (e.g., the clientele effect). These considerations suggest that excluding capital gains can leave out a considerable (and increasing) amount of the income of richer tax units, making static and temporal comparison of effective top income shares across countries more problematic, assuming that the extent of the relevance of capital gains and their dynamics differ among countries.

[45] The Australian dividends tax reform in 1987 increased the corporate profits tax rate to the level of top income marginal tax rate (from 46% to 49%). However, as noted by Burkhauser et al. (2013), "under the new 100 per cent imputation tax system contained in the reform legislation, these company taxes effectively became withholding taxes. This was the case since their payment could be used to offset personal income tax on dividends as well as other taxes."

[46] To better understand the mechanical increase in reported income resulting from the switch to a full imputation system, we refer the interested reader to Burkhauser et al. (2013).

[47] This might be true, especially given the fact that Atkinson and Leigh's series include capital gains.

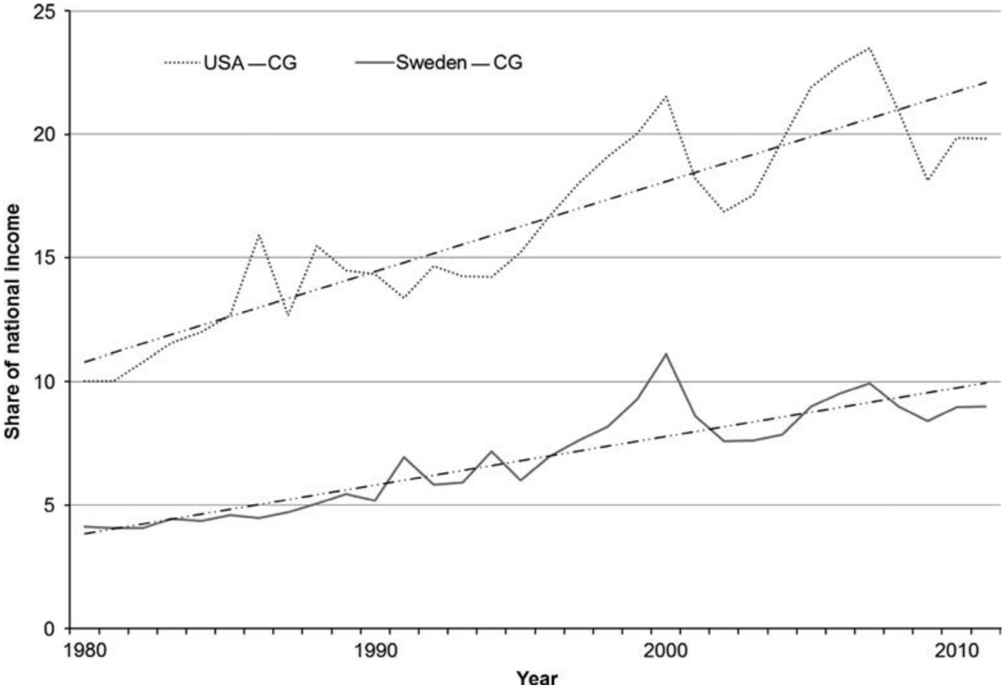

Figure 8.19 Top 1% share trends in the United States and Sweden, including capital gains (CGs). The graph shows that, despite the inclusion of CGs, the levels of the shares are substantially different across the two countries, whereas the trend over time becomes similar. *Source: World Top Income Database, accessed August 2013.*

To illustrate the validity of the argument above, we describe below how the top income share changes once capital gains are taken into account. However, this exercise can be done only for six countries, namely Canada, Japan, Germany, Spain, Sweden, and the United States.[48]

The role of capital gains for top income shares has been discussed by Roine and Waldenströmm (2012) for the case of Sweden, where, they argue, excluding capital gains "severely underestimates the actual increase in inequality and, in particular, top income shares during recent decades." Indeed, Figure 8.19 shows that after including capital gains, the top income share in Sweden has a similar trend to the top 1% in the United States. Yet the difference in level remains substantial. Figure 8.20 depicts the dynamics of top 1% income shares including and excluding capital gains for those countries for which data exist, suggesting that the importance of capital gains may also vary a great deal across

[48] Indeed, most of the top shares series within the WTID exclude capital gains altogether, whereas in a few countries capital gains are only included where taxable. The latter, however, cannot be untangled from the total income because no income source decomposition is provided. This is the case for the United Kingdom (before the introduction of a separate capital gains tax), Australia, New Zealand, and Norway.

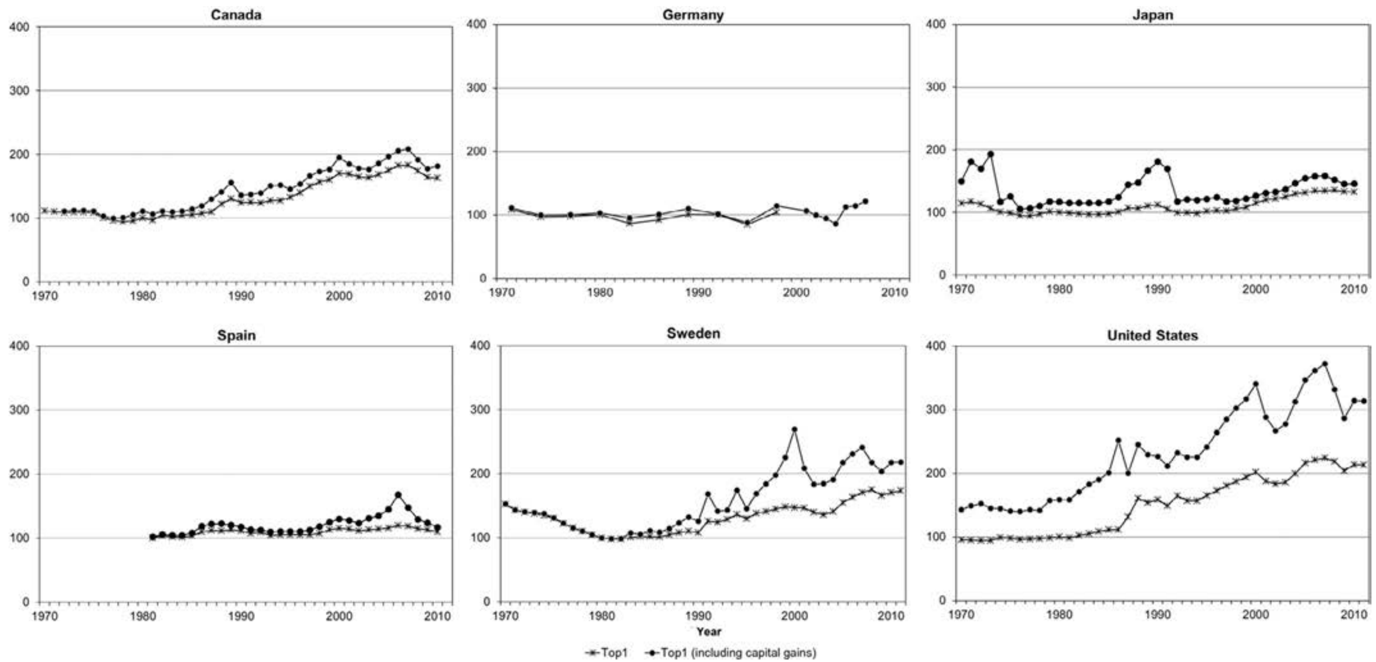

Figure 8.20 Cross-country variation in the impact of including capital gains income for top 1% share trends. The series of top 1% share excluding capital income are set equal to 100 in 1980. The series of top 1% shares including capital gains are calculated as follows: top1cg = 100 * top1cg/top1. *Source: World Top Income Database, accessed September 2013.*

countries. In the case of Germany, including capital gains income has essentially no impact on the top 1% share of income. Capital gains seem to affect the cyclicality of top shares in Japan, creating spikes but not persistent changes in level or trend. In Sweden, Canada, and Spain, the inclusion of capital gains income did not have a marked impact on the top 1% share before 1980 or 1990, but the influence of capital gains has become increasingly large since the 1980s, influencing the perceived trend of the increase in top shares. For the United States, the inclusion of capital gains income has resulted in systematically higher top shares over the entire period. It is crucial to note that the relevant concept of capital gains discussed here is that concerning its "realized" component for tax purposes. Indeed, realized capital gains refers to the wedge between the selling and purchasing prices of the asset. Furthermore, realized losses are subtracted from realized gains to obtain the measure of *net* realized capital gains valid for taxation purposes. This is a concept very different from accrued capital gains, which simply reflects the current differential between the "market price" and the purchase price. Indeed, individuals may realize capital losses for taxation purposes so that a series including capital gains is not necessarily more valid, informative, or complete than a series excluding capital gains.

Changes in tax systems can also affect the unit of reference (e.g., change in tax units); the extent of tax evasion and avoidance, including the phenomena of income shifting (e.g., substitute wages with tax-exempted noncash compensation); and anticipation or postponement of income returns. These issues are of crucial importance and are discussed later in separate sections.

8.4.2.2.4 Changes in Tax Avoidance and Tax Evasion

This section discusses the roles of (unlawful) tax evasion, (lawful) tax avoidance, and other behavioral responses to changes in taxation.

The use of tax data to estimate top income shares poses potentially serious problems resulting from underreporting, retiming of income reporting, and income shifting (depending on fiscal convenience). We discuss these important issues here to understand how they may affect the comparability of top shares series over time and across countries.[49]

Work by Piketty et al. (2012) showed that most of the countries under investigation experienced a reduction in the top marginal tax rate, which was highly correlated with the surge in top income shares we observed in the three decades following the end of the Bretton Woods system (see Figure 8.21). The reduction in the top marginal tax rate could indeed reduce the propensity to evade and avoid taxation, increasing tax collection and

[49] The specific composition of total reported income (e.g., capital vs. wage) may also be driven by tax convenience. In other words, capital and wage incomes are, to some extent, fungible and interchangeable. However, this issue is not discussed here because we are ready to assume that the "fungibility" of income sources does not affect the total reported income, only its composition. This issue becomes relevant in section 8.4.2.5 where we explicitly discuss the composition of income at the top.

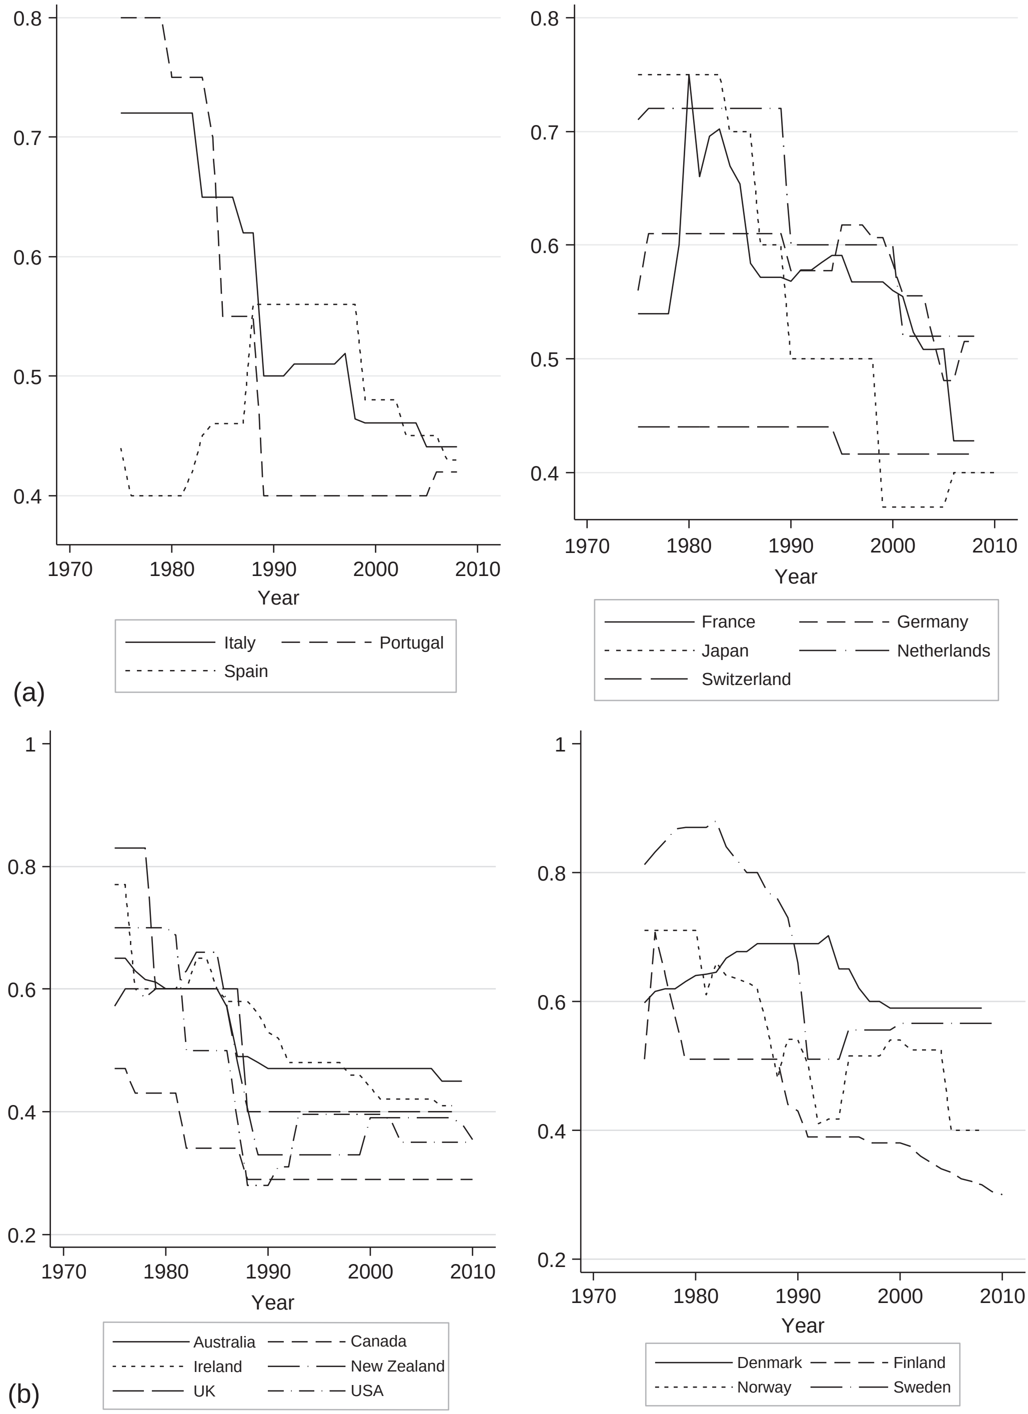

Figure 8.21 Top marginal tax rates across countries, 1970–2010: southern and continental European countries (and Japan) (a) and English-speaking and Nordic European countries (b). The figure depicts the top income tax rates (including both central and local government individual income taxes) over the period from 1970 to 2010. *Source:* Piketty et al. (2012).
