Handbook of Climate Change Mitigation and Adaptation

Second Edition

2017

With 1108 Figures and 352 Tables

Springer

Foreword

Scientific evidence is mounting that human activities have begun to change global climate. As a consequence, attention is increasingly turning in the public, private, and nonprofit sectors to the options available for dealing with that change. As we gradually begin to realize, actually only three options are available to us: mitigation, adaptation, and suffering. Mitigating climate change means cutting and sequestering emissions of greenhouse gases to prevent further increases in their atmospheric concentrations and perhaps even reducing concentrations to levels deemed less unsafe than the ones to which they have been driven since the start of the industrial revolution. Adaptation means finding ways that can help reduce the impacts of climate change on society, the various sectors of its economy, and the places in which we live – be those small rural villages or the cities and towns that by now house the majority of the human population, that account for the bulk of infrastructure investments, and that contribute most to energy consumption and carbon emissions. To the extent that mitigation and adaptation efforts are too timid, suffering will inevitably result.

What are safe concentrations of greenhouse gases is a topic of vigorous debate because we do not yet fully understand the coupled earth system and human system dynamics that will play themselves out in a world of unprecedented greenhouse gas concentrations. How high is too high will be known well after the point of no return has been reached, that is when developments in the global biogeochemical system are kicked off to move in a direction and rate that cannot be undone. Ice sheets may melt and free the methane and carbon dioxide long locked up in the soils underneath, thus further accelerating climate change. Major ocean currents, which move waters and nutrients to support the biological activity in the seas, may abruptly change direction or entirely cease. The established precipitation and temperature patterns, which are so central to agriculture, may be altered in ways that further challenge our abilities to feed a growing human population. And so, the extent to which we embrace mitigation, in part, reflects our aversion – or desire – to take risks in matters pertaining not just to the stability of global climate conditions but the global human condition and that of other species more broadly.

It is against this backdrop that this volume illuminates humanity's mitigation options. From its coverage it is quite obvious that there is no magic knife with which to cut emissions, because the sources of emissions are varied and intricately woven

into the very fabric of our society and economy. Movement from oil, coal, and natural gas, for example, to biological feedstocks for the production of fuels and chemicals is an essential strategy to decarbonize our economies, but the effect of this strategy hinges on the extent to which production of biomass can decouple itself from fossil-based generation of fertilizers and pesticides, minimize land conversation, and prevent the associated release of carbon from soils and impacts on biodiversity. Other, at least equally daunting, challenges surround the conversion of syngas to fuel; the deployment of geothermal, solar, and fusion technology; and the various means to sequester greenhouse gases. Policy and investment decision makers who wish to navigate and shape the resultant dynamics are further challenged in their abilities to understand and project resource and emissions trends into the future because of the rapid changes in technologies and markets, as well as the emergence of new, major players in the game, such as has happened in recent years with the proliferation of shale oil and shale gas developments.

Even if the production of new sources of energy and materials can occur with lower emissions, the end use technologies and infrastructures need to be in place to take full advantage of these improvements. This will require changes in our built environment – from houses to transportation networks to energy storage to power grids and beyond. These changes, in turn, will, at least for the foreseeable future, require continued use of existing infrastructures that have developed around the use of conventional fuels and land use practices.

Decarbonization at the process level, even when combined with the most aggressive efficiency improvements in the end uses of materials and energy, however only translates to net reductions in emissions if "other influences" do not overwhelm the rates at which these improvements are realized. Among these other influences are economic growth that comes from generating ever larger production of output, population growth that leads to ever more demand for goods and services, and climate change itself that is triggering a need for surplus production to built up our safety nets – from personal insurance to large-scale flood control systems – that can help us weather adverse climate conditions.

In the final analysis, it is the interplay of technology change, behavioral change, institutional change, and environmental change that must be managed for mitigation to become effective. How well that interplay is orchestrated will in large part depend on our ability to provide the right incentives for climate mitigation – be it through international agreements or through unilateral action, through market-based approaches, direct government intervention, or a mix of them all. Our success will be indicative not just of the technological prowess of our age, but also of the values and institutions that guide our actions.

Despite all efforts to stabilize and perhaps even reduce, in the long run, atmospheric greenhouse gas concentrations, humans have already committed themselves to decades of temperature changes and centuries of sea level rise. And, to worsen the outlook, rising global temperatures and sea levels will be accompanied by many other changes in our biophysical and socioeconomic environment. Since the heat budget of the globe will be disturbed, the frequency and severity of extreme weather events will likely increase. Disruptions in biophysical conditions will trigger, and be

triggered by, changes in ecosystems – including changes in the productivity of managed forests and croplands, as well as changes in the distribution of pests and diseases. The associated tightening of resource constraints will undermine the livelihoods of people, displace populations, and inflict pain and death.

There are unlikely to be long-term winners from climate change. None of the places already suffering from shortages in water and food, for example, or flooding and crumbling infrastructures will, in the long run, be better off because of climate change. Even if they do feel like "winners" temporarily – perhaps because the length of growing seasons increases with rising temperatures or a melting of sea ice improves shipping and boosts their economy – those benefits are fleeting. Climate will not stop changing once optimal conditions are reached, and benefits in one sector may already be overwhelmed by costs imposed on other parts of the economy and society. Clearly, some form of adaptation will need to take place.

Ideally, adaptation strategies are implemented not just as climate change unfolds, but in anticipation of any further climate change so that people, economic sectors, cities and their infrastructures, as well as natural systems such as wetlands and forests, are better prepared for, and perhaps even protected from, further disruptions. But even if there were no further climate change, there already is considerable variability in the weather conditions with which people, economic sectors, cities, and natural systems must cope. Maintaining vital wetlands well before flooding events will help provide natural buffers for coastal communities. Creating redundancies in lifeline infrastructures, such as the different ways of powering businesses and homes from centralized power plants and small-scale generators, will allow for switching across electricity sources during extreme weather events, for example. And promoting more efficient energy use in the first place will reduce the reliance on some of that energy. To the extent that adaptation helps reduce already existing inefficiencies, it can make good social, economic, and environmental sense irrespective of the details with which future climate conditions manifest themselves.

The conclusion one may draw that "less mitigation today can be balanced by more adaptation in the future," however, is misleading. It suggests that the two strategies are, at some abstract level, substitutable. In reality, though, less mitigation today means not just a need for more adaptation in the future. Rather, less mitigation today means more adaptation over more of our future, because even reduced emissions continue to add to atmospheric greenhouse gas concentrations, *and* because the damages that result will be cumulative in nature – heat waves, droughts, and flooding events, for example, will continuously undermine our wealth and welfare and require ever larger diversion of resources to address the causes and effects of climate change. Understanding the role of mitigation and choosing the proper mitigation strategies is, therefore, an essential forebear to anything else we may be doing about climate change. Recognizing the urgency for preparedness, given the extent to which humanity has already committed itself to a changing climate, is central to motivating investment in new technologies, changes in behaviors, and deployment of infrastructures that can better withstand the vagaries of the climate.

A worldview that is consistent with this understanding sees mitigation and adaptation as complements, offers them as strategies to address persistent and nascent inefficiencies, and treats them as a package that substitutes for the only other option available, namely suffering. It is in this sense that this *Handbook of Climate Change Mitigation and Adaptation* provides valuable insights into the preconditions for a prosperous future.

About the Editors

Wei-Yin Chen is a Chemical Engineering professor with degrees in Chemical Engineering and Applied Mathematics and Statistics. He initiated the Sustainable Energy and Environment (SEE) group, which was formed at the University of Mississippi in 2007 and now has over 200 collaborators around the world. The SEE group has been offering new courses on climate change and sustainable energy, edited this Handbook, been developing experimental modules for outreach with several nationally recognized awards, and been developing a multidisciplinary research program leading to efficient power generation, CO_2 utilization, CO_2 capture, and carbon activation. He has served as a panelist, reviewer, or advisor for research organization in the USA, China, Romania, India, Jordan, Malaysia, etc. He is an adjunct or visiting faculty of five universities in China and Taiwan. He is currently on the editorial board of five journals. He has reviewed manuscripts and book proposals for over 50 journals and publishers. He has received the outstanding research, teaching, and service awards from the School of Engineering of the University of Mississippi. His publications on pedagogy have been cited as the "Best Practice" by a review of *Chemical Engineering Education* in both the thermodynamics and chemical reaction engineering areas.

Toshio Suzuki is Group Leader of Functional Integration Technology Group, at Japan's National Institute of Advanced Industrial Science and Technology (AIST), working in the fields of materials science, electrochemistry, and nanotechnology, especially on the development of next generation electrochemical devices such as solid oxide fuel cells (SOFCs). He is specializing in the design of advanced materials for energy conversion, with R&D experience in electrical, structural, and optical properties of novel ion conducting materials, correlating with microstructure. Dr. Suzuki received his

Ph.D. in Ceramic Engineering from University of Missouri-Rolla, USA, in 2001 and has published over 140 research articles, book chapters, and patents.

Maximilian Lackner received his Ph.D. in Technical Chemistry from Vienna University of Technology, Austria, in 2003, and his habilitation in Chemical Engineering in 2009. His research interests include: climate change mitigation, material science, lasers in chemistry, combustion, biofuels, and biobased plastics. Dr. Lackner was visiting researcher at Munich University of Technology (Germany), Darmstadt University (Germany), and Lund Institute of Technology (Sweden). He held several senior leadership positions in the petrochemical industry in Austria and China and founded five companies. Dr. Lackner has published over 100 research articles, book chapters, and patents. He is lecturer at Vienna University of Technology, the University of Applied Sciences FH Technikum Wien, and Johannes Kepler University (Austria).

Scientific Evidences of Climate Change and Societal Issues

Introduction to Climate Change Mitigation

Maximilian Lackner, Wei-Yin Chen, and Toshio Suzuki

Contents

Abstract

Since the first edition of the Handbook, important new research findings on climate change have been gathered. The handbook was extended to also cover, apart from climate change mitigation, climate change adaptation as one can witness increasing initiatives to cope with the phenomenon. Instrumental

recording shows a temperature increase of 0.5 °C Le Houérou (J Arid Environ 34:133–185, 1996) with rather different regional patterns and trends (Folland CK, Karl TR, Nicholls N, Nyenzi BS, Parker DE, Vinnikov KYA (1992) Observed climate variability and change. In: Houghton JT, Callander BA, Varney SDK (eds) Climate change, the supplementary report to the IPCC scientific assessment. Cambridge University Press, Cambridge, pp 135–170). Over the last several million years, there have been warmer and colder periods on Earth, and the climate fluctuates for a variety of natural reasons as data from tree rings, pollen, and ice core samples have shown. However, human activities on Earth have reached an extent that they impact the globe in potentially catastrophic ways. This chapter is an introduction to climate change.

Climate Change

There has been a heated discussion on climate change in recent years, with a particular focus on global warming. Over the last several million years, there have been warmer and colder periods on Earth, and the climate fluctuates for a variety of natural reasons as data from tree rings, pollen, and ice core samples have shown. For instance, in the Pleistocene, the geological epoch which lasted from about 2,588,000 to 11,700 years ago, the world saw repeated glaciations ("ice age"). More recently, "Little Ice Age" and the "Medieval Warm Period" (IPCC) occurred. Several causes have been suggested such as cyclical lows in solar radiation, heightened volcanic activity, changes in the ocean circulation, and an inherent variability in global climate. Also on Mars, climate change was inferred from orbiting spacecraft images of fluvial landforms on its ancient surfaces and layered terrains in its polar regions (Haberle et al. 2012). Spin axis/orbital variations, which are more pronounced on Mars compared to Earth, are seen as main reasons. As to recent climate change on Earth, there is evidence that it is brought about by human activity and that its magnitude and effects are of strong concern.

Instrumental recording of temperatures has been available for less than 200 years. Over the last 100 years, a temperature increase of 0.5 °C could be measured (Le Houérou 1996) with rather different regional patterns and trends (Folland et al. 1992). In (Ehrlich 2000), Bruce D. Smith is quoted as saying, *"The changes brought over the past 10,000 years as agricultural landscapes replaced wild plant and animal communities, while not so abrupt as those caused by the impact of an asteroid as the Cretaceous-Tertiary boundary some 65 Ma ago or so massive as those caused by advancing glacial ice in the Pleistocene, are nonetheless comparable to these other forces of global change."* At the Earth Summit in Rio de Janeiro in 1992, over 159 countries signed the United Nations Framework Convention on Climate Change (FCCC, also called "Climate Convention") in order to achieve "stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system" (United Nations (UN) 1992). In 2001, the Intergovernmental Panel on Climate Change (IPCC) (Intergovernmental Panel on Climate Change (IPCC) 2007) wrote, *"An increasing body of*

observations gives a collective picture of a warming world and other changes in the climate system… There is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities."

In its fourth assessment report of 2007, the IPCC stated that human actions are "very likely" the cause of global warming. More specifically, there is a 90 % probability that the burning of fossil fuels and other anthropogenic factors such as deforestation and the use of certain chemicals have already led to an increase of 0.75° in average global temperatures over the last 100 years and that the increase in hurricane and tropical cyclone strength since 1970 also results from man-made climate change.

In its fifth assessment report of 2013, the IPCC confirms their findings as *"Warming of the climate system is unequivocal, and since the 1950s, many of the observed changes are unprecedented over decades to millennia. The atmosphere and ocean have warmed, the amounts of snow and ice have diminished, sea level has risen, and the concentrations of greenhouse gases have increased"* (IPCC 2013).

Figures 1 and 2 show some details of IPCC's findings.

In Fig. 2, natural and man-made (anthropogenic) radiative forcings (RF) are depicted. RF, or climate forcing, expressed in W/m^2, is a change in energy flux, viz., the difference of incoming energy (sunlight) absorbed by Earth and outgoing energy (that radiated back into space). A positive forcing warms up the system, while negative forcing cools it down.

(Anthropogenic) CO_2 emissions, which have been accumulating in the atmosphere at an increasing rate since the Industrial Revolution, were identified as the main driver.

The position of the IPCC has been adopted by several renowned scientific societies, and a consensus has emerged on the causes and partially on the consequences of climate change. The history of climate change science is reviewed in (Miller et al. 2009). There are researchers who oppose the scientific mainstream's assessment of global warming (Linden 1993). However, the public seems to be unaware of the high degree of consensus that has been achieved in the scientific community, as elaborated in a 2009 World Bank report (Worldbank 2009). In (Antilla 2005), there is a treatment of the mass media's coverage of the climate change discussion with a focus on rhetoric that emphasizes uncertainty, controversy, and climate scepticism. Climate change skeptic films were found to have a strong influence on the general public's environmental concern (Greitemeyer 2013).

The Greenhouse Effect

A greenhouse, also called a glass house, is a structure enclosed by glass or plastic which allows the penetration of radiation to warm it. Gases capable of absorbing the radiant energy are called the greenhouse gases (GHG). Greenhouses are used to grow flowers, vegetables, fruits, and tobacco throughout the year in a warm, agreeable climate. On Earth, there is a phenomenon called the "natural greenhouse" effect, or the Milankovitch cycles.

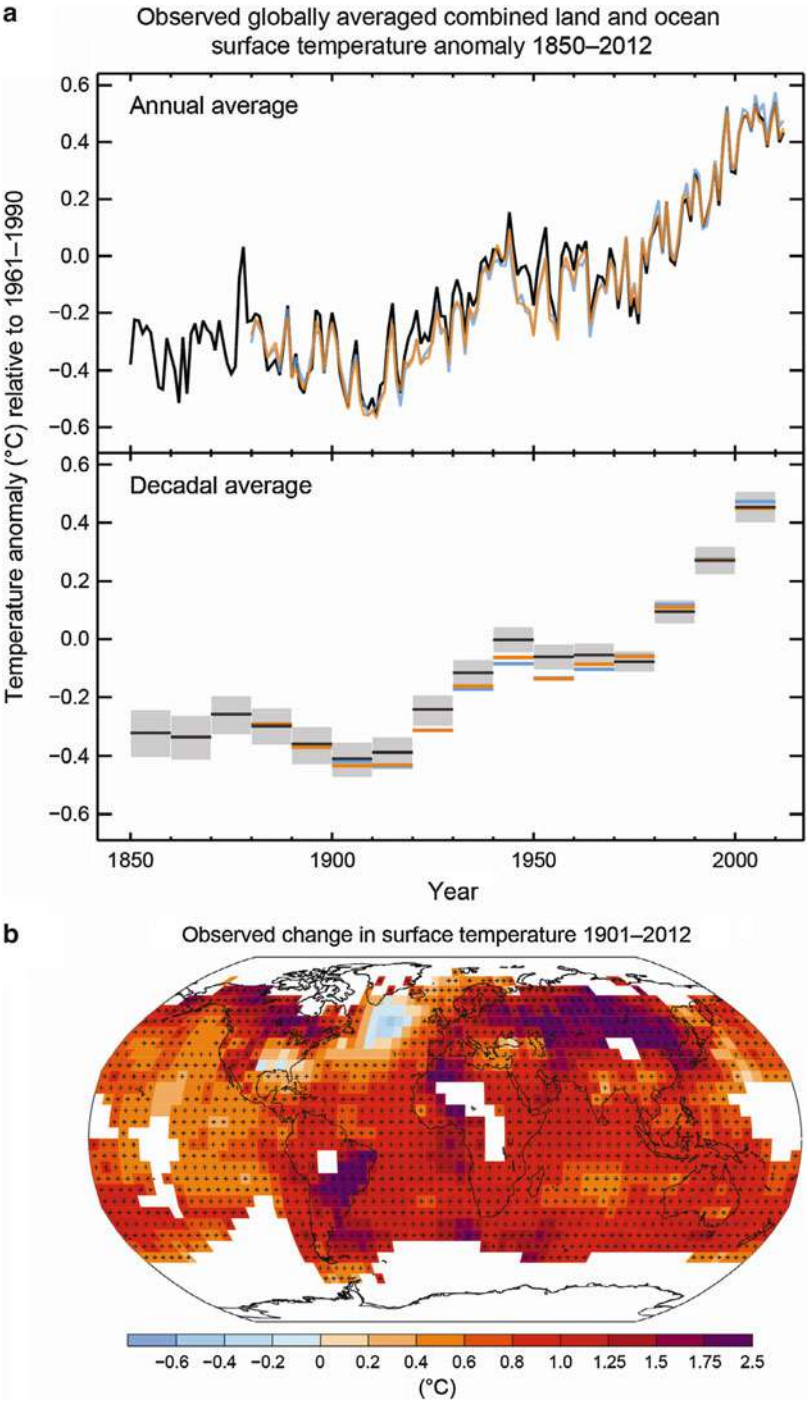

Fig. 1 (continued)

Without the greenhouse gas effect, which is chiefly based on water vapor in the atmosphere (Linden 2005) (i.e., clouds that trap infrared radiation), the average surface temperature on Earth would be 33 °C colder (Karl and Trenberth 2003). The natural greenhouse effect renders Earth habitable since the temperature which would be expected from the thermal equilibrium of the irradiation from the sun and radiative losses into space (radiation balance in the blackbody model) is approximately −18 °C.

On the moon, for instance, where there is hardly any atmosphere, extreme surface temperatures range from −233 °C to 133 °C (Winter 1967). On Venus, by contrast, the greenhouse effect in the dense CO_2− laden atmosphere results in an average surface temperature in excess of 450 °C (Sonnabend et al. 2008; Zasova et al. 2007).

The current discussion about global warming and climate change is centered on the anthropogenic greenhouse effect. This is caused by the emission and accumulation of greenhouse gases in the atmosphere. These gases (water vapor, CO_2, CH_4, N_2O, O_3, and others) act by absorbing and emitting infrared radiation. The combustion of fossil fuels (oil, coal, and natural gas) has led mainly to an increase in the CO_2 concentration in the atmosphere. Preindustrial levels of CO_2 (i.e., before the start of the Industrial Revolution) were approximately 280 ppm, whereas today, they are above 380 ppm with an annual increase of approximately 2 ppm. According to the IPCC Special Report on Emission Scenarios (SRES) (IPCC 2010a), by the end of the twenty-first century, the CO_2 concentration could reach levels between 490 and 1,260 ppm, which are between 75 % and 350 % above the preindustrial levels, respectively.

CO_2 is the most important anthropogenic greenhouse gas because of its comparatively high concentration in the atmosphere. The effect of other greenhouse-active gases depends on their molecular structure and their lifetime in the atmosphere, which can be expressed by their greenhouse warming potential (GWP). GWP is a relative measure of how much heat a greenhouse gas traps in the atmosphere. It compares the amount of heat trapped by a certain mass of the gas in question to the amount of heat trapped by a similar mass of CO_2. With a time horizon of 100 years, the GWP of CH_4, N_2O, and SF_6 with respect to CO_2 is 25, 298, and 22,800, respectively (IPCC 2010b). But CO_2 has a much higher concentration than other GHGs, and it is increasing at a higher rate due to burning of fossil fuels. Thus, while the major mitigating emphasis has mainly been placed on CO_2, efforts on mitigating CH_4, N_2O, and SF_6 have also been active.

Fig. 1 (**a**) Observed global mean combined land and ocean surface temperature anomalies, from 1850 to 2012 from three data sets. *Top panel*: annual mean values. *Bottom panel*: decadal mean values including the estimate of uncertainty for one dataset (*black*). Anomalies are relative to the mean of 1961–1990. (**b**) Map of the observed surface temperature change from 1901 to 2012 derived from temperature trends determined by linear regression from one dataset (*orange line* in panel a). Trends have been calculated where data availability permits a robust estimate (i.e., only for grid boxes with greater than 70 % complete records and more than 20 % data availability in the first and last 10 % of the time period). Other areas are white. Grid boxes where the trend is significant at the 10 % level are indicated by a + sign (Source: IPCC (IPCC 2013))

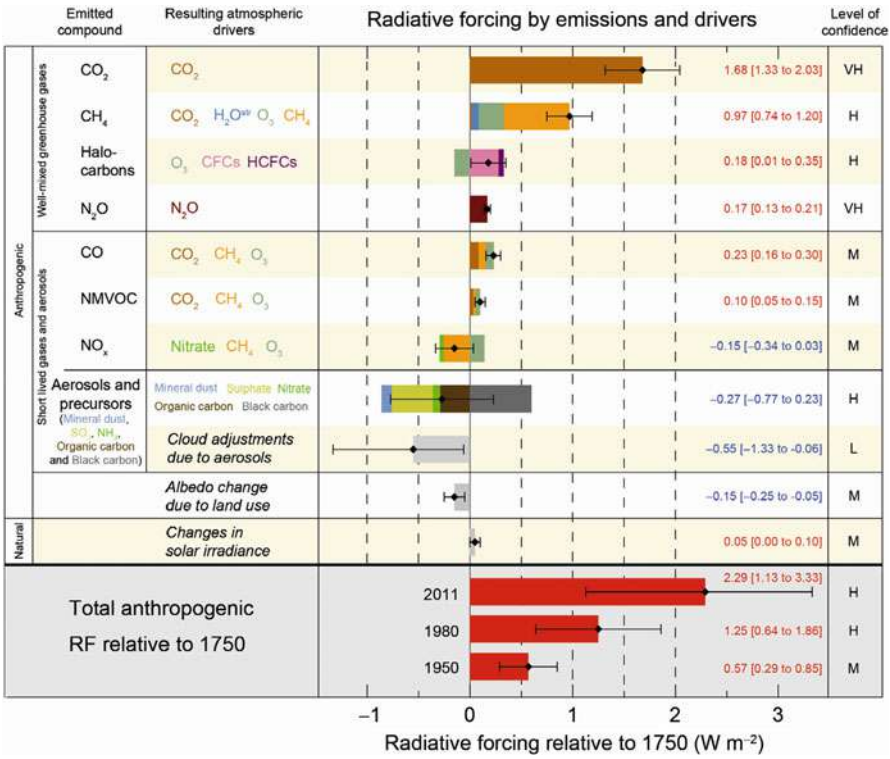

Fig. 2 Radiative forcing estimates in 2011 relative to 1750 and aggregated uncertainties for the main drivers of climate change. Values are global average radiative forcing (*RF*), partitioned according to the emitted compounds or processes that result in a combination of drivers. The best estimates of the net radiative forcing are shown as *black diamonds* with corresponding uncertainty intervals; the numerical values are provided on the *right* of the figure, together with the confidence level in the net forcing (*VH* very high, *H* high, *M* medium, *L* low, *VL* very low). Albedo forcing due to black carbon on snow and ice is included in the black carbon aerosol bar. Small forcings due to contrails (0.05 W m^{-2}, including contrail induced cirrus), and HFCs, PFCs and SF6 (total 0.03 W m^{-2}) are not shown. Concentration-based RFs for gases can be obtained by summing the like-coloured bars. Volcanic forcing is not included as its episodic nature makes is difficult to compare to other forcing mechanisms. Total anthropogenic radiative forcing is provided for three different years relative to 1750 (Source: IPCC (IPCC 2013))

Anthropogenic Climate Change

The climate is governed by natural influences, yet human activities have an impact on it as well. The main impact that humans exert on the climate is via the emission of greenhouse gases. Deforestation is another example of an activity that influences the climate (McMichael et al. 2007). Figure 3 shows the share of greenhouse gas emissions from various sectors taken from (Quadrelli and Peterson 2007). The energy sector is the dominant source of GHG emissions.

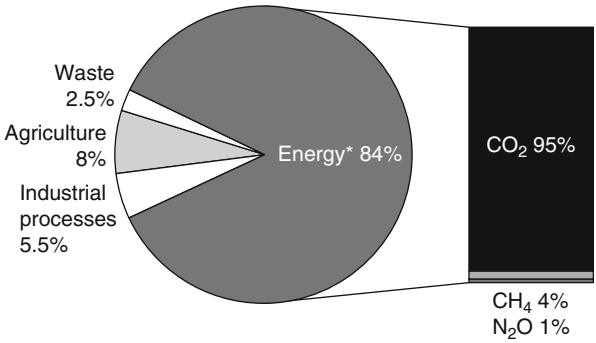

Fig. 3 Shares of global anthropogenic greenhouse gas emissions (Reprinted with permission from (Quadrelli and Peterson 2007))

According to the International Energy Agency (IEA), if no action toward climate change mitigation is taken, global warming could reach an increase of up to 6° in average temperature (International Energy Association IEA 2009). This temperature rise could cause devastating consequences on Earth, which will be discussed briefly below.

Effects of Climate Change

Paleoclimatological data show that 100–200 Ma ago, almost all carbon was in the atmosphere as CO_2, with global temperatures being 10 °C warmer and sea levels 50–100 m higher than today. Photosynthesis and CO_2 uptake into the oceans took almost 200 Ma. Since the Industrial Revolution, i.e., during the last 200 years, this carbon is being put back into the atmosphere to a significant extent. This is a rate which is 10^7 times faster, so there is a risk of a possible "runaway" reaction greenhouse effect.

Figure 4 shows the timescales of several different effects of climate change for the future.

Due to the long lifetime of CO_2 in the atmosphere, the effects of climate change until a new equilibrium has been reached will prove long term. A global temperature increase of 6 °C would be severe, so the IEA has developed a scenario which would limit the temperature increase to 2 °C (International Energy Association IEA 2009) to minimize the effects.

Sea level rise will indeed be the most direct impact. Other impacts including those on weather, flooding, biodiversity, water resources, and diseases are discussed here.

Climate Change: What Will Change?

An overall higher temperature on Earth, depending on the magnitude of the effect and the rate at which it manifests itself, will change the sea level, local climatic conditions, and the proliferation of animal and plant species, to name but a few of the most obvious examples. The debate on the actual consequences of global warming is the most heated part of the climate change discussion.

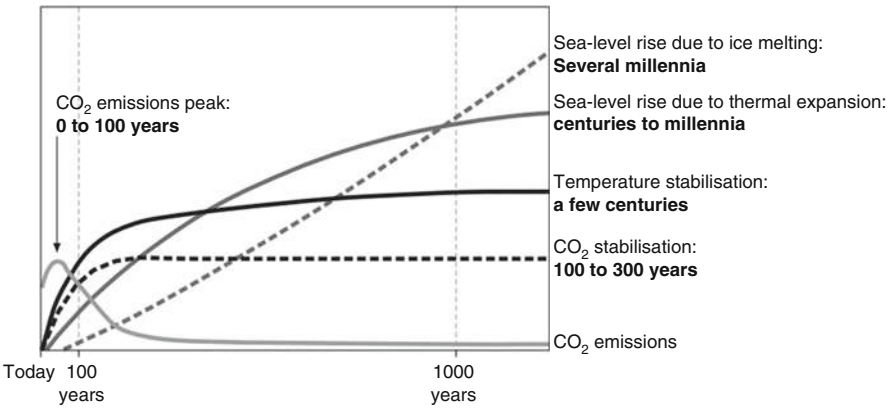

Fig. 4 Time scales of climate change effects based on a stabilization of CO_2 concentration levels between 450 and 1,000 ppm after today's emissions (Reprinted with permission from (Quadrelli and Peterson 2007))

Apart from changes in the environment, there will be various impacts on human activity. One example is the threats to tourism revenue in winter ski resorts (Hoffmann et al. 2009) and low-elevation tropical islands (Becken 2005). Insurance companies will need to devise completely new business models, to cite just one example of businesses being forced to react to climate change.

Impact of Climate Change Mitigation Actions

The purpose of climate change mitigation is to enact measures to limit the extent of climate change. Climate change mitigation can make a difference. In the IEA reference scenario (International Energy Association IEA 2009), the world is headed for a CO_2 concentration in the atmosphere above 1,000 ppm, whereas that level is limited to 450 ppm in the proposed "mitigation action" scenario. In the first case, the global temperature increase will be 6 °C, whereas it is limited to 2 °C in the latter (International Energy Association IEA 2009).

The Intergovernmental Panel on Climate Change has projected that the financial effect of compliance through trading within the Kyoto commitment period will be limited at between 0.1 % and 1.1 % of GDP. By comparison, the Stern report estimated that the cost of mitigating climate change would be 1 % of global GDP and the costs of doing nothing would be 5–20 times higher (IPCC 2010b; Stern 2007).

Climate Change Adaptation Versus Climate Change Mitigation

Individuals (Grothmann and Patt 2005), municipalities (Laukkonen et al. 2009; van Aalst et al. 2008), businesses (Hoffmann et al. 2009), and nations (Næss et al. 2005; Stringer et al. 2009) have started to adapt to the ongoing and expected state of

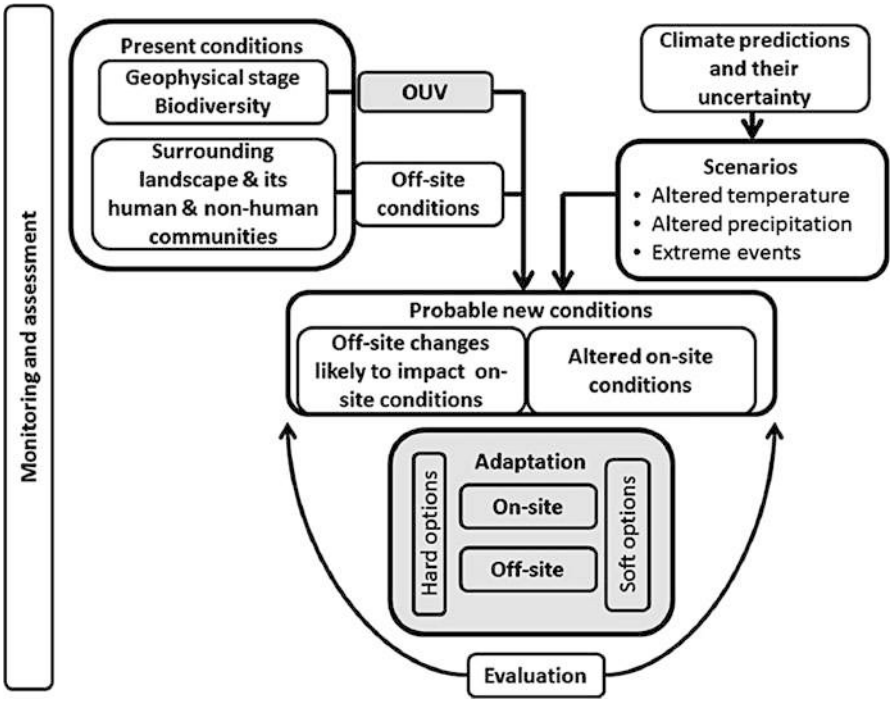

Fig. 5 Conceptual framework for developing a climate change adaptation strategy. *OUV* Outstanding Universal Values (each World Heritage (*WH*) site has one or more such OUV. According to UNESCO, WH represent society's highest conservation designation (Source: Jim Perry (2015))

climate change. Climate change adaptation and climate change mitigation face similar barriers (Hamin and Gurran 2009). To best deal with the situation, there needs to be a balanced approach between climate change mitigation and climate change adaptation (Becken 2005; Laukkonen et al. 2009; Hamin and Gurran 2009). This will prove to be one of mankind's largest modern challenges. Figure 5 shows a conceptual framework for developing a climate change adaptation strategy. Details are presented in this Handbook.

Handbook of Climate Change Mitigation and Adaption

Motivation

The struggle in mitigating climate change is not only to create a sustainable environment but also to build a sustainable economy through renewable energy resources. "Sustainability" has turned into a household phrase as people become increasingly aware of the severity and scope of future climate change. A survey of

the current literature on climate change suggests that there is an urgent need for a comprehensive handbook introducing the mitigation of climate change to a broad audience.

The burning of fossil fuels such as coal, oil, and gas and the clearing of forests has been identified as the major source of greenhouse gas emissions. Reducing the 24 billion metric tons of carbon dioxide emissions per year generated from stationary and mobile sources is an enormous task that involves both technological challenges and monumental financial and societal costs with benefits that will only surface decades later. The Stern Report (2007) provided a detailed analysis of the economic impacts of climate change and the ethical ground of policy responses for mitigation and adaptation.

The decline in the supply of high-quality crude oil has further increased the urgency to identify alternative energy resources and develop energy conversion technologies that are both environmentally sound and economically viable. Various routes for converting renewable energies have emerged – including energy conservation and energy-efficient technologies.

The energy industry currently lacks an infrastructure that can completely replace fossil fuels in the near future. At the same time, energy consumption in developing countries like China and India is rapidly increasing as a result of their economic growth. It is generally recognized that the burning of fossil fuels will continue until an infrastructure for sustainable energy is established. Therefore, there is now a high demand for reducing greenhouse gas emissions from fossil fuel–based power plants.

Adaptation is a pragmatic approach to deal with the facts of climate change so that life, property, and income of individuals can be protected.

The pursuit of sustainable energy resources has become a complex issue across the globe. The *Handbook on Climate Change Mitigation and Adaptation* is a valuable resource for a wide audience who would like to quickly and comprehensively learn the issues surrounding climate change mitigation.

Why This Book Is Needed

There is a mounting consensus that human behaviors are changing the global climate and that its consequence, if left unchecked, could be catastrophic. The fourth climate change report by the Intergovernmental Panel on Climate Change (IPCC 2007) has provided the most detailed assessment ever on climate change's causes, impacts, and solutions. A consortium of experts from 13 US government science agencies, universities, and research institutions released the report *Global Climate Change Impacts in the United States* (2009), which verifies that global warming is primarily human induced and climate changes are underway in the USA and are only expected to worsen.

From its causes and impacts to its solutions, the issues surrounding climate change involve multidisciplinary sciences and technologies. The complexity and scope of these issues warrants a single comprehensive survey of a broad array of topics, something which the *Handbook on Climate Change Mitigation and Adaptation* achieves by providing readers with all the necessary background information on

the mitigation of climate change. The handbook introduces the fundamental issues of climate change mitigation in independent chapters rather than directly giving the detailed advanced analysis presented by the IPCC and others. Therefore, the handbook will be an indispensable companion reference to the complex analysis presented in the IPCC reports. For instance, while the IPCC reports give large amounts of data concerning the impacts of different greenhouse gases, they contain little discussion about the science behind the analysis. Similarly, while the IPCC reports present large amounts of information concerning the impacts of different alternative energies, the reports rarely discuss the science behind the technology. There is currently not a single comprehensive source that enables the readers to learn the science and technology associated with climate change mitigation.

Audience of the Handbook

Since the handbook covers a wide range of topics, it will find broad use as a major reference book in environmental, industrial, and analytical chemistry. Scientists, engineers, and technical managers in the energy and environmental fields are expected to be the primary users. They are likely to have an undergraduate degree in science or engineering with an interest in understanding the science and technology used in addressing climate change and its mitigation.

Scope

This multivolume handbook offers a comprehensive collection of information on climate change and how to minimize its impact. The chapters in this handbook were written by internationally renowned experts from industry and academia. The purpose of this book is to provide the reader with an authoritative reference work toward the goal of understanding climate change, its effects, and the available mitigation *and adaptation* strategies with which it may be tackled:

- Scientific evidence of climate change and related societal issues
- The impact of climate change
- Energy conservation
- Alternative energy sources
- Advanced combustion techniques
- Advanced technologies
- Education and outreach

This handbook presents information on how climate change is intimately involved with two critical issues: available energy resources and environmental policy. Readers will learn that these issues may not be viewed in isolation but are mediated by global economics, politics, and media attention. The focus of these presentations will be current scientific technological development although societal impacts will not be neglected.

Loss and Damage Associated with Climate Change Impacts

Linta M. Mathew and Sonia Akter

Contents

Abstract

The impacts of climate change that are not mitigated, or appropriately adapted or coped with, are referred to as "loss and damage." The global community has recently recognized that addressing and financing the "residual" loss and damage from climate change requires a different approach as such costs cannot or have not been appropriately mitigated or adapted to. Although international pressures to weigh a country's contribution to climate change financing against their contribution to climate change has been proposed, no such legally binding climate change

DOI 10.1007/978-3-319-14409-2_55

deals have been fashioned. Most parties have only agreed to nonbinding actions to either reduce emissions or finance loss and damage in low-income, vulnerable countries. This is because the concept of loss and damage and the approaches to address the concept have been widely contested and debated. Additionally, the lack of a global consensus on an appropriate mechanism to attribute gradual and extreme natural calamities to climate change has further intensified the debate. Given this background, this chapter seeks to synthesize the key issues surrounding this debate. The objectives of this chapter are to review the definitions of loss and damage, examine the evolution of its significance in the international climate politics, present a comparative analysis of the approaches to address climate change-induced loss and damage, and outline empirical evidence of loss and damage in geographically and economically vulnerable nations.

Introduction

In its effort to combat climate change, the global community focused on rapid reduction of greenhouse gases (GHGs) by implementing enhanced mitigation efforts from the early 1990s to the mid-2000s. By the mid-2000s, scientific evidence indicated the likelihood of global temperature rising between 3 °C and 4 °C above the preindustrial level within this century (IPCC 2007a). This evidence suggested that mitigation efforts alone will not be sufficient to avoid climate change as some of the climate change impacts may already have started to take effect. Although steep cuts in global GHGs could stabilize atmospheric GHG concentrations at lower levels than under the status quo, they likely would be above the current levels, thus resulting in further rises in global temperatures. The projected impacts of a 3–4 °C temperature rise would lead to serious consequences for humans and ecosystems due to dangerous sea-level rise, unprecedented heat waves, severe drought, and major floods in many parts of the world (IPCC 2007a).

Once it became clear that mitigation efforts would be insufficient to avoid all climate change impacts, adaptation became a necessary complement to mitigation (Ott et al. 2008). Adaptation was defined by the Intergovernmental Panel for Climate Change (IPCC) (2007b) as "adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities." As of 2007, global adaptation cost estimates ranged from $4 billion to well over $100 billion a year (Parry et al. 2009). These estimates led to the establishment of the Green Climate Fund (GFC) in Durban, South Africa, in 2011 during the 16th session of the Conference of Parties (COP), with the objective of raising a minimum of $100 billion/year by 2020 to support sustainable and climate-resilient development (Institute for Policy Studies 2014; Green Climate Fund 2014). This came to be known as the "adaptation fund."

However, adaptation also appeared to have its limit. It became increasingly apparent that adaptation cannot successfully contain all the adversities invoked by climate change. Such remnants of the adverse effects of climate change came to be

known as "residual loss and damage." Widespread international understanding and agreement on the distinction between adaptation and loss and damage was deemed essential in recognizing that not all adversities of climate change can be successfully mitigated or adapted to. Such remnants of the ill effects of climate change impacts were forecasted to account for two-thirds of all potential impacts across all sectors over the longer term (Parry et al. 2009). This recognition highlighted the need to allocate adequate compensation and relief efforts, above and beyond the GCF, to help the victims of loss and damage in geographically and economically vulnerable countries.

The term loss and damage appeared in the United Nations Framework Convention on Climate Change (UNFCCC) negotiations in 2007 at COP 13, where the Bali Action Plan called for enhanced action on adaptation including the consideration of "disaster risk reduction strategies and means to address loss and damage associated with climate change impacts in vulnerable countries" (Roberts 2012). Loss and damage was recognized as a separate concept from adaptation in 2008, when the Alliance of Small Island States (AOSIS) proposed a Multi-Window Mechanism to address and finance the distinct concept of loss and damage due to climate change impacts. This was followed by the establishment of the UNFCCC Work Program on Loss and Damage in 2010 and the Warsaw International Mechanism on Loss and Damage in 2013. In addition, the Loss and Damage in Vulnerable Countries Initiative was formed in 2012, with the aim of understanding both the national context and the range of accessible implementation options for addressing loss and damage (Roberts 2012). However, no official lifetime commitment by developed countries to provide funds to the vulnerable communities has been undertaken as yet. Hence, the initiatives could be seen as weak attempts by the rich countries to admit liability for their contributions to climate change.

In this chapter, we synthesize the debates surrounding the classification of loss and damage and also uncover the issues around an appropriate compensation mechanism. The purpose of the chapter is to not add to the already substantive literature on loss and damage but to provide a review of the concept, historical treaties and conventions that finally led up to increased international focus on the issue, and the empirical heterogeneity in its estimate and impact across a multi-country sample. The remainder of this chapter is structured as follows: section "Definition of Loss and Damage" provides an in-depth examination of the definition and debates surrounding the concept of loss and damage. Section "History" accommodates a study of the international conventions and treaties on climate change and examines the gradual recognition of the need to address loss and damage in the international climate politics. This is followed by a discussion in section "Approaches to Address Loss and Damage" of the different approaches in addressing loss and damage such as monetary versus nonmonetary costs and insurance versus compensation. Finally, section "Empirical Evidence of Loss and Damage" provides empirical evidence of the global and international estimates of loss and damage as well as multi-country evidence of loss and damage experienced by some of the most geographically and economically vulnerable countries in the world.

Definition of Loss and Damage

A widely accepted definition of loss and damage does not exist. The framing of the definition and its conceptual discussion continue to evolve within the UNFCCC and the academic literature with different groups displaying heterogeneous understanding of the terminology and concept. The UNFCCC defined the concept as one of the "impacts associated with climate change in developing countries that negatively affects human and natural systems" (UNFCCC 2012).

However, the definition offered by the UNFCCC was found to be at its nascent stages and was therefore found to lack much clarity. This led to the formation of the Loss and Damage for Vulnerable Countries Initiative in 2012, headed by the Government of Bangladesh, to understand the meaning of the concept and how it can be approached in vulnerable countries (Roberts 2012). The UNFCCC and Warsaw International Mechanism for Loss and Damage act as guides to the initiative. Loss was defined by the Loss and Damage in Vulnerable Countries Initiative, as the "negative impacts that cannot be repaired or restored (such as loss of geological freshwater sources related to glacial melt or desertification)," whereas damage was defined as the "negative impacts that can be repaired or restored (such as windstorm damage to the roof of a building)." Therefore, the Loss and Damage in Vulnerable Countries Initiative views loss and damage as the avoidable and the unavoidable costs associated with climate change impacts.

The Loss and Damage in Vulnerable Countries Initiative definition also identified the need to include "the full range of climate change related impacts from (changes in) extreme events to slow onset process and combinations thereof." This definition included a continuum of climate change events and not only the extreme calamities resulting from climate change. The UNFCCC's Working Program on Loss and Damage called for a similar attempt to investigate a range of tools and approaches to address all forms of loss and damage resulting from climate change, ranging from slow onset to extreme weather conditions (UNFCCC 2012). However, the convention itself does not define loss and damage as the Work Program, which again indicates the lack of consistency and clarity of the concept.

Another working definition of loss and damage, compiled by Action Aid (2010), characterized loss and damage as consequences of the adverse effects of climate change that cannot be (or have not been) adapted to. This gave rise to the ideology of "residual" loss, i.e., unavoidable and unavoided loss and damage and recognized that certain aspects of climate change cannot be appropriately adapted to, given the limited resources available by many of the vulnerable nations affected by climate change. Action Aid (2010) summarized different categories of loss and damage, of which unavoided and unavoidable loss and damage were regarded as residual loss and damage (Table 1).

Unavoided costs can also be classified as the "avoidable costs of loss and damage," i.e., the costs of climate change impacts that can be avoided through appropriate mitigation and/or adaptation. However, such costs are not always avoided due to limited capacity or resource. It is very important to regionally and internationally allocate appropriate resources, such that the resulting loss and

Table 1 Avoided, unavoided, and unavoidable damage

Avoided damage	Unavoided damage	Unavoidable damage
Avoidable damage avoided	Avoidable damage and loss not avoided	Unavoidable damage and loss
Damage prevented through mitigation and/or adaptation measures	Where the avoidance of further damage was possible through adequate mitigation and/or adaptation, but where adaptation measures were not implemented due to financial or technical constraints	Damage that could not be avoided through mitigation and/or adaptation measures, e.g., coral bleaching, sea-level rise, damage due to extreme events where no adaptation efforts would have helped prevent physical damage

Source: Action Aid (2010)

damage can be reduced or mitigated completely. In least developed countries (LDCs), this often implies that such resulting loss and damage will only be adapted to if national benefits from adaptation exceed national losses and damages. Therefore, the loss and damage resulting from slow onset events and its victims events are often ignored[1]. This remains to be one of the major, but often sidelined, issues in the international climate change debate. Additionally, even in the case of unavoidable loss and damage, appropriate financing/funding still remains to be a problem. This is due to the "attribution problem" in climate change science, which can be briefly described as the inability to completely underpin the loss and damage due to weather-related events to climate change[2].

A technical representation of residual (unavoidable and unavoided) loss and damage was compiled by Rothman et al. (2003). This is represented in Fig. 1, where residual unavoidable and unavoided impacts of climate change with adaptation are demonstrated by the dotted line.

Unavoidable and unavoided residual loss and damage reflects ill effects that have not been mitigated and which cannot/have not been adapted to. One must also note that for stakeholders to undertake adaptation measure, the benefits from adaptation ("effect of adaptation") must be greater than adaptation costs. Although the diagram above seems straightforward enough, the effects of adaptation and the impact of climate change (its cost) are quite hard to calculate and reproduce in such a simple two-dimensional linear frame. Another schematic representation of the residual damage as compiled by Parry et al. (2009) is presented in Fig. 2.

Figure 2a represents the short-term nonlinearity of climate change impacts. Lower adaptation costs are associated with higher avoided damage, therefore giving it a low incremental adaptation cost to avoided damage ratio. This curve is estimated to fluctuate greatly across sectors and gives one a clearer picture of the variability and nonlinearity of such a concept. Figure 2b represents a longer time period of adaptation to damage, which illustrates that over the longer term, all damages will

[1]For more information on this, refer to section "Empirical Evidence of Loss and Damage."

[2]This "attribution problem" and the resulting financing issue will be examined in greater detail in section "Approaches to Address Loss and Damage."

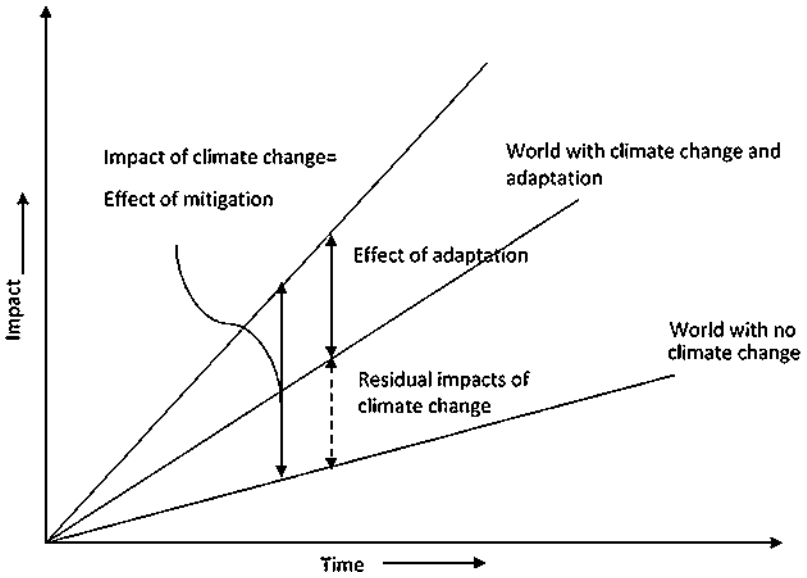

Fig. 1 Traditional representation of climate impacts and adaptation (Source: Rothman et al. (2003))

not be adapted to, due to its lack of economic viability or structural feasibility (Parry et al. 2009). The above representation also considers the trend in damage due to asset growth, therefore normalizing asset damage, such that the increase in damage is not associated with an asset growth.

The impact of loss and damage should be narrowed down to the ones that can be attributed to climate change. This can be accomplished by attempting to distinguish between bad weather and natural calamities that can be attributed to climate change. However, the lack of traceability of such events to climate change has induced reluctances by many stakeholders to officially commit to any binding financial agreements. This is commonly referred to as the "attribution problem" in climate science. Various methods of calculating the odds of relating extreme natural calamities to climate change have been devised to aid the allocation of climate change-related funds (Hulme et al. 2011). One such event attribution, termed as the probabilistic event attribution, compiled by Stone and Allen (2005), seeks to differentiate between weather changes caused as a result of human interference and "bad luck" (Hulme et al. 2011).

History

This section presents a history of evolution of the concept of loss and damage including the formation of the Loss and Damage in Vulnerable Countries Initiative and the Warsaw International Mechanism for Loss and Damage.

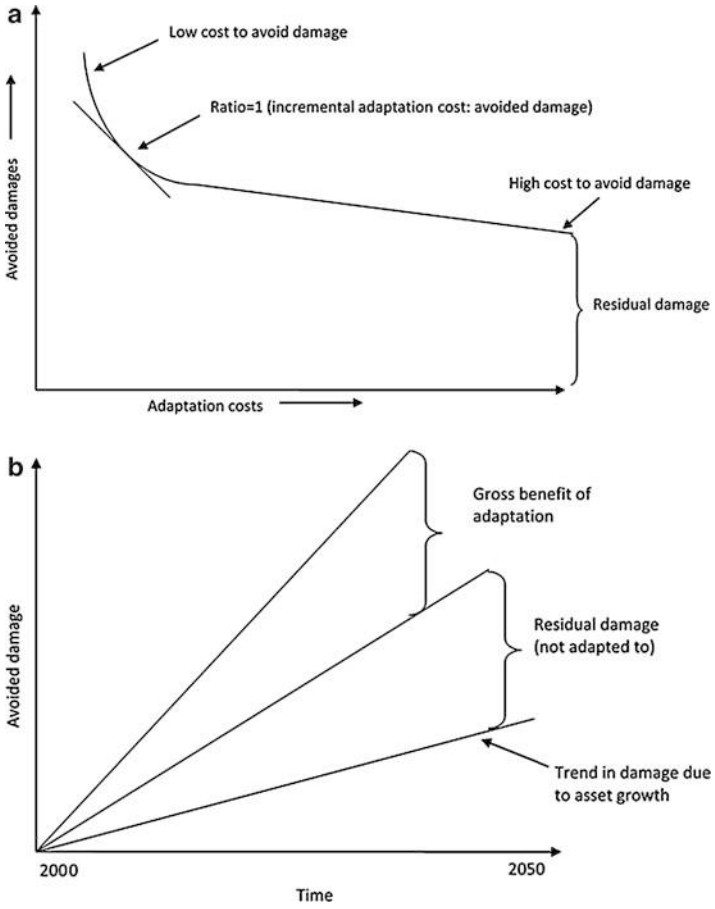

Fig. 2 Avoided damages and residual costs over the short term and long term (Source: Parry et al. (2009))

Conventions and Treaties

Various conventions and treaties were established over the years starting from 1979, which led up to the formation of the IPCC in 1988, followed by the creation of the UNFCCC in 1992. The role of the IPCC is to "assess on a comprehensive, objective, open and transparent basis the scientific, technical and socio-economic information relevant to understanding the scientific basis of risk of human-induced climate change, its potential impacts and options for adaptation and migration" (IPCC 2007b). The scientific evidence on climate change, gathered by the IPCC, underlined the severity of the issue and played a major role in the creation of the UNFCCC (IPCC 1995). The UNFCCC was formed to work to limit average global temperature increases and the resulting climate change and to cope with the unavoidable loss and

damage (UNFCCC 2014e). A summary of the major climate change conventions and treaties, post the initiation of the UNFCCC, is presented in Table 2.

Loss and Damage in Vulnerable Countries Initiative

The Loss and Damage in Vulnerable Countries Initiative was commenced by the Government of Bangladesh and expanded with the help of the Climate and Development Knowledge Network (CDKN), which appointed a consortium of specialists including Germanwatch, United Nations University – Institute for Environmental and Human security (UNU – EHS), International Centre for Climate Change and Development (ICCAD), and Munich Climate Insurance Initiative (MCII) and was implemented from 2012 (Loss and Damage in Vulnerable Countries Initiative 2014).

The Loss and Damage in Vulnerable Countries Initiatives are to:

Understand the scope and significance of loss and damage associated with the adverse impacts of climate change;
Developing and cocreating an approach and vision for loss and damage among decision makers and relevant stakeholders;
Assisting least developed countries and other vulnerable countries to develop a coherent approach to the loss and damage debate;
Identifying and beginning to take necessary steps to support a paradigm shift on loss and damage in the coming years;

Source: Loss and Damage in Vulnerable Countries Initiative (2014)

The activities of the UNFCCC and Warsaw International Mechanism for Loss and Damage guide the initiative. The initiative follows four main activity areas to support less developed nations in their plight to reduce and mitigate loss and damage due to climate change impact and to "create momentum in the climate change debate" (Loss and Damage in Vulnerable Countries Initiative 2014). These activities include supporting and strengthening the position of LDCs in loss and damage negotiations in the UNFCCC Work Program on loss and damage, conceptually framing loss and damage and providing policy assistance, providing country-specific insights on the adverse effects of loss and damage, and imparting the cumulative results of mitigation and adaptation efforts in Bangladesh as an analytical tool for other vulnerable countries.

Warsaw International Mechanism for Loss and Damage

The Warsaw International Mechanism for Loss and Damage was established to address the loss and damage due to climate change, including "extreme and slow onset events" in economically and geographically vulnerable countries (UNFCCC 2013). Two-year work plans were drawn up for the initiative during the resumed initial meeting in September 2014, which involved understanding the concept of loss and damage of extreme and slow onset events, risk management, comprehending the

Table 2 Precedent conventions and treaties

Year	Key event(s)	Description
1992	**AOSIS proposal for an insurance scheme**	Proposal for an insurance scheme was put forward by the members of the Alliance of Small Island States (AOSIS), the principle objective of which was to create an International Climate Fund and an International Insurance Pool to finance measures and to provide appropriate financial insurance respectively to counter the adverse effects of climate change.
		However, the parties only agreed to the insurance pool 10 years onward, provided that over the 10-year period, the "rate of global mean sea-level rise will have reached an agreed figure" (Hayes and Smith 1993).
1995	**The first Conference of Parties (COP 1): Berlin Mandate**	The COP1 held in Germany, where the Berlin mandate established the need for developed countries to "take the lead in combating climate change" and for developing countries to achieve sustainable economic growth (UNFCCC 1995).
1997	**COP 3**: **Kyoto Protocol Adoption**	Adoption of the Kyoto Protocol is undertaken in Kyoto, Japan, setting legally binding emission reduction targets.
		The summit recognized the greater role of developed countries in having historically contributed significantly to greenhouse emissions (through their previously active roles in industrial activity), and therefore placed a'heavier burden'(UNFCCC 2014) on developed nations under the notion of'common but differentiated responsibilities'(UNFCCC 1998).
2001	**COP 7**: **Marrakesh Accords**	Formation of the Marrakesh Accords, which laid out the rules and details for the implementation of the Kyoto Protocol, set up adaptation methodologies, and formed a technology transfer framework (UNFCCC 2014a).
2005	**Meeting of the Parties to the Kyoto Protocol** (**MOP 1**)	The Kyoto Protocol entered into force as the Russian Federation submitted its compliance (United Nations 2014).
		Negotiations for the next phase of the protocol under the Ad Hoc Working Group on Further Commitments for Annex Parties under the Kyoto Protocol (AWG-KP), later known as the "Nairobi Work Program," were also agreed upon.

(*continued*)

Table 2 (continued)

Year	Key event(s)	Description
2007	**COP 13**: **Bali Road Map**	Introduction of the Bali Road Map in Bali, Indonesia, which included the "Bali Action Plan." This plan was envisioned to charter the way toward a post-2012 outcome (UNFCCC 2014e).
		The Bali Action Plan is divided into categories such as shared vision, mitigation, adaptation, technology, and financing.
		However, it is to be noted that no significant effort was made to differentiate between adaptation and loss and damage in this stage.
2008	**COP 14**: **Joint Implementation Mechanism for the Kyoto Protocol**	A joint Implementation Mechanism for the Kyoto Protocol was initiated.
		This was described by UNFCCC (2014d) as an initiative that "allows a country with an emission reduction or limitation commitment under the Protocol to earn emission reduction units from an emission reduction or emission removal project in another country with similar commitments".
	AOSIS proposal of a Multi-Window Mechanism	The Alliance of Small Island States (AOSIS) proposed a Multi-Window Mechanism to address and finance loss and damage from climate change impacts (Alliance of Small Island States 2008).
2009	**COP 15**: **Copenhagen Accord**	The Copenhagen Accord was developed at COP15 in Copenhagen, Denmark, where developed countries undertook emission reduction and mitigation and adaptation action plan for the period of 2010–2012, pledging $30 billion as start-up finance (UNFCCC 2014e; United Nations 2014).
2010	**COP 16**: **Cancun Adaptation Framework**	The Cancun Adaptation Framework was formed at COP16, where governments of developed countries pledged comprehensive packages to assist developing countries to deal with climate change (UNFCCC 2014e).
		The agreements also made the reduction pledges of the countries official, which formed the "largest collective effort to reduce emission in a manually accountable way" (United Nations 2014).
	UNFCCC Work program to address loss and damage	The Cancun Adaptation Framework also established a work program to address the loss and damage impacts of climate change in LDCs vulnerable to the adverse effects of climate change (Roberts 2012).

(*continued*)

Table 2 (continued)

Year	Key event(s)	Description
2011	**COP 17: Durban Platform for Enhanced Action**	Plans to draw up a new universal climate change agreement by 2015, to deal with the adverse effects of climate change beyond 2020, were formed in Durban, South Africa. This led to the formation of the Durban Platform for Enhanced Action or the Ad Hoc Working Group on the Durban Platform for Enhanced Action (ADP) (UNFCCC 2014e).
	Green Climate Fund	COP 17 also led to the formation of the Green Climate Fund (GCF), with an aim of raising $100 billion per year in climate financing by 2020 (Institute for Policy Studies 2014).
2012	**COP 18: Doha Amendments to the Kyoto Protocol**	The Doha Amendments to the Kyoto Protocol commenced.
		This includes new commitments for a second commitment period from January 2010 until December 2020, a revised list of greenhouse gases to be reported by the Parties, and amendments to several articles of the Kyoto Protocol to issues pertaining to the first commitment period (UNFCCC 2014b).
		Governments also agreed to work speedily toward drafting a universal climate change agreement by 2015 (UNFCCC 2014b).
		The Doha Convention further addressed international efforts and strengthened international cooperation on loss and damage as a result of climate change (European Commission 2013).
	Loss and Damage Initiative in Vulnerable Countries Initiative	Loss and Damage Initiative was implemented in February 2012, with the objective of partnering with vulnerable LDCs and other parties to better understand loss and damage (Roberts 2012).
2013	**COP 19: Warsaw Outcomes**	The Decision to progress on the ADP Platform was agreed upon.
		A rulebook for reducing emissions from deforestation and forest degradation, enhancing the conservation and sustainable management of forests and forest carbon stocks in developing countries (REDD+), establishing a mechanism to address loss and damage from long-term climate change impact, and agreeing on capitalizing the GCF in the second half of 2014, as part of the Warsaw Outcome was undertaken (UNFCCC 2014g).

current coping and adaptation mechanisms, and drawing up socioeconomically appropriate policies to adapt to monetary and nonmonetary residual losses as a result of climate change (UNFCCC 2014f). The introduction of the mechanism was seen as a "notable step forward" as it allowed to address and implement socioeconomically appropriate policies to deal with the adversities of climate change in vulnerable communities (Warner 2013).

The primary roles of the Warsaw International Mechanism are to:

Facilitate support of actions to address loss and damage;
Improve coordination of the relevant work of existing bodies under the Convention;
Convene meetings of relevant experts and stakeholders;
Promote the development of, and compile, analyze, synthesize, and review information;
Provide technical guidance and support;
Make recommendations, as appropriate, on how to enhance engagement, actions, and coherence under and outside the Convention, including on how to mobilize resources and expertise at different levels.

Approaches to Address Loss and Damage

This section summarizes the different approaches and their challenges for assessing and addressing loss and damage. Monetary and nonmonetary nature of loss and damage is discussed first followed by a range of economic instruments that can be used to address these costs. Finally, the attribution problem which lies at the center of the loss and damage debate is discussed in detail.

Monetary Versus Nonmonetary Costs

Climate change invokes both monetary and nonmonetary loss and damage in vulnerable countries. These categories are also known as economic and noneconomic loss and damage. Monetary or economic loss and damage refer to the costs for which economic or monetary estimates are readily available, such as structural damage and crop failure due to flooding[3]. Nonmonetary losses are those that cannot be measured in monetary or economic terms, such as loss of biodiversity, loss of livelihoods, or number of deaths caused by flooding. As these goods are not traded in the market, the monetary estimates of loss and damage caused to these goods are not readily available, and hence, these items are generally ignored by the loss and damage accounting (Morrissey and Smith 2013). The concept of nonmonetary

[3]A wide range of the estimates of the monetary costs from climate change have been estimated in previous studies, the details of which have been covered in section "Global Estimate of Loss and Damage."

costs was also highlighted in COP16 in Copenhagen where the parties recognized that all social and environmental loss and damage cannot be adequately captured by monetary measures. However, as such costs are difficult to quantify and monetize, it can be quite problematic to analyze the costs for inaction for such costs.

Nonmarket valuation techniques are often used to assign monetary values to the goods and services that are not traded in the market. Many studies, such as "valuing the ocean" study by the Stockholm Environment Institute (SEI), instead of employing market values to decipher loss and damage, monetized the costs of climate change to the ocean by focusing on five areas, namely, fisheries, sea-level rise, storms, tourism, and the ocean carbon sink (Stockholm Environmental Institute 2012). They pinned monetary values on such components by employing two scenarios: low climate change impact scenario, where emissions are reduced quickly, and a high climate change impact scenario, where the global emissions continue to rise for the next few decades (Stockholm Environmental Institute 2012). However, the results of the study were criticized as it only considers variables that can be "realistically altered by humans and can be monetized" (The Guardian 2012). Thus, the study only took into account the avoidable costs of loss and damage from climate change. Therefore, even though some studies have tried to monetize the marketed and nonmarketed goods affected by climate change, not all nonmarketed costs were effectively captured.

Insurance Versus Compensation

The concrete proposal put forth by the AOSIS in 2008 highlighting the need to finance a "Multi-Window Mechanism to Address Loss and Damage from Climate Change Impacts" placed the issue of financing loss and damage under the limelight. The proposed mechanism suggested three interdependent components for compensation: (1) insurance, (2) rehabilitation/compensation, and (3) risk management (AOSIS 2008). The insurance component was proposed to manage financial risk from extreme weather events and to provide insurance to countries who cannot find access to insurance. The rehabilitation/compensatory component addressed the progressive unavoidable climate change impacts, such as sea-level rise and ocean acidification. Finally, the risk management component was incorporated for risk assessment and management and to inform the insurance and the rehabilitation/compensatory component (AOSIS 2008).

The insurance option is one where regular payment by an individual to a private or public insurance entity subsists, such that the entity insures against any loss and damage that may be accidentally incurred by the individual. Munich Climate Insurance Initiative (MCII) (2012) stated that "insurance options can support adaptation and risk resilience for extreme weather, but are not appropriate for many, usually slower-onset, climate-induced impacts." Therefore, insurance was suggested to be an appropriate adaptation measure against unpredictable extreme events and not for predictable, slow onset events (Warner et al. 2012). This is because insurance companies will only be prepared to provide insurance payouts if the loss and damage

is entirely uncontrolled for and unforeseen. Insurance was suggested to be an adaptation, as opposed to a coping measure, as it reduces the impact of loss and damage and helps a timely recovery in the aftermath of extreme unforeseen calamities (Warner et al. 2012).

Insurance policies were found to be an unpopular method of financing loss and damage among the poorer households in geographically and economically vulnerable countries (Gine et al. 2008; Akter 2012). This was attributed to the lack of knowledge and affordability of insurance premiums in such countries. In some cases, coupling microcredit with insurance schemes was seen as a viable option to extend insurance services to low-income households. For instance, in a study conducted by OECD (2005), the Grameen Bima insurance programs in Bangladesh were found to offer insurance with microcredit, where no premiums were required to be a member of the fund, but payments to the fund were bundled with the interest paid on loans. However, the program was seen to be taken up by the middle class, as opposed to the low-income households, as the poor could not afford the premium (OECD 2005).

Compensation schemes in the context of loss and damage financing are funds provided by states or institutions to reduce the impact of loss and damage. The compensation option is perceived to be more appropriate than insurance schemes in funding the loss and damage from the gradual and predictable impacts of climate change. Therefore, the loss and damage from gradually occurring predictable events such as rising sea levels and desertification are best funded by states or institutions. However, individuals not insured against unpredictable extreme calamities should be considered for compensation schemes. This includes individuals in the poorer counterpart of the society, who are not able to afford the insurance premiums. Additionally, the lack of sufficient resources in low-income vulnerable countries does not enable appropriate compensation for all. The effectiveness in reducing the impact of loss and damage of such compensation packages depends on the efficiency of state policies and their outreach approach.

Attribution

Attributing weather-related range of slow set to extreme calamities to climate change was found to be quite difficult and operates as one of the major limitations in climate change financing. The lack of good traceability measures also provides a good justification for many developed countries to reject liability and therefore fail to make any firm commitments to financing loss and damage in low-income countries. Hence, the following paragraphs examine the effectiveness and limitations of such attribution mechanisms and their potential role in aiding the global community with financing loss and damage from negative climate change impacts.

The most popular method in climate change attribution is the examination of another related variable, which is linked to the characteristics of the extreme natural event. This is done as it is difficult to gain insights from examining trends of extremely rare natural calamities (Huggel et al. 2013). However, such studies have

confirmed the link between some natural calamities and climate change, but not all. Increasingly, studies have identified that the increase in economic damages from extreme events has been attributed to increased "exposed asset values" rather than an increased intensity of extreme natural calamities (Huggel et al. 2013). To this end, Neumayer and Barthel (2011) calculated an actual-to-potential-loss ratio (APLR), which provided a normalization method to measure the economic loss after the onset of a severe natural disaster. Even though no upward trend in normalized loss and damage was found, the authors did not account for mitigation measures, which may have compromised the findings. Additionally, even if the increased loss and damage is accounted to increased asset value, this does not imply that the resulting loss and damage must not be compensated for. Such a finding, if anything, calls for increased insurance or compensation schemes to be implemented by regional and international bodies.

However, many limitations in relying on such attribution methods to allocate any loss and damage funds were found such as the unreliability of such methodologies as they are based on climate estimates without climate change, which cannot be logically verified; the inability to accurately predict the percentage of overall risk attributable to human actions; and the undesirable shift in international climate change initiative from adaptation to compensation, if such methodologies are extensively used to allocate the international adaptation finance (Hulme et al. 2011). The lack of good quality data may also affect the accuracy of such measures. However, even though many such objections to attribution measures exist, formulating attribution mechanisms should be encouraged by the international community as it helps to reduce (to some extent) the moral hazard related to adverse events, where individuals will take greater risks (for instance, building houses in flood-prone areas) in the hope of being compensated. However, care must be taken in order to not get carried away by such measures. Successfully implemented techniques can help eradicate such uncertainty, which can aid the international community to identify the victims of climate change and to allocate funds to communities who are essentially negatively affected from climate change.

The global community should allocate sufficient funds such that until a clear measure of attribution is found, the civilians experiencing loss and damage, especially in geographically and economically vulnerable countries, as a result of climate change impacts, do not suffer substantially. This was highlighted by the Philippines Senate Present Juan Ponce Enrile who stated that "developing countries like the Philippines should be receiving compensation… Instead, however, we are accepting, or worse, being "forced" to avail of loans that are, in the long run, more disadvantageous for the country" (Climate Justice Now 2010).

Empirical Evidence of Loss and Damage

This section presents monetary estimates of loss and damage due to climate change impacts both at the global and local level. The first subsection summarizes the global estimates of loss and damage available in the literature. The second subsection

presents country-specific local estimates of loss and damage from eleven most economically and geographically vulnerable countries in the world. It also outlines the existing loss and damage-coping strategies used by the households in these countries.

Global Estimate of Loss and Damage

Various global estimates of loss and damage have been produced over the years. Global monetary estimates of loss and damage can be measured in terms of the social costs of carbon, which is defined as the "net economic costs of damages from climate change aggregated across the globe and discounted to the present" (IPCC 2007). IPCC's *Fourth Assessment Report* (AR4) disclosed that the peer-reviewed estimate of the social cost of carbon in 2005 has an average value of US$12/t of carbon dioxide. However, the range from 100 estimates was found to be large ($3–$95/t of carbon dioxide), which demonstrates a substantial degree of disagreement on its measurement (IPCC 2007). Natural disasters are estimated to have doubled from an average of 200/year in 1998 to an average of 400/year in 2008, whereas costs of natural disasters in monetary terms have increased sevenfold (United Nations 2009; cited in Action Aid 2010). Therefore, future estimates of climate change have painted a dull portrait of an impending catastrophe.

Monetary values of loss and damage can also be calculated from the overall loss and damage caused by climate change after accounting for certain scenarios of mitigation and adaptation (Action Aid 2010). One such probabilistic estimation method, known as the Policy Analysis for the Greenhouse Effect (PAGE), calculates the regional and global impacts of climate change, social costs of greenhouse gases, and also the cost of abatement and adaptation (UNFCCC 2014d). This model helps one to calculate the economic loss from such climate change adversities. Action Aid (2010) put together a table for global loss and damage under a scenario of no mitigation and the lowest emission scenario proposed by UNFCCC. Adaptation costs were also derived from UNFCCC reports. The costs are accrued over the years 2000–2200 and presented in discounted net present values (NPV).

From the analysis presented in Table 3, it was inferred that with respect to the cost of impact, the optimal action is to combine mitigation and adaptation. However, even with successful mitigation, a residual loss of US$275 trillion was found. However, this method of calculation was found to be more appropriate to predict global, as opposed to regional, loss and damage. Regional calculations of loss and damage are mostly obtainable from local insurance estimates. However, such estimates in low-income developing countries may only adumbrate monetary loss and damage to important sectors such as energy and infrastructure and neglect or overlook the loss and damage to most households. In such circumstances, national statistics are ones' best gamble in obtaining regional loss and damage statistics.

Although the calculation of residual loss and damage has been highly debated, as demonstrated by the noteworthy range of the formulated estimates, a common underlying theme of globally increasing loss and damage was found. Additionally, the calculations of monetary loss and damage also suggested that if appropriate

Table 3 Monetary estimates under "no mitigation" and "mitigation and lowest emission" scenarios

	Trillion US$					
	No mitigation			Lowest emission scenario		
	Lower end	Mean	Higher end	Lower end	Mean	Higher end
Cost of impact (without adaptation)	270	1,240	3,290	100	410	1,070
Cost of impacts (with adaptation)	170	890	2,340	60	275	760
Adaptation costs	4	6	9	4	6	9
Mitigation costs				50	110	170

Source: Action Aid (2010)

measures are not taken to constantly curb global emissions, loss and damage, particularly to low-income vulnerable countries, would only increase exponentially over time. Therefore, communities with a higher exposure to the risks of climate change and with lower adaptive capacity would experience a greater burden of loss and damage in comparison to others. Such vulnerable countries include the Alliance of Small Island States (AOSIS), threatened by the rise in sea level, and low-income developing countries, where a large proportion of the population relies on agricultural income, particularly susceptible to climatic fluctuations. Although developed rich nations may experience greater monetary losses from extreme events due to a higher proportion of exposed assets, the loss and damage as a percentage of GDP is peripheral in comparison to the low-income vulnerable nations. This is demonstrated in the figure below which compares the monetary damage to the monetary damage as a *percentage of GDP* in both developing and developed countries.

Figure 3 shows the damages as a percentage of GDP are higher for low-income developing countries than for the developed rich nations. On average, the agricultural sector contributes substantially to a poor developing nations' GDP, which is particularly vulnerable to the weather changes that have resulted from climate change. Additionally, poorly built infrastructure and households in low-income developing countries are often unable to withstand extreme weather disruptions, causing greater damage as a proportion of GDP in such countries.

Country-Specific Evidence of Loss and Damage

Country-level evidence of loss and damage occurring due to climate change impacts in vulnerable countries is crucial in assessing the future risks of climate change in such countries. Table 4 summarizes the environmental and economic vulnerability facing eleven low-income countries due to climate change impacts. The specific nature of the vulnerability, monetary estimate of loss, and damage resulting from unavoidable climate change impacts and coping strategies are summarized in the following paragraphs.

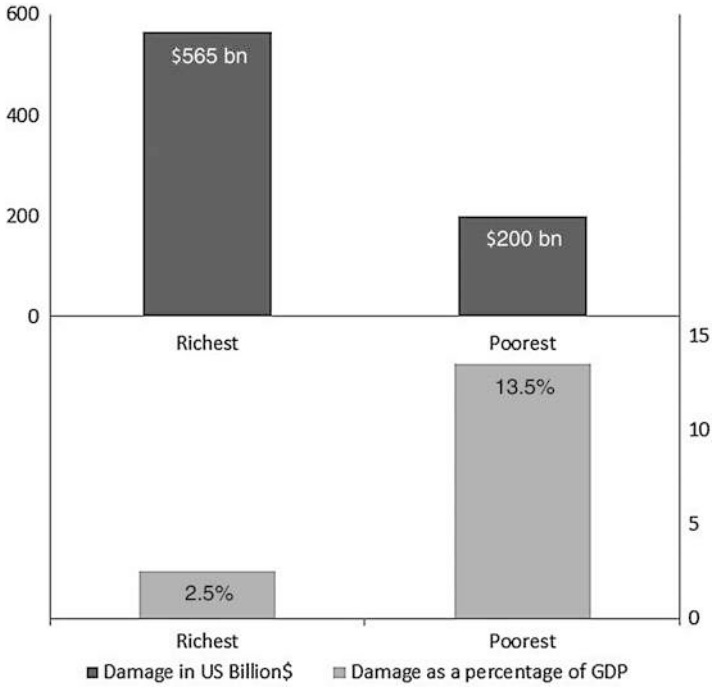

Fig. 3 Disaster losses, total and as a share of GDP, in the richest and poorest nations, 1985–1999 (Source: United Nations Inter-Agency Secretariat for the International Strategy for Disaster Risk Reduction (2003))

Bangladesh

In the case of Bangladesh, it was found that climatic susceptibility along with increased climate change has adverse consequences, especially in the coastal region. Frequent cyclones, such as Sidr in 2007 and Aila in 2009, caused massive loss and damage to the coastal population. Cyclone Sidr claimed 4,234 lives, injured 55,282 people, and damaged 8.9 million people's livelihood (Ministry of Disaster Management and Relief 2014). The economic damage caused by Cyclone Sidr was equivalent to US$1.67 billion (Ministry of Disaster Management and Relief 2014). Eleven out of the 19 coastal districts were severely affected by Cyclone Aila. It claimed 190 lives, injured 7,000 people, killed 100,000 livestock, and caused US$170 million worth of economic damage (United Nations Development Fund 2010 cited in Akter and Mallick 2013). The loss and damage experienced by a cyclone as powerful as Cyclone Sidr are expected to rise nearly fivefold to over $9 billion by 2050, accounting for 0.6 % of GDP (World Bank 2010).

These cyclones forced saline water into the agricultural lands (Rabbani et al. 2013). The rise in sea level, also attributed to global climate change, is expected to push saline water further inland, therefore severely affecting the agricultural productivity and the quality of drinking water in the coastal districts of

Table 4 Climatic susceptibility, long-term climate change threat, and livelihood impact in the nine disaster-prone areas

Country	Region	Climatic susceptibility	Long-term threats	Impacts
Bangladesh	Sathkira	Cyclones	Sea-level rise, salinity intrusion	Rice, drinking water
Bhutan	Punakha	Glacial lake outburst floods	Changing monsoon	Rice
Burkina Faso	Sahel	Drought	Changing rainfall patterns	Livestock, crops
Ethiopia	Gambella	Floods	Changing rainfall patterns	Habitability, crops, livestock
Gambia	North Bank	Drought	Changing rainfall patterns	Agriculture
Kenya	Budalangi	Floods	Changing rainfall patterns	Livestock, crops, property, disruption of social and economic activities
Micronesia	Kosrae	Storms	Sea-level rise, coastal erosion	Crops, livestock, fish
Mozambique	South/ Central	Floods/ droughts	Changing rainfall patterns	Housing, livelihood
Nepal	Udayapur	Floods	Changing rainfall patterns	Staple crops
Pakistan	Baluchistan	Flood, glacial lake outbursts	Changing rainfall patterns	Agriculture, transport and communication
Philippines	Tacloban	Cyclones	Changing storm intensity	Lives, agriculture, livestock, and property

Source: Warner and van der Geest (2013) and (Roberts et al. 2014)

Bangladesh (Rabbani et al. 2013). High yielding rice varieties were unable to withstand the increase in soil salinity (Rabbani et al. 2013). New varieties, such as BINA 8 and BRRI 47, henceforth developed after 2009, to resist high-salinity levels, were however found to be inappropriate for the chosen region (Rabbani et al. 2013). It is also estimated that the region incurred a decrease in its rice production by 0.1 million tons between 2008 and 2010. The total cost of loss to rice production due to salinity was estimated to be US $1.9 million from 2009 to 2011. The dangers of massive rural–urban and coastal-central migration looms in the near future if the region continues to experience such frequent calamities.

Bhutan

The district of Punakha is referred to as Bhutan's "rice bowl," where a substantial proportion of the population engages in small-scale farming (Kusters and Wangdi 2013). Kusters and Wangdi (2013) conducted a study on this region. A large proportion of the research participants recognized a pattern of unreliable monsoon and overall annual precipitation. This observation was confirmed by rainfall data collected over 1990–2008. This changing water availability was reported to have a negative effect on crop production. Coping measures adopted by the households include ritual performance (costing households between US$700 and US$900 per year), developing or modifying water-sharing arrangements, maintaining irrigation channels, changing cropping pattern, buying irrigation water from upstream villages, and using water pumps. Improved availability of fertilizers and modern technology was found to greatly enhance agricultural productivity for many farmers. Nevertheless, most adaptation measures were not without costs, some of which are monetary and some are nonmonetary. For instance, unsuccessful water-sharing arrangements led to local conflicts, disrupting social cohesion. Maintenance of irrigation canals required a substantial contribution, which was typically found to be unaffordable by the poor households, and therefore they were excluded from such water-sharing arrangements. Some farmers changed the cropping pattern from rice to maize resulted in an economic loss equivalent to US$2,000/acre.

Even though improved seed varieties and the availability of fertilizers and pesticides led to an overall increase in rice production in the district between 2002 and 2010, this improvement was not uniform across the whole region as poorer households failed to access these inputs. Therefore, the need to promote equal access to agricultural inputs is identified in the study. Additionally, the local officials often perceive the issue of glacial lake outburst floods due to the melting of glaciers and the threat of destabilizing ice-cored dams as a policy priority in comparison to changes in precipitation levels. This allowed them to overlook the problem of gradual changes in water availability, as the effects were less visible and less severe in relation to the impact of floods.

Burkina Faso

Burkina Faso is a semiarid, landlocked country in western Africa. Ninety percent of its population is engaged in agriculture and livestock sectors (Traore and Owiyo 2013). The high reliance on the agricultural and livestock by a large proportion of the population in the Sahel region of Burkina Faso implied that a substantial proportion of the population is engaged in activities that are weather sensitive. Therefore, their livelihoods depend significantly on climatic conditions. Traore and Owiyo (2013) found draught to be the main climatic stressor in the region. The occurrence of draught was confirmed by rainfall data, which indicated a high variation of rainfall and also a recent history of draught in the Sahel region. Severe negative impact on crop and livestock rearing was reported by a large percentage of the sampled households. Coping measures included reducing food consumption, selling property and livestock, cutting expenditure, receiving external support, migrating, earning extra income, transhumance, and a small proportion of the sample reported resorting

to begging. Modifying food consumption and selling property were found to be the most popular coping mechanisms. However, from the households that reported to undertake coping mechanism, 71 % indicated that they were still experiencing negative effects of the drought. The destruction caused by the onset of draughts, such as the lack of water for crop yields, led to the unavailability of water for the local people and their livestock, which further limited their future coping and adaptation ability. The range of average crop production loss was reported to be between US$577 and US$636 per household, whereas the range of average livestock loss was found to be between US$1,922 and US$8,759 per herder in the region.

Ethiopia

Ethiopia is heavily dependent on rain-fed agriculture. Historically, the country is prone to extreme weather events mostly characterized by highly variable rainfall pattern. Using spatially explicit analyses of climate change effects on selected key sectors of Ethiopia's economy, Robinson et al. (2013) found that the residual loss and damage might cost an annual average of US$0.4–3.0 billion. A case study was conducted by Haile et al. (2013) in the lowlands of Gambella, Ethiopia. The area experienced frequent river flooding that severely affected its people and their livelihoods. The main source of livelihood of the participants was crop cultivation and livestock rearing. The 2007 extreme flooding severely damaged the crops of three quarters of the respondents of the study and damaged the household properties of a quarter of the respondents. Most of the participants described the effect of the flood as either "very severe" or "disastrous" (Haile et al. 2013).

However, unlike in the case of Sahel in Burkina Faso, the ability to relocate livestock ensured a better source of livelihood for the livestock owners as opposed to the farmers, most of who reported that the yield of their next cropping season severely suffered as a result of the floods. Coping mechanisms included relying on assistance from NGOs, social networks, government support, and religious organizations. NGOs and social networks provided support to the largest proportion of the affected households. Nevertheless, the erosive quality of some coping measures is highlighted, where the respondents believed that the goodwill and resources of their reliable contacts will gradually diminish, inhibiting their future coping ability. Hence, the reliance on social networks was not perceived to ensure a long-term adaptation solution. Moreover, a majority of the households who had undertaken preventive measures such as increasing the floor height, harvesting premature crops, and constructing a high stage for livestock were unable to fully evade the negative effects of the 2007 flood. Additionally, as voluntary government resettlement plans are underway, the villagers are questioning its habitability as the new villages are lacking essential services such as health services and potential security.

Gambia

A study by Njie et al. (2007) estimated the residual damages from climate change in Gambia to range between US$123 million and US$130 million/year in the near term. For the more distant 2070–2099 period, residual damage cost estimated to

range from US$955 million to US$1.0 billion (Njie et al. 2007). A case study conducted by Yaffa (2013) in severely drought-prone regions of Gambia found that the varying level of rainfall and shorter duration of the rainy season along with rising temperatures implied severe calamity for its community that was mostly reliant on agriculture for their livelihoods. The prominent ill effects incurred by the community included food shortage, rise in food prices and reduction in crop production, and livestock ownership. Similar coping measures, as seen in the previous case studies, were adopted, where most of the measures were seen to aid short-term relief.

Kenya

Climate change poses a serious threat to Kenya's economy. Currently climate change accounts for an approximate monetary loss of approximately US$0.5 billion/year which is equivalent to 2 % of the country's GDP (Stockholm Environment Institute 2009). This cost is expected to rise and eventually claim 3 % of Kenya's GDP by 2030 (Stockholm Environment Institute 2009). A forecasted increase in rainfall in Kenya, due to climate change, along with human activities such as deforestation and overgrazing, is speculated to have increased the severity of flooding in the low-lying coastal regions of Kenya (Opondo 2013). The main sources of livelihood in the flood-prone regions are crop cultivation, livestock rearing, and other nonagricultural activities such as fishing, small-scale trade, and manual labor. It was found that more than three fourths of the farmers in the affected region reported that their livelihood had been severely affected by the flooding. Additionally, almost three fourths of all participants from all the occupational and income categories had reported that they were severely affected. The most common coping strategies included reducing food consumption and receiving help from local governments, NGOs, and religious organizations. However, most coping strategies, as in the case of the previous case studies, were found to be short-term solutions and most of such coping mechanisms implied "long term negative effects on the household economy" (Van der Geest and Dietz 2004 cited in Opondo 2013). For instance, undertaking the sale of property implied a reduced household asset base, unfavorable for a longer-term sustainable means of adaptation.

Micronesia

The case study examined below demonstrates a principal environmental concern of Micronesia as well as other small island states of the Pacific Ocean. Monnereau and Abraham (2013) confirmed that the rising sea level (attributed to climate change) has led to severe coastal erosion in the coastal region of Kosrae and has threatened the livelihood and habitability of many of its inhabitants. A rise in the sea level and coastal erosion is particularly dangerous to such island territories as it leads to a reduction in island size. The study revealed that the households who had adopted coping measures such as building seawalls, reinforcing their homes, and planting trees provided only temporary protection for the local inhabitants and had adverse long-term environmental effects. For instance, the building of sea walls and the

planting of trees only provided short-term solutions and only protected small sections of coastline. This highlighted the requirement of a large-scale or even state-level investment to provide sufficient barriers for the coastline. However, no initiatives have been successfully implemented to date as previous studies had indicated that the building of sea walls was found to have caused current changes and beach loss. The majority of the participants had indicated that they suffered from the effect of coastal erosion and that the coping strategies pursued was not sufficient to counter its adverse effects.

Mozambique

With a large coastline, Mozambique was found to experience severe floods in the lowlands (central), which adversely affected the livelihood of the rural farmers. In the year 2007 itself, Mozambique experienced a total economic loss and damage of $71 million from severe flooding (United Nations Office for Disaster Risk Reduction 2014). Brida et al. (2013) provided an account of the struggle of the community and the coping and adoption measures adopted and their effectiveness. The government of the country undertook resettlement projects, relocating communities to the uplands (south). However, this turned out to be as disastrous to the community as the uplands experienced frequent draughts, forcing many to go back to the lowlands and endure the negative effects of the floods. Crop cultivation, livestock rearing, and fishing were the most prominent sources of income in decreasing order of importance. Overall, a "double blow" from both the floods and the droughts was found to affect the entire sample interviewed, where the greatest ill effect was experienced by the farmers (Brida et al. 2013). As a result of food shortage, food prices increased, therefore further intensifying the adversity. The most prominent coping mechanisms included looking for other sources of income that includes laboring for the better-off households and selling property. However, as seen in previous case studies, such measures did not provide any long-term solutions. Moreover, the government resettlement initiative was found to worsen the situation for many.

Nepal

Frequent floods are one of the recurrent natural disasters that affect Nepal. Between 1971 and 2007, a staggering amount of 2,500 floods were recorded, which claimed more than 3,000 lives and damaged at least 150,000 buildings. The region of Udayapur in Nepal was found to be particularly susceptible to increasingly severe floods and vulnerable to the impact of climate change (Bauer 2013). The two main rivers in Udaypur reported increased rate of flooding. This was worsened by man-made obstructions such as roads and bridge piers, along with other activities such as deforestation which made the rivers shallower and accelerated sedimentation. Agriculture constituted the largest source of livelihood for many. More than 4/5 of all households reported that their agricultural output has decreased over the past years. Prevention and coping mechanisms undertaken by the farmers such as constructing stonewalls and seeking help from institutions such as NGOs was inadequate to avoid the recurrent loss and damage. Another frequent coping

mechanism was labor migration to cities and overseas. The relatives of the migrants often relied on their remittances as an extra source of income, but often male migration was associated with increased work load for the women.

Pakistan

Flooding and overflowing rivers caused substantial damage to 14 districts, particularly to the southern and northern parts of the district in 2010. It directly affected an estimated 14-20 million people, and killed over 1,700 (Kirsch et al. 2012). The floods also severely affected crops and livestock, where the crops were either partially or completely submerged and the livestock suffered from a lack of fodder availability. A total country-wide loss of US$9.7 billion was expected to have occurred in the agricultural sector (Kirsch et al. 2012). Food insecurity and malnutrition were also reported to have occurred in poorer societies. The average reported household monthly income of the affected community decreased by 50% (Kirsch et al. 2012). National response mechanisms included the use of military-affiliated rescue and aid operations, civil society relief operations included aid and establishment of social welfare infrastructure, and international donor aid and assistance was provided to affected areas (Asian Development Bank 2011). Rebuilding projects are being undertaken with the aim of constructing a flood-resilient society. However, the lack of proper pre-disaster awareness techniques prevents adequate preparation procedures. Therefore, loss and damage due to extreme flooding can almost be perceived as an unavoidable consequence. Additionally, even though civilians were requested to not reside in low-lying areas or near rivers, such a request is unfeasible as most of the rural poor reside in such vulnerable areas.

Philippines

According to National Disaster Reduction and Management Council (NDRRMC) (2014) 6,201 persons were killed, 28,626 were injured and 1,785 are missing over the entire Philippines in the aftermath of Typhoon Haiyan. The typhoon was the most powerful typhoon to make landfall to date which also caused significant economic damage to infrastructure and property. The damage to infrastructure and agriculture damages were estimated at US$802 million (Mori et al. 2014). Most of the residents were recorded to have taken sufficient coping and adopting mechanisms to frequent storms that hit the country. Local residents were reported to have never experienced a typhoon even remotely as brutal as Haiyan and were therefore defenseless. National and international relief efforts were mobilized post disaster, although the collapse of the local airport slowed down the process. Local inhabitants, with little or no socioeconomic assets and connections, are still known to be suffering from the adversities of the typhoon and were soon after subject to the adversities. After the onset of such a calamity, the Philippines hosted the Conference of United Nations Risk Reduction and Management in Manila to emphasize the importance of an available, accessible, and affordable disaster risk information system as part of the "Post-Haiyan Tacloban Declaration" (The United Nations Office for Disaster Risk Reduction 2014). During the 2013 Warsaw Conference, the Philippine Climate Change Commissioner, Naderev Yeb Sano, fought back tears while warning the

international community that his country is particularly suffering as a result of climate change, reflecting on the recently acquired news of his family's safe residence after Typhoon Haiyan (Galarraga and Roman 2013).

Conclusions

Loss and damage was recognized as a separate concept from adaptation in 2008, when the AOSIS proposed a Multi-Window Mechanism to address and finance the distinct concept of loss and damage arising due to climate change impacts. This was followed by the establishment of the UNFCCC Work Program on Loss and Damage in 2010 and the Warsaw International Mechanism on Loss and Damage in 2013 to further comprehend and address the issue. The Loss and Damage in Vulnerable Countries Initiative, formed in 2012, was the largest independent entity solely dedicated to building a common understanding of loss and damage. However, despite current global efforts in understanding the concept of loss and damage, the exact definition is still as elusive as ever and is still widely contested among the stakeholders.

Additional issues such as distinguishing between avoidable and unavoidable loss and damage, slow onset and extreme events, and monetary and nonmonetary loss and damage were also highlighted in this chapter. Discriminating between such categories of loss and damage from climate change adversities is essential as each category would require a different approach. For instance, in the case of avoidable and unavoidable loss and damage, it was pointed out previously that institutions and individuals must dedicate resources such that avoidable losses and damages can be successfully mitigated or adapted to and unavoidable losses and damages can be appropriately financed. Additionally, the debate regarding the constituents of loss and damage impacts from climate change makes it quite difficult to converge on a global estimate, therefore impeding a concrete commitment to tackle such an adversity. However, a global climate deal is being furnished and will be executed in 2015, where parties have agreed to adhere to a legally binding international climate change deal. Nevertheless, this agreement was only concurred by the EU, some other European nations, and Australia. Although this can be seen as a significant step forward, the lack of commitment by all developed countries still poses a great obstacle in obtaining an ideal climate change deal.

The biggest limitation in forming a concrete deal to address loss and damage was found to be the attribution problem. This can be described as lack of solid traceability of adverse weather impacts to climate change, which was found to impede any solid commitments by countries. To resolve the attribution problem, many studies have devised mechanisms to examine the extent to which adverse weather impacts can be attributed to climate change. However, as of now, no globally agreed upon mechanism has been fashioned. Additionally, the degree of impact of loss and damage due to climate change on livelihoods differed substantially across developing and developed countries. On the one hand, civilians in developed countries were mostly insured against the loss and damage from natural calamities or their losses and damages were mostly compensated for, where insurance or compensation policies

depended on country-specific requirements and regional policies. On the other hand, the poor farmers and livestock owners in vulnerable low-income countries were found to suffer substantially as a result of such climatic changes.

Country-specific loss and damage estimates and coping strategies from some of the most economically vulnerable countries have been analyzed in this chapter. The degree to which such adversities affected households depended on their socioeconomic status and geographical location. The livelihood of the poorer farmers and livestock owners was generally seen to be affected the most due to their restricted mobility and limited livelihood options (after a partial/complete destruction of their farms and livestock from extreme natural calamities). Common coping measures for predictable events included modifying food consumption, selling property and livestock, cutting expenditure, receiving external support, and finding extra income sources. However, many of the coping strategies adopted by the locals were seen as temporary and some measures even eroded their long-term coping capacity. Additionally, extreme and unexpected events, such as typhoon Haiyan in the Philippines, addressed the need to identify disaster identification technologies to reduce the loss and damage from such natural calamities. Overall, the case studies of economically and geographically vulnerable countries highlighted the need to identify and implement long-term measures to mitigate loss and damage and the need for active collaboration between international organizations, NGOs, and local governments to draw up cost-effective and feasible policies to combat such residual loss and damage.

Future Directions

Future directions for research include extended research work on regional- or country-specific insurance or compensation schemes for low-income countries, such that financing options that are best suited to address the environmental and social vulnerability of the region can be devised. Additionally, it was found that one of the biggest limitations in the climate change debate was the "attribution problem." Therefore, such a problem must be appropriately conceptualized and addressed, where better attribution techniques should be thoroughly examined and critiqued, and its applicability to the entire range of slow on set to extreme climatic conditions should be studied.

Paleoclimate Changes and Significance of Present Global Warming

Asadullah Kazi

Contents

Abstract

Earth's climate has been changing since the conceivable beginning of the geological history of Earth. This is reflected by paleoclimate occurrences of ice ages, followed by consequent warmer interglacial episodes. The most recent ice age has been tentatively traced back to some three million years ago. However, the onslaught of industrial revolution has greatly affected the framework of climate change. Atmospheric carbon dioxide levels are now 40 % higher than before the industrial revolution. This, in turn, has given rise to increase in temperature during the past couple of centuries. Glaciers have recently started melting, and the global average sea level has risen by more than 25 cm. Study of core records from Antarctica and Greenland disclose that paleoclimate ice cores dating back to 800,000 years revealed that the current concentrations of greenhouse gases exceeded the concentration of these gases, preserved in those

ice cores. Currently, global warming has emerged as the most serious environmental threat to mankind, and unless a drastic cut is made in the emission of greenhouse gases, the world would be heading toward an unretractable disaster. Consequently, this requires a global approach for development to combat the situation. To start with, there has to be awareness and preparedness, followed by capacity building through community education and training, as well as enforcement of regulations. This approach supports strategy of adaptation to vulnerability reduction and readiness to policy-supporting development, as the future course of action.

Introduction

Earth's climate is a global challenge. It is an ever-changing long-term phenomenon, whose incidence is manifested by repeated ice ages and the corresponding warmer interglacial periods, during paleoclimate episodes, in the geological history of Earth. Incidentally, such glacial and interglacial events occur in a cyclic pattern in conformity with average global temperature. A number of ice ages have occurred throughout Earth's history; the earliest was over two billion years ago, and the most recent one began approximately three million years ago and is followed by an interglacial stage of events. Earth was warmer than at present for most of this time interrupted by sporadic ice ages (Fig. 1).

Carbon dioxide is the primary greenhouse gas resulting from human activities (such as burning fossil fuels for energy and transportation). Incidentally, human activity-derived greenhouse gases are the largest potential cause of global warming.

It is reported that there is a direct relationship between the concentration of greenhouse gases, particularly carbon dioxide (CO_2) in the atmosphere, and the temperature of Earth, during the past 400,000 years (NOAA 2008) (Fig. 2).

It is also important to recognize that CO_2, CH_4, and NO_2 show high concentration during interglacial times and lower concentrations during the glacial episode. The atmosphere already contains over 25 % more CO_2 than it had done for the last 160,000 years (Leggett 1990).

In his lecture, "Changing Planet: Past, Present, Future – Earth's Climate back to the Future," Schrag (2012) portrayed a history of how the Earth's climate changed over since its birth.

Table 1 shades light on sources and buildup of common greenhouse gases and their relative contribution in the atmosphere. Currently, we are in a warm interglacial episode that began about 11,000 years ago. The main question that worries us is what if the continuing buildup of greenhouse gases in the atmosphere, resulting in the warm-up of Earth, would lead to abundant melting of ice? And if so, what needs to be done to circumvent this impending devastation?

NASA (2014) is preparing to launch a satellite to measure atmospheric concentrations of CO_2, a greenhouse gas that contributes almost 55 % to global warming (Table 1). It is stated that CO_2 levels have reached their highest concentration in the

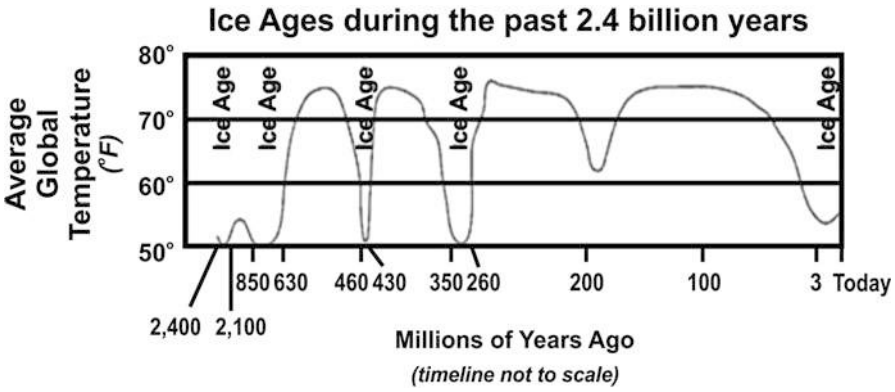

Fig. 1 Time history of five major ice ages of Earth's history (Adapted from Saltzman (2002), and Eldredge and Biely (2010))

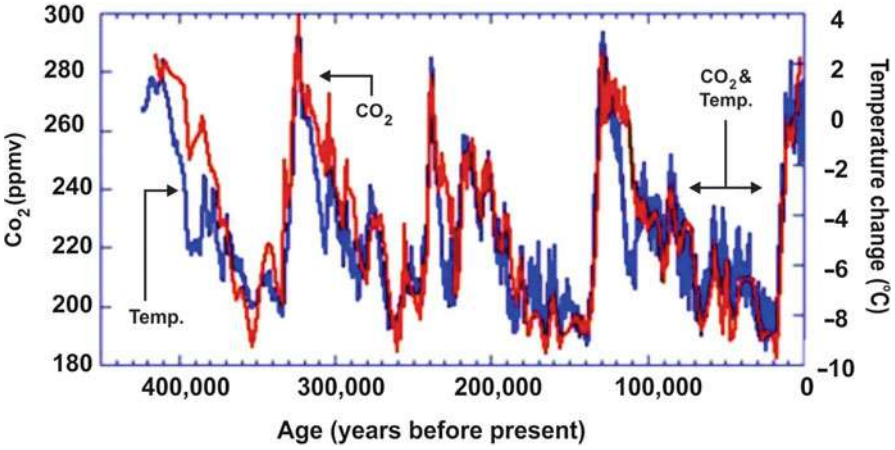

Fig. 2 Temperature change and carbon dioxide change observed, in ice core records (Adapted from NOAA (2008))

past 800,000 years or so. In the northern hemisphere, it has reached 400 parts per million by volume (ppmv), for the first time in human history. This level is 40 % up since the wide use of fossil fuels began with the industrial revolution. The World Meteorological Organization expects the global average concentration to be above 400 ppmv in 2015–2016. Rising concentration of this heat-trapping gas raises risks of more heat waves, droughts, and rising sea level. It may be mentioned that during the last 800,000 years, the level of atmospheric CO_2 fluctuated between 180 and 280 ppmv and has probably not been above 400 ppmv. The UN panel of experts, on greenhouse gas, suggested that the concentration of CO_2 gas would have to be kept below 450 ppmv to give a good chance of achieving less than 2 °C increase in global temperature, before the end of this century.

Table 1 The common greenhouse gases, their origins, rates of buildup in the atmosphere, and their contribution to global warming in the 1980s (Source: Leggett 1990)

Gas	Principal sources	Current rate of annual increase and concentration[a]	Contribution to global warming (%)
Carbon dioxide (CO_2)	Fossil fuel burning (77 %), deforestation (23 %)	0.5 % (353 ppmv)	55
Chlorofluorocarbons (CFCs) and related gases (HFCs and HCFCs)	Various industrial uses: refrigerants, foam-blowing solvents	4 % (764 pptv)	24
Methane (CH_4)	Rice paddies, enteric fermentation, gas leakage	0.9 % (1.72 ppmv)	15
Nitrous oxide (N_2O)	Biomass burning, fertilizer use, fossil fuel combustion	0.8 % (310 ppbv)	6

[a]*ppmv* parts per million by volume, *ppbv* parts per billion by volume, *pptv* parts per trillion by volume

Human activities are altering the carbon cycle, both by adding more CO_2 to the atmosphere and by influencing the ability of natural sinks, like forests and oceans, which absorb and trap (capture) CO_2 and keep the temperature rise within permissible limits.

Slightly different values of greenhouse gas contribution to global warming are quoted by the UN Framework Convention on Climate change (UNFCCC) (1992). Nevertheless, estimated contribution of greenhouse gases to global warming, during the last 100 years, as reported by the UNFCCC is as follows:

$$CO_2 - 66\%;\ CH_4 - 23\%;\ \text{CFC's} - 8\%;\ N_2O - 3\%.$$

Comparing these concentrations with those in 1980s, by UNFCCC, reveals that in terms of contributions to global warming, CO_2 has increased by 17 %, CH_4 has decreased by 5 %, HCFCs increased by 6 %, and NO_2 increased by 3 %. The increase in the magnitude of CO_2 can obviously be attributed to higher consumption of fossil fuels in the energy mix; United States, China, and India, among others, are the countries that make the maximum use of fossil fuels in the energy sector of their strong economies.

Paleoclimate Perspective

Carbon dioxide, as described above, is a major greenhouse gas, which contributes to Earth's global warming leading to climate change. Paleoclimate sources of information, leading to an assessment of conditions that prevailed during the life history of Earth, are important in predicting likely climatic changes in the future (Fig. 3).

Research in the study of ice cores drilled in Greenland and Antarctica provides much-needed information about variations in past temperatures and composition of

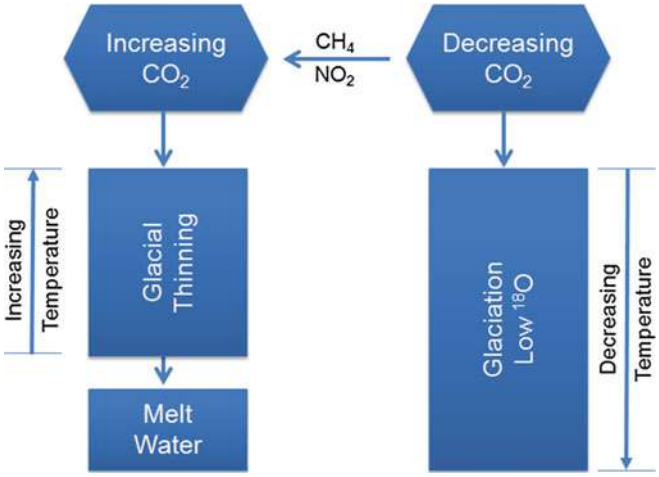

Fig. 3 Climatic changes during glacial and interglacial episodes of the history of Earth

atmospheric gases such as CO_2, NO_2, and CH_4, as well as many other aspects of the global environment.

It is also understood that, among other things, the warming of glacial periods is essentially synchronized by gradual shift in Earth's rotation (USEPA 2014a; Hansen and Sato 2011). However, changes in climate change are accompanied mainly by changes in CO_2, NO_2 and CH_4, leading to changes in the temperature.

Ice Core Records of Temperature

Crucially, the ice cores enclose small bubbles of air in the atmosphere, and from these, it is possible to measure the past concentration of gases. According to briefings of British Antarctic Survey (BAS), pertaining to "ice cores and climate change," the oldest ice core records extend to 123,000 years in Greenland and 800,000 years in Antarctica. The longest ice cores lengthen to 3 km in depth. Analysis of these ice core records reveals details of Earth's past climate and is, therefore, useful in recreating long-term records of temperature as well as other environmental counterparts that allow us to explore the past climate. It may be pointed out that in the instance of temperature, no direct measurement of temperature is available (www.climatedata.info, 2010). However, the ratio of heavy oxygen (^{18}O) to light oxygen (^{16}O) is helpful in elucidating climate changes, which occurred in the past.

Water molecules, containing light oxygen, evaporate easily as compared to water molecules containing heavy oxygen atom. At the same time, water vapor molecules, containing the heavy oxygen, condense more easily. Furthermore, the concentration of ^{18}O in precipitation decreases with temperature. As shown in Fig. 4, the difference in ^{18}O concentrations in annual precipitation, compared to

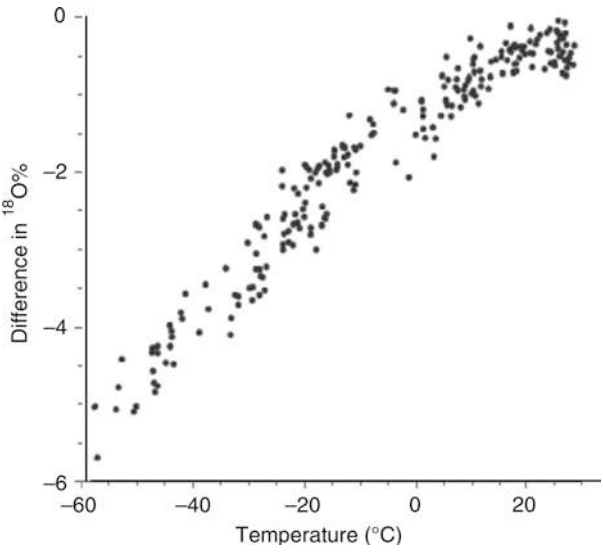

Fig. 4 Concentration of ^{18}O decreases with temperature (Adapted from Jonzel et al. (1994))

the average annual temperature, at the present-day ice-capped locations is fairly obvious.

As explained in the feature articles of NASA (paleontology: the oxygen balance), air cools by moving toward the poles, and the moisture begins to condense and falls as precipitation. Initially, the rain contains a higher ratio of water made of heavy oxygen molecules, which condense more easily than water vapor containing light oxygen. The remaining moisture in the air becomes depleted in of heavy oxygen, as the air continues to move toward colder upper latitudes. Consequently, the falling rain or snow now is made up of more water-containing light oxygen. Less heavy oxygen in the frozen water means that temperatures were cooler.

According to NASA (2010), the Earth moved out of ice ages, over the past millions of years; the glacial temperature rose by a total of 4–7 °C, over approximately 5,000 years. The stage of changes in temperature and CO_2 across glacial–interglacial episodes in the past is consistent with the proposition that CO_2 acts as an important amplifier of climate changes in the natural system (Wolff 2011). In the past century alone, the temperature in response to increase in CO_2 has climbed 0.7 °C, which is roughly 10 times faster than the average rate of ice age recovery warming. This leaves many questions to answers in the context of the present global warming.

Changing Atmospheric Chemical Composition

Unlike temperature, the ice cores allow direct measurements of atmospheric gases, like carbon dioxide and methane. The fastest natural increase in carbon dioxide (CO_2) and methane (CH_4), measured in older ice cores, is 20 parts per million by

volume, in 1000 years. This is seen as the order of magnitude during Earth's emergence from the last ice age, around 12,000 years ago. The concentration of carbon dioxide (CO_2) increased in the last two centuries by the same amount. Similarly, methane (CH_4) also shows unprecedented increase in concentration over the last 200 years. Its concentration is now much more than double its preindustrial levels. Nitrous oxide (NO_2) is yet another constituent which increased from a preindustrial concentration of about 265 ppb to the present-day value of 319 ppb (Forster et al. 2007). Atmospheric CO_2 levels are now 40 % higher than before the industrial revolution (British Antarctic Survey 2014).

The increase in the magnitude of global temperature is crucially important as it is proportional to increase in CO_2. UN Secretary-General, Ban Ki-moon (2013), pointed out, "We must limit global temperature rise to 2°. We are far from there, and even that is enough to cause dire consequences. If we continue along current path, we are close to 6° increase." At the end of most interglacial episodes, NO_2 remains considerably longer on interglacial levels than methane. This is substantiated by studies on glacial–interglacial and millennial scale variations in the atmospheric NO_2 concentrations during the last 800,000 years (Schilt et al. 2010). Furthermore, it is noted that increase in the nitrous (NO_2) concentration starts before the onset of the warming period (Flückiger et al. 2004).

Current Climate Change and Global Warming Perspective

Global warming, resulting from climate change, has emerged as the most serious environmental threat, suggesting that the mankind is heading for deep trouble unless a drastic cut is made in emission of greenhouse gases into the atmosphere. In a report by the Intergovernmental Panel on Climate (IPCC), a body set by the UN General Assembly in 1988, emissions resulting from human activities are substantially increasing the atmospheric concentration of greenhouse gases. If this increase in the greenhouse gas continued at the present rates, the world average temperature will rise by one degree centigrade or thereabouts within just 30 years.

Counteracting Present-Day Climate Change

From the human point of view, "if you change climate, you change everything." It is, therefore, pertinent to build a future in which humans live in harmony with nature. Table 2 presents a summary of the potential of greenhouse gases and the effects that occur over a period of about 100 years, after a particular mass of a gas is emitted (USEPA 2014c).

Some gases stay longer in the atmosphere than others. Indeed, there is no doubt that there is a climate change, and part of this change is caused by human activities (Cook et al 2013). But, is the part played by humans significant enough to bring about change in the natural glacial–interglacial cycle of episodes, prior to the existence of humans on the Earth?

Table 2 Major long-lived greenhouse gases and their characteristics (USEPA 2014b)

Greenhouse gas	How it is produced	Average lifetime in the atmosphere	100-year global warming potential
Carbon dioxide	Emitted primarily through the burning of fossil fuels (oil, natural gas, and coal), solid waste, and trees and wood products. Changes in land use also play a role. Deforestation and soil degradation add carbon dioxide to the atmosphere, while forest regrowth takes it out of the atmosphere		1
Methane	Emitted during the production and transport of coal, natural gas, and oil. Methane emissions also result from livestock and agricultural practices and from the anaerobic decay of organic waste in municipal solid waste landfills	12 years	28
Nitrous oxide	Emitted during agricultural and industrial activities, as well as during combustion of fossil fuels and solid waste	121 years	265
Fluorinated gases	A group of gases that contain fluorine, including hydrofluorocarbons, perfluorocarbons, and sulfur hexafluoride, among other chemicals. These gases are emitted from a variety of industrial processes and commercial and household uses and do not occur naturally. Sometimes used as substitutes for ozone-depleting substances such as chlorofluorocarbons (CFCs)	A few weeks to thousands of years	Varies (the highest is sulfur hexafluoride at 23,500)

Figure 5 shows the impact of climate change in terms of projected increase in temperature by the year 2100. Five types of risk factors are identified together with the likely future temperature. There is a range of scenarios and uncertainties accompanied with each risk factor. Under worst conditions, if the future temperature rises above 3 °C, there will be a risk of irreversible large-scale and abrupt transition.

Knowing that the present-day anthropological factors have accelerated the climate change, efforts must be to stop, or adapt or mitigate, the arrival of the advent of the natural cycle of events, which can be nothing less than disastrous. It may not be humanly possible to stop; nevertheless, efforts must be made to adapt or mitigate and continue to make developments in the fast-moving socioeconomic setup of knowledge-based society.

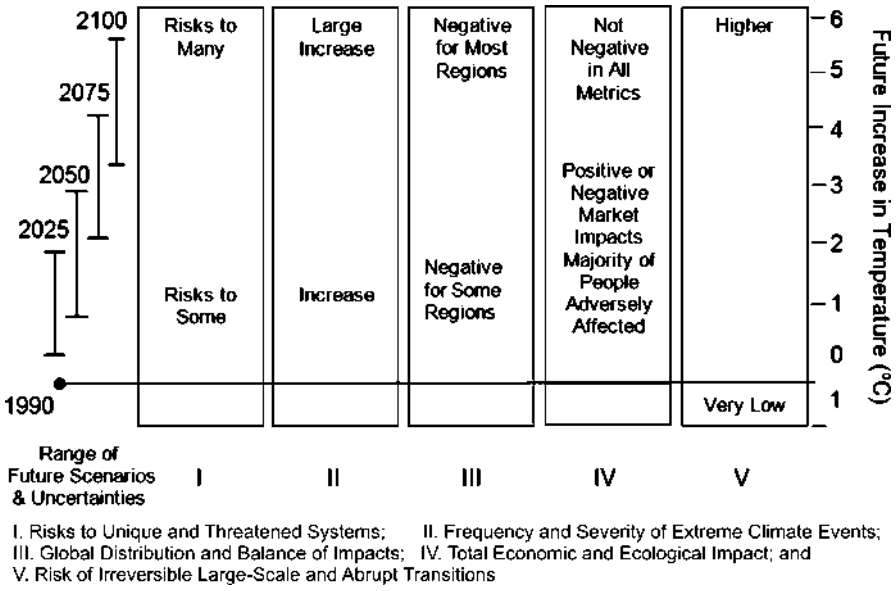

Fig. 5 Risks and impact of climate change (Source: Smith et al. 2009)

For a sustainable development, holistic approach integrating climate change in policy making for resource development is presented, in a guideline entitled "Training Manual on Climate Change Adaptation and Development," compiled by Geene et al. (2010). In 1997, the Kyoto Protocol was concluded and established legally binding obligations for developed countries to reduce their greenhouse gas emissions. Furthermore, Millennium Development Goals (MDG) of the United Nations (2014) also put emphasis on efforts to ensure environmental sustainability (goal number 7) and to develop a global partnership for development (goal number 8). Figure 5 shows the impact of climate change in terms of projected increase in temperature by the year 2100.

In order to control and reverse the process of global warming, it is essential to look into adaption and development together with awareness and mitigation measures.

Awareness and Mitigation

Climate change is a global challenge. This challenge will continue to affect all forms of life. Apparently, there was little awareness of this calamity prior to preindustrial period (prior to 1760 AD), but at the present time, if nothing is done to curb this menace, irreparable damage may jeopardize the entire ecosystem and the human development process.

Management of greenhouse gases includes measures, which are necessary before a catastrophic situation appears. Emphasis is placed on awareness and

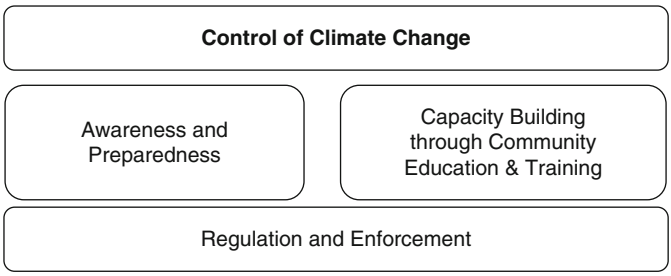

Fig. 6 Steps to control climate change

preparedness, capacity building through community education and training, as well as enforcement of regulations (Fig. 6), meant to reduce or capture emissions. This requires a global partnership, for development to combat the situation.

The principal cause of climate change as noted in Fig. 3 is attributed to three principal greenhouse houses, namely, CO_2, NO_2, and CH_4. The former is the utmost contributor of change in temperature, which has affected the climate, both in the paleoclimate and the present scenario. The IPCC (2001, 2007) has clearly spelled out that "adaptation will be necessary to address impacts resulting from warming, which is already unavoidable due to past emissions." This supports the idea that adaptation and development should be treated as a complimentary response strategy to awareness and mitigation.

Adaption and Development

Adaption to climate change can either be planned or automatic. Plants and animals have no plan to control over environment. For them, adaptation in response to environmental changes is necessary for their survival else they will disappear. For humans, in spite of being aware of the effects of climate change, it is necessary to take measures which may not stop but at least reduce the impact of environmental changes through specific policy framework (Füssel and Klein 2006). Adaption can, therefore, be taken as an option after mitigation. It implies reduction of impacts rather than vulnerability for development (Fig. 7).

Indeed, climate change is a reality, and there is a general agreement that "we must stop and reverse this process now or face a devastating cascade of natural disasters that will change life on earth, as we know it."

Reversal of Climate Change

Climate change can be looked into paleoclimate and preindustrial perspectives. It is only in the postindustrial period that the effects of climate change were noticed. Nevertheless, there is growing and convincing evidence that climate change has

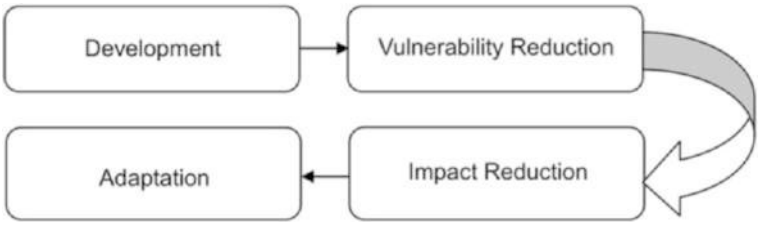

Fig. 7 Development preceded by adaptation

been occurring throughout the geological history of Earth due to natural causes. However, the anthropogenic activities have added to causes of climate change manifested by a growing increase in temperature in the postindustrial instance. It is, therefore, pertinent to control as well as reverse the process of global warming by awareness, mitigation, and adaptation to bring about the much-needed development (Fig. 8).

Reducing deforestation and encouraging reforestation can reduce emission from fossil fuels by trapping CO_2 and thus play a significant role in the long run to curtail global warming (Union of Concerned Scientists 2013). But, this may not be the only solution. At the global community level, it may be useful to reverse the global warming process and follow adaptation and development together with awareness and mitigation.

This is well and good, but research is being conducted to curb the release of CO_2, which acts as cover to stop it from escaping into the upper layers of atmosphere and as a result raises the temperature of Earth. Today, the power sector alone represents global CO_2 emissions approximating 40 %. As reported by Curry (2004), researchers in the MIT Laboratory for Energy and the Environment have been studying a global climate change mitigation technology called "carbon dioxide capture and storage," since 1989, under the auspices of a program currently called the "Carbon Capture and Sequestration Technologies Program." Similar research is being conducted at centers and institutes of research and development elsewhere.

Basically, there are three steps involved in this venture. The first step is to trap and separate CO_2 from other gases. In the second step, this gas is taken to a far-flung storage location, away from the atmosphere, and lastly, the gas is carefully stored deep inside the Earth's crust or deep in oceans. Furthermore, there are three methods of capture, namely, post-combustion carbon capture, pre-combustion capture, and oxyfuel carbon capture (GreenFacts 2014).

Future Directions

Paleoclimate sources of information, leading to an assessment of conditions that prevailed during the life history of Earth, are important in predicting likely climatic changes in the future. The Earth's climate is constantly changing. There are a number of processes that can influence this fluctuation. Increase in CO_2, among

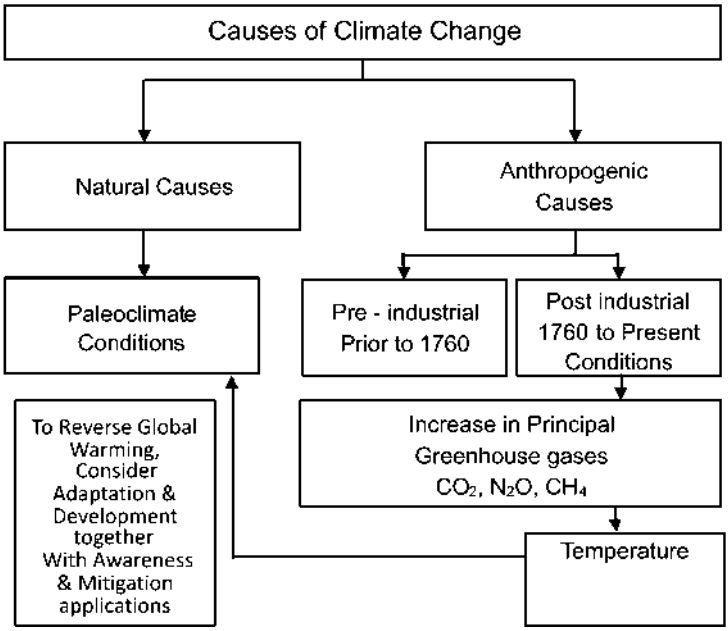

Fig. 8 Historic perspective of climate change and reversal approach of combating climate change

other variables, is the main ingredient of this variation. Comparison with prehistoric records reveals that the concentration of CO_2 has been on the rise since postindustrial times. This has led to fears that the consequent rise in the temperature of atmosphere may be extraordinarily difficult to handle.

The UN panel of experts on greenhouse gases, led by CO_2, suggested that the concentration of this gas would have to be kept below 450 ppmv to give a good chance of achieving less than 2 °C increase (2014) in global temperature, before the end of this century. Failure to control the rising concentration of CO_2 can be nothing less than disastrous in this regard. The best way of control would be to reduce emission from the fossil fuel (oil, gas, and coal)-based power plants, industrial units, or the transport sector in this situation. Reducing deforestation and encouraging reforestation can reduce emission from fossil fuels by trapping CO_2 and thus play a significant role in the long run to curtail global warming. The concern is that anthropogenic emissions of greenhouse gases may be driving average global temperature higher than previously recorded or estimated.

At the global community level, it may be useful to reverse the global warming process and follow adaptation and development together with awareness and mitigation. Research is being conducted in some developed countries to find a technically feasible and economically affordable solution to capture CO_2 at source and store the same at depth either in the sea or in the Earth's crust.

Abstract

Life cycle assessments of greenhouse gas emissions have been developed for analyzing products "from cradle to grave": from resource extraction to waste disposal. Life cycle assessment methodology has also been applied to economies, trade between countries, aspects of production, and waste management, including CO_2 capture and sequestration. Life cycle assessments of greenhouse gas emissions are often part of wider environmental assessments, which also cover other environmental impacts. Such wider-ranging assessments allow for considering "trade-offs" between (reduction of) greenhouse gas emissions and other environmental impacts and co-benefits of reduced greenhouse gas emissions. Databases exist which contain estimates of current greenhouse gas emissions linked to fossil fuel use and to many current agricultural and industrial activities. However, these databases do allow for substantial uncertainties in emission estimates. Assessments of greenhouse gas emissions linked to new processes and products are subject to even greater data-linked uncertainty. Variability in outcomes of life cycle assessments of greenhouse gas emissions may furthermore originate in different choices regarding functional units, system boundaries, time horizons, and the allocation of greenhouse gas emissions to outputs in multi-output processes.

Life cycle assessments may be useful in the identification of life cycle stages that are major contributors to greenhouse gas emissions and of major reduction options, in the verification of alleged climate benefits, and to establish major differences between competing products. They may also be helpful in the analysis and development of options, policies, and innovations aimed at mitigation of climate change.

The main findings from available life cycle assessments of greenhouse gas emissions are summarized, offering guidance in mitigating climate change. Future directions in developing life cycle assessment and its application are indicated. These include better handling of indirect effects, of uncertainty, and of changes in carbon stock of recent biogenic origin and improved comprehensiveness in dealing with climate warming.

Introduction

This handbook is about climate change mitigation. In decision-making about climate change mitigation, question marks about proper choices regularly emerge. Is going for electric cars a good thing, when power production is largely coal based? Do the extra inputs in car production invalidate the energy efficiency gains of

hybrid cars? Should a company focus its greenhouse gas management on its own operations or on those of raw material suppliers? Is material recycling better or worse for climate change mitigation than incineration in the case of milk cartons? And what about biofuels: should their use be encouraged or not? Regarding all these questions, assessment of the life cycle emission of greenhouse gases, or more in general the environmental burden, is important for giving proper answers.

Life cycle assessments may lead to anti-intuitive results. This can be illustrated by the case of liquid biofuels (Hertwich 2009). It has been argued that biofuels are "climate neutral" (e.g., Sann et al. 2006; De Gorter and Just 2010). The CO_2 which emerges from burning biofuels has been recently fixed by photosynthesis, so, it has been argued, there should be no net effect of burning biofuels on the atmospheric concentration of CO_2. However, if one looks at the "seed-to-wheel" life cycle of biofuels, a different picture may emerge. Consider, e.g., corn ethanol used as a transport biofuel in the USA. In the actual production thereof, there are substantial inputs of fossil fuels (Fargione et al. 2008; Searchinger et al. 2008). Corn cultivation also leads to emissions of the major greenhouse gas N_2O (Crutzen et al. 2007). And corn cultivation is associated with changes in carbon stocks of agroecosystems (Searchinger et al. 2008). Considering the life cycle emissions of greenhouse gases leads to the conclusion that bioethanol from the US corn is far from "climate neutral" but is rather associated with larger greenhouse gas emissions than conventional gasoline (Searchinger et al. 2008; Reijnders and Huijbregts 2009). This has clearly implications for making good decisions about mitigating climate change linked to fuel choice (Hertwich 2009).

Against this background, this chapter will consider current life cycle assessment, with a focus on the life cycle emission of greenhouse gases. First, it will be discussed what life cycle assessment is and how it is done. It will appear that such assessment may give rise to substantial uncertainty. Notwithstanding such uncertainty, life cycle assessments can be helpful in making proper choices about climate change mitigation. To illustrate this, main findings from available peer-reviewed life cycle assessments of greenhouse gas emissions will be summarized.

What Is Life Cycle Assessment and How Does It Work?

Life cycle assessment has been developed for analyzing current products from resource extraction to final waste disposal, or from cradle to grave. Apart from analyzing the status quo, life cycle assessments may also deal with changes in demand for, and supply of, products and with novel products. The latter type of assessment has been called *consequential*, as distinguished from the analysis of status quo products, which has been called *attributional* (Sanden and Kalström 2007; Frischknecht et al. 2009). The assessment of novel products has also occasionally been called: *prospective attributional* (Hospido et al. 2010; Song and Lee 2010).

Different data may be needed in attributional and consequential life cycle assessment. Whereas in attributional life cycle assessment one, e.g., uses electricity data reflecting current power production, in consequential life, one needs data regarding

changes in electricity supply. For the short term, assessing a marginal change in capacity of current electricity supply may suffice to deal with changes in electricity supply. When the longer term is at stake, major changes in energy supply, including complex sets of energy supply technologies, should be assessed (Lund et al. 2010).

When novel products go beyond existing components, materials, and processes, knowledge often partly or fully relates to the research and development stage or to the limited production stage. These stages reflect immature technologies. Comparing these with products of much more mature technologies may be unfair, as maturing technologies are optimized and tend to allow for better resource efficiency and a lower environmental impact (Wernet et al. 2010; Mohr et al. 2009). Also, novel products may be subject to currently uncommon environmental improvement options and may have to operate under conditions that diverge from those that are currently common (Sanden and Kalström 2007; Frischknecht et al. 2009). The latter conditions may, e.g., include constraints on resource availability which currently do not exist, new infrastructures, budget constraints, higher resource costs which are conducive to resource efficiency, and strict caps on greenhouse gas emissions. A solution to such divergence from "business as usual" may be found in assuming technological trajectories and/or constructing scenarios which include assumptions about the environmental performance of future mature technologies under particular conditions (Frischknecht et al. 2009; Mohr et al. 2009; Jorquera et al. 2010; Spatari et al. 2010).

It should be realized that the assumptions involved lead to considerable uncertainty regarding the outcomes of consequential life cycle assessments, as these assumptions may be at variance with "real life" in the future.

Life cycle assessment is generally divided in four stages (Guinee 2002; Rebitzer et al. 2004):

- Goal and scope definition
- Inventory analysis
- Impact assessment
- Interpretation

Goal and Scope Definition

In the *goal and scope definition* stage, the aim and the subject of life cycle assessment are determined. This implies the establishment of "system boundaries" and usually the definition of a "functional unit."

A functional unit is a quantitative description of service performance of the product(s) under investigation. It may, for instance, be the production of a megawatt hour (MWh) of electricity. This allows for comparing different products having the same output: e.g., photovoltaic cells, a coal-fired power plant, a gas-fired power plant, and a wind turbine. It should be noted though that the functional unit may cover only a part of the service performance, because products may have special properties. For instance, in the case of power generation, the production of a MWh of electricity as a functional unit does not take account of the

phenomenon that a coal-fired power plant is most suitable for base load and a gas-fired power plant for peak load.

In the *goal and scope definition* stage, a number of questions have to be answered. For instance, the life cycle of products usually includes a transport stage. As to transport the question arises what to include into the assessment: production of the transport vehicle? road building? building storage facilities for products? Similarly, in the life cycle assessment of fishery products, questions arise such as: should one include the bycatch of fish which is currently discarded? the energy input in shipbuilding and ship maintenance? and/or the energy input in building harbor facilities?

In the *goal and scope definition* stage, one should also consider the matter of significant indirect effects of products. A well-known example thereof is the rebound effect in the case of more energy-efficient products with lowered costs of ownership. Such products may, for instance, increase use of the product and may lead to spending of money saved by the energy-efficient product, which in turn may impact energy consumption, and associated greenhouse gas emissions (Schipper and Grubb 2000; Thiesen et al. 2008; Greene 2011). Another case in point concerns biofuels from crops that currently serve as source for food or feed. When carbohydrates or lipids from such crops are diverted to biofuel production, this diversion may give rise to additional food and/or feed production elsewhere, because demand for food and feed is highly inelastic (Searchinger et al. 2008). This, in turn, may have a substantial impact on estimated greenhouse gas emissions. Similarly, the use of waste fat for biodiesel production may have the indirect effect of reducing the amount of fat available for feed production, which in turn might lead to an increased use of virgin fat, which will impact land use and may thus change carbon stocks of recent biogenic origin. However, indirect effects of decisions about biofuels do not end with the consideration of indirect effects on land use. It may, for instance, be argued that not expanding biofuel production may increase dependency on mineral oil and that this may increase military activities to safeguard oil installations and shipping and associated emissions of greenhouse gases (De Gorter and Just 2010). Still another example of indirect effects regards wood products. These may have the indirect effect of substituting for non-wood products, and including such substitution has a significant effect on estimated greenhouse gas emissions (Sathre and O'Connor 2010). Decision-making about significant indirect effects is not straightforward. This has led some to the conclusion that including indirect effects is futile (e.g., De Gorter and Just 2010), whereas others have argued that including at least some indirect effects is conducive to good decision-making (e.g., Searchinger et al. 2008; Sathre and O'Connor 2010).

System boundaries refer to what is included in life cycle assessment. In general, system boundaries are drawn between technical systems and the environment, between relevant and irrelevant processes, between significant and insignificant processes, and between technological systems. An example of the latter is, for instance, a boundary between the motorcar life cycle and the life cycle of the building in which the car is produced. The choice of system boundaries may have a substantial effect on the outcomes of life cycle assessments (also: Finnveden et al. 2009; Gandreault et al. 2010).

Inventory Analysis

The *inventory analysis* gathers the necessary data for all processes involved in the product life cycle. This is a difficult matter when one is very specific about a product: for instance, the apples which I bought last Saturday in my local supermarket. However, databases have been developed, such as Ecoinvent (Frischknecht et al. 2005), the Chinese National Database (Gong et al. 2008), Spine (www.globalspine.com), JEMAI (Narita et al. 2004), and the European Reference Life Cycle Data System (ELCD 2008), which give estimates about resource extraction and emissions that are common in Europe, China, the USA, and Japan for specified processes (for instance, the production and use of phosphate fertilizer). Also, there are databases which extend to economic input–output analyses and give resource extraction and emission data at a higher level of aggregation than the process level (Tukker et al. 2006). A study of De Eicker et al. (2010), which also gives a fuller survey of available databases, suggests that among available databases the Ecoinvent database is preferable for relatively demanding LCA studies. If only greenhouse gas emissions are considered, the 2006 guidelines for national greenhouse gas inventories of the IPCC (Intergovernmental Panel on Climate Change; www.ipcc.ch/) were found to be useful (De Eicker et al. 2010).

Available databases do not always give the same emissions for the same functional units. For instance, according to a study of Fruergaard et al. (2009), data about the average emission of greenhouse gases linked to 1 kWh electricity production in 25 EU countries varied between databases by up to 20 %. For similar estimates in the USA, an even greater between-database uncertainty (on average 40 %) was found (Weber et al. 2010). Though such uncertainties are substantial, they should not detract from using databases such as Ecoinvent, Spine, and JEMAI, if only because between-process differences often exceed uncertainty. This may be illustrated by the geographical variability in greenhouse gas emissions linked to electricity production. For instance, country-specific average emissions of greenhouse gases per kWh of electricity in such databases vary by a factor of 160 (Fruergaard et al. 2009). For marginal emissions of greenhouse gases per kWh of electricity (which are used to assess changes in supply or demand as needed for consequential life cycle assessment), variations were even larger: up to 400–750 times (Fruergaard et al. 2009).

In the *inventory* stage of life cycle assessments of greenhouse gas emissions, the focus is evidently on the latter emissions. In wider-ranging life cycle assessments, the inventory may comprise all extractions of resources and emissions of substances causally linked to the functional unit for each product under consideration, within the system boundaries that were established in the stage of goal and scope definition. Such wider-ranging life cycle assessments have a benefit over life cycle assessments, which only focus on greenhouse gas emissions. First, they give a better picture of the overall environmental impact, for which life cycle greenhouse gas emissions may well be a poor indicator (Huijbregts et al. 2006, 2010; Laurent et al. 2010). Also, such wider-ranging LCAs allow for considering “trade-offs”

between environmental impacts and the occurrence of co-benefits linked to reducing greenhouse gas emissions (Nishioka et al. 2006; Haines et al. 2009; Markandya et al. 2009; Chester and Horvath 2010; Walmsley and Godbold 2010). For instance, Walmsley and Godbold (2010) concluded that stump harvesting for bioenergy may not only impact greenhouse gas emissions but may have the co-benefit of reducing fungal infections and may have negative co-impacts linked to erosion, nutrient depletion and loss, increased soil compaction, increased herbicide use, and loss of valuable habitat for a variety of (non-pest) species. Many current transport biofuels have larger life cycle greenhouse gas emissions than the fossil fuel which they replace but have the benefit that dependence on mineral oil is reduced (Reijnders and Huijbregts 2009).

A large part of the impacts which go beyond climate change can be covered by standard wider-ranging LCAs. Aspects of environmental impact which are, apart from the emission of greenhouse gases, often covered by such wider-ranging life cycle assessments are summarized in Box 1.

In evaluating buildings, the indoor environment may also be a matter to consider (Demou et al. 2009; Hellweg et al. 2009). New operationalizations of some of the aspects of environmental impact mentioned in Box 1 and additions to the list of Box 1 are under development. The latter include ecosystem services (Koellner and de Baan 2013) and the impacts of freshwater use (Boulay et al. 2011; Verones et al. 2013). Adding to the aspects often covered in wide ranging LCAs, a proposal has been published for the inclusion into life cycle assessment of change in albedo which is relevant to climate, characterized in terms of CO_2 equivalents (Munoz et al. 2010). An estimate of the contribution inclusion of black carbon emissions to climate change has also become available (IPPC Working Group I 2013).

In life cycle assessments, the problem arises that many production systems have more than one output. For instance, rapeseed processing not only leads to the output oil, which may be used for biodiesel production, but also to rapeseed cake, which may be used as feed. Similarly, mineral oil refinery processes may not only generate gasoline but also kerosene, heavy fuel oil, and bitumen, and biorefineries produce a variety of product outputs too (Brehmer et al. 2009). In the case of multi-output processes, extractions of resources and emissions have to be allocated to the different outputs. There are several ways to do so. Major ways to allocate are based on physical units (e.g., energy content or weight of outputs) or on monetary value (price). There may also be allocation on the basis of substitution. In the latter case, the environmental burden of a coproduct is established on the basis of another, similar product. Different kinds of allocation may lead to different outcomes of life cycle assessment (Reijnders and Huijbregts 2009; Finnveden et al. 2009; Fruergaard et al. 2009; Sayagh et al. 2009).

The usual outcome of the *inventory analysis* of a wide ranging life cycle assessment is a list with all extractions of resources and emissions of substances causally linked to the functional unit for the product considered and, apart from the case of nuisance, commonly disregarding place and time of the extractions and emissions.

Box 1: Aspects of Environmental Impact Which Are Often Considered in Wide Ranging Life Cycle Assessments
Resource depletion (abiotic, biotic)
Effect of land use on ecosystems and landscape
Desiccation
Impact on the ozone layer
Acidification
Photooxidant formation
Eutrophication or nitrification
Human toxicity
Ecotoxicity
Nuisance (odor, noise)
Radiation
Casualties
Waste heat
Water footprint

Impact Assessment

The next stage in life cycle assessment is *impact assessment*. This firstly implies a step called characterization. In this step, extractions of resources and emissions are aggregated for a number of impact categories. When only greenhouse gas emissions are considered, the aggregation aims at establishing the emission of other greenhouse gases in terms of CO_2 equivalents (CO_2eq), which means that the emission of greenhouse gases like N_2O, CH_4, and CF_4 are recalculated in terms of CO_2 emissions. To do so, one needs to choose a time horizon (e.g., 25 years, 100 years, 10^4 years), because the greenhouse gas effect of emitted greenhouse gases may be different dependent on the time horizon chosen (see Table 1). The time-dependent differences in Table 1 reflect differences in atmospheric fate of greenhouse gases. For instance, the removal of CH_4 from the atmosphere is much faster than the removal of CO_2 (Myrhe et al. 2013).

In practice, often a time horizon of 100 years is chosen and the global warming potentials (GWP) from the corresponding column of Table 1 are commonly used in life cycle assessments.

Table 1 considers only direct impacts or effects of the greenhouse gases. There are however also indirect impacts. For instance, the emission of CH_4 may affect the presence of ozone, which is also a greenhouse gas. There have been proposals for including such indirect effects in global warming potentials. Using a 100-year time horizon and assuming the GWP of CO_2 to be 1, Brakkee et al. (2008) proposed, for instance, a GWP for CH_4 of 28 and for non-methane volatile organic compounds, a GWP of 8. The latter have a direct GWP of 0. A number of estimated examples of global warming potentials calculated with and without indirect effects are in Table 2.

Table 1 Estimated global warming potentials (GWP) in CO_2eq of CH_4 and N_2O for time horizons of 20 and 100 years as proposed by the Intergovernmental Panel on Climate Change (IPCC) (Myrhe et al. 2013). Apart from climate–carbon interactions, only direct effects are considered

Gas/time horizon	20 years	100 years
CO_2	1	1
CH_4	86	34
N_2O	268	298

Table 2 Estimated global warming potentials (GWP) with a time horizon of 100 years relative to the GWP of CO_2 for a number of gases as calculated by Brakkee et al. (2008)

Gas/type of GWP	GWP, direct effect only; time horizon 100 years	GWP, including indirect effects; time horizon 100 years
CH_4	18	28
CO	0	3
Non-methane volatile organic compounds (NMVOC)	0	8
Chlorofluorocarbon (CFC) 11	4,800	3,300
Chlorofluorocarbon (CFC) 12	11,000	6,100
Chlorofluorocarbon (CFC) 113	6,200	4,700
CF_4	6,100	6,100
CO_2	1	1

Table 3 Global warming potentials in CO_2eq for a number of gases

Gas/global warming potential	GWP assuming 70 % removal from atmosphere (direct effect only) (Sekiya and Omamoto 2010)	GWP as in Table 1 with a time horizon of 100 years as calculated by IPCC (Myrhe et al. 2013)
CH_4	10.6	34
Chlorofluorocarbon (CFC) 11	2,249	5,350
CF4	1,560,558	7,350
CO_2	1	1

One may note that Brakkee et al. (2008) give an estimate for the GWP of CH_4 (direct effect only), which is different from the value in Table 1.

Still another possibility is to calculate GWPs on the basis of a similar percentage of greenhouse gas remaining in, or lost from, the atmosphere. This is exemplified by Table 3, with values as calculated by Sekiya and Okamoto (2010).

In the case of life cycle assessment of greenhouse gas emissions, calculating the emission in terms of CO_2eq is where the impact assessment stage often ends, though there is also the option to quantify the impact in terms of damage to public

health (e.g., Haines et al. 2009), human health, and ecosystems (De Schryver et al. 2009) and in terms of negative effects on the economy (e.g., Stern 2006). Such damage-based characterizations facilitate weighing of trade-offs and co-benefits, when a variety of environmental impacts (cf. Box 1) are included in life cycle assessment.

Having CO_2eq emissions as an outcome of life cycle assessment is often sufficient to guide the selection of product life cycle options, policies, and innovations aimed at mitigation of climate change, because the emission of greenhouse gases is in a first approximation directly causally linked with environmental impact (climate change).

Still, it should be noted that the temporal pattern of greenhouse emissions may affect the rate of climate change, which in turn is, e.g., a major determinant of impact on ecosystems. When the temporal pattern of the emissions is important, as, for instance, in the case of land use change or capital investments in production systems, it is possible to adapt life cycle assessment by including the estimated temporal pattern of greenhouse gas emissions linked to the object of life cycle assessment (cf. Reijnders and Huijbregts 2003; Kendall et al. 2009).

Also, one may note that effect of activities on climate may go beyond the emission of greenhouse gases. For instance, agricultural activities may change albedo, evaporation, and wind speed, which may in turn affect climate (Reijnders and Huijbregts 2009). Also, the greenhouse effect of air traffic may be different than expected solely on the basis of CO_2, N_2O, and CH_4 emissions, because air traffic triggers formation of contrails and cirrus clouds (Lee et al. 2010a).

A direct causal link between emission and impact for greenhouse gas emissions may be at variance with other environmental impact categories. For instance, lead emissions which do not lead to exceeding a no-effect level for exposure of organisms will have no direct environmental impact. Also, specificity as to time and place can be very important for other impacts than climate change caused by greenhouse gases, such as the impacts of the emissions of hazardous and acidifying substances (Schöpp et al. 1998; Hellweg et al. 2005; Pottimg and Hauschild 2005; Basset-Mens et al. 2006). It may be noted, however, that in such cases time and place specificity may be introduced by adaptation of life cycle assessment or combining life cycle assessment with other tools (e.g., Hellweg et al. 2005; Huijbregts et al. 2000; Rehr et al. 2010).

Interpretation

The *interpretation* stage connects the outcome of the impact assessment to the real world.

Much of the practical usefulness of life cycle assessments of greenhouse gas emissions in this respect depends upon the uncertainty of outcomes, which has a variety of sources (e.g., Finnveden et al. 2009; Huijbregts et al. 2001, 2003; Geisler et al. 2005; De Koning et al. 2010; Williams et al. 2009). These can be categorized as uncertainties due to choices, uncertainties due to modeling, and parameter

uncertainty (Huijbregts et al. 2001, 2003). Parameter uncertainty and uncertainty due to choice (e.g., regarding time horizon, type of allocation, system boundaries, and functional unit) would seem to be the most important types of uncertainty in the case of estimating life cycle greenhouse gas emissions.

Uncertainty in the outcomes of life cycle assessments of greenhouse gas emissions partly depends on the reliability of input data (categorized as parameter uncertainty). As pointed out above, databases regarding fossil fuel use in industrialized countries such as the USA, China, and Japan and EU countries allow for substantial uncertainties in this respect (Sann et al. 2006; Fruergaard et al. 2009). Similar data regarding other countries tend to be still more uncertain. Greenhouse gas emissions linked to land use, N_2O emissions, and animal husbandry are also characterized by a relatively large uncertainty (Reijnders and Huijbregts 2009; Röös et al. 2010).

Additional variability in outcomes of life cycle assessments of greenhouse gas emissions may originate in different choices regarding system boundaries. This has, for instance, been shown by Christensen et al. (2009) and Gandreault et al. (2010), who analyzed life cycle greenhouse gas emissions of forestry products. They found that different assumptions about the boundary to the forestry industry and interactions between the forestry industry on one hand and on the other hand the energy industry and the recycled paper market might lead to substantial differences in outcomes of life cycle assessments. Choices regarding time horizons and the allocation of greenhouse gas emissions to outputs in multi-output processes may also have major consequences for such outcomes (Reijnders and Huijbregts 2009).

Sensitivity analysis may be part of the *interpretation* stage and, for instance, consider the dependence on different assumptions regarding allocation and time horizon. Similarly, uncertainty analysis may be part of the *interpretation* stage. Several approaches to uncertainty analysis have been proposed, using Monte Carlo techniques (Huijbregts et al. 2003; Hertwich et al. 2000), matrix perturbation (Heijungs and Suh 2002), or Taylor series expansion (Hong et al. 2010). In practice, uncertainty analysis has been applied in a limited way.

Also, in the interpretation stage, conclusions can be drawn. For instance, stages or elements of the product life cycle can be identified, which are linked to relatively high greenhouse gas emissions. These can be prioritized for emission reduction options and policies. Also, it may be established that, given a functional unit and specified assumptions, one product has lower greenhouse gas emissions (in CO_2eq) than another. Examples of conclusions which can be drawn from life cycle assessments are given in section "Main Findings from Life Cycle Studies of Greenhouse Gas Emissions."

Though life cycle assessment has been developed for products, in practice the methodology has been applied more widely (cf. "Published Life Cycle Assessments"). To the extent that life cycle assessment methodology, which does not focus on products, essentially assesses parts of product life cycles (e.g., the nickel industry, waste incineration, and CO_2 capture and sequestration), the usefulness of assessment may be similar to the assessment of products: one may find, prioritize, and validate emission reduction options.

Some of the applications of life cycle assessments, which go beyond products, give rise to additional problems. For instance, applying life cycle assessments to state economies and trade may give rise to double counting of emissions (Lenzen 2008). On the other hand, e.g., expansion of life cycle assessments to trade between states may give useful insights about the actual environmental impacts of imports and exports. This is a useful addition to climate regimes such as the Kyoto protocol, which focus on greenhouse gas emissions within state borders. Also, economy-wide LCAs may help in prioritizing product categories or economic sectors for policy development (Jansen and Thollier 2006).

Life Cycle Assessments Focusing on Greenhouse Gas Emissions or a Part Thereof

The emergence of climate change as a major environmental concern has led to a rapid increase in life cycle assessments focusing on the emission of greenhouse gases. However, it should be pointed out that there are also life cycle assessments which cover only a part of the greenhouse gases. In this context, one may note the growing popularity of "carbon footprinting" (e.g., De Koning et al. 2010; Barber 2009; Johnson 2008; Weber and Matthews 2008; Schmidt 2009). There is no generally agreed upon definition of carbon footprinting. In practice, the focus of carbon footprinting is often on the emission of carbonaceous greenhouse gases, if the footprinting is not being "slimlined" to covering CO_2 only (e.g., Schmidt 2009). Also, there is an increasing interest in life cycle assessments focusing on the cumulative input of fossil fuels, which in turn is closely related to the life cycle emission of the major greenhouse gas CO_2 (Laurent et al. 2010; Nishioka et al. 2006).

The focus on carbonaceous greenhouse gases may lead to outcomes which substantially deviate from overall greenhouse gas emissions. As several authors (Crutzen et al. 2007; Reijnders and Huijbregts 2009; Laurent et al. 2010; Nishioka et al. 2006) have pointed out, cumulative energy demand may be substantially at variance with overall environmental performance and life cycle emissions of greenhouse gases, in the case of agricultural commodities and in other cases in which life cycles impact land use. The same will hold in the case of a number of compounds, such as adipic acid, caprolactam, and nitric acid, when syntheses are used which generate N_2O in a poorly controlled way (Fehnann 2000; Perez-Ramirez et al. 2003). Also, there can be a major divergence of "carbon footprinting" from overall life cycle greenhouse gas emissions when there are substantial emissions of halogenated greenhouse gases. The latter, e.g., applies to the case of halogenated refrigerant use (Ciantar and Hadfield 2000), the use of halogenated blowing agents for the production of insulation (Johnson 2004), to primary aluminum production, which is associated with the emission of potent fluorinated greenhouse gases such as CF_4 (Fehnann 2000; Weston 1996), and to circuit breakers using SF_6 and magnesium foundries (Fehnann 2000; Harrison et al. 2010). In the following, only assessments will be used which give an estimate of all greenhouse gas emissions, recalculated as CO_2eq emissions.

Simplified Life Cycle Assessments

Full life cycle assessments require extensive data acquisition, which tends to be laborious and time-consuming, and this may well be beyond what practice in industry and policy requires (Bala et al. 2010). This has led to the emergence of simplified tools for the life cycle assessment of greenhouse gas emissions, such as screening LCAs. These tend to focus on major causes of life cycle greenhouse gas emissions ("hotspots") and are often useful in identifying and prioritizing emission reduction options (Andersson et al. 1998; Rehbitzer and Buxmann 2005).

Published Life Cycle Assessments

A wide variety of products has been the object of life cycle assessments of greenhouse gas emissions. Examples range from teddy bears to power generators, from pesticides to motorcars, from tomato ketchup to buildings, and from a cup of coffee to tablet e-newspapers. Products have not been the only objects of life cycle assessments of greenhouse gas emissions. Life cycle assessment has also been used for state economies, trade between countries, branches of industry, industrial symbiosis, aspects of production and product technologies, networks, soil and groundwater remediation, and waste management options, including CO_2 capture and sequestration.

Main Findings from Life Cycle Studies of Greenhouse Gas Emissions

Though, as pointed out in section "Goal and Scope Definition," there are substantial uncertainties in assessments of life cycle greenhouse gas emissions, some outcomes of such assessments are robust to such an extent that they provide a sufficiently firm basis for conclusions. The latter are summarized here, assuming a time horizon of 100 years, using the values for global warming potentials as given by IPCC (Myrhe et al. 2013) (see Table 1), and focusing on direct effects only, unless indicated otherwise. After this summary, options for life cycle greenhouse gas emission reduction which commonly emerge from life cycle assessments will be briefly discussed.

Energy Conversion Efficiency

Improvements in efficiency of the conversion of primary energy to energy services, including reduction of heat loss, often lead to lower life cycle greenhouse gas emissions for energy services (e.g., Erlandsson et al. 1997; Citherlet et al. 2000; Nakamura and Kondo 2006; Citherlet and Defaux 2007;

Boyd et al. 2009) when only direct effects are considered. There are some exceptions. Phase change materials, which may be used in buildings to improve energy conversion efficiency, have been shown to not significantly reduce the life cycle greenhouse gas emission of buildings in a Mediterranean climate (De Gracia et al. 2010). Electric heat pumps, though generally giving rise to lower life cycle greenhouse gas emissions for space heating, may increase life cycle greenhouse gas emissions when electricity generation is coal based (Saner et al. 2010). Also, the III/V solar cells, which contain, e.g., In (indium) and Ga (gallium) and have higher conversion efficiencies for solar energy into electricity than Si (silicium)-based photovoltaic cells, do not appear to have lower life cycle greenhouse gas emissions per kWh than multicrystalline Si solar cells (Mohr et al. 2009).

Noteworthy is the potential for indirect effects linked to improvements of energy efficiency. As noted before: in the case that improvements in energy conversion lead to lower costs of ownership, there may be a rebound effect on energy use because money linked to such lower costs tends to be spend on increased use of the product or elsewhere, which in turn entails additional energy consumption and emission of greenhouse gases (Schipper and Grubb 2000; Thiesen et al. 2008; Greene 2011). Lower costs may also be conducive to economic growth (Thiesen et al. 2008). When only microeconomic effects of improved energy efficiency are considered, life cycle greenhouse gas emissions tend to be still lowered, though less so than when only the effect of energy efficiency by itself is considered (Schipper and Grubb 2000; Greene 2011). Including economy-wide rebound effects in life cycle assessments of improved energy conversion efficiency has as yet no firm empirical basis (Thiesen et al. 2008).

Products Consuming Energy

Life cycle greenhouse gas emissions of products which consume energy are often dominated by emissions during the use stage of the life cycle, when shares of fossil fuels in the production and consumption stages are similar (Nakamura and Kondo 2006; Boyd et al. 2009, 2010; Finkbeiner et al. 2006; Kofoworola and Gheewala 2008; Yung et al. 2008; Cullen and Allwood 2009; Duan et al. 2009; Ortiz et al. 2010; Rossello-Batle et al. 2010). There are exceptions, however, such as, for instance, a personal computer for limited household use (Choi et al. 2006), mobile phones (Andrae and Andersen 2010), and very energy-efficient dwellings (Citherlet and Defaux 2007). The latter illustrates a more general point. To the extent that energy conversion efficiency in the use stage improves, energy embodied in the product (e.g., Kakudate et al. 2002; Blengini and di Carlo 2010) and in the case of transport also energy embodied in infrastructure (e.g., Frederici et al. 2009) often become a more important factor in life cycle greenhouse gas emissions. It may be noted, though, that there are exceptions as to the growing importance of energy embodied in the product, such as CMOS chips for personal computers and other electronics (Boyd et al. 2009, 2010).

Transport

At continental distances in the order of <500 km, where train transport and air transport can be competitors, train transport tends to be associated with relatively low life cycle greenhouse gas emissions per person kilometer when occupancy rates are high (Chester and Horvath 2010; Blengini and di Carlo 2010; Frederici et al. 2009).

In freight transport, ships tend to do relatively well per ton kilometer regarding life cycle greenhouse gas emissions if compared with truck transport (Chapman 2007). Ceteris paribus, the diesel personal car has a lower life cycle greenhouse gas emission than the gasoline-powered car, whereas lighter cars tend to have lower greenhouse gas emissions than heavier cars, even when highly energy-intensive materials such as aluminum are used for weight reduction (Kakudate et al. 2002; Spielman and Althaus 2007; Bertram et al. 2009). The electric car might do better as to life cycle greenhouse gas emissions than the conventional car, unless electricity supply is heavily dependent on coal (Granovskii et al. 2006).

Conventional and Unconventional Fossil Fuels

Among current fossil fuels, the life cycles of conventional natural gas tend to give rise to the lowest greenhouse gas emissions and lignite to the highest. Burning (hard) coal leads to somewhat lower life cycle greenhouse gas emissions than burning lignite, whereas the life cycle emissions for burning conventional mineral oil and its derivative fuels tend to be between those of conventional natural gas and coal. Fuels derived from fossil carbonaceous stocks remaining beyond the peaks of conventional natural gas and conventional mineral oil supply are likely to be associated with higher life cycle greenhouse gas emissions than current conventional gas and mineral oil-derived fuels, with greenhouse gas emissions for tight gas and shale gas dependent on methane leakage from casing and cement impairment and soil layers subject to fracking (Ingraffea et al. 2014; Lave et al. 2000; Petron et al. 2012; Jaramillo et al. 2009; Reijnders 2009a).

Green Energy Supply

Among the options for expanding "green energy supply," solar boilers; solar cells; solar-assisted heating, ventilating, and air conditioning (HVAC) systems; marine current turbines; and wind turbines do relatively well if compared with fossil fuel-based alternatives (Mohr et al. 2009; Jorquera et al. 2010; Rebitzer et al. 2004; Schipper and Grubb 2000; Thiesen et al. 2008; Greene 2011; Sathre and O'Connor 2010; Finnveden et al. 2009; Gandreault et al. 2010; Frischknecht et al. 2005; Gong et al. 2008; Narita et al. 2004; ELCD 2008; Tukker et al. 2006; De Eicker et al. 2010; Fruergaard et al. 2009; Weber et al. 2010; Huijbregts et al. 2000, 2001, 2003, 2006, 2010; Laurent et al. 2010; Nishioka et al. 2006; Haines et al. 2009;

Markandya et al. 2009; Chester and Horvath 2010; Walmsley and Godbold 2010; Demou et al. 2009; Hellweg et al. 2005, 2009; Koellner and de Baan 2013; Boulay et al. 2011; Verones et al. 2013; Munoz et al. 2010; IPPC Working Group I 2013; Brehmer et al. 2009; Sayagh et al. 2009; Myrhe et al. 2013; Brakkee et al. 2008; Sekiya and Omamoto 2010; De Schryver et al. 2009; Stern 2006; Reijnders and Huijbregts 2003; Kendall et al. 2009; Lee et al. 2010a, b; Schöpp et al. 1998; Pottimg and Hauschild 2005; Basset-Mens et al. 2006; Rehr et al. 2010; Geisler et al. 2005; De Koning et al. 2010; Williams et al. 2009; Röös et al. 2010; Christensen et al. 2009; Hertwich et al. 2000; Heijungs and Suh 2002; Hong et al. 2010; Lenzen 2008; Jansen and Thollier 2006; Barber 2009; Johnson 2004, 2008; Weber and Matthews 2008; Schmidt 2009; Fehnann 2000; Perez-Ramirez et al. 2003; Ciantar and Hadfield 2000; Weston 1996; Harrison et al. 2010; Bala et al. 2010; Andersson et al. 1998; Rehbitzer and Buxmann 2005; Erlandsson et al. 1997; Citherlet et al. 2000; Nakamura and Kondo 2006; Citherlet and Defaux 2007; Boyd et al. 2009, 2010; De Gracia et al. 2010; Saner et al. 2010; Finkbeiner et al. 2006; Kofoworola and Gheewala 2008; Yung et al. 2008; Cullen and Allwood 2009; Duan et al. 2009; Ortiz et al. 2010; Rossello-Batle et al. 2010; Choi et al. 2006; Andrae and Andersen 2010; Kakudate et al. 2002; Blengini and di Carlo 2010; Frederici et al. 2009; Chapman 2007; Spielman and Althaus 2007; Bertram et al. 2009; Granovskii et al. 2006; Ingraffea et al. 2014; Lave et al. 2000; Petron et al. 2012; Jaramillo et al. 2009; Reijnders 2009a; Martinez et al. 2009; Ardente et al. 2005; Douglas et al. 2008; Nugent and Sovakool 2014; Batlles et al. 2010). When intermittent forms of energy supply increase their share in energy supply, energy storage systems may be needed. These have also been evaluated regarding their life cycle greenhouse gas emissions (e.g., Lee et al. 2010b; Froese et al. 2010). It would seem that energy storage systems do not invalidate the climate benefits from the intermittent energy supply options considered here. Greenhouse gas emissions of hydropower facilities strongly depend on submerged carbon stocks and their anaerobic conversion, and low greenhouse gas emissions are correlated by low land use per unit of electricity generated (Hertwich 2013).

Biofuels

Greenhouse gas emissions associated with the life cycle of biofuels vary widely, dependent on fossil fuel inputs, changes in soil and aboveground carbon stocks, and N_2O emissions (Reijnders and Huijbregts 2009; Kloverpris et al. 2010). Burning woody residues from forests with (at least) constant carbon stocks in power plants tend to do relatively well in this respect, if compared with its main fossil fuel-based competitor: burning coal (Reijnders and Huijbregts 2009; Zhang et al. 2010; Denholm and Kulcinski 2004). However, with a few exceptions such as ethanol from sugarcane in the Brazilian Cerrado region, current liquid biofuels from crops which compete with food crops for good soils compare unfavorably with conventional gasoline and diesel when indirect effects on land use are included, when

biofuel production expands rapidly and when allocation of life cycle emissions is on the basis of monetary value of outputs (Searchinger et al. 2008; Reijnders and Huijbregts 2009; Hertel et al. 2010). Such liquid biofuels would have much lower life cycle greenhouse gas emissions when the crops from which they are derived would be grown on abandoned agricultural soils which have sequestered little carbon, but use of such abandoned soils is unattractive under market conditions (Reijnders and Huijbregts 2009). Still, a policy decision restricting feedstock generation for biofuels to abandoned soils which have sequestered little carbon would lead to life cycle greenhouse gas emissions for liquid biofuels that will usually be lower than those linked to fossil fuels.

A relatively poor performance will probably also apply to the life cycle greenhouse gas emissions linked to methane for injection into the gas grid originating in the anaerobic conversion of energy crops in temperate climates if compared (fossil) with natural gas. The reason for this is that, without taking into consideration the indirect effect of expanding the cultivation of energy crops on land use, the life cycle emission of (cleaned-up) biogas is only slightly lower than the corresponding emission of natural gas (Jury et al. 2010). Fossil fuel inputs to achieve an elevated optimum temperature are an important contributor to the relatively poor performance of anaerobic conversion in temperate climates (Jury et al. 2010). In warmer climates, anaerobic conversion may well do better. Microbial fuel cells producing electricity have been reported to have a lifetime environmental performance and a life cycle CO_2 emission, similar to anaerobic conversion (Foley et al. 2010).

The actual greenhouse gas emissions linked to the life cycle of future biofuels, such as ethanol, produced from lignocellulosic crops and algal biodiesel are highly uncertain. Relatively poor yields and/or high fossil fuel inputs, which are characteristic for current lignocellulosic ethanol and algal biodiesel production technology, are associated with relatively high life cycle greenhouse gas emissions (Reijnders and Huijbregts 2009; Havlik et al. 2011; Reijnders 2010). Predictions of relatively low life cycle greenhouse gas emissions in the future are typically linked to large increases in biofuel yield and reductions in fossil fuel input (e.g., Jorquera et al. 2010; Spatari et al. 2010), to the use of abandoned soils for lignocellulosic crops (Havlik et al. 2011; Reijnders 2010), or, in the case of algae, the use of "wastes" conducive to growth (Clarens et al. 2010; Reijnders 2013). In the latter case, it is assumed that there is no allocation to the wastes of greenhouse gas emissions associated with the process from which they are derived. Ultimately, life cycle greenhouse gas emissions associated with liquid biofuels produced from part of the lignocellulosic harvest residues from no-till agriculture may be more favorable than the use of mineral oil-derived products (Reijnders and Huijbregts 2009; Spatari et al. 2010).

Food

Food consumption by relatively rich people in industrialized countries is often linked to a higher life cycle greenhouse gas emission than food consumption by relatively poor people (e.g., Weber and Matthews 2008). However, food consumption by (poor)

swidden ("slash-and-burn") agriculturalists practicing short fallow periods may be associated with relatively high life cycle greenhouse gas emissions, as it is linked with a large reduction of the carbon stock in agroecosystems (Reijnders 2006; Bruun et al. 2009). Diets do matter: plant protein-based foods tend to have lower life cycle greenhouse gas emissions than meat, and the same tends to hold for vegetarian diets versus diets with much produce for animal husbandry, unless vegetarian foods are frozen, flown in by airplanes, or produced in greenhouses intensively heated by fossil fuels (Weber and Matthews 2008; Reijnders and Soret 2003; Carlsson-Kanyama and Gonzalez 2009). One kilogram of beef protein is usually linked to greater life cycle greenhouse gas emissions than 1 kg chicken or pork protein (Carlsson-Kanyama and Gonzalez 2009; De Vries and de Boer 2010; Gössling et al. 2010). Per unit of food energy, pelagic fishes (e.g., mackerel, herring) tend to be associated with lower life cycle greenhouse gas emissions linked to fossil fuel use than deep-sea fishes (e.g., cod), shrimps, or lobster (Gössling et al. 2010).

Per unit of cereal-based food energy, rice is on average associated with relatively high greenhouse gas emissions, if compared with wheat and rye. A major cause thereof is the relatively high CH_4 emission during rice cultivation (Gössling et al. 2010). When transport distances are similar, produce from greenhouses seems on average linked with higher greenhouse gas emissions per unit of food energy than cultivation in the open field (Gössling et al. 2010). Canning and commercial freezing for food conservation do much increase the life cycle greenhouse gas emissions of foods (Reijnders and Soret 2003; Iribarren et al. 2010).

Current expansion of arable land for food production is linked with high greenhouse gas emissions because it mainly replaces forests and wooded lands with much larger carbon stocks than arable land (Reijnders and Huijbregts 2009; Hertel et al. 2010).

Chemicals

Complex "fine chemicals" synthesized in a relatively large number of "steps" tend to be associated with relatively high life cycle greenhouse gas emissions per kg (Wernet et al. 2010). A study comparing a range of synthetic chemicals with biobased equivalents (Weiss et al. 2012) suggested lower greenhouse gas emissions for biobased substances excepting acetic acid. Changes in ecosystem carbon stocks were not included, but the conclusion that biobased caprolactam does better than its synthetic equivalent seems robust.

Polymeric Materials

In a number of cases, it is possible to replace the plastic PVC by other materials, having a lower life cycle greenhouse gas emission (Kleijn et al. 2008). However, large-scale substitution of PVC might have indirect effects, originating in impacts on caustic soda production, which might lead to a net increase of greenhouse gas

emissions (Kleijn et al. 2008). LCA studies (van der Velden et al. 2014) suggest that when polymeric textiles are compared, acryl and polyester do relatively well if compared with cotton and nylon. The bioplastic PLA and PHB derived from starch crops, such as corn, by current technology (Searchinger et al. 2008; Khoo et al. 2010; Kim and Dale 2008; Tabone et al. 2010), and the production of PHB by genetically modified plants (Kurdikar et al. 2000) might well do worse than their petrochemical competitors, when indirect effects and land use are included and non-food applications of starch crops rapidly expand. This may be changed by future changes in bioplastic production.

Using sugarcane bagasse fibers instead of talc to reinforce polypropylene composites was found to lower life cycle greenhouse gas emissions (Luz et al. 2010).

Crop-Based Lubricants and Solvents

There is marketing of crop-based lubricant oils and solvents for general purpose cleaning (Curran 2003). There are few LCAs of such products (Curran 2003). These do not take account of direct and indirect changes in ecosystem carbon sequestration linked to crop cultivation. To the extent that LCA studies of crop-based lubricants and solvents are available (Curran 2003), it would seem unlikely that such lubricant oils and solvents are better than their fossil fuel-based competitors regarding life cycle greenhouse gas emissions. They may, however, have other benefits, such as reduced dependence on mineral oil or lower toxicity.

Recycling

Provided that transport distances and inputs in recycling and remanufacturing processes remain modest, product reuse, remanufacturing, and recycling of materials used in products tend to be associated with lower life cycle greenhouse gas emissions than the use of virgin virtually nonrenewable resources (such as metal ores and fossil carbon) (e.g., Björklund and Finnveden 2005; Lankey and McMichael 2000; Nakinawa and Graedel 2002; Rydh and Karlström 2002; Huang et al. 2009). Supposed that the same provision regarding modest transport distances and inputs in recycling holds, recycling can also be associated with relatively low greenhouse gas emissions in the case of renewable resources such as wood (Björklund and Finnveden 2005; Hoglmeier et al. 2014). Use of recycled concrete does well regarding greenhouse gas emissions (Wu et al. 2014).

Nanotechnology

Outcomes of LCAs regarding engineered nanomaterials tend to be uncertain but suggest that the alleged advantage of nanotechnology ("less is better") does not necessarily materialize (Kushnir and Sanden 2008; Meyer et al. 2009; Hischier and

Walser 2012). This can be traced back to factors such as limited durability and efficiency, relatively high inputs in producing nanoparticulate materials, and relatively low recyclability (Kushnir and Sanden 2008; Meyer et al. 2009; Hischier and Walser 2012). Further maturing and upscaling of nanotechnology may improve the outcomes of LCAs regarding greenhouse gas emissions.

Reduction of Life Cycle Greenhouse Gas Emissions

In previous sections, the use of life cycle assessments in the reduction of life cycle greenhouse gas emissions has already been briefly referred to. In practice, life cycle assessments are often used in identifying elements of the life cycle, which are linked to relatively high greenhouse gas emissions. Also, life cycle assessments can be used to evaluate the impact of improvement options on life cycle greenhouse gas emissions. There is some evidence that communicating about programs for the reduction of product-related life cycle greenhouse gas emissions does provide a better fit to consumer perceptions than expecting producers to choose between products on the basis of the lowest life cycle greenhouse gas emissions (Upham et al. 2010).

Elements which are often included in programs for the reduction of product-related life cycle greenhouse gas emissions are briefly summarized in Box 2.

Many of these elements mentioned in Box 2 are uncontroversial and often also serve the reduction of other environmental problems, but some may give rise to discussion about the net benefit, including the reduction of life cycle greenhouse gas emissions. Controversies about the use of "biobased" products, such as biofuels, have been referred to earlier in this section. There is also controversy about the net effect of climate compensation. For instance, planting trees has been argued to not properly provide climate compensation for the use of fossil fuels, because the lifetime of trees is limited, if compared with the 30,000–35,000 years needed for the complete removal of CO_2 emitted by burning fossil fuels, because ongoing existence of forests over this period cannot be guaranteed and because tree planting projects often give rise to "leakage": land use changes in which trees are cut (Reijnders 2009b).

Box 2: Elements That Are Often Included in Programs for the Reduction of Product-Related Life Cycle Greenhouse Gas Emissions

- Reduced life cycle fossil energy use
- Use of energy supply with low greenhouse gas emissions per joule
- Reduction of land use change
- Lower non-energy inputs in production
- Lowering non-product outputs ("wastes" and emissions) of production processes, especially emissions with a relatively large "greenhouse effect" (e.g., of halogenated compounds, CH_4, N_2O)
- Dematerialization of products

(continued)

- Increased recycling
- Reduced "downstream" greenhouse gas emissions linked to improved energy efficiency, e.g., using means of transport that have relatively low greenhouse gas emissions per ton kilometer, by increasing electronic retailing, or improving energy efficiency of products which consume energy
- Reduction of transport distances, more efficient logistics
- Increased carbon sequestration and/or "climate compensation"

Future Directions

There is a growing societal interest in life cycle assessments of greenhouse gas emissions and related assessments, such as life cycle carbon footprinting (e.g., Fava et al. 2009). This seems to be paralleled by a trend to simplification (see, e.g., section "Simplified Life Cycle Assessments"). However, one should be aware that there are several methodological issues that have substantial relevance to the correspondence of the outcomes of life cycle assessments and impact on climate change in the real world. These issues will be briefly addressed. They are partly in the domain of those involved in methodology development and partly in the domain of those applying life cycle assessment.

Change in Carbon Stocks of Recent Biogenic Origin

Changes in carbon stocks of recent biogenic origin have turned out to be very important to life cycle greenhouse gas emissions of food and biofuels. However, their inclusion in life cycle assessments of food and biofuels is so far patchy. Also, one might expect such changes to be important in other "biobased" products, such as "bioplastics" and crop-based lubricants, solvents, and other chemicals. However, their inclusion of life cycle assessments of such products is rare. Buildings, roads, hydroelectric dams, and other infrastructural works might also be expected to impact carbon stocks of recent biogenic origin, but again their inclusion in life cycle assessments is very rare. Studies thoroughly evaluating impacts of changes in carbon stocks of recent biogenic origin on life cycle greenhouse emissions would be welcome. These might provide better knowledge regarding the cases that such changes have at least a substantial impact on life cycle greenhouse gas emissions.

Indirect Effects

Product life cycles may have indirect effects which are substantial when evaluating their life cycle greenhouse gas emissions. Indirect effects of biofuels on land use

change, linked to the inelasticity of demand for food and feed (see section "Published Life Cycle Assessments"), are a case in point. The same holds for the rebound effect linked to lowered costs by improved energy (see section "Published Life Cycle Assessments"). Relations between economic activities as reflected in input–output tables constructed by economists may also be important (Lifset and Anes 2009). A more thorough study and discussion of the question when which indirect effects should be within the system boundaries drawn for life cycle assessment would seem appropriate.

Uncertainty

As pointed out in section "Interpretation," there is substantial uncertainty regarding the outcome of life cycle assessments of greenhouse gas emissions, largely originating in parameter uncertainty and uncertainty due to choices. Transparency about the actual uncertainties regarding the outcome of life cycle assessments of greenhouse gas emissions is in practice very limited. Comprehensive uncertainty and sensitivity analyses are rare. However, it is important that societal stakeholders get at least a rough indication of the uncertainties in the outcomes of life cycle assessments presented to them.

Comprehensives of Dealing with Climate Warming

As noted in section "Inventory Analysis," a proposal has been made to include changes in albedo linked to land use change into life cycle assessment (Munoz et al. 2010). Also, there have been proposals for the quantitative inclusion of the climate effects linked to contrails and cirrus clouds in the climate impact estimates for air traffic (Lee et al. 2010a). However, there is still some way to go for a comprehensive coverage of climate warming in life cycle assessment. On a time scale of centuries, there are changes in albedo, which will probably contribute to further warming, following from climate change (e.g., due to loss of ice and desertification) (Hansen et al. 2008). These changes in albedo are as yet not covered by life cycle assessments. A contributor to climate change currently absent from life cycle assessment of climate impact is black carbon (carbonaceous aerosol, soot) (Highwood and Kinnersly 2006; McConnell et al. 2007; Ming et al. 2009; Andreae and Gelenesér 2006). Black carbon has a variety of effects which are relevant to climate (Highwood and Kinnersly 2006; McConnell et al. 2007; Ming et al. 2009; Andreae and Gelenesér 2006). When emitted, black carbon absorbs and scatters solar radiation and may affect humidity profiles (cloud formation) and droplet size in clouds. When deposited, black carbon may have an effect on surface albedo. It is currently estimated that the net effect of black carbon emissions on climate is warming (Andreae and Gelenesér 2006). For comprehensiveness in dealing with life cycle impacts on climate, it would seem proper to include both black carbon emissions and long-term changes in albedo in life cycle assessment.

Consequential Life Cycle Assessment

In mitigating climate change, changes in products and technologies are much more important than studies of existing products and technologies. Such changes are the object of consequential life cycle assessment. As pointed out in section "What is Life Cycle Assessment and How Does It Work?," consequential life cycle assessment is a relatively recent development. The methodological approach, such as constructing scenarios and technological trajectories, deserves substantial attention, if only to provide a more solid basis for more widespread application in the development of new products and technologies.

Concluding Remarks

Life cycle assessments of greenhouse gas emissions may be helpful in the analysis and development of options, policies, and innovations aimed at mitigation of climate change. The main findings from available life cycle assessments summarized in section "Main Findings from Life Cycle Studies of Greenhouse Gas Emissions" provide for guidance in that respect. It can be noted that in several cases, indirect effects have significant effects on the overall climate impact of products, and including those effects in considering options, policies and innovations aimed at mitigation of climate change would seem important.

For any product, or part of the product life cycle, life cycle assessment can be useful in identifying the aspects of production which are main contributors to life cycle greenhouse gas emissions. This can provide a focus for trying to identify or develop options which might reduce such emissions and for life cycle management. Furthermore, life cycle assessments may help in providing guidance for future research and development work, though it should be noted that such guidance may be characterized by relatively large uncertainties.

Abstract

This chapter discusses economic aspects of international efforts to curb the global warming threat. The first commitment period of the Kyoto Protocol expired in 2012, which has until then been the dominant climate agreement although competing – or allegedly complement – international climate protection schemes like the Asia-Pacific Partnership on Clean Development and Climate also existed. While as of 5 April 2011, the Asia-Pacific Partnership on Clean Development and Climate (APP) formally concluded its joint work, tangible preparations for a second commitment period of the Kyoto Protocol started at the climate conference in Montreal (comprising MOP and COP-11) in 2005. In Montreal, a new working group was established for the discussion of future commitments (after 2012). And at the COP-18 in Doha in 2012, an agreement on a second commitment period of the Kyoto Protocol for 2013–2020 could be reached.

In this chapter, we describe the main features of Kyoto and APP schemes and their failure to establish an efficient global climate protection regime, and we elaborate on the disincentives for countries to commit to efficient climate protection efforts in an international agreement. In doing so we also take into account the growing importance of adaptation to climate change in the international climate policy arena.

The situation in international negotiations on climate change mitigation faced by national governments is depicted in game theoretic settings, and private ancillary benefits of climate policy are identified to raise the likelihood for countries joining an international agreement. Yet, it remains quite disputable to which extent ancillary benefits can be an impetus for more action in international climate policy. Finally, after dedicating a large part of the chapter to agreements, like the Kyoto Protocol, stipulating abatement quantities, alternative schemes are presented which were coined "price ducks" since they influence the effective prices of climate protection. By manipulating prices, e.g., via an international carbon tax, incentives are generated for producing higher climate protection levels. Recently, the so-called matching schemes influencing effective prices of climate protection raised much attention in the scientific literature. Such schemes may attenuate free- or easy-rider incentives in international climate policy and may even induce a globally efficient climate protection level.

Introduction

Global environmental threats have gained much attention in the political as well as the scientific arena during recent decades. Among the most prominent examples of such environmental problems are climate change, the destruction of the ozone layer, the pollution of international waters, and the loss of biodiversity. These problems are likely to have an important impact on the quality of life on earth: "Traditionally, the next generation's well-being improves compared with that of preceding generations

as knowledge, capital, and other assets are passed down. If environmental deterioration continues to destroy the earth's assets, this tradition will end" (Sandler 1997, Preface). By the time the Brundtland Commission presented its report "Our Common Future" (WCED 1987) at the latest, the necessity to stop international environmental deterioration had become largely undisputed. Nevertheless, the way to achieve this is subject to an extremely controversial discussion.

A main cause of this dispute lies in the fact that, in contrast to local environmental problems, international challenges cannot be counteracted by regulations invented by a coercive central authority. Because of this lack of a coercive authority that can force sovereign nations to take protective actions, international environmental policy crucially depends on the decisions made by the individual countries. These decisions are unlikely to produce a globally efficient level of protection efforts, because countries have incentives to take an easy ride with respect to the protection of global commons like the atmospheric system.

International environmental problems have been regularly addressed by international negotiations aiming at agreements on protection efforts. With respect to climate change, the central global challenge to be addressed in this book chapter, the Framework Convention on Climate Change constituted an important a landmark in this respect. It was ultimately signed by more than 150 countries at the Rio "Earth Summit" in 1992. However, the convention only stipulates strategies for protecting the climate, as well as general principles; it does not specify targets for greenhouse gas emission reductions. The following meetings of the Conference of Parties (COP) to the Framework Convention on Climate Change were assigned to make decisions on specific obligations for climate protection.

Outstanding was the third meeting in Kyoto 1997 where the so-called "Kyoto Protocol" was agreed upon. The protocol stipulates that the parties included in Annex I to the Framework Convention (industrialized countries and European economies in transition) have to reduce their greenhouse gas emission levels within a specified time frame. At the COP-13 in Bali in 2007, a 2-year process was launched in order to already promote a post-Kyoto agreement (Gupta 2010).

As Edenhofer et al. (2010) point out: "achieving deep emission reductions requires a comprehensive global effort which includes both a complete change in the energy supply of industrialized countries and the establishment of low-carbon systems in developing countries and emerging markets – in essence, nothing short of a full-scale transformation towards a carbon-free economic system." Hence, international negotiations pursuing an efficient global agreement on climate change are an immense challenge.

This book chapter will describe past international efforts to curb the global warming threat, and it will also outline why the past efforts have failed to yield an efficient global climate protection scheme. Finally, "price ducks" are presented which are international policy regimes targeting the rise in international climate protection efforts by manipulating the effective prices of such efforts. These schemes represent an interesting alternative to "quantity ducks" like the Kyoto scheme which primarily focus on the agreement of greenhouse gas abatement quantities.

This chapter is organized as follows. In section "International Climate Policy," it provides an overview of past international agreements on climate change. It does not consider national agreements like the British Climate Change Agreements and largely disregards other national instruments like the British emission trading scheme, although it was launched even before the European Emissions Trading Scheme started. For a discussion of the British Climate Change Agreements, see, e.g., Glachant and de Muizon (2006) and Dijkstra and Rübbelke (2013), and for an analysis of the UK Emissions Trading Scheme, see, e.g., Smith and Swierzbinski (2007). Policies like carbon taxes, matching grants, or side payments are only discussed in an international context. In section "Why Efficient Climate Protection is so Difficult to Achieve," the public good properties of climate protection are outlined, and the conditions and interplays which lead to a suboptimal low level of climate protection efforts on a global scale are explained. Due to these conditions and interplays and the lack of a global coercive authority, the attainment of an efficient global agreement on climate change is a very difficult task. Alternative negotiation schemes, which differ from the Kyoto concept of negotiating emission-reduction quantities, are described. These schemes, the so-called price ducks, draw on manipulating prices in such a way that it becomes rational for the individual countries to raise their climate protection efforts up to a globally efficient level. Section "Future Directions" concludes.

International Climate Policy

Global Challenges

After the UN Conference on the Human Environment took place in Stockholm in 1972, research gradually found alarming facts about the development of the earth's state. One among the several hints of the deterioration of the earth's condition was given by the chemists Mario Molina and Sherwood Rowland from the University of California who published a scientific paper (Molina and Rowland 1974) in 1974 which stresses that the emission of chlorofluorocarbons (CFCs) might deplete the stratospheric ozone layer. CFCs are very stable artificially generated gases whose production is rather inexpensive. They were used as, e.g., propellants in spray cans, refrigerants in air-conditioning systems, and solvents in cleaning processes. Stratospheric ozone, which is indeed destroyed by CFCs, absorbs a large part of hostile ultraviolet radiation of the sun and thereby renders possible human life on earth. The depletion of stratospheric ozone causes the so-called ozone holes which are areas in the stratosphere where the concentration of ozone declines below 200 Dobson units and where damaging ultraviolet radiation can advance to a larger extent toward the earth's surface. Among the negative impacts of the penetration of short-wave ultraviolet radiation is the more frequent occurrence of skin cancer and eye impairments.

The problem of the ozone layer depletion was already addressed in 1987, when the Montreal Protocol was opened for signature. In the Montreal Protocol, which

entered into force in 1989, and its amendments, reductions and bans of CFCs were agreed upon on an international level. These international environmental agreements have been the first in whose negotiation process multinational companies (like the globally largest producer of CFCs in 1988, i.e., Du Pont) have been involved (Smith 1998, p. 557). The international efforts to curb CFC emissions were complemented by a reinforcement of the CFC-producing companies' efforts in researching and developing environmentally friendly substitutes for CFCs.

While the problem of ozone layer depletion is largely regarded to be solved, there are many other international environmental problems which are still threatening the earth. These threats have been addressed by the United Nations Conference on Environment and Development (UNCED) which took place in Rio de Janeiro, Brazil, on June 2–14, 1992. Five major agreements are associated with this conference: (1) Rio Declaration on Environment and Development, (2) Agenda 21, (3) Statement of Principles for the Sustainable Management of Forests, (4) United Nations Convention on Biological Diversity, and (5) United Nations Framework Convention on Climate Change.

The Rio Declaration on Environment and Development contains a set of 27 legally nonbinding principles which are designed to commit governments to ensure environmental protection and responsible development. The Agenda 21 is an international plan of action to sustainable development which outlines key policies for achieving sustainable development that meets the needs of the poor and recognizes the limits of development to meet global needs. The Statement of Forest Principles is the first global agreement concerning sustainability of forest management, and the United Nations Convention on Biological Diversity stipulates the aims of the conservation of biological diversity, the sustainable use of its components, and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources.

Since the United Nations Framework Convention on Climate Change (UNFCCC) is the document of the UNCED which is most important for the analysis in this chapter, the UNFCCC and its offspring agreement, i.e., the Kyoto Protocol, will be discussed in more detail.

The UNFCC and the Kyoto Protocol

The United Nations Framework Convention on Climate Change stipulates general strategies for protecting the climate as well as general principles, but it does not specify concrete targets for greenhouse gas emission reductions. The following meetings of the Conference of Parties to the Framework Convention on Climate Change were assigned to make decisions on specific obligations for climate protection. At the third meeting in Kyoto 1997, the so-called "Kyoto Protocol" was agreed upon. The protocol stipulates that the parties included in Annex I to the Framework Convention (industrialized countries and European economies in transition) have to reduce their greenhouse gas emission levels within a specified time frame. The EU-15, for example, has agreed to cut its emissions by 8 % between 1990 and

2008–12, but reduction obligations vary among individual EU countries as well as among Annex-I parties in general (as stipulated in Annex B to the protocol). The EU-15 has agreed to share the burden of its overall Kyoto target as depicted in Fig. 1 (the so-called burden sharing agreement).

If the sub-targets of the individual countries are compared with the GDP per capita in these countries in 1998 (see Fig. 2), when the burden sharing was negotiated, it is conspicuous that the poorest countries (Spain, Portugal, and Greece) have

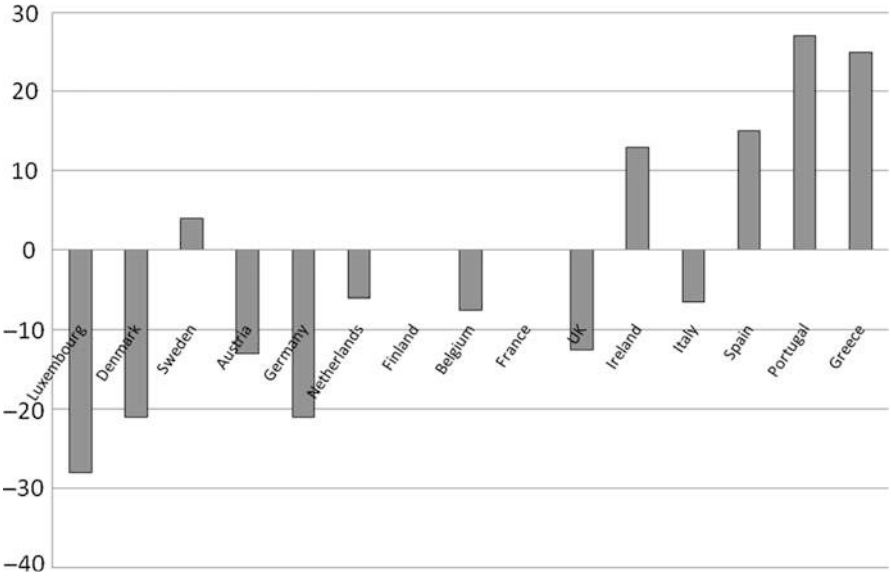

Fig. 1 National commitments under the EU burden sharing agreement in percentage change of GHG emissions between 1990 and 2008–12

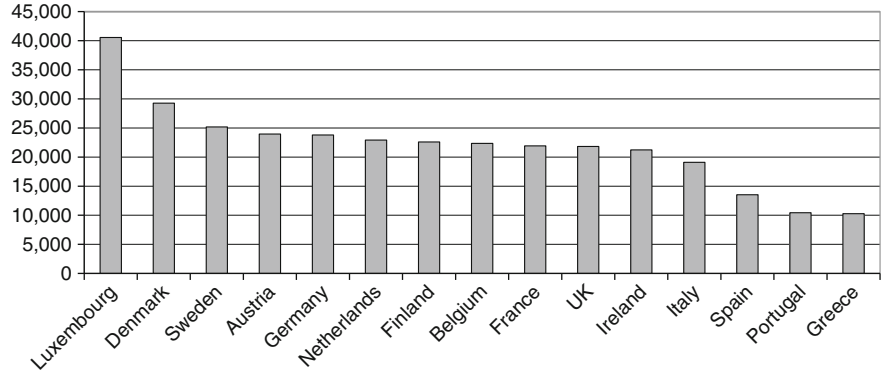

Fig. 2 GDP per capita in the EU-15 in 1998 (data from Eurostat 2006) in Euro

the largest tolerance for emission changes. And indeed the political decision about reduction loads within the EU-15 was made taking into account different country-specific characteristics among which was the economic development of the individual EU countries: "The −8 % target for the EU as a whole has been shared out amongst Member States so as to allow for different economic development patterns" (EC 2000, p. 2). Dessai and Michaelowa (2001), p. 329, point out regarding the climate policy process at the EU level that it tends to prefer less-stringent emission targets for countries *with lower per capita income*.

The aim was for the overall emissions of the Annex-I parties to be at least 5.2 % below the 1990 levels in the commitment period 2008–2012. However, for the protocol to come into effect, at least 55 parties had to sign it. Among these, there had to be Annex-I countries that together account for at least 55 % of the 1990 CO_2 emissions of the whole group of Annex-I parties. At the sixth session of the Conference of Parties in Bonn 2001, most industrialized countries, not the USA though, agreed upon the ratification of an undermined version of the protocol which then entered into force on 16 February 2005.

The Kyoto Protocol limits emissions of the greenhouse gases carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF6). Of these gases, CO_2 is the most important contributor to climate change. Estimates of its contribution to the anthropogenic greenhouse effect vary, however, widely, predominantly in the range of 50–80 %. Since CO_2 represents the most important greenhouse gas, environmental policies that induce reductions of CO_2 emissions and concentrations are attractive means for mitigating climate change. Therefore, the main focus in this chapter will be on these policies. Regarding the properties of greenhouse gases (illustrated for the examples of carbon dioxide, methane, and nitrous oxides) and the determinants of their importance to climate change, see the short overview in Box 1.

Anthropogenic CO_2 emissions are – except for emissions by deforestation and to a lower extent by cement production – almost entirely generated by the burning of fossil fuels. With it, many other pollutants like sulfur dioxide (SO_2) and nitrogen oxides (NO_X) are emitted. In contrast to the local/regional pollutants SO_2 and NO_2, the emissions of CO_2 can still not be removed from post-combustion exhaust in a cost-effective way. Thus major remaining reasonable approaches to mitigate CO_2 concentrations are the reduction of the combustion of substances or the shift to fuels or energies with lower CO_2 content. Sequestration of carbon is another option. As Lal (2004) explains, soil carbon sequestration is not only an option for mitigating climate change, but it is also a strategy to achieve food security through improvement in soil quality.

Box 1: Greenhouse Gases and their Contribution to Climate Change

The gas mainly responsible for the anthropogenic greenhouse effect is CO_2. Other pollutants contributing to the anthropogenic greenhouse effect are

(continued)

Box 1: (continued)
especially CH_4, N_2O, and CFCs (Enquete-Kommission 1995, pp. 35–75; Houghton 1997, p. 22). The contribution of CFCs to the anthropogenic greenhouse effect will decline in the future, since their reduction and phasing out were agreed on in the Montreal Protocol and its amendments. Tropospheric ozone (O_3) also plays an important role in aggravating global warming (Enquete-Kommission 1990, p. 216, 1995, pp. 33–36), yet its importance is difficult to quantify because of the strong variability in its concentration as a consequence of its short lifetime (Bauer 1993, pp. 23–24). Dickinson and Cicerone (1986, p. 122), explain that the ozone "is of considerable interest because of its important roles, its complex behavior, and its susceptibility to human-induced global change."

The importance of the respective greenhouse gases, i.e., their contribution to the anthropogenic greenhouse effect, depends on the following three "properties":

Global Warming Potential

The IPCC (1996, p. 21) defines the global warming potential (GWP) "as the cumulative radiative forcing between the present and some chosen time horizon caused by a unit mass of gas emitted now, expressed relative to that for some reference gas." The radiative forcing is defined as "the change in average net radiation at the top of the troposphere . . . which occurs because of a change in the concentration of a greenhouse gas" (Houghton 1997, pp. 22–23). With CO_2 representing the reference gas and for a time horizon of 100 years, the GWPs of CH_4 and N_2O are 21 and 310 respectively (IPCC 1996, p. 22); of course, from the definition it follows that the GWP of CO_2 equals unity. Yet, as Smith and Wigley (2000) point out, global warming potentials are accurate only for short time horizons.

Concentration in the Atmosphere

The atmospheric concentration of CO_2 has grown significantly from about 280 ppmv in preindustrial times (about 1,750 AD) to 391 ppmv in 2011 (IPCC 2013b); ppmv stands for parts per million by volume. The IPCC (2013b) reports a CH_4 concentration of 1.803 ppmv and a N_2O concentration of 0.324 ppmv in 2011. Thus, the preindustrial concentrations of CO_2, CH_4, and N_2O are already exceeded by about 40 %, 150 %, and 20 % (IPCC 2013b).

Lifetime

CO_2 prevails for 50–200 years in the atmosphere, CH_4 only for 12 ± 3 years, and N_2O for about 120 years (IPCC 1996, pp. 15–19). Thus the importance of the single greenhouse gases varies depending on the time horizon of

(continued)

Box 1: (continued)
investigations. Short horizons tend to understate the importance of greenhouse gases which prevail for a long time in the atmosphere.

Since CO_2 represents the most important anthropogenic greenhouse gas,[1] environmental policies that induce reductions of CO_2 emissions and concentrations are attractive means for mitigating climate change. Therefore, the main focus in this chapter will be on these policies. Anthropogenic CO_2 emissions are – except for emissions by deforestation and to a lower extent by cement production – almost entirely generated by the burning of fossil fuels. With it, many other pollutants like sulfur dioxide (SO_2) and nitrogen oxides (NO_X) are emitted. In contrast to the local/regional pollutants SO_2 and NO_2, the emissions of CO_2 can still not be removed from post-combustion exhaust in a cost-effective way. Thus major remaining reasonable approaches to mitigate CO_2 concentrations are the reduction of the combustion of substances or the shift to fuels or energies with lower CO_2 content. Sequestration of carbon is another option. As Lal (2004) explains, soil carbon sequestration is not only an option for mitigating climate change, but it is also a strategy to achieve food security through improvement in soil quality.

Assessment of the Kyoto Protocol/UNFCCC Scheme and Flexible Mechanisms

There have been intense disputes about whether the Kyoto Protocol leads a good way to protect the world's climate. Nordhaus (1998, p. 1) criticizes the Kyoto Protocol: "Given the lack of political support, the Kyoto Protocol is a dead duck. Given its inefficiency, it probably deserves to be a dead duck. We need to go back to the duck drawing board."

The Kyoto Protocol does not prescribe greenhouse gas (GHG) reductions to developing countries, and this fact is employed by opponents to the Kyoto Protocol to stress its inefficiency, since GHG emission mitigation options can regularly be exploited more cheaply in the developing world. The USA which refused to join the Protocol demands participation of developing countries in international GHG emission-reduction efforts. This demand is rejected by the developing world because of the economic burden which such efforts would imply. Furthermore, developing countries argue that the industrialized world is mainly responsible for the current dimension of the global warming threat. "North America and Europe have produced around 70 % of CO_2 emissions from energy production since 1850, while developing countries – non-Annex 1 parties under the Kyoto Protocol – account for less than

[1]Water vapor is of course the overall most important greenhouse gas, yet anthropogenic emissions of water vapor contribute very little to climate change (see IPCC 2013a, Chap. 8). For this reason, we do not discuss the role of water vapor in detail but rather refer the interested reader to IPCC (2013a) and references within.

one quarter of cumulative emissions" (Stern 2007, Chap. 7). Therefore, from the developing world's perspective, it is mainly the industrialized world's responsibility to combat global warming.

Yet, the Kyoto Protocol integrates a mechanism which addresses both opponent views. This mechanism, the Clean Development Mechanism (CDM), allows industrialized countries to fulfill their GHG abatement obligations partly by mitigating GHG emissions in developing countries, where mitigation options can be exploited in a cheaper way. The CDM-associated costs of climate protection are borne by the industrialized world. "With the already huge and growing amount of greenhouse gas emissions and a great deal of low-cost abatement options available, China is widely expected as the world's number one host country of CDM projects" (Zhang 2006). According to UNFCCC (2014a), about 60 % of the expected Certified Emission Reduction (CER)[2] units from registered projects in the year 2014 will be earned by China. As Rive and Rübbelke (2010) show for CDM transfers from Europe to China, this mechanism may not only help to improve the efficiency and to raise the level of international climate protection, but it may also support development in poor countries. Yet, as they find out, the level of success of the mechanism in supporting development depends to a large extent on the domestic environmental regulations in the host country of CDM projects.

The CDM is only one of the three flexible mechanisms comprised in the Kyoto scheme, the other two being joint implementation and emission permit trading (or for short: emissions trading). ("The Kyoto mechanisms include international emissions trading, Joint Implementation (JI), the Clean Development Mechanism (CDM), and some would argue joint fulfilment" (Dessai and Schipper 2003, p. 150). Hence, some would also regard the burden sharing agreement within the EU-15 as an application of a flexible Kyoto mechanism (joint fulfillment)).

Joint implementation (JI) allows Annex-I countries to fulfill their GHG abatement obligations partly by mitigating GHG emissions in other Annex-I countries (industrialized countries and European economies in transition). Laroui, Tellegen, and Tourilova (2004, p. 901) describe the mutual benefits arising for JI investor countries and for host countries of JI projects. For investing countries, JI means a contribution to meeting the emission-reduction targets at lower cost than this could be achieved by own national measures. Furthermore, they argue that it creates new business opportunities for renewables, efficiency technologies, management tools, products, and consultants. According to Laroui, Tellegen, and Tourilova (2004, p. 901), JI provides opportunities for the host country, e.g., to attract foreign investments, to create incentives for starting new businesses in the sectors for renewable and efficiency technologies, and to enhance energy security and independence by lessening demand for energy use.

[2]A CER is a unit issued for emission reductions from CDM project activities in accordance with the CDM rules and requirements, and it is equal to one metric ton of carbon dioxide equivalent (UNFCCC 2014b).

The key idea of emission permit trading is to stipulate an allowed amount of GHG emissions, to partition this amount, and to allocate the parts on tradable emission permits. By allowing transferability of these permits, an emission permit market is constituted. The owners of permits can relinquish their permits and sell them to other agents. Hence, while the total amount of emission permits is preassigned, the permit price is formed in the market. In environmental economics, permit schemes are known as options to cost efficiently internalize externalities. In the EU, the CO_2 emissions trading system (EU-ETS) started on the first of January 2005.

At the COP-18 in Doha in 2012, an agreement on a second commitment period of the Kyoto Protocol for 2013–2020 was reached. Yet, several Annex-I countries (e.g., Canada, Japan, Russia, and the USA) decided not to participate in the second commitment period. The remaining Annex-I countries (e.g., Australia, the EU, and its member states) committed to quantified emission reductions. At the COP-17 in Durban, it was agreed "to launch a process to develop a protocol, another legal instrument or an agreed outcome with legal force under the Convention applicable to all Parties" (UNFCCC 2011), and this process should bring about a protocol, another legal instrument, or an agreed outcome with legal force that enters into force in 2020.

One important issue regarding a post-Kyoto agreement is the question of whether and how to integrate climate policy's second pillar besides mitigation: adaptation to climate change. As the IPCC stresses "Societies can respond to climate change by adapting to its impacts and by reducing GHG emissions (mitigation), thereby reducing the rate and magnitude of change" (IPCC 2007, p. 56). However, in the early years of the UNFCCC's operation, adaptation issues hardly played a role in international negotiations (Yamin and Depledge 2004; Pickering and Rübbelke 2014). Then, at the COP-7 in Marrakesh in 2001, it was agreed to establish three funds (Least Developed Countries Fund, Special Climate Change Fund, and the Adaptation Fund) that are dedicated to international adaptation support which was a strong sign of the – meanwhile – increased importance of the adaptation pillar in international climate policy. Also a large share of the 100 billion USD annually that developed countries formally pledged (at the COP-16 in Cancun in 2010) to mobilize by 2020 in order to support climate policies in developing countries will be channeled toward adaptation projects in developing countries. As Rübbelke (2011) and Pittel and Rübbelke (2013) argue, this adaptation support for developing countries might raise fairness perception in international negotiations on climate change mitigation and with it increase developing countries' willingness to contribute to international mitigation efforts. Then, successful negotiations within the Kyoto scheme might become more likely.

Despite the flexible mechanisms and current as well as planned international transfers, the Kyoto mechanism is unlikely to generate an efficient global climate protection level. Before reasons for the difficulties in reaching an efficient international environmental agreement are discussed, an alternative international scheme to protect the environment, i.e., the Asia-Pacific Partnership on Clean Development and Climate, is shortly described.

Asia-Pacific Partnership on Clean Development and Climate

The Asia-Pacific Partnership on Clean Development and Climate (APP) was announced in July 2005 and formally launched in January 2006. In fact, Australia and the USA were the driving forces behind the APP and convinced China, India, Japan, and South Korea to join the partnership; Canada joined in 2007. The APP partners agreed to work together and with private sector partners to meet goals for energy security, national air pollution reduction, and climate change in ways that promote sustainable economic growth and poverty reduction. Hence, according to McGee and Taplin (2006, p. 191): "No longer is Kyoto the "only game in town" in terms of national participation in international climate-change initiatives." For a discussion of further non-UN climate change initiatives, see McGee and Taplin (2009).

The APP focused on expanding investment and trade in cleaner energy technologies, goods, and services in key market sectors. Projects supported by the APP typically involved small amounts of government funding in conjunction with private investment (Lawrence 2009, p. 282). The APP was remarkable not only because it constituted an additional "game in town" but also because of the fact that the involved seven partner countries collectively account for more than half of the world's economy, population, and energy use. They produce about 65 % of the world's coal, 62 % of the world's cement, 52 % of world's aluminum, and more than 60 % of the world's steel (see: http://www.asiapacificpartnership.org/english/default.aspx). Hence, the APP succeeded in gathering countries without which no solution to the global warming threat is attainable, since their economies cause climate change to a large extent. The question, however, remained how effective their cooperation in APP would be with respect to lowering emissions.

The partnership established eight public-private task forces to develop and implement action plans as depicted in Fig. 3. The Policy and Implementation Committee oversaw the APP as a whole, guided the task forces, and reviewed their work. The Administrative Support Group coordinated the APP's communications and activities and supported the Policy and Implementation Committee as well as the partnership more broadly (APP 2008, p. 3).

In contrast to the Kyoto Protocol, the APP formulated no legally binding commitments on greenhouse gas reduction or the placing of a price upon greenhouse gas emissions. Instead, the individual members of the APP were free to set their own targets based upon individual national circumstances; there were no compulsory contributions to funding climate protection projects. The voluntary national targets were aiming at reductions of greenhouse gas intensities, rather than committing to emission reductions in absolute terms. As Pezzey, Jotzo, and Quiggin (2008, p. 107) point out: "Unrealistic assumptions were made about how much innovation can be achieved by voluntarism and cooperation supported by only paltry funding, in the absence of either market price incentives or mandatory measures."

McGee and Taplin (2006) saw the real problem posed by the APP in the diversion of attention away from absolute GHG reduction targets. If the partnership "takes hold as a fully-fledged alternative climate-change regime, or as a modifier of the

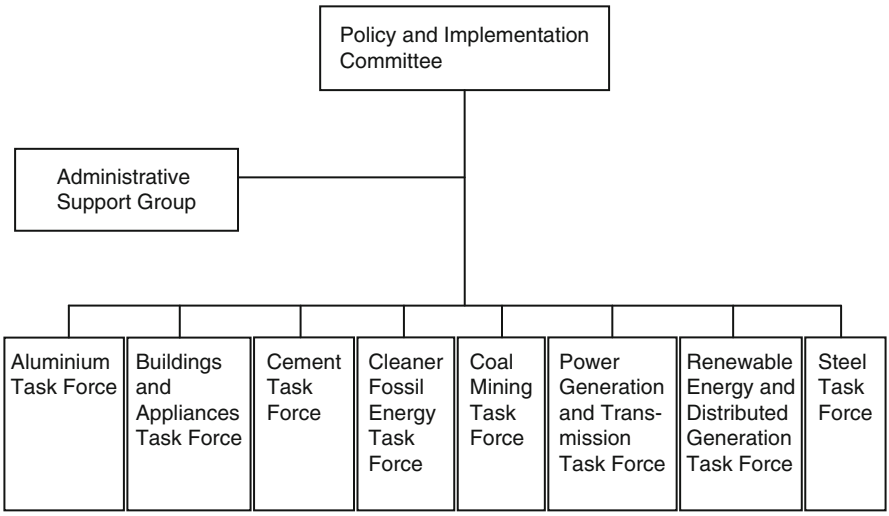

Fig. 3 Organizational structure of the partnership (Figure adopted from APP 2008, p. 3)

future shape of Kyoto, there will be no absolute global emissions reduction and hence a greater risk of dangerous climate change" (McGee and Taplin 2006, p. 192).

The motivation behind launching a scheme – which was described by its founders as a complement to the Kyoto Protocol – was questioned by many researchers. McGee and Taplin (2006, p. 191) drew the conclusion from their analysis that the regime interaction between APP and Kyoto scheme was most likely to be obstructive and competitive and that the claims of complementarity between both regimes would consequently not be justified. As Lawrence (2009, p. 282) argued, "Australia's strong advocacy of the APP in this early period was linked to coal and energy-intensive industry interests." And Karlsson-Vinkhuyzen and van Asselt (2009, p. 202) pointed out that in February 2005, when the world was celebrating the entry of the Kyoto Protocol "into force in a sort of defiant support of multilateralism after the US rejection, it is quite natural that the US wanted to improve their reputation and show some initiative. It seems logical that the US sought the support of the other Kyoto 'defector' in the enterprise." Yet, although the initial motivations to launch the APP may have been dubious, this does not mean that the scheme could not have had positive effects.

However, as Heggelund and Buan (2009, p. 314) argued, given the enormous challenge of global warming, the relatively low number of APP projects set up since its inception "makes us question the likelihood of the APP significantly contributing to climate change mitigation, even if it could make a contribution to technology transfer." Furthermore, as Karlsson-Vinkhuyzen and van Asselt (2009, p. 206) argued, there were political signs which could be interpreted as unequivocal support for the UN climate regime. Indeed, as of 5 April 2011, the APP formally concluded its joint work.

Why Efficient Climate Protection Is So Difficult to Achieve

Despite all the efforts going into international negotiations and despite the international cooperation within the Kyoto Protocol and the APP, global climate protection still remains on a suboptimal low level. To a large extent, the reason for this dismal result is a global-scale market failure. Climate protection has global public good properties, i.e., climate protection exerts positive externalities which are not compensated via markets. This in turn causes a suboptimal low provision of the public good "climate protection."

In the economics discipline, a pure public good is considered to have two distinguishing properties: (1) non-excludability of consumption and (2) non-rivalry in consumption; in contrast, a private good has none of these two properties (see Cornes and Sandler 1996, p. 3).

Non-excludability with respect to climate protection means that every country in the world benefits from climate protection activities, regardless where these activities have been accomplished. Hence, for a country it does not make a difference whether GHGs are abated in Australia, China, the UK, or the USA; the abatement will positively affect the global climate, and no country can be excluded from the respective benefits.

Non-rivalry in the consumption of climate protection means that one country enjoying the benefits of the mitigation of global warming does not affect the benefits received by another country from this mitigation.

Welfare Optimum

If countries individually decide about the provision of public goods like climate protection, they will provide a – from a global perspective – suboptimally low amount since they face the so-called free-rider incentives. Since non-excludability of benefits from climate protection prevails (country A cannot force country B "not to enjoy" the benefits of the climate protection produced by country A), no price can be charged on a market for these benefits. Since production of climate protection is costly, while its consumption is free of charge, countries prefer that others produce more climate protection, while they themselves prefer to contribute less and to enjoy the benefits from the others' efforts for free.

In general the notion of "free riding" is employed in the scientific literature in order to characterize such a situation. But in contrast to, e.g., agreements on climate change where countries may take a "free ride" from participation, the problem regarded here is one of degree. As can be shown, it is rational for each single country to provide the public good up to a level where its own marginal abatement benefits coincide with its own marginal abatement costs. Hence, it might be more appropriate to employ the expression "easy riding," since this is not equivalent to "not providing anything to the public good." Therefore, Cornes and Sandler (1996, p. 30) suggest using the notion "easy riding" in such contexts.

In the economics discipline, efficiency or optimality describes a situation where welfare is maximized. In a next step, the maximization problem which the government of an individual country i faces is illustrated, or put differently, the case where the national government intends to act in a way that maximizes the welfare of the country's residents is regarded. The national welfare function characterizes the preferences of the residents, and the government can enhance the residents' welfare by allocating the country's resources in such a way that the respective function is maximized subject to the national income constraint. Let us for simplicity assume that income can be spent on two different groups of commodities: the first commodity is a private good y_i, and the second is the public good climate protection x_i.

Due to the public good property of climate protection, the total level X of climate protection consumable by country i can be expressed as the sum of all countries' or regions' individual contributions to climate protection. In a world of n countries (with $i = 1,\ldots, n$), the total level of climate protection is this given by

$$X = x_i + \sum\nolimits_{i \neq j} x_j = x_i + \tilde{X}_i, \tag{1}$$

where $\tilde{X}_i$ is the sum of climate protection by all countries except for the climate protection x_i provided by the regarded country i.

The preferences of country i concerning both goods are represented by the utility function which is continuous, strictly increasing, strictly quasi-concave, and everywhere twice differentiable.

The individual country i maximizes its welfare U_i

$$\max_{y_i, x_i} U_i\left(y_i, x_i + \tilde{X}_i\right) = U_i(y_i, X) \tag{2}$$

s.t.

$$y_i + x_i c = I_i, \tag{3}$$

where I_i is the monetary income of country i. For all countries, the unit price of the private commodity is set equal to unity, and the unit price of climate protection is set equal to c (with c being constant and strictly positive, i.e., $c > 0$). In the maximization the Nash assumption is employed, i.e., the welfare-maximizing country supposes that its choices do not affect the behavior of the other countries, i.e., it takes $\tilde{X}_i$ to be exogenous.

From the first-order conditions for the welfare maximum, we get

$$MRS_i = \frac{\partial U_i / \partial X}{\partial U_i / \partial y_i} = c. \tag{4}$$

Consequently, it is optimal for the individual country to provide climate protection up to the level where the marginal rate of substitution (left-hand side of Eq. 4)

between public good and private good becomes equal to the unit price ratio (right-hand side of Eq. 4) between public and private good (i.e., $\frac{c}{1}$). To put it plainly, when deciding about allocating its income between private goods and climate protection, a country fares best when it invests in climate protection until the benefit from spending another dollar on the climate compared to the benefits from spending another dollar on private goods is equal to the relative costs of buying the two goods.

While this provision level is optimal from an individual country's point of view, it is not optimal from a global perspective. Global welfare could be raised by deviating from the provision levels associated with condition (4). In order to illustrate this, global welfare is maximized in a next step.

It seems reasonable to assume that global welfare is a function of the individual countries' welfare levels. The global welfare level attainable from the consumption of private goods and climate protection is, however, restricted by the aggregate income that the countries can spend on private goods and climate protection. Thus the global welfare maximization problem reads

$$\max_{y_1,\ldots,y_n,X} U(U_1(y_1,X),U_2(y_2,X),\ldots,U_n(y_n,X)) \tag{5}$$

s.t.

$$\sum_{i=1}^{n} y_i + cX = \sum_{i=1}^{n} I_i. \tag{6}$$

Let us – for simplicity – assume that each individual country's welfare has an equal weight with respect to global welfare, i.e., $U(U_1(y_1,X),U_2(y_2,X),\ldots,U_n(y_n,X)) = U_1(y_1,X)+U_2(y_2,X)+\ldots+U_n(y_n,X)$. Then, optimization yields the so-called Samuelson condition (see Samuelson 1954, 1955)

$$\sum_{i=1}^{n} MRS_i = \sum_{i=1}^{n} \frac{\partial U_i/\partial X}{\partial U_i/\partial y_i} = c. \tag{7}$$

Therefore, in order to maximize global welfare, an individual country should provide climate protection up to a level where the sum of all countries' marginal rates of substitution between public and private good becomes equal to the unit price ratio between public and private good. Such outcomes, where no country can improve its welfare without harming another one, are called Pareto optima.

Condition (7) deviates from condition (4), since – without international coordination – an individual country would only take into account its own marginal rate of substitution between public and private goods (i.e., its own benefits from the two goods) when deciding about its climate protection efforts, while Pareto efficiency requires that countries also take into account spillovers exerted on other countries (i.e., the global benefits generated by its climate protection efforts). Therefore also the other countries' marginal rates of substitution between the public and private good have to be included in the efficiency condition.

Fig. 4 Prisoner's dilemma game

B's strategy / A's strategy	no participation	participation
no participation	0, –1	6, –3
participation	–4, 7	5, 6

On a national level, efficient public good provision can be enforced by the government, but on the global scale there is no central coercive authority which can enforce an efficient global climate protection level. Therefore, the only option is for countries to voluntarily negotiate a climate protection agreement in order to get closer to the globally efficient protection level.

International Negotiations in Normal Form Games

Such international negotiations on climate change can be comfortably depicted in a game-theoretical setting. Regularly, such negotiations are described as a prisoner's dilemma game which captures the free-rider incentives associated with the provision of public goods. A normal form game in the shape of a prisoner's dilemma (PD) situation with two agents or countries is presented in Fig. 4.

Both considered countries have the choice between "participation" in an international climate protection agreement (or climate protection efforts) and "no participation" in international climate protection efforts. In the matrix, the numbers in front of the commas represent the payoffs for country A, while the numbers behind the commas stand for the payoffs received by country B. In the prisoner's dilemma case of Fig. 4, the dominant strategy for each agent is to choose "no participation" in an international climate protection agreement (a dominant strategy is a strategy which always yields the highest payoff for the agent choosing this strategy, regardless of the choice of the opponents. For a more detailed discussion of these and related game theoretic concepts, see, e.g., Fudenberg and Tirole (1991)).

This outcome is the so-called Nash equilibrium where no country has anything to gain by changing only its own strategy unilaterally. While this equilibrium is stable, the payoffs of countries A and B are merely 0 and −1, respectively. However, "From an economic viewpoint an ideal state of cooperation has two features: It is a Pareto-optimum and it is stable" (Buchholz and Peters 2003, p. 82). The Nash equilibrium in the depicted PD situation is of course not Pareto optimal. Both agents would obtain a higher payoff if they would both participate in the international agreement.

Fig. 5 Chicken game

B's strategy / A's strategy	no participation	participation	
no participation	–6, –6	6, –3	$1-p$
participation	–3, 6	3, 3	p
	$1-q$	q	

Alternatively, a "Chicken" game setting can be employed in order to illustrate the negotiation situation. Lipnowski and Maital (1983) provide an analysis of voluntary provision of a pure public good in general as the game of Chicken. In fact, a Chicken game tends to describe international negotiations on the provision of the specific public good "climate protection" in a more adequate way than the prisoner's dilemma game (see Carraro and Siniscalco 1993). The case of a Chicken game, which belongs to the group of coordination games, is depicted in Fig. 5. In contrast to the PD situation, there exists no dominant strategy.

There are a couple of papers investigating the differences associated with the two, PD and Chicken, games. Ecchia and Mariotti (1998) investigate coalition formation in international environmental agreements and compare different versions of the two game types using simple three-country examples. In their paper, Rapoport and Chammah (1966) stress the difference between both games with respect to the attractiveness of retaliation decisions. Snyder (1971) examines differences in the logic and social implications of PD and Chicken games in the context of international politics. Lipman (1986) and Hauert and Doebeli (2004) analyze how the evolution of cooperation differs in the two games. Rabin (1993), Rübbelke (2011), and Pittel and Rübbelke (2013) investigate fairness in these settings. Pittel and Rübbelke (2012) depict negotiations on climate change in (3×3) matrices in which they integrate both Chicken and PD settings simultaneously. Hence, in their study they allow for a broader range of choices for the involved countries.

The main difference between both games, i.e., between PD and Chicken games, is that the agents in the PD situation obtain the lowest payoffs when they play unilateral "participation," while in the Chicken game, they face the lowest payoffs if they mutually play "no participation." This outcome is the reason why the Chicken game is said to represent international negotiations better: in case of mutual non-participation, the whole world is threatened by a global warming catastrophe. This catastrophe can be prevented in the best way by means of mutual cooperation in international climate protection. However, if the other agent refuses to cooperate, then unilateral participation in international climate protection efforts would be the best choice since this is the only remaining way to prevent the global warming

catastrophe. Yet, if the other agent provides climate protection (and thus chooses "participation"), it would be best to choose "no participation" and thus to take a free ride.

Each agent hopes that the other agent provides climate protection, such that he himself can take a free ride in climate protection. As can be observed from Fig. 5, there exist multiple Nash equilibria, which are associated with pure and mixed strategies. The Nash equilibria in connection with pure strategies prevail where the payoffs (−3,6) and (6,−3) arise.

Given possible uncertainties regarding the countries' behavior, mixed strategies become germane. Agents form probabilities about the other agent's behavior. Country A assesses the likelihood with which country B will participate (q) or not participate ($1 - q$) and vice versa for country B (p and $1 - p$). In order to determine the mixed strategies in the Chicken game situation in Fig. 5, the likelihood q^* (resp. p^*) of participation by country B (country A) has to be calculated that makes country A (country B) indifferent between playing "participation" and "no participation." Probability q^* is determined by calculating the level of q, for which the expected payoffs of both strategies of A ("participation" and "no participation") are equal. This is the case if

$$-3(1-q)+3q=-6(1-q)+6q. \tag{8}$$

The left-hand side represents A's expected payoff from participation, and the right-hand side reflects A's expected payoff from defection. Analogously p^* can be determined from solving

$$-3(1-p)+3p=-6(1-p)+6p \tag{9}$$

for p. In this case, the mixed-strategy equilibrium requires

$$q^*=p^*=½. \tag{10}$$

If country A or country B is uncertain whether the other country participates or defects, then it should cooperate (participate) provided it expects the antagonist to play "participation" with a probability of less than ½.

Integration of Ancillary Benefits into the Negotiations

Climate policies regularly generate side effects. Afforestation and reforestation, for example, do not only mitigate CO_2-induced global warming by sequestering carbon; these measures also increase the habitat for endangered species. Furthermore, forests can serve as recreational areas and reduce soil erosion. As Ojea, Nunes, and Loureiro (2010) stress, forests' "provision of goods and services plays an important role in the overall health of the planet and is of fundamental importance to human economy and welfare." Furthermore, Sandler and Sargent (1995, p. 160) point out that tropical

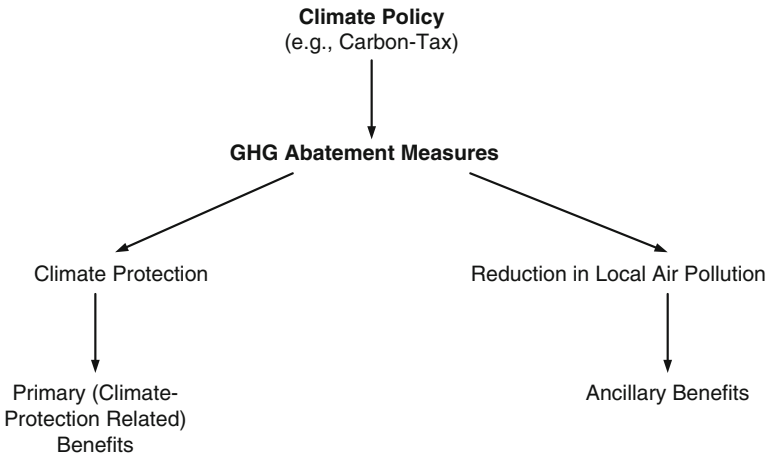

Fig. 6 Climate policy generating primary and ancillary benefits, see Rübbelke (2002, p. 36)

forests provide a bequest value which the current generation derives from passing on the forests to future generations. Concerning the case of Brazil, Fearnside (2001, p. 180) stresses: "The environmental and social impacts of mitigation options such as large hydropower projects, mega-plantations or nuclear energy, contrast with the "ancillary" benefits of forest maintenance." An overview of studies assessing the co-effects of afforestation is provided by Elbakidze and McCarl (2007, p. 565).

Similarly, side effects arise from the implementation of more efficient technologies, the reduction of road traffic, and the substitution of carbon-intensive fuels. Ancillary or secondary benefits induced by these CO_2-emission-reducing activities accrue, for example, when the emissions of other pollutants like particulate matter are reduced simultaneously (see Fig. 6). There are a number of terms which convey the idea of ancillary or secondary benefits. The others are co-benefits and spillover benefits (see IPCC 2001). The main difference is the relative emphasis given to the climate change mitigation benefits versus the other benefits (Markandya and Rübbelke 2004, p. 489).

In fuel combustion processes, CO_2 emissions are accompanied by emissions of, e.g., NO_X, SO_2, N_2O, and others. Therefore, fuel combustion reductions do not only cause a decrease in CO_2 emissions but also diminish the emissions of other pollutants. In general, positive health effects of air pollution reduction that accompany climate protection measures are assessed to represent the most important category of secondary benefits. (However, Aunan et al. (2003, p. 289) annotate that "some particulate air pollution has a cooling effect on the atmosphere, reducing it may exacerbate global warming.") Further negative impacts of air pollution, like accelerated surface corrosion, weathering of materials, and impaired visibility are mitigated by fuel combustion reductions, too. But, road traffic mitigation does not only produce ancillary benefits by reducing the emission of air pollutants, but it is also accompanied by lower noise levels and reduced frequency of accidents, less traffic congestion, and less road surface damage.

While primary benefits accrue globally from the prevention of climate change-induced damages, ancillary benefits are mostly local or regional (IPCC 1996, p. 217; Pearce 1992, p. 5). They represent domestic public goods for individual countries. (However, regarding the abatement of the greenhouse gases chlorofluorocarbons (CFCs), the ancillary effect of ozone layer protection and the respective ancillary benefits can be enjoyed globally.) Local air pollution mitigation generated by climate policy, for example, can be exclusively enjoyed by the protecting country. Therefore, ancillary effects can be considered to be private to the host country of a climate policy. Consequently, they differ from climate protection-related primary benefits which exhibit global publicness. Global damages arise, e.g., in the form of droughts caused by global warming. Rübbelke and Vögele (2011, 2013) recently analyzed the effects of such droughts on the power sector.

Several studies ascertaining the level of ancillary benefits found that such benefits even represent a multiple of climate protection-related primary benefits, as Pearce (2000, p. 523) illustrates in an overview.

In the next stage, ancillary benefits will be explicitly introduced into our normal form game. It will be taken into account that ancillary benefits are enjoyed (mainly) privately by the host country of the climate protection activity. Ancillary benefits arise regardless of the behavior of the antagonist. In Fig. 7, ancillary benefits (AB_A, AB_B) are explicitly included into the matrix of the Chicken game, where it is assumed that $AB_A < AB_B$.

Analogously to the procedure concerning the Chicken game situation without ancillary benefits, the mixed strategies can be investigated here. Again, probability q^* is determined by identifying the level of q, where the expected payoffs of both strategies of A ("participation" and "no participation") balance. This is the case if

$$(-3 + AB_A)\ (1 - q) + (3 + AB_A)q = -6\ (1 - q) + 6q. \tag{11}$$

Analogously p^* can be specified

$$(-3 + AB_B)\ (1 - p) + (3 + AB_B)p = -6\,(1 - p) + 6p. \tag{12}$$

Fig. 7 Chicken game with ancillary benefits

B's strategy / A's strategy	no participation	participation	
no participation	–6, –6	6, –3 + AB_B	1–p
participation	–3 + AB_A, 6	3 + AB_A, 3 + AB_B	p
	1–q	q	

From Eqs. 11 and 12, q^* and p^* can be derived. Scientific studies largely assess that there are especially important co-benefits of local/regional air pollution reduction in developing countries; an overview of a selection of studies investigating ancillary benefits in developing countries can be found in Appendix 1. Neglecting potential differences in the primary benefits and supposing that A represents the group of industrialized countries, while B represents the developing world, we obtain:

$$q^* = ½ + AB_A/6 < p^* = ½ + AB_B/6. \tag{13}$$

If country A (resp. country B) is uncertain whether the antagonist participates or defects, then it should participate provided it expects the antagonist to play "participation" with a probability of less than $½ + AB_A/6$ (resp. $½ + AB_B/6$).

Comparison of Eqs. 10 and 13 shows that q^* and p^* rise due to the inclusion of ancillary benefits into the analysis. Consequently, for the Chicken game example illustrated above, it is found that taking ancillary benefits into account will increase the likelihood of cooperative behavior in international negotiations on climate change. According to Eq. 13, the inclusion of ancillary benefits into the reasoning brings about especially an increase in the likelihood that developing countries will participate in international climate protection efforts (for a more general analysis of the influence of ancillary benefits in international negotiations on climate change, see Pittel and Rübbelke 2008). Consequently, these results confirm Halsnæs and Olhoff (2005, p. 2324) who stress that "the inclusion of local benefits in developing countries in GHG emission reduction efforts will [...] create stronger incentives for the countries to participate in international climate change policies."

Yet, in their analysis of qualitative and strategic implications associated with ancillary benefits, Finus and Rübbelke (2013) find a more moderate influence of co-benefits on the participation in international climate agreements and on the success of these treaties in welfare terms. They employ a setting of noncooperative coalition formation in the context of climate change. According to their results, ancillary benefits will not raise the likelihood of an efficient global agreement on climate change to come about although ancillary benefits provide additional incentives to protect the climate. The rationale behind this result is that countries taking the private ancillary benefits to a greater extent into account will undertake more emission reduction, irrespective of an international agreement.

However, if we consider the high local/regional pollution levels in developing countries, it remains at least highly disputable whether developing countries conduct efficient local/regional environmental policies. Hence, the commitment in an international climate protection agreement will most likely help to raise the efficiency in local/regional environmental protection in these countries. Consequently, ancillary benefits – although not being the major impetus for immediate action – may take the role of a catalyst to climate policy (rather than that of a direct driver). Joining international climate protection efforts may become politically more feasible for

developing countries (like China and India) which face serious local/regional pollution problems, when ancillary benefits are included in the political reasoning.

Price Ducks: An Approach to Break the Deadlock?

Due to the inefficiency of the Kyoto Protocol scheme, which is a quantity duck since it stipulates emission-reduction quantity targets, there arose an intense discussion about general alternatives to such quantity ducks (which are more than just technology-focused climate policy partnerships like the APP). Nordhaus (2006, p. 31) points out: "Unless there is a dramatic breakthrough or a new design the Protocol threatens to be seen as a monument to institutional overreach."

- Price-influencing international climate protection schemes have been proposed by Nordhaus (2006) as a proper successor of the quantity approach of the Kyoto type. "This is essentially a dynamic Pigovian pollution tax for a global public good" (Nordhaus 2006, p. 32). An international carbon tax scheme where no international emission limits are dictated is considered to have several significant advantages over the Kyoto mechanism. This scheme could also contain side payments in order to motivate countries to participate: "Additionally, poor countries might receive transfers to encourage early participation," Nordhaus (2006, p. 32).
- Such a scheme is a price duck, because via the taxes, the prices of polluting activities are increased, such that there are additional incentives to mitigate the level of such polluting activities.
- In contrast to taxing polluting activities in order to protect the climate, of course, prices can be influenced by subsidizing climate-protecting activities (e.g., energy-efficient appliances or carbon sequestration measures could be subsidized). The subsidy will reduce the effective price of climate-protecting activities, and hence the agents receiving the subsidy will raise their provision level of climate protection.
- Recently, Altemeyer-Bartscher, Rübbelke, and Sheshinski (2010) elaborated Nordhaus' proposal of an international carbon tax scheme. They analyze how individual countries or regions could negotiate the design of such a tax scheme in a decentralized way. In the scheme they suggest countries offer side payments to their opponents that are conditional on the level of the environmental tax rates implemented in the transfer-receiving opponent country. As can be shown, such a side-payment scheme might yield the first-best optimal tax policy and hence an efficient global climate protection regime. The scheme does not require the coercive power of a central global authority as the individual countries implement carbon taxes voluntarily. Altemeyer-Bartscher, Markandya, and Rübbelke (2014) investigate the effects of ancillary benefits on the outcomes of this scheme.

- Other price-influencing schemes which work in a similar way and do not require an international coercive authority are matching schemes which were first developed by Guttman (1978, 1987). Danziger and Schnytzer (1991) provide a general formulation of Guttman's matching idea which allows for income effects, non-identical players, and nonsymmetric equilibria. Guttman's matching approach has been applied to the sphere of international environmental agreements by Rübbelke (2006) and Boadway, Song, and Tremblay (2007, 2011).

Guttman's basic scheme consists of two stages. Each agent i's contribution x_i to the public good can be written as:

$$x_i = a_i + b_i \sum_{j=1}^{n} a_j \qquad (j \neq i), \tag{14}$$

where a_i is the agent's unconditional or flat contribution to the public good (in our case "climate protection") and b_i is his matching rate, which he provides for each unit of flat public good contributions by other agents. Therefore, the agent's matching contribution is $b_i \sum_{j=1}^{n} a_j \; (j \neq i)$. The unit costs of the goods are supposed to be equal to unity. The budget constraint of the agent in the shape of the income restriction is:

$$y_i + a_i + b_i \sum_{j=1}^{n} a_j = I_i \qquad (j \neq i). \tag{15}$$

I_i is again the monetary income of the considered agent i.

In the first stage of the game, each agent makes a decision on the level of the matching rates he wants to offer to the other agents. It could be assumed that this decision is stipulated in an international agreement on matching rates, where all negotiating agents or decision makers – as representatives of their nations – agree on the matching rates their countries will provide (see Rübbelke 2006). All the agents' actions in both stages of the game are guided by welfare-maximizing behavior, i.e., the agents aim to maximize their individual countries' welfare as represented by the function in Eq. 2.

In the second stage, all agents will make decisions about their flat contributions. Total public good contribution of all agents then becomes equal to:

$$X = \sum_{i=1}^{n} \left(a_i + b_i \sum_{j=1}^{n} a_j \right) \qquad (j \neq i). \tag{16}$$

Given the matching rates of the other agents, the considered agent will contribute flat contributions to the public good up to the level where the marginal rate of

substitution between public and private good is equal to the effective price of the public good, i.e., where

$$MRS_i = \frac{1}{1 + \sum_{j=1}^{n} b_j} \qquad (j \neq i). \tag{17}$$

The decline in the effective price, from unity to the level specified on the right-hand side of Eq. 17, induces an increase in the private provision of the public good. Comparison of the right-hand sides of Eq. 4 (for which it is assumed that $c = 1$) and of Eq. 17 shows that in the matching scheme the considered agent or country faces a decline in the effective price of the public good "climate protection" as long as at least one other agent provides a positive matching rate b_j. As Bergstrom (1989) illustrates, there are indeed incentives to announce positive matching rates.

Consequently, the matching scheme has a price-influencing effect (similar to that of a subsidy) which the quantity targets stipulated by the Kyoto Protocol do not exert. Due to the decline in the effective price, the agent tends to raise the level of his public good provision. Put differently, within the matching scheme, individual countries manipulate (via their matching commitments) the effective price of climate protection from other countries' point of view in order to influence these opponent countries to raise their public good provision levels. And as Boadway, Song, and Tremblay (2007, p. 682) point out: "the notion that countries might attempt to influence other countries' contributions by preemptive matching commitments is not far-fetched in light of recent examples of disaster relief or international campaigns to combat the effects of infectious diseases."

In the case of identical agents, Summing (Eq.17) up over all i generates

$$\sum_{i=1}^{n} MRS_i = n \frac{1}{1 + (n-1)b_j} (j \neq i) \tag{18}$$

Hence, a Pareto optimum is attainable if each agent would choose $b_i = 1$. As Buchholz, Cornes, and Rübbelke (2009) demonstrate, matching may work better if there is a large number of agents/countries (than when there is a small number of agents), which is an important result if it is taken into account that international negotiations involve many countries.

Future Directions

The Kyoto Protocol has been an inefficient agreement, although its flexible mechanisms (CDM, Joint Implementation, ETS) helped to mitigate this inefficiency. Efficiency would require that the cheapest GHG abatement options are abated first, which is not generally the case under the Kyoto Protocol. Furthermore, the

emissions of large greenhouse gas emitters in the industrialized world, e.g., Russia and the USA, are not restricted under the protocol in the second commitment period.

The immense threat of global warming necessitates an improved global climate protection regime, since otherwise the world might experience dramatic and life-threatening consequences. Among the possible negative effects are the melting of glaciers, a decline in crop yields (especially in Africa), rising sea levels, sudden shifts in regional weather patterns, and an increase in worldwide deaths from malnutrition and heat stress (Stern 2007, Chap. 3).

An improved future international climate protection regime has to organize climate protection more effectively, and it has to stipulate significant GHG emission reductions for all major polluters. Developing countries like China and India belong to the group of major emitter countries. Consequently, if international climate policy is to succeed in combating global warming, developing countries will also have to commit to emission reductions under an international agreement.

Since there is no global coercive authority which could enforce countries to conduct an efficient climate protection in the future, mutual voluntary negotiations are the only means by which international coordination in climate protection can be accomplished. Put differently, "international treaties have to rely on voluntary participation and must be designed in a self-enforcing way" (Eyckmans and Finus 2007, p. 74). Yet, international easy- or free-rider incentives which are due to the global public good property of climate protection make the agreement on such an international treaty a difficult task.

Another way to protect the global climate, which deviates from the Kyoto concept of stipulating GHG emission-reduction quantities, is the negotiation of international price-influencing regimes. These regimes manipulate effective prices via taxes, subsidies, or matching grants in order to influence the behavior of individual countries in such a way that globally efficient climate protection levels are reached.

An international carbon tax, as suggested by Nordhaus (2006), might indeed yield a more efficient outcome, but due to the lack of will in the political arena to launch such a tax, it might be more promising to base the future global climate protection architecture on the already established structures associated with the Kyoto scheme. Yet, the advantages of price ducks like matching schemes are remarkable, and international price-influencing concepts like the global carbon tax or matching schemes should not be dismissed with levity.

Private ancillary benefits may take the role of a catalyst to climate policy rather than a direct driver to international climate negotiations. Joining international climate protection efforts may become politically more feasible for developing countries (like China and India) which face serious local/regional pollution problems when ancillary benefits are included in the political reasoning. Not only co-effects in terms of reduced local/regional air pollution are relevant but also co-benefits in the shape of, e.g., economic development, energy security, and employment.

Ethics and Environmental Policy

David J. Rutherford and Eric Thomas Weber

Contents

Abstract

This chapter offers a survey of important factors for the consideration of the moral obligations involved in confronting the challenges of climate change. The first step is to identify as carefully as possible what is known about climate change science, predictions, concerns, models, and both mitigation and adaptation efforts. While the present volume is focused primarily on the mitigation side of reactions to climate change, these mitigation efforts ought to be planned in part with reference to what options and actions are available, likely, and desirable for adaptation. Section "Understanding Climate Change," therefore, provides an

overview of the current understanding of climate change with careful definitions of terminology and concepts along with the presentation of the increasingly strong evidence that validates growing concern about climate change and its probable consequences. Section "Uncertainties and Moral Obligations Despite Them" addresses the kinds of uncertainty at issue when it comes to climate science. The fact that there are uncertainties involved in the understanding of climate change will be shown to be consistent with there being moral obligations to address climate change, obligations that include expanding the knowledge of the subject, developing plans for a variety of possible adaptation needs, and studying further the various options for mitigation and their myriad costs. Section "Traditions and New Developments in Environmental Ethics" covers a number of moral considerations for climate change mitigation, opening with an examination of the traditional approaches to environmental ethics and then presenting three pressing areas of concern for mitigation efforts: differential levels of responsibility for action that affects the whole globe, the dangers of causing greater harm than is resolved, and the motivating force of diminishing and increasingly expensive fossil fuels that will necessitate and likely speed up innovation in energy production and consumption that will be required for human beings to survive once fossil fuels are exhausted.

Introduction

Few subjects are as complex and as frequently oversimplified as climate change. After big snowfalls in winters past, news outlets have featured various observers of these local events, who dismiss the idea of global warming with statements such as "so much for the global warming theory" (LaHay 2000). On the other hand, climate scientists note that Earth's average temperature has risen over time, and as a result, they predict increases in temperature extremes and vaporization of water that, in turn, lead to an expectation of increased snowfall in some years. Problems of understanding and misunderstanding such as these are important causes of confusion in discussions about climate change, and those problems and that confusion combined with the complexity of the issues at stake add considerable challenge to addressing the topic of focus in this chapter: the ethics of climate change mitigation.

This chapter will argue that despite limitations to knowledge about the complexities of the climate system, certain efforts must be undertaken to prepare for and address the developments in climate change. The science on the subject is growing increasingly compelling, showing that there is need to work toward mitigating the causal forces that are bringing about climate change along with preparing adaptations to changes in climate, some of which have already begun (Walther et al. 2002). Furthermore, the existence of uncertainties with respect to climate science calls for more study of the subject of climate change, with greater collaboration than is already at work. Calling for further study of the subject, however, does not imply the postponement of all or any particular measure of precaution and potential action. This chapter will examine the current knowledge about climate change as well as the

moral dimensions at issue in both seeking to minimize those changes and working to prepare for the changes and their effects.

When the term "mitigation" arises in this chapter, it is important to keep in mind a consistent meaning. To mitigate something generally means to make it less harsh and less severe, but in relation to climate change, mitigation carries a more precise meaning. The term refers to human actions taken to reduce the forces that are believed responsible for the increase of the average temperature of the Earth. The primary concern with climate change is the increase of global average temperature, and mitigation is aimed at decreasing the rate of growth of this global temperature and stabilizing it or even decreasing it should it rise too high. Mitigation is sometimes referred to as abatement. Generally, the idea of abatement is either to reduce the rate of growth that is or will likely be problematic or to actually reverse the trend and reduce global average temperature. In contrast to mitigation, a second category of response to climate change is to find ways of adapting life to new conditions, the method of adaptation. Adaptation refers to adjustments made in response to changing climates that moderate harm or exploit beneficial opportunities (Intergovernmental Panel on Climate Change 2007a). The interesting issue that arises in focusing on climate change mitigation – the efforts to decrease the causal forces of rising global temperatures – is that subtle changes in temperature might be the kind to which some or even many people will be able to adapt relatively easily. For instance, if people live on coastal lands that are increasingly inundated, there are ways of reclaiming land from water or places to which people can move in adaptation to the climate changes. Other adaptations might include systems of planned agricultural crop changes prepared to avoid problems that could arise in growing food for the world's increasing population. An important consideration about adaptation is that while humans may be able to change and adjust to changing climates, natural ecosystems and habitats may not, a point that will also be addressed in this chapter.

There are certainly reasons to worry about sudden, great changes, but more gradual and less severe changes raise a host of ethical issues. For instance, it is reasonable to ask whether a farmer has the moral right to grow a certain crop. If so, then it may be that people have a responsibility to avoid changing the climate. Belief in such a right, however, could be considered highly controversial. What if farmers could reasonably expect some help in adapting the crops that they raise to new conditions? This idea would lessen the moral concern over the ability to grow a certain crop in a particular region, and thus a matter of adaptation would have bearing on the moral dimensions of climate change mitigation.

It is likely that the best solution to address the ill effects of climate change will require a combination of mitigation and adaptation strategies. A central claim of this chapter, therefore, is that the ethics of climate change mitigation must not be considered in isolation from the options available for adaptation. Of the two, however, the more controversial, morally speaking, are abatement efforts or mitigation. This is because when climate conditions change, there will be no choice for people but to adapt to new circumstances if presented with serious challenges for survival, at least until humans are able to exert control in a desirable way on the trends in global climate. But abatement efforts, on the other hand, require sacrifices

early, before certainty exists about the exact nature and extent of the problems to come and whom the problems, benefits, and mitigating efforts will most affect and how.

Accompanying the problem of complexity that exists in climate change is a necessary challenge of uncertainty. The approach of addressing change through adaptive measures can be started early and is also possible as some more gradual changes occur, such as in the evacuation of islands that slowly disappear under the rising level of the sea. Other problems, however, are predicted to occur swiftly, such as in the potential disruption of the ocean conveyor, a "major threshold phenomenon" that could bring "significant climatic consequences," such as severe droughts (Gardiner 2004, pp. 562–563). The problem of knowledge, of the limits to human abilities to identify where suffering or benefits will occur, under what form, by which mechanisms, implies that preventive adaptations may be impossible in the face of sudden changes in global climates. Furthermore, if there existed no idea of changes that might occur, this limited knowledge might render the effects of changing conditions less troubling morally speaking. But the fact is that today many scientists have devised models that suggest potential outcomes of climate change and so undercut the option of ignorant dismissal or avoidance of moral obligation. Limited knowledge about climate change first and foremost calls for increasing the knowledge and study of the subject, but it also demands consideration of the kinds of problems that can be expected, weighed against the anticipated costs of alleviating the worst of the threats.

This chapter will offer a survey of a number of important factors for the consideration of the moral obligations involved in confronting the challenges of climate change. The first step is to identify as carefully as possible what is known about climate change science, predictions, concerns, models, and both mitigation and adaptation efforts. While the present volume is focused primarily on the mitigation side of reactions to climate change, these mitigation efforts ought to be planned in part with reference to what options and actions are available, likely, and desirable for adaptation. Section "Understanding Climate Change," therefore, provides an overview of current understanding of climate change with careful definitions of terminology and concepts along with the presentation of the increasingly strong evidence that validates growing concern about climate change and its probable consequences. Next, section "Uncertainties and Moral Obligations Despite Them" will address the kinds of uncertainty at issue when it comes to climate science. The fact that there are uncertainties involved in human understanding of climate change will be shown to be consistent with there being moral obligations to address climate change. As mentioned above, these are obligations to know more than is currently known, to develop plans for a variety of possible adaptation needs, and to study further the various options for mitigation and their myriad costs. Plus, Gardiner (2004) presented a convincing case for the weighing of options that concludes in accepting the consequences of a small decrease in GNP from setting limits on global greenhouse gas emissions. Gardiner's argument is compelling even in the face of uncertainty. After all, the uncertainties involved in climate change resemble uncertainties that motivate moral precaution in so many other spheres of human conduct. Finally,

section "Traditions and New Developments in Environmental Ethics" covers a number of moral considerations for climate change mitigation. This section opens with an examination of the traditional approaches to environmental ethics and then presents three pressing areas of concern for mitigation efforts: differential levels of responsibility for action that affects the whole globe, the dangers of causing greater harm than is resolved (with geoengineering efforts, among others), and the motivating forces of diminishing and increasingly expensive fossil fuels that will necessitate and likely speed up innovation in energy production and consumption that will be required for human beings to survive once fossil fuels are exhausted.

Understanding Climate Change

Given the complexity of addressing global climate change, it is crucial to clarify the meaning of a number of key terms, forces, and strategies for mitigation, so this first section will begin with a description of central terms and concepts at issue. The section then covers perceptions and methods for describing climate change because ideologies and affective influences on discourse about climate change can be used to mislead the public about the nature and the state of climate science. After that, the section examines the state of scientific knowledge and the predictions that the scientific community has presented about the future of climate change. This is important in order to grasp the extent of concern that world leaders and publics ought to feel about the future of the world's climates. Finally, this section will close with a brief description of the various proposals that have been considered for mitigating climate change.

Terminology and Concepts

Uncertainty, confusion, and misunderstanding result from poorly or ambiguously defined terminology and concepts, and this is especially the case with the topic of climate change. Climate change is complex and often elicits heated and impassioned public discourse. To reduce such problems, this section provides definitions for terms and concepts that are essential for both an explanation of what is known about climate change and for consideration of the broader topic of ethics and climate change mitigation. Some of these definitions are contested, and in such cases, the preferred definitions presented here will be contrasted with other definitions found in the literature, along with provision of an explanation for the selections made.

Weather and Climate

The term "weather" refers to short-term atmospheric conditions occurring in a specific time and place and identified by the sum of selected defining variables that can include temperature, precipitation, humidity, cloudiness, air pressure, wind (velocity and direction), storminess, and more. Weather is measured and reported at the scale of moments, hours, days, and weeks. Climate, on the other hand, is defined

(in a narrow sense) as the aggregate of day-to-day weather conditions that have been averaged over longer periods of time such as a month, a season, a year, decades, or thousands to millions of years. Climate is a statistical description that includes not just the average or mean values of the relevant variables but also the variability of those values and the extremes (McKnight and Hess 2000; Intergovernmental Panel on Climate Change 2007b).

The Climate System

Understanding climate entails more than consideration of just the aggregated day-to-day weather conditions averaged over longer periods of time. Those average atmospheric conditions operate within the wider context of what is called the climate system that includes not just the atmosphere but also the hydrosphere, the cryosphere, the Earth's land surface, and the biosphere.

- The *atmosphere* is a mixture of gasses that lie in a relatively thin envelope that surrounds the Earth and is held in place by gravity. The atmosphere also contains suspended liquid and solid particles that "can vary considerably in type and concentration and from time to time and place to place" (Kemp 2004, p. 37). On average, 50 % of the atmospheric mass lies between sea level and 5.6 km (3.48 miles or 18,372 ft) of altitude. To highlight how thin this is, consider that the peak of Mt. McKinley in Alaska is 6.19 km (20,320 ft) above sea level and, as a result, the density of air is less than 50 % of that available at sea level or that the peak of Mt. Everest at 8.85 km (29,029 ft) has less than 32 % of the air density that is available at sea level. Commercial jet airliners generally fly at about 10.5 km (35,000 ft) above sea level, and humans would lapse into unconsciousness very quickly if cabin pressure were to decrease suddenly at this altitude (Strahler and Strahler 1978).
- The *hydrosphere* consists of liquid surface water such as the ocean, seas, lakes, and rivers, along with groundwater, soil water, and, importantly, water vapor in the atmosphere.
- The *cryosphere* consists of all snow, ice (glaciers and ice sheets), and frozen ground (including permafrost) that lie on and beneath the surface of the Earth.
- Earth's *land surface* consists of the naturally occurring rock and soil along with the structures (buildings, roads, etc.) that humans have constructed.
- The *biosphere* consists of all living organisms, both plant and animal, on land, in fresh water, and in the ocean, including derived dead organic matter such as litter, soil organic matter, and ocean detritus.

The climate system functions by means of complex interactions among these five components in which flows and fluxes of energy and matter take place through myriad processes such as radiation, convection, evaporation, transpiration, chemical exchanges, and many more (Climate Change 2007c). Given this complexity, climate science is an interdisciplinary endeavor that necessarily involves the interactions and contributions of a wide range of the physical sciences such as physics, chemistry, biology, ecology, oceanography, and the atmospheric sciences. Moreover, because

human existence involves interactions with climate, the social sciences such as psychology, political science, and sociology also play important roles in human understanding. In addition, climate operates over time and space, so the synthesizing disciplines of history and geography have much to contribute as well. Furthermore, as shown later in this chapter, the humanities contribute to the understanding of the social dimensions of climate systems when it comes to considering the moral implications of various situations and actions in response to climate change.

Climate Change

The most recent definition of climate change developed by the Intergovernmental Panel on Climate Change (IPCC) will be used in this chapter:

> Climate change refers to a change in the state of the climate that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties, and that persists for an extended period, typically decades or longer (Climate Change 2007c, p. 78; see also USCCSP (United States Climate Change Science Program) 2007).

Importantly, this definition is solely descriptive and includes no reference to causation, particularly no indication of the extent to which any changes in climate result from natural or human (anthropogenic) causes. Other definitions of climate change include causation, such as the United Nations Framework Convention on Climate Change:

> "Climate change" means a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods (UNFCCC (United Nations Framework Convention on Climate Change) 1992, p. 3).

The first definition was selected for use in this chapter because it focuses on identifying and describing observed changes in climate and specifically refrains from assigning causation to either natural or anthropogenic processes. As a result, it draws attention to the distinction between two aspects of inquiry: (1) questions related to the presence, extent, and direction of changes in climate and (2) questions about causation of any observed changes, especially determinations of natural or anthropogenic causes. Views about (2) are often disconnected from questions about presence, extent, and direction of change and also tend to generate more contentious debate, especially in public and political discourse. As means to reduce contention, it is helpful to make the clear distinction between these two aspects of inquiry, and such clarity is especially important in this chapter, considering issues of ethics, mitigation, and adaptation. Additionally, and importantly, the selected definition implies no specific type of change(s) but instead fosters recognition that changes can occur in all manner of the variables that constitute climate such as temperature, precipitation, humidity, cloud cover, etc. (this point is further elaborated below with respect to the terms "climate change" and "global warming").

An additional reason to clarify the difference between (1) and (2) is that consideration of (1) generally engenders less controversy, while the task of determining

who should act in addressing any needs that arise from climate change will depend in part on how one addresses issue (2). As such, (2) is not to be ignored in addressing the ethics of climate change, but after untangling (1) from (2), the problems to be addressed can be recognized for what they are more easily.

Climate Variability

Most definitions of climate variability found in the literature differ little from the above definitions of climate change. For example, as defined in the Synthesis Report for the IPCC Fourth Assessment (Climate Change 2007c, pp. 78–79), the two terms actually seem synonymous in that they both refer to changes occurring on timescales of multiple decades or longer and they both allow for natural and anthropogenic causes. Other definitions of climate variability retain the focus on timescales of multiple decades or longer but limit climate variability to only natural causes (Batterbee and Binney 2008; Climate Research Program 2010). In this chapter, however, the term will refer to something different from either of these uses.

The term "climate variability" is used in this chapter in recognition that the long-term, statistical averages of the variables that define climates can contain substantial variation around the mean. Droughts, rainy periods, El Niño events, etc., occur in time periods of a year to as much as three decades within climates that are considered to be stable as well as within climates that are experiencing changes in the longer term. This variability is different from extreme weather events such as floods and heat waves that occur on timescales of hours, days, and weeks, and it is also different from the long-term climate changes that occur on scales that span multiple decades to millions of years (which have already been defined above as "climate change").

The reasons to differentiate climate variability from climate change in this way are twofold. First, climate variability can generate considerable "noise" in the data that can lead to erroneous conclusions about climate change. For example, Fig. 1 shows two levels of variability – interannual and multi-decadal – that are present in the observed global temperature record that extends from 1880 to 2009. Interannual

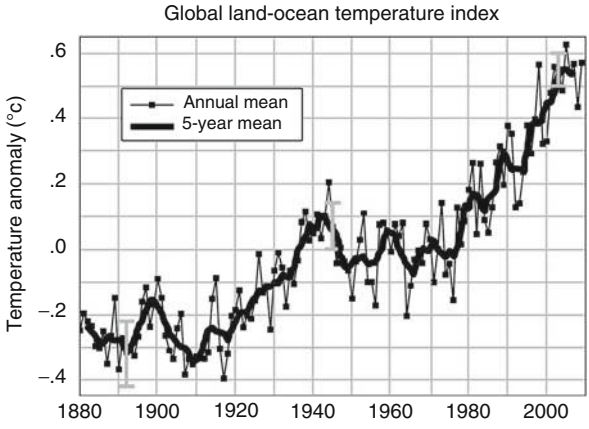

Fig. 1 A *line plot* of the global land-ocean temperature index from 1880 to 2009, with the base period 1951–1980. The *dotted black line* is the annual mean and the *solid black line* is the 5-year mean. The *gray bars* show uncertainty estimates (GISS (Goddard Institute for Space Studies) 2010a)

variability (variability from year to year) is as much as 0.3 °C (0.54 °F), a range that could be expressed as 1 year with a very hot summer and a mild winter followed by a second year with a mild summer and a very cold winter. The conditions present in either of these years could lead people to make poor judgments about climate. In particular, the long-term warming trend that the graph shows occurring across the full 119-year period is sometimes dismissed because people generally give greater weight in decision making and opinion formation to immediate affective sensory input over cognitive consideration of statistics (Weber 2010) (more will be said below about human decision making that is affect based compared to a basis on statistical description). The variability over several decades is exhibited in Fig. 1 for the time period 1940–1980, which shows a plateau within the longer-term, 119-year warming trend. During this shorter time period, media reports and even a few researchers erroneously forecast "global cooling" based on the observational record at the time that included inadequate and uncertain data from years earlier than this time period and, obviously, no data beyond 1980 (de Blij 2005, p. 85).

The second important reason for distinguishing between climate variability and climate change in the way defined in this chapter is related to dynamic equilibrium in ecosystems. Dynamic equilibrium results as ecosystems adapt to dynamic, ongoing forces that are not so extreme as to produce catastrophic changes. This dynamic equilibrium occurs because the change forces are not dramatic enough (or they cancel each other out), so that relative stability in the ecosystem can be perpetuated as the organisms (plants and animals) and the physical environment respond with adjustments that are within their adaptive capacities. In general, ecosystem adaptive capacity is not exceeded (and dynamic equilibrium is maintained) as a result of climate variability as defined here, but climate change, on the other hand, often exceeds this capacity and leads to fundamental alterations of the ecosystems. Such fundamental alterations occurring in natural ecosystems include processes such as species extinction, changes in community compositions, changes in ecological interactions, changes in geographical distributions, etc. Fundamental alterations can also occur within ecosystems upon which humans depend, leading to such changes as increases/decreases in agricultural productivity and the availability of water, changes in storm patterns, etc. (Intergovernmental Panel on Climate Change 2007a). These effects on both natural and human ecosystems will be discussed in more detail in what follows, but the important point here is that climate variability rarely produces such fundamental alterations, whereas climate change frequently can.

Global Warming and Global Average Temperature

Global warming is defined as an increase in the average temperature of Earth's surface NASA (National Aeronautics and Space Administration) 2007. As Fig. 1 illustrates, this average surface temperature has increased by 0.75 °C ± 0.3 °C (1.35 °F ± 0.54 °F) between 1880 and 2009. While this change might seem small, the paleoclimate record demonstrates that even "mild heating can have dramatic consequences" such as advancing or retreating glaciers, sea level changes, and changes in precipitation patterns that can all force considerable changes in human activity and

push natural ecosystems beyond dynamic equilibrium (Hansen 2009). The graph in Fig. 1 comes from NASA's Goddard Institute for Space Studies Surface Temperature Analysis (GISTEMP) database which contains temperature observations from land and sea from 1880 to the present (GISS (Goddard Institute for Space Studies) 2010b). It is one of the three such large databases of Earth surface atmospheric observations that all begin in the mid- to late nineteenth century and extend to the present. The National Oceanic and Atmospheric Administration (NOAA) maintains the second database that is titled the Global Historical Climatology Network (GHCN), and while this database contains observations from land stations only, it includes precipitation and air pressure data as well as temperature (National Climatic Data Center 2008). The third database is abbreviated HadCRUT3 which reflects the source of the dataset being a collaborative project of the Met Office Hadley Center of the UK National Weather Service ("Had") and the Climate Research Unit ("CRU") at the University of East Anglia. The Hadley Center provides marine surface temperature data, and the Climate Research Unit provides the land surface temperature data. These three databases are not completely independent because they share some of the same observation stations, but nevertheless, some differences in the raw data exist, and the three centers work independently using different approaches to the compilation and analysis done on the datasets. As such, the comparisons of results from the different databases allow for verification. Considerable consistency is apparent across the databases, especially in the overall trend of global warming since 1880. The different centers "work independently and use different methods in the way they collect and process data to calculate the global average temperature. Despite this, the results of each are similar from month to month and year to year, and there is definite agreement on temperature trends from decade to decade. Most importantly, they all agree that global average temperature has increased over the past century and this warming has been particularly rapid since the 1970s" (Stott 2011).

Figure 2 shows the temperature record for each of the three datasets superimposed upon one another, and the consistency among them is clear. In addition, research has been done to identify and quantify uncertainty in the data, and good estimates of the uncertainty indicate that the data are valid. As one such study stated:

> Since the mid twentieth century, the uncertainties in global and hemispheric mean temperatures are small, and the temperature increase greatly exceeds its uncertainty. In earlier periods the uncertainties are larger, but the temperature increase over the twentieth century is still significantly larger than its uncertainty (Brohan et al. 2006, p. 1).

The temperature records shown in Fig. 2 for each of the three centers are developed as each center uses its dataset to calculate a "global average temperature," both for the past and for monthly updates, and it is these values that are displayed on the graphs in the figure. While these calculations are done differently at the three centers, all three use the following general procedure. First, they expend considerable efforts to obtain the most accurate data possible and define the uncertainty that remains in those data. Then, the monthly average temperature value for each

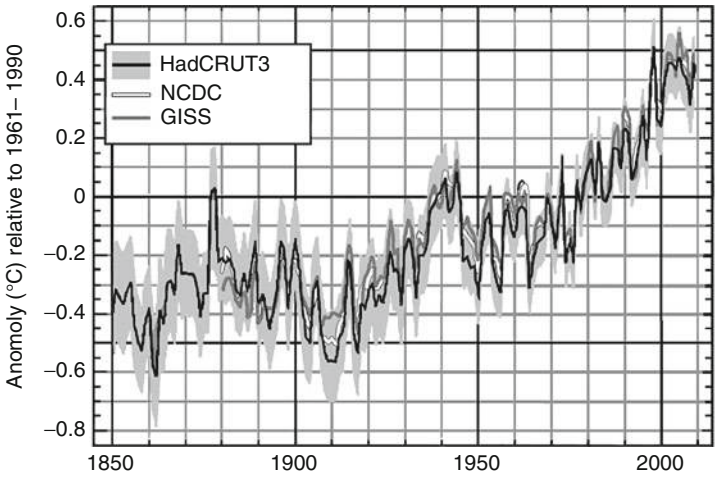

Fig. 2 Correlation between the three global average temperature records. All three datasets show clear correlation and a marked warming trend, particularly over the past three decades. The *HadCRUT3 graph* shows uncertainty bands which tighten up considerably after 1945 (WMO (World Meteorological Organization) 2010)

reporting station is converted into what is called an "anomaly." The anomaly of each reporting station is calculated by subtracting the monthly average value from the average value that the station has maintained over some relatively long-term "base period" (e.g., the HadCRUT3 uses the period 1961–1990 as its base period). The reason for using anomalies is stated as follows:

> For example, if the 1961–1990 average September temperature for Edinburgh in Scotland is 12 °C and the recorded average temperature for that month in 2009 is 13 °C, the difference of 1 °C is the anomaly and this would be used in the calculation of the global average (Stott 2011).

One of the main reasons for using anomalies is that they remain fairly constant over large areas. So, for example, an anomaly in Edinburgh is likely to be the same as the anomaly further north in Fort William and at the top of Ben Nevis, the UK's highest mountain. This is even though there may be large differences in absolute temperature at each of these locations.

The anomaly method also helps to avoid biases. For example, if actual temperatures were used and information from an Arctic observation station was missing for that month, it would mean the global temperature record would seem warmer. Using anomalies means missing data such as this will not bias the temperature record (Stott 2011; see National Climatic Data Center 2010a for additional explanation of the calculation and use of anomalies as used for the National Climate Data Center's GHCN system).

Even though using anomalies produces the most accurate record of Earth's global average temperature, it is still interesting to calculate one single absolute "global

average temperature." Using the GHCN dataset (National Climatic Data Center 2010b), the average value for the last 10 years, the warmest decade on record (GISS (Goddard Institute for Space Studies) 2010a; Atmospheric Administration 2009; WMO (World Meteorological Organization) 2009), produces a global average temperature for planet Earth of 14.4 °C or 58 °F.

Climate Forcing and Climate Feedback

Climate forcing refers to the processes that produce changes in the climate. The word force is generally defined as "strength or energy that is exerted or brought to bear [and that often] causes motion or change" (Merriam-Webster 2003). With respect to Earth's climate system, a variety of forces cause climates to change. These are called "climate forcings," and they are all related to Earth's "energy balance," that is, the balance between incoming energy from the Sun and outgoing energy from the Earth. The forcings can be internal or external. "Internal forcings" occur within the climate system and include processes such as changes in atmospheric composition or changes in ice cover that cause different rates of absorption/reflection of solar radiation. "External forcings" originate from outside the climate system and include processes such as changes in Earth's orbit around the Sun and volcanic eruptions. Forcings can be naturally occurring, such as those resulting from solar activity or volcanic eruptions, or anthropogenic in origin, for example, the emission of greenhouse gases or deforestation (Intergovernmental Panel on Climate Change 2007a, p. 9).

A feedback is defined as a change that occurs within the climate system in response to a forcing mechanism. A feedback is called "positive" when it augments or intensifies the effects of the forcing mechanism or "negative" when it diminishes or reduces the effects caused by that original forcing mechanism (Intergovernmental Panel on Climate Change 2007a, p. 875).

Forcing and feedback mechanisms often interact in complex ways that make it difficult to decipher the processes and dynamics of climate change. This difficulty also frequently frustrates policymakers, the media, and the public, and it can result in the dissemination of misinformation, both intentional and unintentional, into the public discourse. One example of this relates to the relationship between carbon dioxide (CO_2) and temperature. While it is relatively easy to understand that increasing concentrations of atmospheric CO_2 can increase the naturally occurring greenhouse effect thereby causing global warming, confusion and misinformation result when research brings to light a climate record in which changes in the atmospheric CO_2 level lag behind changes in temperature by 800–1,000 years. The legitimate question arises as to how it could be possible that CO_2 causes global warming if the rise in temperature occurs before the increase in the atmospheric concentration of CO_2. While the question is legitimate, unfortunately, some who are disposed to doubt claims of global warming neither seek answers to the question nor pursue additional investigation. Instead, they simply assert the premise that because CO_2 lags temperature, it cannot possibly be the cause of global warming. However, a more objective review of the scientific literature emphasizes the importance of distinguishing between forcings and feedbacks.

The initial, external forcing that begins the temperature changes observed in the climate record stems from fluctuations in the orbital relations between the Sun and Earth, and these fluctuations produce rather small changes in the amount of solar radiation reaching Earth (Hays et al. 1976). This relatively weak forcing action causes small temperature changes that are then amplified by other processes (Lorius et al. 1990). One such amplifying process that appears to be quite significant occurs because ocean temperature changes also change the ocean's capacity to retain soluble CO_2. As this capacity changes, it causes CO_2 to either be released from the oceans into the atmosphere (during times of warming temperatures) or removed from the atmosphere and dissolved into the oceans (during times of cooling temperatures). Consequently, CO_2 operates in these situations as a *positive feedback* mechanism that augments the temperature change. In other words, it enhances the greenhouse effect and amplifies temperature increases during times of warming and reduces the greenhouse effect and reinforces temperature decreases during times of cooling (Martin et al. 2005). Careful analysis therefore suggests that a climate record which shows CO_2 operating as a feedback mechanism neither negates nor renders less likely the potential that CO_2 could operate as an initial forcing mechanism as well. Considering that the atmospheric concentration of CO_2 has increased by 25 % in the last 50 years (Atmospheric Administration 2010), it is entirely possible that this increasing CO_2 concentration is functioning as the forcing agent for contemporary global warming. Simply put, it is a false premise to claim that CO_2 could not be causing contemporary global warming because CO_2 has been observed to lag behind temperature changes in the past. This false premise has been lampooned by the analogous statement that "Chickens do not lay eggs, because they have been observed to hatch from them" (Bruno 2009).

Global Warming Versus Climate Change

The terms "global warming" and "climate change" have been defined above, and those definitions will not be repeated here. But it is important to emphasize the difference between the two terms and the significance of exercising precision in use of them. While "global warming" is a useful way to refer to the increase of global average temperature that strong scientific evidence shows has occurred over the last 130 years (Fig. 2), for some people, the term carries the automatic connotation that human activity is the cause of this observed temperature increase. As stated earlier, a clear distinction should be made between questions that, on the one hand, relate to the changes in climate, if any, that are occurring and, on the other hand, the causes of any identified changes, specifically, naturally occurring or anthropogenic. Because the term "global warming" carries the more polemical and politicized connotation, it poses a higher probability of conflating the two questions than does the term "climate change" which has not yet attracted such politicized interpretations. Consequently, in general, the term "climate change" is preferable.

A second deficiency with the term "global warming" is the one-dimensional and totalizing change that it implies. Although the average temperature of planet Earth is increasing, the temperature change that any particular place on the Earth might

experience could be cooling instead of warming, or perhaps that place might be experiencing no change in temperature at all. But the term "global warming" is easily, and perhaps most naturally, understood to mean that all places on the Earth will experience warming. Moreover, even if the term is explained, it does not readily lend itself to the broader understanding that although the global average temperature is increasing, it is not necessarily the case that temperature is increasing at any given place on Earth. The term "climate change," on the other hand, does not imply this uniform nature of change and thus possesses greater capacity to communicate the potential for different changes occurring in different places and regions. In addition, the term "global warming" implies a narrow view of the nature of changes that can occur in the climate system, namely, an exclusive focus on temperature. But the possible changes to climate are not restricted to just the climate variable of temperature, and the observed increase in global average temperature has been associated with changes in a range of other climate variables that include precipitation amounts, timing and patterns, cloudiness, humidity, wind direction and velocity, storminess, and more. While the term "global warming" places the focus on temperature, the term "climate change" offers a much richer capacity to incorporate these other types of changes as well and, as a result, is generally emerging as the preferred term.

Thresholds and Tipping Points

The term "threshold" in ecology and environmental science means "a fixed value at which an abrupt change in the behavior of a system is observed" (Park 2008, p. 450). In climate science, the term "climate threshold" means the point at which some forcing of the climate system "triggers a significant climatic or environmental event which is considered unalterable, or recoverable only on very long time-scales, such as widespread bleaching of corals or a collapse of oceanic circulation systems" (Intergovernmental Panel on Climate Change 2007a, p. 872). Substantial research indicates that climate changes are prone to such thresholds, or "tipping points," at which climate on a global scale or climates at regional scales can suddenly experience major change (Committee on Abrupt Climate Change 2002; Lenton et al. 2008). A wide number of complex systems exhibit similar threshold events – financial markets, ecosystems, and even epileptic seizures and asthma attacks – in which the system seems stable right up until the time when the sudden change occurs (Scheffer et al. 2009). Research has provided general ideas on where these thresholds or tipping points might operate with respect to climate – the loss of Arctic sea ice or Antarctic ice shelves, the release of methane into the atmosphere from the melting of Siberian permafrost, or the disruption of the "oceanic conveyor belt" – but this knowledge is rudimentary at best. Scheffer and colleagues (2009) report tentative efforts to identify "early warning signs" that precede threshold events, and with respect to climate, they state that "flickering," "rapid alterations," or increased weather and climate "variability" seem to have preceded sudden changes observed in the climate record. But at present, predicting these climatic thresholds is vague at best. One of the authors explained the idea of thresholds and the uncertainty about them in an interview with *Time* magazine, "Managing the environment is like

driving [on] a foggy road at night by a cliff. . . .You know it's there, but you don't know where exactly" (Walsh 2009).

Defining and Communicating Uncertainty

Clearly, climate science contains uncertainties that are endemic to the data sources used, to the understanding of processes involved, and to predictions of future trends, impacts, and outcomes. Consequently, it is essential to accompany any study of climate change with careful, explicit, and candid assessments of the levels of certainty or confidence associated with the findings or claims made. Indeed, reports or studies are suspect if they fail to include such information and/or if they make unequivocal statements about "proving" their points. To some extent, the same can be said about commentaries, news reports, or various information sources. While the politicized environment in which climate change is debated might encourage strong and definite affirmations, such statements can prove counterproductive if they are perceived or exposed as exaggerated (Weber 2010; Hodder and Martin 2009).

Numerous approaches exist for defining and communicating uncertainty, and this brief discussion here does not attempt a comprehensive overview. Instead, it focuses on the approach that the IPCC has developed for its assessment reports. The main function of the IPCC is to "assess the state of our understanding and to judge the *confidence* with which we can make projections of climate change, its impacts, and costs and efficacy of options," but in its first and second assessments (1990 and 1995, respectively), the IPCC gave inadequate attention to "systematizing the process of reaching collective judgments about uncertainties and levels of confidence or standardizing the terms used to convey uncertainties and levels of confidence to the decision-maker audience" (Moss 2006, p. 5 emphasis added). Consequently, the IPCC conducted a comprehensive project to rectify these inadequacies (Moss and Schneider 2000; Manning et al. 2004), and the result was the following system for defining and communicating uncertainties in the Fourth Assessment Report published in 2007.

The first step is to present a general summary of the state of knowledge related to the topic being presented. This summary should include (1) the amount of evidence available in support of the findings and (2) the degree of consensus among experts on the interpretation of the evidence (Climate Change 2005). Figure 3 illustrates how these two factors form interacting continua that produce qualitative categories.

The IPCC guidance notes for addressing uncertainty (Climate Change 2005, p. 3 emphasis in original) state that in cases where the level of knowledge is determined to be "*high agreement*, *much evidence*, or where otherwise appropriate," additional information about uncertainty should be provided through specification of a level of confidence scale and a likelihood scale. The level of confidence scale addresses the degree of certainty that the results are correct, while the likelihood scale specifies a probability that the occurrence or outcome is taking place or will take place. The IPCC guidelines state that the level of confidence scale "can be used to characterize uncertainty that is based on expert judgment as to the correctness of a model, an analysis or a statement. The last two terms in the scale should be reserved for areas of major concern that need to be considered from a risk or opportunity perspective, and

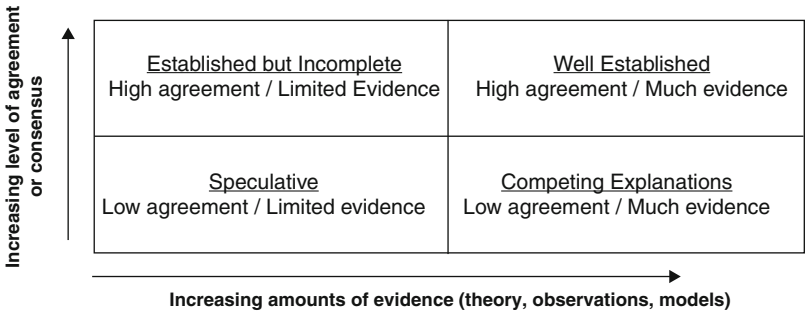

Fig. 3 Conceptual framework for assessing the current level of understanding (Moss 2006; Climate Change 2005)

the reason for their use should be carefully explained" (Climate Change 2005, p. 4). Table 1 shows the scale. The likelihood scale is used to refer to "a probabilistic assessment of some well defined outcome having occurred or occurring in the future" (Climate Change 2005, p. 4).

Adaptation and Mitigation

The terms "adaptation" and "mitigation" were briefly discussed in the introduction of this chapter, but the more detailed definition and explanation in Table 2 outline important distinctions that will be helpful for the sections of the chapter that follow.

Perceptions, Communication, and Language of Climate Change

Moser (Moser 2010, p. 33) writes that "a number of challenging traits make climate change a tough issue to engage with," and she implies that something in the nature of climate change itself makes it more challenging for people to perceive and communicate about than many other, even related issues (environmental, hazards, health). She lists the following characteristics of climate change that produce this substantial challenge:

- Invisible causes: Greenhouse gasses are not visible and have no direct or immediate health implications. The same is true for other forcing agents such as Earth/Sun relations.
- Distant impacts: The lack of immediacy in temporal and geographic distance.
- Insulation of modern humans from their environment: This diminishes the perception of any changes in the climate or their significance.
- Delayed or absent gratification for taking action: Action taken today is not likely to reduce global average temperature within the lifetime of the person taking the action.
- The lack of recognition that humans have of their technological power: This produces disbelief that humans have the capacity to alter the global climate.

Table 1 Scales of uncertainty used in the IPCC Fourth Assessment Report, 2007. None of these are statistically significant because no tests are conducted to determine the values. Instead, they are based on expert judgment

Qualitatively calibrated levels of confidence (Climate Change2005)	
Terminology	Degree of confidence in being correct
Very high confidence	At least 9 out of 10 chances of being correct
High confidence	About 8 out of 10 chances of being correct
Medium confidence	About 5 out of 10 chances of being correct
Low confidence	About 2 out of 10 chances of being correct
Very low confidence	Less than 1 out of 10 chances of being correct
Likelihood scale (Intergovernmental Panel on Climate Change2007b)	
Terminology	Likelihood of the occurrence or outcome (%)
Virtually certain	>99
Extremely likely	>95
Very likely	>90
Likely	>66
More likely than not	>50
About as likely as not	33–66
Unlikely	<33
Very unlikely	<10
Extremely unlikely	<5
Exceptionally unlikely	<1

- Complexity and uncertainty: This leads to considerations of climate change taking on less importance than immediate needs such as family and job responsibilities.
- Inadequate signals indicating the need for change: Inertia in the climate system and lack of observable economic or social costs or benefits reduce incentives for action.
- Self-interest: Not only are many powerful forces in society interested in maintaining the status quo, but also the majority of people in developed countries defend the comforts of their modern lifestyles, even if unintentionally and unconsciously.

Weber (2010) adds additional factors that make the perception and communication of climate change difficult. First is the difference between *affect-based* and *analysis-based* processing of environmental information. The general public relies heavily on affect-based processing, that is, relying on personal experience. However, climate change is not easily detected in this manner. Climate, defined above as the aggregate of day-to-day weather conditions that have been averaged over longer periods of time, requires analysis-based processing of statistical information that includes averages, trends, and uncertainty estimates, among others. The majority of people are simply ill equipped to process this type of information, and they have little patience in attempting to decipher it. Compounding the difficulty is that "People's fundamental values and worldviews influence which phenomena and risks they attend to and

Table 2 Definitions and explanations of the terms adaptation and mitigation from the IPCC Fourth Assessment Report 2007

Adaptation	"Adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities: Various types of adaptation can be distinguished including anticipatory, autonomous, and planned adaptation
Anticipatory adaptation	Adaptation that takes place before impacts of climate change are observed. Also referred to as proactive adaptation
Autonomous adaptation	Adaptation that does not constitute a conscious response to climatic stimuli but is triggered by ecological changes in natural systems and by market or welfare changes in human systems. Also referred to as spontaneous adaptation
Planned adaptation	Adaptation that is the result of a deliberate policy decision, based on an awareness that conditions have changed or are about to change and that action is required to return to, maintain, or achieve a desired state" (Intergovernmental Panel on Climate Change 2007a, p. 869)
Mitigation	"An anthropogenic intervention to reduce the anthropogenic forcing of the climate system; it includes strategies to reduce greenhouse gas sources and emissions and enhancing greenhouse gas sinks"
Mitigative capacity	"This is a country's ability to reduce anthropogenic greenhouse gas emissions or to enhance natural sinks, where ability refers to skills, competencies, fitness and proficiencies that a country has attained and depends on technology, institutions, wealth, equity, infrastructure and information. Mitigative capacity is rooted in a country's sustainable development path" (Intergovernmental Panel on Climate Change 2007a, p. 84)
Mitigation potential	"In the context of climate change mitigation, the mitigation potential is the amount of mitigation that could be – but is not yet – realised over time
	Market potential is the mitigation potential based on private costs and private discount rates, which might be expected to occur under forecast market conditions, including policies and measures currently in place, noting that barriers limit actual uptake. Private costs and discount rates reflect the perspective of private consumers and companies
	Economic potential is the mitigation potential that takes into account social costs and benefits and social discount rates, assuming that market efficiency is improved by policies and measures and barriers are removed. Social costs and discount rates reflect the perspective of society. Social discount rates are lower than those used by private investors
	Studies of market potential can be used to inform policy makers about mitigation potential with existing policies and barriers, while studies of economic potential show what might be achieved if appropriate new and additional policies were put into place to remove barriers and include social costs and benefits. The economic potential is therefore generally greater than the market potential
	Technical potential is the amount by which it is possible to reduce greenhouse gas emissions or improve energy efficiency by implementing a technology or practice that has already been demonstrated. No explicit reference to costs is made but adopting 'practical constraints' may take implicit economic considerations into account" (Intergovernmental Panel on Climate Change 2007a, p. 84)

Table 3 "Repertories" employed by people in response to information about climate change (Ereaut and Segnit 2006)

Alarmism	Climate change is constructed as "awesome, terrible, immense, and beyond human control. . . an inflated or exaggerated rhetoric. . . urgent tone. . . quasi-religious register of death and doom. . . language of acceleration and irreversibility. . . sensationalism [and that it] undermines its ability to help bring about action"
Settlerdom	". . . named after 'settlers'. . . people with sustenance-driven needs. . . optimistic but non-pragmatic. . . rejects and mocks the alarmist. . . invoking 'common sense' on behalf of the 'sane majority'. . . dismisses climate change as a thing so fantastic that it cannot be true. . . a refusal to engage in the debate. . . broadly right-wing. . . immune to scientific argument"
British comic nihilism	". . . an evasive rhetorical repertoire. . . rejection of climate change is whimsical, unserious, blithely irresponsible. . . a sunny refusal to engage in the debate. . . comic musings on the positive possibilities of a future with climate change. . . dealing with adversity and threat by use of humour"
Small actions	". . . the eminent 'pragmatic' optimist. . . asking a large number of people to do small things. . . language of ease, convenience and effortless agency. . . easily lapses into 'wallpaper' – the domestic, the routine, the boring and too easily ignorable. . . lacking in energy. . . may not feel compelling. . . the unspoken but obvious question: how can small actions really make a difference to things happening on this epic scale?"

which they ignore or deny" (Weber 2010, p. 335). When limited processing capacity and patience wane, people default to reliance on their fundamental values and worldviews, which generate a wide range of responses that are generally politicized and deeply held. Several typologies exist for categorizing these responses, but Ereaut and Segnit (2006, p. 7) have developed a very useful one from empirical studies conducted in the UK that contain the four "repertoires" presented in Table 3.

Future Directions: The State of Climate Change Knowledge and Future Predictions

As stated earlier, consideration of human knowledge of climate change and future predictions must differentiate two questions: What is the direction and rate of change, if any, in Earth's climate? What is the cause, natural or anthropogenic, of any observed climate change? It is almost universally accepted across the scientific community that global average temperature is increasing in accordance with the data presented in the graph in Fig. 1. This is summarized as follows:

> Since the mid twentieth century, the uncertainties in global and hemispheric mean temperatures are small, and the temperature increase greatly exceeds its uncertainty. In earlier periods the uncertainties are larger, but the temperature increase over the twentieth century is still significantly larger than its uncertainty (Brohan et al. 2006, p. 1).

With respect to differentiating natural from anthropogenic causes of this observed warming, although broad consensus of scientific judgment suggests anthropogenic

Table 4 Statements from the various IPCC Assessment Reports showing the increasing levels of certainty regarding the causes of the observed increase in global average temperature spanning the period 1990–2007

1990. First assessment report (Climate Change 1990, emphasis added)	"The size of this warming is broadly consistent with prediction of climate models, but it is also of the same magnitude as natural climate variability. Thus the observed increase *could be largely due* to this natural variability; alternatively this variability and other human factors could have offset a still larger human-induced greenhouse warming. The unequivocal detection of the enhanced greenhouse effect is not likely for a decade or more"
1995. Second assessment report (Climate Change 1995, p. 22 emphasis added)	"Since the 1990 IPCC Report, considerable progress has been made in attempts to distinguish between natural and anthropogenic influences on climate. The balance of evidence *suggests* a discernible human influence on global climate"
2001. Third assessment report (Climate Change 2001, p. 31 emphasis added)	"There is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities (p. 5). Most of observed warming over last 50 years is *likely* due to increases in greenhouse gas concentrations due to human activities"
2007. Fourth assessment report (Climate Change 2007d, p. 39 emphasis added)	"Most of the observed increase in global average temperatures since the mid-twentieth century is *very likely* due to the observed increase in anthropogenic GHG concentrations. This is an advance since the TAR's [Third Assessment Report] conclusion that 'most of the observed warming over the last 50 years is likely to have been due to the increase in GHG concentrations'"

causes, a substantial minority remains less convinced. The IPCC represents the former group that assigns causation to anthropogenic causes. But it has taken almost 20 years for the IPCC to reach this conclusion. Table 4 outlines relevant statements from the various IPCC Assessment Reports spanning the period 1990–2007.

Types of Mitigation Strategies

Because the focus of this handbook is climate change mitigation, various mitigation strategies are detailed elsewhere. Consequently, this section will not attempt thorough explanation of them, but will briefly list and outline the major types of mitigation strategies as a foundation for considering the ethical issues associated with them.

The most often discussed category of strategies for mitigating climate change is to reduce the emission of CO_2 that results from the combustion of fossil fuels. Public policy actions serve as the primary driver for effecting these mitigation strategies.

One policy action is to simply *set limits on the CO_2emissions* from the various sources (electrical generation plants, cars, etc.) as the impetus to develop cleaner technologies. Another is the well-known *cap and trade system* in which a government body limits the amount of CO_2 that can be emitted and then issues (allocates or sells) permits to private firms to emit specified amounts of CO_2. Firms can then sell or buy permits as needed depending on their amount of emissions. Cap and trade has been criticized on a number of counts, most notably (1) that it increases the cost of fuel and so disproportionally affects the poor rather than the wealthy and (2) that in the places where it has been tried, for a variety of reasons, it has not reduced CO_2 emissions and has resulted in volatile emissions trading market. A proposed alternative to "cap and trade" is known as the *fee and dividend system*, described as follows:

> . . . a fee is collected at the mine or port of entry for each fossil fuel (coal, oil, and gas), i.e., at its first sale in the country. The fee is uniform, a single number, in dollars per ton of carbon dioxide in the fuel. The public does not directly pay any fee or tax, but the price of the goods they buy increases in proportion to how much fossil fuel is used in their production. . .The carbon fee will rise gradually so that the public will have time to adjust their lifestyle, choice of vehicle, home insulation, etc., so as to minimize their carbon footprint. . .100 percent of the money collected from the fossil fuel companies at the mine or well is distributed uniformly to the public. Thus those who do better than average in reducing their carbon footprint will receive more of the dividend than they will pay in the added costs of the products they buy. (Hansen 2009, p. 209)

Proponents of the fee and dividend system list some of its additional benefits as (1) it is revenue neutral in that it does not raise taxes; (2) only a very small government bureaucracy is needed; (3) it "internalizes" the incentives to reduce the use of fossil energy (e.g., cost savings) across "billions of decisions ranging from commuting behavior to the design of vehicles, aircraft, cities, and so forth" (Hansen 2009, p. 211); and (4) it raises the cost of fossil energy sources to reflect their cost to society and the environment (pollution, climate change, health impacts, etc.) and to improve the competitiveness of renewables that do not carry these costs. Another climate change mitigation strategy focused on reducing production of CO_2 is *population control*, though it is highly controversial. Proponents argue that increasing human population causes increasing emissions of CO_2, and as a result, stabilization of human population is necessary to stabilize or reduce concentrations of atmospheric CO_2. Opponents respond that people are not pollution, but rather, the blame lies on the system that depends on fossil fuels for economic development. Instead of reducing population, they argue, policy should focus on changing that system. Further controversy has to do with the issues of liberty and family values, which can be said to conflict with policies limiting family size. A final strategy for reducing emissions of CO_2 involves *improving energy efficiency and conservation*. As efficiency increases, less fuel will be used, and as a result, less CO_2 will be emitted. This readily achievable and cost-effective strategy could not only reduce CO_2 emissions substantially but could also significantly reduce the world's energy demand (IEA (International Energy Agency) 2006).

In contrast to strategies that reduce the emission of CO_2, the second category of mitigation strategies removes CO_2 from the atmosphere once it has been produced. There are a number of such strategies. *Reforestation* involves the planting of forests, either new forests or the restocking of existing forests that have experienced deforestation, as means to sequestrate more CO_2 from the atmosphere. The process is explained as follows:

> Carbon dioxide is constantly exchanged between the atmosphere, the oceans and terrestrial ecosystems. Vegetation and soils can accumulate carbon, thus reducing the rate of CO_2 build-up in the atmosphere that is responsible for climate change… Forest ecosystems contain the majority (approximately 60 per cent) of the carbon stored in terrestrial ecosystems. Thus the world's forests sequester and conserve more carbon than all other terrestrial ecosystems and account for 90 per cent of the annual carbon flux between the atmosphere and the earth's land surface. (Strech and Scholz 2006, p. 861)

While reforestation efforts have potential to sequester CO_2, the effect is less than envisioned in virtually all such measures. The predominant means of reforestation is the "forest plantation" where a single species of tree is planted. The amount of carbon sequestration has been found to be 28 % less in forest plantations than in naturally occurring primary or secondary forests (Liao et al. 2010). Consequently, while not diminishing the importance of reforestation, it seems that the most efficient efforts involving forests would be to preserve existing ones. This provides good rationale to pursue a related strategy of *preventingdeforestation* which retains the natural, primary, and secondary forests.

Another strategy to remove CO_2 from the atmosphere is called *carbon capture and storage* (or sometimes carbon capture and sequestration). Other chapters in this handbook provide considerable detail on this topic, so it will only be briefly defined here. Carbon capture entails trapping the CO_2 at its emission source and then transporting it to a location where it can be stored so that it does not escape into the atmosphere (usually in underground rock formations).

A final suite of strategies to mitigate the effects of CO_2 is called *geoengineering*, defined as a "large-scale engineering of the environment in order to combat or counteract the effects of changes in atmospheric chemistry" (Committee on Science, Engineering, and Public Policy 1992, p. 433). They take the form of either shielding Earth from incoming solar radiation or facilitating the transport of heat energy from Earth to space, primarily by reducing the concentration of atmospheric CO_2. One of the most talked-about is to inject sulfur dioxide (several million tons per year) into the stratosphere (Kunzig 2008), where it would undergo various chemical reactions to produce sulfate particles that would scatter incoming sunlight and thereby cool the planet. It is known that this works because of observations of the effects of volcanoes that produce sulfur dioxide (SO_2), most recently, the Pinatubo volcano that injected over 20 million tons of SO_2 into the stratosphere in 1991, which resulted in a decrease of global average temperature by about 0.5 °C (1 °F) for about 1 year. The delivery of SO_2 into the stratosphere is proposed using either balloons or with planes burning high sulfur fuel, at an estimated cost of $25–$50 billion annually (Kunzig 2008). While studies indicate it would reduce global average temperature, it

would not address problems associated with increasing CO_2 levels, most notably, acidification of the ocean which causes negative impacts on organisms that make calcareous structures, such as shells and corals, along with the ecosystems of which they are a part. Another strategy that promises to reduce global average temperature by reducing atmospheric CO_2 is called *artificial iron fertilization* of the ocean. Such fertilization occurs naturally when dust storms carry iron into the ocean and cause blooms of the photosynthesizing organisms known as phytoplankton. By artificially spreading powdered iron into the ocean, the idea is to promote the phytoplankton blooms that would absorb CO_2 through the photosynthesis process. A commercial firm named Planktos explored this idea and conducted some small-scale tests. However, they failed to gain adequate investor funding to scale up the project, primarily as a result of questions about various and potentially negative unintended consequences of the project that included adverse effects on marine organisms and ecosystems (Courtland 2008). This highlights a serious drawback to these and the various other geoengineering strategies and possible unintended consequences that would be global in scale and sometimes unstoppable.

Uncertainties and Moral Obligations Despite Them

The previous section introduced the kinds of uncertainties involved in human understanding of climate change. The first point to address concerning moral obligations in the face of uncertainty is that it is wrong to overstate the uncertainties involved. This is the case because, in large part, consequences for denying what has been well established include delaying and softening the response to problems that are likely to require significant effort and collaboration to address. Democratically, furthermore, obfuscations of the kinds that the previous section sought to undo, such as in the conflation of the issues of warming global temperatures with the causal forces bringing the warming about, only get in the way of making intelligent progress in addressing either of these concerns.

Three issues are worth covering in this section given their bearing on uncertainties and moral obligations despite them. The first concerns the ethics of news reporting about scientific developments regarding uncertainties with respect to climate change. The second regards a fallacy of reason that is committed all too often about climate change. The third one concerns caution and collective obligations in the face of uncertainty.

Ethics and Reporting About Climate Science

One important development in news reporting has been the recognition that news outlets often exhibit biases. A traditional way of thinking suggested that reporting should only be considered the relaying of facts. This outlook is generally ascribed to modernism and has inspired a reaction that has been called postmodern, a view that holds that no outlook in news reporting can be considered perfectly objective or

absolutely without bias. While the postmodern movement has its flaws and excesses, it is not wrong in seeing that the long-held ideal of a "view from nowhere," a point of view without bias, may be unachievable and imaginary.

Building upon postmodern thinking, more pragmatic approaches to knowledge have come to see biases as things to be recognized and controlled. What has come about as a result of this shift is an effort in countless news outlets always to demonstrate balance about issues that get reported. A problem that emerges is that news outlets sometimes make use of commentators, explicitly holding a point of view, but then contrast them with people whose points of view are minimally relevant to the topic being reported.

One troubling consequence of this effort to appear more credible, to issue news that is more purposefully and intentionally balanced from a political point of view, is the fact that some people want to deny the findings of science. Examples of this problem include detractors of climate science along with other examples such as those who believe that the age of the Earth should be determined by reading religious texts rather than with the scientific method. In short, when a vocal minority of people speaks up, they can make it appear as though there is balance, a 50–50 way of reporting the facts about scientific developments. When it comes to matters such as climate science, however, this development is pernicious because it promotes the idea that genuine controversies exist within the sciences when no fundamental disagreement exists among scientists. There is a moral problem at issue here in which some people use the idea of media balance to "spin" a point of view that makes uncertainties appear far greater than they are.

The motivations for misinformation or for the propagation of claims unjustified or even contradicted by science are varied. While people certainly have a right to beliefs from religious or other sources, this fact produces tension wherever such beliefs conflict with the findings of science. In many cases, these tensions are dealt with in constructive ways, but in other cases, some persons may think that their interests would be best served if scientific developments were stalled or obfuscated. Efforts of this kind surely produce troubling manipulations of the democratic need for carefully evaluated and verified political as well as scientific information.

Avoiding the Fallacy of Appealing to Ignorance

Uncertainties about climate change precipitate a common challenge to the idea that action should be taken to address it. There is an important fallacy at play in such arguments, beyond the fact that often obfuscations are made about what uncertainties there are exactly involved in climate change. It is the fallacy of appealing to ignorance.

An appeal to ignorance is a fallacy of reason that occurs when one makes a strong conclusion about the state of some subject matter on the grounds that knowledge is lacking about it. Take an example of Jack, who is a serial killer. Mindy and Alex do not know that Jack is a killer, but Mindy has a bad feeling about him, and she says so to Alex. Alex defends Jack by stating "you don't actually know that Jack's a bad guy,

so he's a good guy, really." Alex holds a kind assumption that people are nice unless proven otherwise, but in this case, it is clearly wrong. Alex moves from the fact that someone lacks knowledge to some other substantive fact that the lack of knowledge clearly cannot substantiate. This fallacy of reason is called an appeal to ignorance.

The appeal to ignorance seems to be one of the most common responses to climate change efforts. People tend to imagine or pretend that the science is inconclusive, but in a way that in fact may be insufficient a challenge to the idea that people ought perhaps to take precautions. Beside this precautionary motivation, known as the Precautionary Principle, the fact is that the science is stronger than it has been in many cases portrayed, as shown in the previous sections in this chapter.

The Limits of Challenges About Uncertainty

The first thing to say here is that the uncertainty people claim is involved in scientists' understanding of climate change is frequently overstated or misstated. In this section, let us imagine that some of the bolder claims about uncertainty with respect to climate change were true. There is still reason, nonetheless, to think that moral obligations could and do exist for people despite such a hypothetically strong uncertainty.

The common response in the environmental ethics literature to the challenge of uncertainty is that the potential harm that can come from problems such as climate change can be catastrophic (Manson 1999). Thus, even if there is uncertainty about a problem or a very small likelihood of trouble, it is typically wise and a moral obligation to avoid that catastrophic scenario. This is general practice in medical situations. When a set of possible medical courses of action are generally safe and yield little risk of adverse effects, they are almost always what one should do before other options whose effects could be catastrophic. The reason for the moral obligation to choose the less risky option is known as the Precautionary Principle. The Precautionary Principle in the context of climate change resembles what in the history of philosophy has been called Pascal's Wager.

Pascal's Wager is about belief in God. He argued that four options exist:

- If one does not believe in God and God exists, then a devastating outcome could ensue – eternal damnation for one's disbelief.
- If one does not believe in God and there is no God, no problem.
- If one believes in God and there is none, then one has lost some time and effort.
- If one believes in God and there is a God, then one could receive great rewards.

This set of options, Pascal believed, is excellent reason to believe in God. Of course, religious arguments can analyze whether or not such motivations are enough for genuine belief, but the point of relation to the subject here, climate change mitigation, concerns especially the one similar circumstance that could arise for the environment. In other words, what if people do not concern themselves about the environment and in fact allow or increase the chances of catastrophic circumstances

as a result? The worry involved there is something akin to that involved in risky medical practices that are not accepted in all but the rarest of cases.

The response to the wager for the environmental context is to say that there are costs of mitigation and adaptation to climate change. Of course, if there is no choice but to adapt, then those costs cannot be avoided, though they can be distributed more or less justly. When it comes to efforts to mitigate climate change, however, things like caps on greenhouse gas emissions can have profound effects on the ways in which businesses work. In short, a challenge to the Precautionary Principle emerges related to the cost-benefit analysis of action to address climate change. Neil Manson (1999) estimates that the costs of inaction could be seen as enormous, which is why people should not be afraid to enter into discussions about precautions and valuations of climate change. Environmentalists are often wary of entering into cost-benefit analyses, since it is difficult to value things like the survival of species. However, Manson also argues that environmentalists could devise strategies for valuing the costs of changes to climate. In short, there are a number of important elements that can factor into moral obligation even if there are uncertainties about climate change. There is a whole industry in the insurance business that practices the process of putting monetary value on things that average persons would have an extraordinarily difficult time valuing, since people in general do not think of the world as do those who manage risk for a living. It is important to note here in concluding this section that none of these responses to challenges of uncertainty about climate change should be construed as reason to doubt the increasingly strong evidence that suggests human beings have a significant impact on the environments on a large scale or the even more strongly defended judgment that global temperatures are increasing over the long run, occurrences for which the Precautionary Principle would prescribe that humanity to prepare (see Gardiner 2006 for an explanation of the Precautionary Principle).

Traditions and New Developments in Environmental Ethics

The study of environmental ethics has grown substantially in the last 30 years. In the background of developments in this study lie cultural beliefs about the world and humankind's place in it. Often, the Earth is conceived as God's gift to mankind, to be used for human purposes. At the same time, things that are gifts from God could also be considered important targets for stewardship. Stewardship refers to the duties one has to objects or property bestowed on oneself in some honored fashion, like a family heirloom or in this case a divine gift. Whether one approaches environmental ethics with a religious motivation or a secular one, a tension arises often between the idea that the Earth is property, a mere tool for human ends, and the opposing belief that human beings have a duty to take the best care they can of shared resources. This tension arises in the study of environmental ethics in the form of arguments that address human interests primarily, the anthropocentric approach, and arguments that give moral weight to things like places, animals, ecosystems, etc. The present section will cover a number of the approaches that environmental ethicists have taken for

considering the moral duties human beings have to care for the environments on which they depend. The section will begin with a discussion on the tradition of environmental ethics, focusing on theories about the source of value in ethics. Next, the matter of who is affected in problems of environmental ethics is important to consider. Finally, some recent developments will be discussed, which suggest that a cultural shift is noticeably growing public acceptance for environmental values and precautions.

Sources of Value in Environmental Ethics

The traditional way of thinking about land and environments has largely been religious. In 2010, founder of southern Indiana's Corydon Tea Party Norman Dennison explained a traditional outlook on religiously motivated opposition to understanding about climate change. Dennison explained that human-induced climate change "is a flat out lie." According to a *New York Times* article, Dennison explained that "he had based his view on the preaching of Rush Limbaugh and the teaching of scripture. 'I read my Bible,' Mr. Dennison said. 'He [God] made this earth for us to utilize'" (Broder 2010). Here, Dennison illustrates contempt for the findings of climate science, to be sure, but he also demonstrates the central background for thinking about environmental concern as uniquely anthropocentric and based on God's purported decision that the Earth is intended to be used up. Rachel Carson has argued that the tradition treats the Earth as an object to be exploited and conquered, without consideration for its well-being (Carson 1962/1987).

Religious outlooks on environmental policy do not exclusively follow Dennison's orientation to deny climate science. Matthew Hay Brown in *The Baltimore Sun*, for instance, asks "Where would Jesus drill?" in his article "Religious Environmentalists Hope Spill Wins Converts" (Brown 2010). What is noticeable, therefore, is that although traditional views may suggest that humankind ought to have great powers over God's gift of the Earth, even in religious discussions, the source of environmental value and what ought to be done is neither settled nor determined for all. In particular, a central challenge to such traditional views concerns the idea that environmental ethics ought to be anthropocentric.

One of the most influential thinkers to challenge solely anthropocentric values in environmental ethics was Aldo Leopold. In *A Sand County Almanac*, he called for an expansive view of the source of value in ethics (Leopold 1968). He named a new kind of ethic the Land Ethic. Although Leopold was a hunter and enjoyed nature very much, he saw in nature a source of value that is independent of his enjoyment of it. In this section, it should become clear that there is common ground to be found between the different views that are presented here. Whether value is inherent in nature or not, ultimately anyone concerned must convince others to share that concern. Therefore, the anthropocentrism or the inherent value theorist like Leopold needs not only to attend significantly to human interests but to expand people's understandings of what those interests could more intelligently appreciate.

The common tendency in debates about ethics and environmental issues is to have human beings pitted against something like an endangered animal. Some people wonder why they must be terribly concerned about rarefied fish, for example, especially when countless species have gone extinct in the past. Plus, in biology, students are taught that animals survive when they are fit for their environments. Thus, one might argue that any animal that is in danger of becoming extinct is simply showing its unfitness for present conditions, whether those conditions are man-made or not. If they become unfit for the environment by accident or by purposeful human action, what is the moral difference?

Environmentalist responses have varied to such challenges, and Leopold's answer is straightforward. He said that inasmuch as you and he have rights and worth and deserve respect in efforts to live, so do other animals and environments. He believed that the problem fundamentally has to do with the fact that people think they simply have no obligation to the things and other forms of life in this world. As such, it follows that the right of things to live and to be can in many circumstances trump human claims on freedom to change the environments in ways that harm the natural habitats of animals, thought Leopold. In this sense, Leopold believed in the importance of human stewardship of land. He saw not only animals and plants as living things but ecosystems and natural environments as having lives as well. The reason people generally do not think about mountains as alive comes from not seeing the place of mountains in an overall living system and also not looking at them on the right scale. After all, mountains, streams, and grasslands all change and grow, erode, and serve as homes for countless animal and plant species. If people care about their own lives, it is life ultimately that counts, Leopold argued. He saw the history of ethics as a growth in consideration for people and groups and then pets and other cared-for things in an expanding circle of consideration. He believed the next step was for humans to broaden consideration even further, to include the environment. The most important element that Leopold brought to the attention of moral thought had to do with this broadening of moral consideration beyond the simply anthropocentric view. Today, the existence of laws about the treatment of animals is one form of outgrowth of theories like Leopold's.

Two matters are important to note at this point about global climate change and the ethics involved in efforts to mitigate it and its effects. First, the idea of speaking for the Earth as a whole is one strategy that has been appealed to in ethics. Environmental ethics scholar J. Baird Callicott (1994) has on several occasions argued, however, that it is quite certain that the Earth itself will be here whatever human beings do to it. Thus, the strategy of arguing for the Earth's sake, an approach that Callicott claims to be too diffuse to be practical in inspiring people, is also misguided in a greater sense. The people who would argue for human-centered values in ethics are not taking the wrong track. It is life on Earth, including human life, which will be affected substantially by things like climate change. Thus, it is not problematic to focus on the values of environmental efforts that are based on the quality of human life and the cares of human beings.

Following Callicott's advice, whether one believes in the independent theory of environmental value or only the anthropocentric theory, it seems most rhetorically

powerful not only to argue according to human interests but to expand how people think of these. Philosopher Andrew Light has taken this approach, for example (Light 2002). One might differ from Leopold in how to defend things like unique fish in a river that could be destroyed due to some construction change or industrial practice and might instead consider the possible effects of such changes for human beings. One way to think of human interest with regard to generally unfamiliar animals or environments has been studied under the category of "ecosystem services" (Ecosystem Assessment 2005). Among the effects that have been considered in arguing for the defense of ecosystems are the kinds of benefits that come from biological diversity. The first among these is the fact that animals serve as food for other animals. As such, then, when one species is wiped out, it almost invariably has a rippling effect on other species, who either have to change their diets substantially, sometimes failing and thus dying out also, or to bring a substantial shift in effect on other animals that then become prey, potentially wiping them out. The number of animals and species affected can be enormous, then, from one simple change in biodiversity in a particular environment. When one realizes the breadth of possible effects from climate change, the results could be truly catastrophic (Gardiner 2004). The idea of "ecosystem services" points out the fact that humans get things like clean drinking water from a whole ecosystem. When people affect a significant element of an ecosystem, a great chain of events can mean danger for human beings as well as the animals and environments initially altered.

The skeptic could ask, however, what it matters if an ecosystem changes substantially, beyond the occasional cases in which things like drinking water are affected. What practical consequences are there for human beings in other cases? The first answer here would be that human beings enjoy their environments. Change to those environments could easily affect human beings negatively, therefore. Examples include changes for simple appreciation of beautiful environments that become less beautiful – the element of aesthetics in ethics. When one's landscape is beautiful and valuable as such, one's property values decrease significantly if the environments become less beautiful and desirable, which is a financial aspect of an aesthetic change. Another aesthetic change similarly can occur for hunters, who are no longer able to enjoy either their hunting environments or the animals that they hunt because of effects on populations due to environmental changes. As mentioned above, Leopold was a hunter too, who enjoyed environments as he respected their inherent value at the same time.

A second consequence could be agricultural. When an animal is eliminated that would otherwise keep insects in check, crops can be devastated all of a sudden because the insects are more able to multiply in huge numbers. Famines can result from such changes, if crops become devastated. The costs of shifts in agriculture are more immediately obvious for human interests. They can also be direr for human beings than aesthetic changes. In relation to issues of climate change, whatever the cause of changes in climates, farmers have begun to report the need to change the kinds of crops that they farm because of environmental changes. According to Mendelsohn,

> The largest known economic impact of climate change is upon agriculture because of the size and sensitivity of the sector. Warming causes the greatest harm to agriculture in

> developing countries primarily because many farms in the low latitudes already endure climates that are too hot. . . Even though adaptation will blunt some of the worst predicted outcomes, warming is expected to cause large damages to agriculture in developing countries over the next century. (Mendelsohn 2009, p. 5)

Agriculture, economies, and food supplies are each threatened by changes in climate, therefore. So, when confronting problems in ethics for climate change, cost and benefit analyses of action surely bear weighty elements for consideration. At the same time, the people who are affected by these costs are important to consider. The point here at first, however, has simply been to show that one does not abandon consideration of environmental problems when one takes the impacts on human beings of things like climate change as essential sources of value for decision making. After all, those who care deeply about the value of a certain species alone need to make their cases in ethical debates with human beings, who bring their interests to the table. The strength for such persons, however, in the process is the profound impact on people that changes in environments can have.

Persons Who Experience Benefits and Costs

The subject of who is affected by changes in climate is important to consider. There is an intensely complex set of conflicting interests involved in considerations of who is affected by climate change and by efforts to mitigate it. The tradition in ethics has nearly always been to consider first and foremost the values and effects on persons who are presently living when debating the costs and benefits of action or of constraints on freedom. In the case of climate change, there certainly are people who are affected in the present through changes in things like aesthetics, hunting, and agriculture, as outlined in the previous section. For example, rivers that are drying up and that had attracted animals in some countries now no longer bring them, which affects agriculture and a vast number of organisms, in turn affecting food supply and economies for human beings (Mendelsohn 2009).

At the same time, some of the greatest potential worries about climate change are expected to come in the next few generations, not in the present. Thus, when it comes to ethics, an important question arises concerning the nature of present human beings' responsibilities to future generations. After all, the people to whom some say living human beings have obligations are not even here today. They have not yet been born. How can people alive today have moral obligations to nonexistent people? The Stern Review (Stern 2007) has generated fairly profound impact on this subject, and the basic arguments have been summarized by the editors of *Scientific American*:

- Future generations will suffer most of the harmful effects of global climate change. Yet if the world economy grows, they will be richer than we are.
- The present generation must decide, with the help of expert advice from economists, whether to aggressively reduce the chances of future harm or to let our richer descendants largely fend for themselves.

- Economists cannot avoid making ethical choices in formulating their advices.
- Even the small chance of utter catastrophe from global warming raises special problems for ethical discussion (Broome 2008, p. 97).

There are a number of practices already observable that offer examples to follow regarding these questions of responsibilities to generations that are not present. First, when persons die, in most societies, people honor obligations to persons who have passed away. Part of the reason for this has to do with legal codes, and part of it has to do with resolving conflict among the living about those who die. But there are ways in which people honor those who have died in various ways, such as with memorials.

What is more interesting for the present issue of debate has to do with future generations. With regard to them, politicians in recent years, such as Senator John McCain, have argued for clear obligations to children and grandchildren in the United States. McCain argues that accruing debt today is wrong because of the negative effect it will have on future generations, who will be "saddled" with debt (McCain 2009). In these instances, politicians like McCain raise problems about the national debt and the deficits that cause it to grow. What deficits do is to increase the country's future financial obligations to pay back loans incurred for the purpose of present spending. Those who defend such spending argue that there are long-term effects of such spending, such as in rebuilding an economy that can pay back the debts and avoid greater recessions or another depression. At the same time, then, both sides of the debate about rising deficits are making claims about moral obligations both to present *and future* citizens. The claim some detractors make about government spending is that it is irresponsible, it is wrong, to create negative future financial circumstances for future generations – children, their children, and their children after that. The argument goes that people have obligations to their children's grandchildren. Such ideas are not farfetched, and they can be seen clearly to apply to matters of environmental ethics.

Those who would reject obligations to future generations make quite a controversial claim. The more common line would be by analogy to the idea of proximity. In some ethical circumstances, it seems quite clear, for instance, that people have obligations to help someone if they can when that person is close and is in great pain. If people can help and choose not to do so, they allow greater suffering to continue than would occur if they were to intervene. Thus, in the view of some moral philosophers, people are partly responsible for the outcome that ensues from inaction. Even inaction has effects, in other words. The key point here is that one may have an obligation to help someone drowning 15 f. away, but the person who is drowning a mile away is someone either who cannot be helped or who is not sufficiently proximal. A better example is starvation, since it is not quite as immediate a problem. If someone nearby is starving and so someone is far away, people have a tendency to think that either the person close to them is the one for whom they have the greater obligation or it is the person with the greater pain. When all things are equal regarding the extent of the suffering, people perhaps naturally feel a greater obligation to those who are closest to them. Translate this trend that is here described spatially to the temporal level and the same pattern seems to hold. If people are

starving today, human beings seem to have a far greater moral obligation to them than to address the starvation of possible people who may or may not come to be born tomorrow or in several generations. This at least is the set of options for considering obligations to people present and in the future. The common motivation for taking present and close persons to be more important is understandable, therefore, all things equal, compared with people who are not present or close. The trouble is, however, that the future which is put on hold in moral consideration could be deeply affected by choices that provide only small benefits or pose only small costs today. In fiscal terms, consider the US Congress throwing an incredible national party at enormous expense to future generations. It may be fun, but the benefits would be short-lived and appear incredibly thoughtless to future generations who then have to suffer the burdens of an inconsiderate earlier society. When it comes to ethics and climate change, it is hard to think that people have no obligation to future generations. There are also long-term predictions that appear quite worrisome given the apparent increase in the rates of temperature rise and other factors relevant to climate change. Thus, policymakers must think about the environmental crisis that future generations might have to face, much as they already consider the problem of passing on debt to future generations of children and grandchildren.

Beyond the problems of obligations for present and future persons is the fact that the costs and benefits of constraints on freedom and of positive action regarding climate change mitigation are disconnected. In other words, the persons who are affected by costs are rarely the same people who reap benefits. The following are three important examples of this idea.

The first example concerns persons currently affected by climate change. Consider the farmers who presently have to change their crops or who have lost their crops and the potential to raise them. Whether climate change can be attributed clearly to the production of greenhouse gases or not, the persons who are benefiting from greenhouse gas consumption the most, especially the recipients of wealth that come as a result, or at least the persons most likely to pay the costs of action about climate change, typically the wealthier nations, are either going to lose some of the benefits they get or incur some of the costs of the response to climate change mitigation when they themselves are to a far less devastating extent affected by the change in climate. In this sense, then, climate change is something unlikely to be addressed in profound ways by individuals acting only in their own self-interest, at least until sufficient problems occur to bring about a serious threat for the wealthier nations and persons. In this sense, then, the disconnection in present time is a real problem for bringing about one kind of response to climate change mitigation. It makes it far more likely that any real effort to address climate change will take place primarily at the state (national) level or through channels for which there is private benefit for making changes, which might include, for instance, the development of energy-efficient technologies that get sold for profit.

Another similar disconnect occurs at the level of present and future people. While future consequences can only be addressed by present people at any given time, benefits in equations of cost and benefit can seem less weighty because future people are not present. As such, then, the people who will make the sacrifice for future

generations are present and feel less the impulse to help those whom they cannot see. This entails the idea of discounting the future. The problem occurs in many spheres. When roads are unsafe but are costly to change, it often takes catastrophe in terms of loss of life for people to feel sufficiently motivated to bring about change. The same problem occurs for issues of fiscal discipline. Also, the arguments against present action in favor, for instance, of allowing present businesses to continue unhampered in their practices that promote climate change see importance in the effects of changes to economic success as ripples. In other words, greater constraint on economic growth now can have negative effects on future generations also. The matter of who is affected by climate change and efforts to mitigate it is quite complicated, therefore, and is most likely to occur at the larger, state level or at the level of vast agreements for changes that are established with cooperation between government and industry.

A further disconnect is important to notice in considering who will be affected by constraints on the production of greenhouse gases or other efforts to mitigate climate change. Poor nations argue that limitations on their industries are limitations on their development. In other words, when burning fuels like coal is the cheaper energy route that makes places like China and India grow, they argue that to push them not to use such fuels is unfair in terms of market competition. They argue that the United States and other such wealthy nations that industrialized first would perpetuate poverty in poor nations for the sake of environmental concerns, when poor countries' development needs are great. Therefore, the people affected by efforts to change industries, practices, and efforts that mitigate climate change not only concern poor farmers and wealthy nations but also those nations seeking economic growth out of poverty. They wish for the freedom to develop in ways that will bring masses of people out of poverty, raising the standard of living for human beings in poor places. The result of making allowances for such cases, however, is that those nations who accept responsibility to act for the sake of mitigating climate change may argue, with debatable merit, that double standards are hypocritical. These kinds of problems and arguments demonstrate how difficult it is and will be to create significant coalitions in efforts to mitigate climate change. The web of conflicting interests involved renders the problem of laying out a simple ethic of environmental action enormously difficult. The motivation for clarifying these issues, however, is powerful nonetheless, since the potential harm to humanity of inaction could be catastrophic. Incredibly complex circumstances have been resolved before, but only with great effort and time. The effort and time spent to date in climate change have yet to resolve these issues.

New Developments

With still so much to be developed about the future of climate change, adaptation options, and potential methods of mitigation, the ethical responsibilities involved may take shape in a variety of ways. An important shift has occurred since the start of the environmental movement. That shift is cultural. A movement has taken hold to

consider future steps for addressing environmental problems. Early on in the environmental movement, there was far less study of environmental science than is available today. Cultural elements like the development of recycling systems have become commonplace in countless population centers worldwide. Plus, what started as an apparently politically polarized concern for the environment has grown to be recognized in many spheres. Just one example of this is in sanitation. It is clear to people that the faster landfills fill up, for instance, the sooner new costs will come for more land, farther carrying of trash at greater fuel expenses, etc. Also, in communities with well-run recycling efforts, municipalities can see financial benefit from the materials recycled that would otherwise just fill up landfills. These elements I call cultural because they are not measures that address climate change directly. Rather, they are elements of a culture of consideration for what it means to be a part of an ecosystem today.

At one level, something like a cultural shift is necessary, since no one solution is likely to resolve the problems of climate change. Andrew Light's environmental pragmatism suggests an effort to move beyond traditional philosophical debates about the nature of environmental value. He argued that "the important thing to impress upon environmental philosophers [is] the need to take up the largely empirical question of what morally motivates human to change their attitudes, behaviors, and policy preferences toward those more supportive of long-term environmental sustainability" (Light 2002, p. 446). What is most likely is that a variety of efforts combined will be necessary to bring about both the will for change and the consequent support for public policy that addresses environmental concern adequately. Those efforts should include both adaptation and some potential measures of mitigation, and these will inescapably have to be joined with developments in new technologies whose benefits should bring about a decrease in harmful emissions, a decrease in demand for finite energy resources, and an increase in sustainable practices. These joint goals do not yet have a singular solution for achieving them all, but together they embody the various important elements that will enable cultural shifts in energy use and thus emissions to take hold in wealthier nations and abroad. But the problems of climate change may require drastic action in some regions, and with any drastic action, costs arise, both in carrying out the action and in dealing with its new effects. The most effective outcomes will likely occur with the help of interdisciplinary teams working in concert to bring about maximally beneficial environmental results, such as are starting to arise with projects like architectural planning for new buildings. Even if changes come, yielding a culture of concern for the environment, however, some new developments in ethics and in climate change considerations will grow increasingly important and complex and will continue to challenge cultural beliefs and practices. These include the following:

- The need for new technologies, such as trapping of GHG's, and energy efficiencies
- The possible need for population controls and the conflicts that will likely arise regarding fairness and freedom in relation to such controls
- Policies and plans for the future migrations of people who have no other choice

- Challenges of dividing up responsibilities when changes require costs
- The offset of cost involved in choosing practices that are sustainable over ones that are simpler and cheaper, but at greater environmental cost

A final consideration is worth noting. There are regions in which people do not yet live. In those places, there are natural resources that could be gathered. Among these circumstances is the Arctic National Wildlife Refuge (ANWR) in the United States, which has been at the center of controversy about drilling for oil in new locations. People argue that America ought to exploit this location since no one uses it. A few considerations already mentioned combine in rendering such cases more complex. For instance, it could be claimed that such areas will not have future benefit for people because people do not travel there. As climate changes, however, it is altogether possible that uninhabitable places become inhabitable. In that process, places like refuges near the poles will become more frequented as a result of the thawing of cold regions, but it is uncertain whether or not future generations will make use of such refuges. In this instance, then, the problem of uncertainty for the future returns, while not directing specific action – since people must not commit the fallacy of appealing to ignorance – it is important nevertheless to raise the question about whether it is true that the ANWR will not be used in the future. Also, it appears that climate change, while potentially devastating in some regions, may bring benefit to colder regions to some degree. Finally, the matter of responsibilities to future generations arises, when coupled with these first two considerations, showing concern for children and grandchildren, who may 1 day frequent places like the Arctic National Wildlife Refuge. Nevertheless, the people of today need to be concerned about sources of energy, as well as their economic well-being, for without the necessary financial and energy resources, expensive efforts to mitigate climate change will be impossible.

Conclusion

Changes in climate are of the immensely complex sort that will require consideration about a vast array of responsibilities and inputs. This fact has slowed the development of a culture of environmental concern, but today that culture is building and appears to recognize more than ever before the need for concerted efforts to get ready for the greater changes and costs that climate change will bring about. For the present volume on climate change mitigation, the focus has been on terminology, options for mitigation, as well as the various ways of thinking and the considerations that should be taken into account for ethical approaches to human conduct about climate change. At the same time, in the cost and benefit analyses to be used in evaluation of the various methods that are and will become available for responding to new problems, it is important to factor in options for adaptation to new circumstances, remaining as open as possible to intelligent deliberation about the ideal resolution of the problems of climate change. People must also take into account the fact that measures to mitigate climate change always come with costs of their own, both direct and

indirect. The fact that there are costs to the work of addressing climate change, however, ought not to be seen as implying that the world would lose equally from action as from inaction. Climate science, mitigation strategies, and projections of adaptation options, all are becoming better understood as further inquiry develops into these areas. Skepticism is often a healthy force in inspiring further study and justification for public action. Past skepticism has inspired more and more study over time, which appears to be converging on the conclusion that the need for action must be taken seriously and proposals weighed. This chapter has been aimed at exposing readers to a number of issues related to a broad understanding of climate change, mitigation, and the moral norms that ought to be taken into account as international efforts are shaped to address the future of the global climate.

Mass Media Roles in Climate Change Mitigation

Kristen Alley Swain

Contents

Abstract

News media portrayals of climate change have strongly influenced personal and global efforts to mitigate it through news production, individual media consumption, and personal engagement. This chapter explores the media framing of climate change mitigation and adaptation strategies, including the effects of media routines, factors that drive news coverage, the influences of claims-makers, scientists, and other information sources, the role of scientific literacy in interpreting climate change stories, and specific messages that mobilize action or paralysis. It also examines how journalists often explain complex climate science and legitimize sources, how audiences process competing messages

about scientific uncertainty, how climate stories compete with other issues for public attention, how large-scale economic and political factors shape news production, and how the media can engage public audiences in climate change issues.

Introduction

By the end of the twenty-first century, global climate change is predicted to raise sea levels and increase the frequency and severity of storms. Rising temperatures would create heat waves, drought, and disease pandemics. Hundreds of thousands of square miles of coastal wetlands and lowlands could be inundated. Flooding from excessive rain and sea-level rise would threaten lives, agriculture, livestock, buildings, and infrastructures. Salt water advancing into aquifers and estuaries would threaten water supplies, ecosystems, and agriculture.

The effectiveness of climate change mitigation and adaptation is linked to public understanding of climate change issues, which people gain through daily media consumption. News is ubiquitous in everyday life, "a sort of instant historical record of the pace, progress, problems, and hopes of society." It also can influence the outcomes of the events it describes. However, mainstream U.S. news media have failed to adequately report on climate change.[1]

Public awareness of climate change issues continues to rise worldwide, but in most nations, coverage of sports, celebrities, politics, the economy, and crime dwarfs that of climate change. The news media often represent climate change mitigation and adaptation as dynamic and contested issues within the intersecting realms of policy, science, and the public. Although science has confirmed that human activities are heavily implicated in climate change, the global phenomenon has been increasingly framed as catastrophic as though it must be considered dreaded and irreversible to warrant public attention. Social scares that accelerate political demands can spark broad social change.[2]

Media framing can strongly influence audience motivations to act or to become fatalistic. The cost of inaction could be severe in the case of climate change. The predicted consequences of inaction include ozone depletion, melting of the polar ice caps, destruction of wildlife habitats, catastrophic sea level rise, extreme weather patterns, flooding and drought, increase in average temperatures, and other irreversible climatic changes. Even if all greenhouse gas emissions could stop immediately, more major climate changes still would occur because of lags in the Earth-atmosphere system.

Rapidly shifting attitudes among nongovernmental groups on the issue of global climate change can affect the public debate and the international negotiating process. Climate and adaptation leadership involves a struggle for meaning that can rapidly shift over time. Leaders must guide deliberation about whether to aim at emission

[1] Bennett (2002), Kenix (2008)

[2] Shanahan (2007), Boykoff and Roberts (2007), Hulme (2006), Ungar (1992)

reduction targets that would be stringent enough to effectively fight climate change and to evaluate methods to reach the emission reduction targets in light of the ends that are reached.[3]

David King, the UK government's chief scientific advisor, asserts that climate change is a greater threat than global terrorism, while former U.S. vice-president Al Gore has equated the need for collective action to that posed by the rise of fascism in the twentieth century. According to the 700-page *Stern Review on the Economics of Climate Change*, climate change could shrink the global economy by 20 %, but acting now to address climate change would cost only 1 % of global GDP.[4]

Since 2006, adaptation has emerged as a newsworthy focus of climate change coverage in the global news media. A review of 75 studies from across the world revealed that increasing numbers of people (between 25 % and 65 % in most nations) perceive changes in the environment or believe they have already experienced the impacts of climate change. Others still place climate change in the distant future.[5]

This chapter explores the media framing of mitigation and adaptation strategies, including the effects of media routines, the factors that drive news coverage, the influences of claims-makers, scientists, and other information sources, the role of scientific literacy in interpreting climate change stories, and specific messages that mobilize action or paralysis. It also examines how journalists often explain complex climate science and legitimize sources, how audiences process competing messages about scientific uncertainty, how climate stories compete with other issues for public attention, how large-scale economic and political factors shape news production, and how the media can engage public audiences in climate change issues.

History of Climate Change Coverage

Global climate change has been a major issue on the U.S. political agenda since 1988. The conjecture that humanity might change the climate of the entire planet first appeared in 1896 in a prediction that carbon dioxide from fossil fuel combustion could gradually warm the globe. Climate change was first reported in the U.S. press in the 1930s, but coverage of human contributions to climate change did not clearly appear until the 1950s. For example, in 1957, the International Geophysical Year, a *Christian Science Monitor* article posed the question, "Are men changing the Earth's weather?" In the subsequent three decades, climate coverage remained sparse.[6]

During the 1960s, research suggested that small perturbations might lead to an abrupt change in the climate system. Some began to frame global warming as an environmental risk, a security risk, a practical policy question, an international relations issue, and even a moral problem. By the late 1970s, a scientific consensus

[3]Carpenter (2002), Uusi-Rauva (2010)

[4]Shanahan (2007), Stern (2006)

[5]Moser (2014a)

[6]Gushee (2004), Weart (2009)

began to take shape. Three media-science-policy spheres intersected in the mid-1980s, when coverage of climate change began to increase dramatically.[7]

When the issue of global warming first rose to prominence in the U.S.A. and UK in the late 1980s, it focused on mitigation. This coverage was fueled by public interest about chlorofluorocarbons, the ozone hole, and the U.S. presidential election. Coverage in the late 1980s and early 1990 was dominated by discussions of nuclear energy as a potential alternative to carbon-based consumption, as well as U.S. Senate bills to reduce anthropogenic emissions. Boykoff and Roberts explored newspaper coverage of climate change in 40 English-language newspapers in 17 countries, across five continents. Among 40 of the most influential English-language world newspapers, climate coverage increased globally when the Intergovernmental Panel on Climate Change reports were released in 1990, 1995, and 2001, during the UN Framework Convention on Climate Change in 1992, and during the Kyoto Protocol convention in 1997.[8]

Distinct phases in climate science policy have been reflected in media attention over time. The 1990s were characterized by a complex politicization of climate science, media, and policy. A small group of skeptical spokesmen and scientists, many of whom received funding from carbon-based industry interests, gained prominence in the news in the early 1990s by refuting scientific findings about human contributions to climate change.[9]

Since 1995, a strong scientific consensus of more than 2,000 researchers has asserted that humans influence the global climate. By the end of the 1990s, increasing media warnings of peril made most of the literate world public aware of the issue, but skepticism and aversion to regulation persisted. Most people in the world were now concerned but not motivated to take action. Between 2003 and 2006, coverage of climate change adaptation increased substantially. In developing countries and rural areas, climate change news is communicated primarily through radio.[10]

News coverage of climate change in the aftermath of Hurricane Katrina in 2005 emphasized conflict and immediacy frames, which could have inhibited public understanding of climate issues. Climate change news coverage between 2006 and 2010 sparked a surge in public interest in articles about the environment, energy, and pollution. This coverage coincided with the greatest turmoil in the history of the news industry, a time when journalism jobs were drastically reduced, news outlets had extremely limited print space and airtime, and editors were often disinterested in climate issues. As public interest in "going green" increased during the first decade of the twenty-first century, editors and reporters became more attentive to the ethical line between writing about the environment and writing on behalf of the environment (Thompson 2009; Brainerd 2007a).[11]

[7]Boykoff and Roberts (2007), Weart (2009)

[8]Ungar (1992), Weisskopf (1988), Boykoff and Roberts (2007)

[9]Trumbo (1996), Boykoff and Boykoff (2004), Gelbspan (1998), Schneider (2001)

[10]Weart (2009), Boykoff and Roberts (2007), Luganda (2005)

[11]Thompson (2009), Brainard (2007a)

The Intergovernmental Panel on Climate Change consensus report in 2007 asserted that human activities are more than 90 % likely to be the cause of climate change and that impacts could be abrupt and irreversible. It added that if urgent steps are taken, climate change could be addressed at a reasonable cost. Nearly 200 nations endorsed the IPCC findings in 2007, which were based on thousands of published, peer-reviewed studies. In the same year, China suddenly and quickly overtook the U.S.A. as the world's worst in greenhouse gas emissions because of its rapid economic expansion. Most special reports on climate change in news publications mentioned China because global efforts to make the planet greener hinge on China's politics, emissions, and actions. In 2007, Patrick Symmes said in *Outside* magazine, "China is the asterisk at the end of every conversation about the environment." In this piece, he related his own story of whitewater rafting down the Yangtze River, whose valleys may soon be flooded from the construction of hydroelectric dams. The best U.S. print news coverage of China's economic growth has used visual storytelling to highlight its extreme pollution and environmental degradation. Many stories emphasized China's reliance on coal, inefficient use of energy, pollution-related death toll, and preference for growth over environmental protection.[12]

In 2007, Andrew Revkin, former environment reporter for *The New York Times*, started Dot Earth, an innovative blog where he posts and exchanges ideas about climate and sustainability issues. In the same year, CBS's Katie Couric asked each presidential candidate to answer a single question during a 7-minute segment: "Is the threat of climate change overblown?" Some critics felt Couric's pointed question was posed irresponsibly within a skeptical and meaningless frame and that it only allowed for candidates to spout talking points. In any case, CBS was the first network to draw voter attention to a new and underrepresented campaign issue on national, prime-time television.[13] By 2008, news coverage moved beyond climate change science into the broader arena of action – what governments, entrepreneurs, and ordinary citizens are doing about it. As of 2010, Abu Dhabi announced it will have the first city in the world with zero carbon emissions by 2018. In addition, developers plan to build a desert city for 50,000 residents relying completely on solar power and other renewable energy, and the Dutch are developing ways to protect vulnerable coastlines against rising sea levels.[14]

The IPCC defines adaptation as any "*adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities*"[15] Although the news media rarely mentions "adaptation," the climate science community frequently uses the term in both scholarship and policy. For instance, the UN Framework Convention on Climate Change clearly identified adaptation as the complementary approach to mitigation (emission reductions).

[12]Brainard (2007b)

[13]Brainard (2007c)

[14]Russell (2008)

[15]Goidel et al. (2012)

Adaptation measures needed to protect human life and property fall into three categories: retreat, accommodation, and protection. Retreat involves migration or abandoning the coastal zone, while accommodation measures include flood shelters, elevating buildings, converting agriculture to fish farming, innovative irrigation, reforestation, drought-tolerant crops, rainwater storage, or growing flood/salt-tolerant crops. Protection includes more permanent and expensive measures such as geoengineering, weather control, damming glacial lakes, hard structures such as sea walls and dikes, as well as soft solutions such as dunes and vegetation, to protect the land from the sea so that existing land uses can continue.

Between 1988 and 2006, adaptation represented less than 1 % of all climate-related news coverage in major news outlets within the U.S.A. and Great Britain. However, between 2003 and 2007, coverage of this topic rose dramatically. Moser (2014)[16] observed a multifold spike in newspaper coverage of adaptation in 2006 and 2007. Adaptation coverage peaked in 2007 in the U.S.A. and India, coinciding with the release of the IPCC Fourth Assessment Report, and again in 2009 in covering the Copenhagen Conference of the Parties.[17]

Media Framing of Climate Change

As a news topic, climate change has potential narrative elements that include the oil industry and the earth's climatic balance. The world's leading scientists now insist that the story should shift from whether climate change is happening to what will be done about it. While newspapers in the U.S.A. might be avoiding the issue, all regions hesitated to frame climate change in light of extreme weather consequences or oil reduction solutions.[18]

Individuals "frame" an issue by mentally organizing and discussing with others an issue's central ideas. This framing can greatly influence how they understand the nature of the problem, who or what they see as being responsible for the problem, and what they feel should be done to address the problem.[19] Similarly, news framing is the process of organizing and packaging information. It involves selecting aspects of a perceived reality to make them more salient. It promotes a particular problem definition, assignment of responsibility, causal interpretation, ethical or moral interpretation, or recommended solution. News frames are embodied in key words and concepts emphasized in stories. Most news content is either framed episodically in terms of specific events or thematically to emphasize broad or abstract concepts. For example, describing the impact of climate change on polar bears with an episodic or thematic frame in a news story does not prompt individual behavior change.

[16]Moser (2014)

[17]Boykoff et al. (2013)

[18]Good (2008), Herman and Chomsky (1988)

[19]Gamson et al. (1992), Price et al. (2005)

However, the use of a thematic frame promotes greater support for policies that address climate change than the use of an episodic frame.[20]

The media tend to reframe a major scientific debate when they increase attention to ethical issues, more prominent public discourse, or scientific-economic issues. Gamson and Modigliani identified eight frames that consistently appear across science-related policy debates: social progress, economic development/competitiveness, morality/ethics, scientific/technical uncertainty, Pandora's box/runaway science, public accountability/governance, middle way/alternative path, and conflict/strategy. Claims-makers compete for legitimacy through the news media, while the news media construct, interpret, and frame the claims-makers and their issues.[21]

Solutions and effect frames dominated Peruvian coverage of an international climate conference, while policy and science frames were limited. In a cross-national comparison of Dutch and French newspaper framing of climate change during the annual United Nations Conferences of the Parties between 2001 and 2007, Dirikx and Gelders identified five dominant frames in the coverage: nonpursuit, consequences, responsibility, conflict, and human interest. Most stories referred to the consequences of not pursuing a certain course of action and of possible losses and gains, a consequences frame. The responsibility frame included the need for urgent actions and possible solutions, as well as the responsibility of governments for alleviating climate change problems. The conflict frame appeared less frequently than the other four frames but more regularly than the human interest frame.[22]

The growing enormity of challenges created by climate change has redefined international security in global media coverage since 2007. This new norm has defined climate change as a security threat, in light of authoritative scientific evidence. It emerged in the wake of an international legal framework constituted through the 1992 United Nations Framework Convention on Climate Change, the 1997 Kyoto Protocol, and the 2009 Copenhagen Accord. However, internalizing the security threat norm within treaties was not sufficient to crystallize the norm. A dramatic and complex position shift in U.S. domestic policy was required, as well as the participation of many local and state governments and the private sector. The shift eventually led to greater media attention to the security aspects of climate change, which afforded this dimension of the debate enormous prominence.[23]

In the broadest sense, the media tend to frame climate change problems in light of underlying concerns, such as the character of capitalism, the relationship between nature and culture, the social process of defining problems, and societal transformation in response to climate change. Progress, conflict, generic risk, and the interplay between market incentives and regulation are the most common frames used in controversial science stories. These frames imply responsibility for societal outcomes from science and technology. Citizens also are more likely to dissociate

[23]Garcia (2010)

themselves from the causes, impacts, and responsibility for tackling climate change when news media use the term "climate change" instead of "global warming."[24]

Lakoff argues that people unconsciously reject facts that appear to fall outside the frame they use to see the world. A person's frame, often created by values instilled in childhood, leads him to see only the world that agrees with his values, while blocking out conflicting facts and arguments.[25] British newspaper stories that use a religious metaphor to denigrate anthropogenic climate change undermine the scientific status of climate change by presenting it as irrational faith-based religion and its proponents as religious extremists intolerant of criticism. Some stories mock climate change using notions of sin such as describing "green" behaviors as atonement or sacrifice. The religious metaphor damages constructive debate by emphasizing morality and how climate change is discussed and by detracting attention from the content of scientific data and theories. News framing of controversial science also can affect perceived ethics of research when it includes a political conflict frame but not when it uses a scientific progress frame. People who believe that science is morally neutral perceive greater usefulness of research. Individuals with higher self-reported science interest and exposure tend to rate the research as more credible.[26]

To convince a skeptic that climate change is an emergency worthy of attention, a message must tailor its arguments to fit within the person's existing framework. To communicate climate change ideas and policies to political conservatives, the term "climate change" could be replaced with "climate security" to better explain how the changing climate adversely affects America's economic health, national security, and prosperity. Highlighting clean "energy advancement" could avoid negative connotations associated with reducing emissions and economic growth, and the objective of cap-and-trade policies could be emphasized, to "harness the power of the market."[27]

The news plays a major role in informing the public about the science and policy of climate change. The framing of climate change coverage involves interview source selection, presentation and evaluation of conflicting arguments, and scientific uncertainty interpretations. Climate stories shape and influence public opinion, politics, public understanding, and action in complex, dynamic, and nonlinear ways. For many journalists, the climate change topic is new, extremely complex, and easy to get wrong. BBC's Richard Black and Roger Harrabin warned fellow journalists how critical it was for them to catch up: "If we do not have a strong grasp of the fundamentals of the climate debate, we risk presenting our audiences with a set of opinions which is outdated, driven by spin, or simply wrong."[28]

Over time, various leaders have framed climate change stories about social, political, and cultural issues according to their political agendas. Carvalho and

[28]Boykoff and Roberts (2007), Herrmann (2007)

Burgess identified three major themes in this coverage: power mobilization, the public sphere, and personal engagement. The most frequent frames in climate change coverage have been political, consequences, and scientific frames. Elite Western media tend to frame emissions as global, without challenging or differentiating available data, and often frame climate change in terms of regulatory frameworks, political constraints, and economic drivers. The media frames in this coverage are created through complex relationships between scientists, policy actors, and the public. Wire service stories strongly influence how climate change science is framed to the public. Three clusters of "carbon compounds," common catchphrases that focus on finance, lifestyle, and attitudes include "carbon footprint" and "carbon finance." These phrases serve as tools of communication about climate change mitigation.[29]

Worldwide news coverage of climate change sharply declined after it spiked around the 2009 United Nations Climate Change Conference meetings in Copenhagen. This decline may have occurred because news organizations had to devote coverage to many other critical issues competing for news attention. According to public arena theory, the public, political actors, and news organizations each can only pay attention to a few problems at any given time. As one issue rises in prominence, attention to other issues declines. The number of public arenas available for coverage in a given day is limited by the carrying capacity of individual media outlets.[30]

Climate coverage is more attention getting when it focuses on one specific aspect of the story. For instance, the scientific uncertainty frame appeals to people who do not want to change, but the national security frame could inspire action from the same individuals. The polar bear frame appeals most to animal lovers, but few people have ever seen a polar bear or would miss it if it went extinct. The money frame presents climate change as a business opportunity or outlines the costs and benefits of mitigation or inaction. However, messages framed in terms of economics and losses do no better than messages framed in terms of environment and gains in encouraging the adoption of sustainable behaviors. While the catastrophe frame may leave people feeling helpless, a justice or equity frame could be empowering.[31]

Two dominant themes, weather and renewable energy, often appear in both fear-laden and inspirational representations of climate change. Much of the climate change coverage in the U.S.A. has been tied to specific events, such as severe weather, rather than ongoing issues. In a content analysis of a decade of evening news programs about energy and environmental news topics, news in both Canada and the U.S.A. tend to focus on severe weather, with a somewhat greater focus on severe weather events in the U.S.A. The tone of climate change coverage in Canada has been more critical than comparable climate change coverage in the

[30]Boykoff (2008), Nisbet (2011), Hilgartner and Bosk (1988)

[31]Shanahan (2007), Walton (2007)

U.S.A. Granger causality tests reveal that coverage of climate change, pollution, and related issues depends on coverage of disasters and other weather events. Journalists are more likely to discuss climate during unusually warm periods. For example, local temperatures in New York and Washington, DC have been positively related to frequency of attention to climate issues.[32]

Positive frames are more likely to prompt active engagement with climate change issues than negative frames, which can lead people to disengage or become fatalistic. For example, an April 2008 headline on *Time* magazine's cover, "How to win the war on global warming" showed the famous image of the Iwo Jima soldiers planting a tree instead of a flag. *Time*'s framing of climate change in that issue "marks a major departure from a past emphasis on doom and impending disaster, offering a new focus on national unity around a common challenge similar in nature to the Great Depression, the Space Race, or World War II." Some media critics felt the *Time* story crossed over the line of objectivity into advocacy, while others argued that the coverage provided more analysis and depth than most climate change stories do. Negative frames, including predicted climate change impacts and frightening statistics, have been covered by more TV stations and in more detail than the more positive frames of solutions, adaptation, or mitigating greenhouse gas emissions. Only 25 % of climate change stories in UK newspapers focused more on solutions than problems. Alarmism and small actions are the most common media frames in climate change coverage, but these narratives can be confusing, contradictory, and disempower the public.[33]

One example of negative framing appeared in the Australian news coverage of climate change–related sea level rise in the tiny island of Tuvalu. The stories often framed Tuvalu inhabitants as the tragic victims of environmental displacement, marginalized discourses of adaptation for Tuvaluans and other inhabitants of low-lying islands, and silenced alternative constructions of Tuvaluan identity that could emphasize resilience and resourcefulness. A recent British Medical Journal editorial asserted that failure of the world's nations to successfully curtail emissions will likely lead to a global health catastrophe, yet most Americans are only dimly aware of the health implications of climate change. However, most people respond more positively to information about the potential health benefits associated with specific climate mitigation–related policy actions than to basic information about health risks of climate change. Thus, emphasizing the health benefits of mitigation could make the overall climate change problem more personally relevant, significant, and understandable to members of the public.[34]

News framing of climate change affects how and whether audiences respond to the problem. Recent coverage has been characterized by a catastrophe narrative that disempowers people, as well as lack of relevance to audiences, little attention

[32]Manzo (2010), Soroka et al. (2009), Shanahan and Good (2000)

[33]Carvalho (2010), Nisbet (2008), Painter (2007), Futerra Sustainability Communications (2006), Institute for Public Policy Research (2006)

[34]Farbotko (2005), Jay and Marmot (2009), Leiserowitz (2005), Maibach et al. (2010)

devoted to adaptation and the perspectives of the poor, and lack of reporting on ways to address climate change that bring benefits. Climate problem indicators, high-profile international events, and climate science feedback are all attention-grabbing factors that influence media and congressional attention to climate change. These factors promote issue salience, focus attention on climate change, and promote interagenda interaction and partisan advantage on agenda setting.

For individual citizens, media representations can construct particular positions, cultivate their dispositions to action or inaction, or constrain their political engagement with climate change issues. Policymakers, however, often view climate change coverage in terms of singular concerns about security or economic interests. For example, policymakers tend to view natural disasters abetted by the man-made effects of climate change as simple emergencies requiring a straightforward response in terms of providing food, shelter, and medical supplies. They rarely talk about climate-driven emergencies as man-made, complex emergencies where humans are self-evidently at fault.[35]

The media are more likely to reinforce rather than change existing attitudes about climate change. Sometimes, the media reflect a cultural anxiety or perspective as much as they create it. Over time, coverage may progressively cultivate a particular way of looking at the world or how society should set priorities. Media interest in science issues often is triggered by the release of articles in major journals, policy decisions, political controversies, or public protest. Coverage of these topics may contain sensationalism or scaremongering because of the inherent dramatic value of these stories. The visuals and narrative structure of a story tend to be more compelling than the logic or explanations within a media text. When media attention, framing, and sourcing shift across key stages of scientific, political, and policy development, forces can combine to emphasize certain dimensions of a science controversy over others. The issue then gains, maintains, or loses political and media attention.[36]

Effective policymaking involves the ability to control media attention to an issue, while framing an issue in favorable terms. These two characteristics of media coverage both reflect and shape where an issue is decided, by whom, and with what outcomes. Over time, cyclical waves in media attention and historical shifts determine how an issue is framed and link it to policy decisions. The mediated issue development model accounts for the type of policy arena where debate takes place, the media lobbying activities of strategic actors, the journalistic need for narrative structure, and the competition from other issues for attention across policy and media environments. Related factors include the type of journalist-assigned coverage and the level of attention from opinion pages.[37]

Climate change reporting in the elite U.S. press has reflected issue attention cycles sparked by dramatic events. Over time, climate change lost much of its

[35]Shanahan (2007), Liu et al. (2009), Carvalho (2010), Moeller (2008)

[36]Kitzinger (2006), Nisbet et al. (2003)

[37]Nisbet and Huge (2006)

perceived dramatic storytelling value, which previously had driven journalists' coverage. In the past, open political conflict, personality clashes, and contested claims over risks had allowed journalists to develop news sagas they could track over time. The up and down cycles of attention hinge mainly on dramatic political events. Audience response also depends to some extent on how the current phase of the problem is framed.[38]

Public attention to environmental issues moves through five sequential stages in an issue attention cycle: preproblem, alarmed discovery and euphoric enthusiasm, gradual realization of the cost, gradual decline of intense public interest, and postproblem. In the preproblem stage, an ecological problem exists but has not yet captured public attention. Expert communities are aware of the risks, but the information is not widely disseminated. Climate change coverage was in the preproblem stage prior to 1988. In the second stage, alarmed discovery and euphoric enthusiasm, dramatic events make the public aware of the problem and alarmed about it. In the late 1980s, when more news hooks for climate change stories emerged, the public became increasingly alarmed. In the third stage, gradual realization of the cost, various claims-makers acknowledge the costs of dealing with the problem.

When a cohesive group of climate skeptics emerged in the early 1990s, they began to challenge scientific findings about anthropogenic climate change. In the fourth stage, gradual decline of intense public interest, key actors become discouraged at the prospect of appropriately dealing with the problem, and crises are normalized through suppression or boredom. This may have prompted the decline in climate change coverage in the mid-1990s. In the postproblem stage, the formerly "hot" issue "moves into a prolonged limbo – a twilight realm of lesser attention or spasmodic reoccurrences of interest… [and the issue] once elevated to national prominence may sporadically recapture public interest."[39]

Climate change and other environmental issues may not conform to Downs' issue attention cycle, since these problems have worsened, new problems have arisen, and social movement organizations have emerged to keep them alive. Cycles may have sped up in recent years and become less apparent. While the Downs model offers useful explanations about public attention, it cannot explain how media representations of climate change are constructed.[40]

Media Framing of Adaptation

Most adaptation news coverage has originated from Western European and North American newspapers and to a lesser extent from English-speaking newspapers in Australia, New Zealand, the Middle East, Asia, Eastern Europe, and South Africa.[41]

[38]McComas and Shanahan (1999), Downs (1972)

[39]Boykoff and Roberts (2007), Downs (1972, pp. 39–41)

[40]Dunlap (1992), Brossard et al. (2004), Jordan and O'Riordan (2000), Boykoff and Roberts (2007)

[41]Boykoff and Roberts (2007)

Early-stage adaptation measures, which tend to be agency internal thus less visible to the public, are needed to plan and build capacity but are perceived as not newsworthy.[42] News media often rely on a limited cast list in telling climate change stories because of journalistic training, traditions of the craft, deadlines, competition, as well as limited resources including staff, time, and money. These routines often produce distorted or cramped representations of climate change risks and prevent regular and in-depth treatment of adaptation.[43] Identifying trends and widely applicable insights is challenging for journalists, not only because of the language used to explain adaptation but also by the fact that adaptation language is often not used at all.[44]

Moser (2014)[45] notes that tracking media coverage of adaptation is challenging because often the word "adaptation" is not explicitly mentioned in stories. For instance, in coastal areas, stories may discuss adaptation plans or measures such as beach nourishment, building shoreline protection, residents retreating from the coast, or relocation of roads, airports, or water-related infrastructure. The number of small local newspapers and qualified journalists that could report on adaptation is in decline. Many media scholars examine coverage in leading national newspapers and magazines, so their analyses often do not reflect adaptation efforts at the local level. Adaptation coverage in national elite newspapers typically depicts international climate policy debates and how countries should position themselves. However, the more locally based adaptation news coverage tends to focus on concrete impacts and specific needs for adaptive actions.[46]

Takahashi and Meisner[47] found a predominance of the "effects frame" (a focus on impacts) in their study of Peruvian news coverage of climate change. This emphasis also appeared in specialized farming magazines in Sweden,[48] as well as on websites of U.S. NGOs and government agencies.[49] Major news outlets tend to cover developed nations,[50] while underrepresenting less wealthy parts of the world. Developing nations cannot afford the large-scale infrastructure adaptation projects seen in richer countries, the projects that attract most of the media attention. Therefore, smaller-scale projects and innovations may receive little or no attention.[51]

Although the term "adaptation" has been widely taken up in discussions in Europe, Canada, Australia, and Asia, it has not been easily accepted in

[51]Moser (2014)

U.S. discourse. The resistance to "adaptation" in the U.S.A. is rooted in the challenge of communicating climate change more generally to American audiences.[52] In conservative political contexts where climate change or sea level rise are considered ideological positions rather than real phenomena,[53] early adaptation efforts are frequently not named but rather hidden in disaster preparedness or hazard mitigation plans, general land use plans, or redevelopment strategies.[54]

Funfgeld and McEvoy[55] identified four common adaptation frames: hazards (natural disasters), risk management, vulnerability (who/what will be affected and how), and resilience (a community's ability to cope with external stressors). Effort to make the abstract concept of "adaptation" more meaningful and acceptable to decision-makers and public audiences has led to the use of many catchphrases such as climate-smart, climate-resistant, climate-resilient, and climate-ready. In media coverage and other public communications, the word "adaptation" is often replaced with more familiar terms such as "preparation," "preparedness," "readiness," "adjustments," "planning," "coping," "triage," "climate risk management," or "mitigating the impacts of climate change."[56]

Some introduce adaptation via more familiar, concrete actions, such as installing irrigation, building a sea wall, managing fuel to prevent wildfires, wetland restoration, reforestation, increasing urban forest cover, ensuring food security, or establishing heat-health warning systems. For example, in announcing New York City's adaptation plan in 2013, Mayor Bloomberg never mentioned the word "adaptation." Instead, he described specific plans to build a "stronger, more resilient city" in the face of climate change and extreme events.[57]

Moser[58] identified several challenges in using the term "adaptation" in public communications. It is still a relatively new term, allowing a variety of alternate terms to be field tested before one becomes widely accepted and a common understanding of it stabilizes. "Adaptation" is an abstract jargon term, which does not allow for simple, intuitive interpretation. Journalists and other local professionals rarely follow peer-reviewed adaptation literature,[59] so they may lack both scientific understanding and access to experts who can effectively translate that science. How adaptation is framed often depends on the lead actors involved. The word "adaptation" often carries connotations that are unacceptable or not motivational to different audiences.

Adaptation language is often used to achieve a certain effect within a specific audience, such as to be alarming, provocative, appeasing, inclusive, or

encouraging.[60] Adaptation must be translated from a global problem into a specific national or local problem.[61] Finally, adaptation is colored by historical legacies of communicating climate change science and mitigation,[62] including the deeply polarized political context in the U.S.A. Depending on the local context, there may be value in avoiding using the term or avoid naming causes.[63]

One study found the "preparedness" frame 15 % more compelling than "adaptation," while 100 climate and sustainability leaders and social science and communication experts judged the word "adaptation" to be "negative and demobilizing."[64] A more recent study identified two common adaptation frames in public communications: those emphasizing climate change impacts, disruptions, and extremes and the need to prepare for them, as well as by frames that introduced and explained the notion of adaptation for species, landscapes, and the built environment.[65] Discussion about economic impacts of extreme events in the U.S.A. has drawn in influential actors and helped to break the climate change and adaptation impasse in many locations.[66]

Extreme events like fire and floods – or resource scarcity issues like water and drought – are typically local (or at most regional) stories. Even so, in light of how climate change has been reported for years, adaptation is still largely a global story, as well.[67]Global climate stories often include science and policy debates about whether global warming is real, human caused, and what to do about its causes.[68] However, as common sources of information on environmental news stories, scientists often are reluctant to link local extreme events to global warming.[69] Although stories often do not link individual events to climate change, recently more coverage has emphasized the consistency of patterns of the more extreme events with global warming theory.[70]

In many areas of the world, extreme weather events are part of normal life, sometimes seen as cyclical[71] or just the wrath of Mother Nature. Where these perceptions prevail, they may hinder adaptation discussions outside of the usual "getting back to normal" postdisaster responses.[72] For some intractable climate

change challenges like drought or sea level rise, socially acceptable adaptation solutions are rare.[73]

Since adaptation researchers assume lower vulnerability and greater adaptive capacity in developed countries than in developing countries, they have focused more research in the latter.[74] Climate vulnerability is determined by many factors, including variations in wealth, social equality, food availability, health and education status, physical and institutional infrastructure, and access to natural resources and technology.[75]

Although vulnerability is an important dimension of adaptation coverage, the media in developed nations often portray people in developing countries as victims.[76] For instance, Australian news reporting on the impacts of sea level rise on the small island nation of Tuvalu constructed Tuvaluans as tragic victims of environmental displacement, reducing their identity to individuals lacking resilience and resourcefulness.[77] Some scholars argue that framing poor people as climate change victims can be demoralizing and paralyzing[78] and promote a false sense of safety in developed nations.[79]

Audiences often turn to local television news for information about weather extremes. However, since many TV meteorologists are skeptical about the human causation of climate change, they are reluctant to link local extreme events with global trends.[80]Trust in weather forecasters is a key factor in making climate change information acceptable to TV viewers.[81] Extreme weather events can increase the amount of climate change media coverage when journalists link these extremes to climate change.[82] But journalists rarely do this. For instance, British news coverage of flood events between 2001 and 2007 was linked to climate change infrequently, and whenever a possible connection was discussed, the message was mixed and inconsistent.[83]

Similarly, news coverage of drought in the U.S. Southeast between 1997 and 2007 included details about the dynamics of vulnerability and higher-order impacts of water shortage and drought responses but provided no discussion of climate change.[84] TV and print coverage of wildfires in the Western U.S.A. in 2012 and 2013 found the stories linked wildfires to climate change in only 3 % and 6 % of

cases, respectively,[85] with an increase to 14 % during the summer wildfire season.[86] Resource Media[87] observed that the water/climate connection is nearly invisible in U.S. news coverage,and innovative adaptation solutions are hardly discussed at all.

Risk Perception

Most news stories about environmental issues do not mention environmental risks, and the stories that do discuss risks tend to be dramatic and ambiguous and provide little information that would help the public understand the risks. Climate stories also frequently fail to highlight the most significant facts, as defined by scientists or risk assessments. Political debate obfuscates risk assessments in news coverage. For example, when Sen. James Inhofe railed against the climate research "hoax" and the "alarmist" scientific press in 2006, journalists struggled to untangle his arguments about bad science and bad reporting. Mainly, Inhofe criticized overblown predictions of doom in news coverage that alternated scientific predictions of global warming and cooling over the last 100 years. Many journalists have pegged stories about climate change to disasters like hurricane intensity, drought, wildfires, crop failure, and other hazards, without discussing how greenhouse gases spur climate change or including a skeptic's viewpoint. Public opinion turned against climate reporters whose stories were "balanced" to a fault.[88]

In Britain, climate change coverage has reframed nuclear power as part of the solution to the need for low-carbon energy options. Framing of nuclear power in Britain often centers on risk trade-off scenarios. Citizens express reluctant acceptance of nuclear power but renegotiate their position on nuclear energy when it is positioned alongside climate change. Various countries have tried to calculate the most rational global economic response to climate change threats in different ways. The social sciences, including economics, have had a limited role in projections about climate change impacts and about societies' responses to changing climates. In light of the dimensions of risk description and prescription in the media, environmentalists and scientific media tend to feature more proactive discourse, while industry and political media feature more reactive discourse. The way the news media frame a story about environmental issues also can influence audience perceptions of risk. In light of a guard-dog perspective of the media, social change or status quo news frames can affect individual risk perceptions about environmental issues. People who read news stories that use a social change frame report higher risk awareness than those who read stories containing a status quo frame. The risk information seeking and processing model has been used to isolate predictors of public knowledge of global warming. The number of media sources used, individual

[85]Fitzsimmons et al. (2012), Greenberg (2013)

[86]Fitzsimmons (2012)

[87]Resource Media (2012)

[88]Major and Atwood (2004), Kitzinger (2006), Brainard (2006a)

information seeking effort, and general education about climate change are relatively strong predictors of climate change knowledge.[89]

Most people realize the benefits of a future centered on sustainable resource use and societal welfare, but individual considerations about the future are not largely influenced by scenarios. The credibility of climate change projections depends on individuals' prior beliefs and trust in the science portrayed. In light of spatial data that maps individual physical risk associated with expected climate change, the relationship between actual and perceived risk is driven by specific physical conditions and experiences. Mutually reinforcing processes of media influence and selective attention to the media can elicit individual fear or anxiety about climate change, which in turn can enhance information seeking. The reinforcing spirals model has shown mutual influence between individual media use and global warming perceptions. Analysis of data from the 2006 General Social Survey showed that media use mediates the effects of age, race, and education on perceived knowledge about global warming. Perceived knowledge and concern over global warming also predict future information seeking about the polar regions.[90]

Climate change issues in general, and mitigation technologies specifically, are often poorly understood among public audiences. A 2007 Nielsen survey found that Latin Americans and Europeans were the most aware and concerned about climate change, while North Americans were the least aware and concerned. People in their teens and 20s appeared to be the least informed but among the most concerned about climate change, highlighting the need to reach younger people with accurate information on climate change. Many climate stories are fraught with overstatement, overcertainty, and confusion. These reporting problems can lead people to greatly overestimate scientific scenarios for temperature and sea level rises to confuse the greenhouse effect and ozone depletion. There is often a considerable mismatch between reporting of scientific information and the public's understanding of causes of the greenhouse effect. Ultimately, ignorance about climate change science leads the public away from dealing with the consumption of fossil fuels.[91]

Even those most concerned about climate change are less concerned about it than other daily issues. However, people are more likely to take action if they feel they can and should make a difference and if they trust government and other institutions to mitigate risks and achieve change. Most do not support adaptation measures when they perceive the costs as concentrated and the benefits as diffuse, relative to other daily concerns. According to the Gallup Organization's annual survey on environmental issues, Americans have become increasingly concerned about environmental quality over the last decade. More than a third typically express a great deal of worry about the quality of the environment, even though the issue ranks in the middle among a dozen different issues. Americans typically worry more about global

[89]Bickerstaff et al. (2008), Yearley (2009), Sonnett (2010), Durfee (2006), Kahlor and Rosenthal (2009)

[90]Lorenzoni and Hulme (2009), Brody et al. (2008), Zhao (2009)

[91]Herzog et al. (2005), Bell (1994a)

warming than any other environmental issue, and most believe global warming is mostly the result of human activities rather than natural changes. On climate change policy, Americans believe that science leaders, compared with leaders in other sectors, are relatively knowledgeable and impartial and should be relatively influential. However, they also perceive a significant lack of consensus among scientists on this issue.[92]

Many people are demobilized by feelings of isolation, hopelessness, powerlessness, and lack of public trust in government to effectively address climate issues. As public concern about the global economy rises, concern about the environment drops. This may represent a shift to public concern about an immediate rather than potential catastrophe. A large international survey identified three limitations that can make responses unrepresentative of larger public understanding: levels of acquiescence, different cultural interpretations of "global warming," and varying socioeconomic and educational levels of Internet users. U.S. audiences labeled "alarmists" tend to be younger, while those who believe anthropogenic global warming is negligible and overhyped tend to be white males who are Republican, individualist, religious, and rely on radio as their main source of news.[93]

Political ideology and partisanship are critical factors in credibility assessments and perceived bias in climate news. Climate change stories that use moderate sources or that suggest solutions or compromise are often seen as less biased and more credible than articles that use confrontational language and sources with intense viewpoints. The hostile media phenomenon holds that highly partisan individuals judge media to be biased against their side and favorable to their opponent's. This effect has been strongest among Republicans and conservatives, in opposing environmental protection.

A hostile media phenomenon often occurs in consumption of climate change news when highly partisan individuals judge media to be biased against their side and favorable to their opponent's. However, climate change stories that use moderate sources and suggestions of compromise are seen as lower in bias and higher in credibility than articles using confrontational language and sources with intense viewpoints. Hostile media perception is a major audience barrier to stimulating urgent concern about climate change. Partisanship can play a significant role in perceived media bias about climate change news coverage. News consumers' anger can mediate hostile media perception, which in turn predicts individual trust in climate change coverage and selective media use.[94]

When news reports don't favor preferred policy positions, whether it is election politics or scientific topics like global warming, conservatives attack the messenger. The public has been split on whether the media exaggerate climate change threats, although more Americans believe the media downplays them. The most common

[93]Boykoff and Roberts (2007), Will (2009), Leiserowitz (2005)

[94]Marlowe (2005), Kim (2010)

risk categories in international newspaper coverage of climate change, in light of Slovic's risk perception framework, were no risk, severe risk, future risk, immediate risk, catastrophic risk, and risk to nonhuman life. Beliefs about the severity of climate change are a function of personal experiences such as exposure to weather disasters, perceived consequences or vulnerability to climate change, and messages from informants such as scientists. Knowledge reduces uncertainty, which can increase assessments of national seriousness. In turn, these assessments increase policy support when attitudes and beliefs about human responsibility facilitate necessary reasoning. Public perception of global climate change has been strongly influenced by media constructions of scientific knowledge. Non-U.S. news organizations, especially in Britain, are at the forefront of discourse on climate feedback loops and climate thresholds. However, U.S. coverage of these topics generally has been poor because of self-censorship.[95]

To some extent, media coverage of climate change reflects the U.S. risk management system, which tries to create pockets of insulated expertise in an effort to neutralize unfounded public fears through rationality, efficiency, and authority. However, this leaves little room or reason for lay inputs. Putting too little faith in people and too much in the objectivity of formal analysis can lead to a breakdown in civic dialogue. When an event involves controversial science, citizens and public institutions can experience a communication breakdown, when a mismatch exists between what governmental institutions are supposed to do for the public and what they actually do.

In the U.S.A., citizen trust often rests in formal processes and styles of reasoning designed to ensure the transparency and objectivity of governmental decisions. But when citizens do lose trust in government, they look elsewhere for information and advice. In a situation involving pervasive uncertainty, the distance between citizens and experts is reduced, so that the lay public is almost as well positioned as experts to make sensible decisions about risk reduction. People tend to perceive climate change as a moderate risk, and melting glaciers and polar ice were the most prominent images associated with climate change and with bipartisan support for emission reduction policies at the international and national levels.

Broad support for policy action often is not linked to support for specific policies, such as raising gas prices, which could curb behaviors related to global emissions. However, climate change messages are effective when they are tailored to the needs and predispositions of particular audiences to either directly challenge fundamental misconceptions or to resonate with strongly held values. Most people prefer mitigation of emissions over adaptation measures such as providing economic assistance and also prefer to help people in one's own country before people in other countries.[96]

Research on intertemporal discounting suggests that individuals tend to believe future costs are much steeper than upfront costs[97] and thus might see the future costs of adaptation as lower than the current costs of mitigation. However, negative image

[95]Nisbet (2006), Slovic (1987), Weintraub (2007), Krosnick and Holbrook (2006), Antilla (2010)
[96]Jasanoff (1997), Leiserowitz (2006), Baron (2006)
[97]Soman et al. (2005)

associations can increase risk perceptions of global warming.[98] Thus, news coverage of adaptation options could help audiences visualize the impacts of climate change by considering adjustments needed to adapt to a warmer climate. For example, Evans and colleagues[99] found that individuals who answered questions about sea level rise and climate change adaptation measures in their local community reported a greater willingness to perform emission-reducing behaviors, compared to those who had not received the questions.

Conversely, the risk compensation hypothesis suggests that remedies to reduce the impacts of risky behaviors can unintentionally reinforce and increase those risky behaviors. For example, drivers who feel more secure when wearing seatbelts may compensate by driving more recklessly, leading to more traffic accidents. This phenomenon is known as an "offsetting effect" or "compensatory behavior."[100] Adaptation news coverage could contribute to this lulling effect, if audiences see adaptation as a remedy to a problem that can be paid for in the distant future and that costly preventative mitigation actions are no longer needed.[101] The other extreme can occur when news coverage promotes fatalism. When the media frames climate change impacts as a pending apocalypse or irreversible tipping point, in an effort to convey urgency and mobilize communities to act, this reporting may have the opposite effect by demoralizing its audiences .[102]

Media Routines

Media representations shape and affect international climate science policy and the translation of scientific uncertainty through the routines, norms, and pressures that guide daily journalistic decision-making. Most climate coverage reflects news pressures, values, and norms. Press coverage of climate science is shaped by both macro-level and micro-level factors. Macro-level factors include media ownership and cultural values, while micro-level factors include journalistic routines, professional values, and organizational norms. News reporting on climate science occurs within the wider context of the growing concentration and globalization of news media ownership. When scientific projections call for revolutionary mitigation efforts, media outlets in a capitalist society must try to report on this while appeasing advertisers who pay their salaries and other expenses. The greatest amount of advertising promotes automobiles, real estate, airlines, fast food, and home furnishings, the consumption of which may increase climate change emissions and prohibit effective mitigation.[103]

In Canadian newspapers, science stories are typically event-oriented, nonlocal wire reports that have a positive tone but are not prominent in terms of frequency and placement. These newspapers publish more medical stories than environmental items, and the environmental stories more often highlight negative consequences. Few science stories include information on science processes. Canadian journalists often cover environmental issues as hard news and less frequently and more negatively than other topics because of organizational constraints on media workers and the perceived marketability of science as a news product. Although the percentage of U.S. science stories has steadily increased over the last three decades, the range of topics covered did not change nor has comprehensiveness of accounts. Science stories still frequently omit methodological and contextual information.[104]

Many climate stories lack easy, event-driven news pegs, moments on which a front-page or top-of-the-news story can be hung. These stories demand that the media devote significant resources of time, labor, and money, with little perceived bang for the buck. Journalists must focus on events and have difficulty reporting "creeping" stories about chronic problems and their contexts, especially stories that do not culminate in obvious events. Tight deadlines limit journalists' ability to comprehend and communicate complex climate science concepts. The bottom line also can limit climate coverage. In many countries, editors cite insufficient financial resources as a key reason they do not cover climate change adaptation issues, including migration to the cities, renewable energy, recycling, irrigation, seed saving, fuel changes, and tree planting. Although drama can give social problems life and sustain their growth, dramatized or alarmist news can downplay detailed analysis of long-term problems. Sensationalism in climate coverage also can trivialize content, block out facts that do not hold an immediate sense of excitement or controversy, or preclude a constructive message. Reporters often overlook underlying causes and long-term consequences in their day-to-day pursuit of new angles on deadline.[105]

Although the public relies primarily on television news as a source of climate change information, few environment and/or science reporters cover the topic for broadcast stations. The attitudes and values the weathercasters hold about climate change influences their knowledge of the scientific consensus on climate change and their cognitive understanding of the topic. Reporters who primarily use scientists as sources and who work the environmental beat full time have the most accurate climate change knowledge. Scientists often rate overall climate coverage as worse than their own story evaluations of accuracy. Specific accuracy problems include overstating the progression of climate change and confusing ozone depletion and the greenhouse effect. Experts have a higher level of

[104]Einsiedel (1992), Pellechia (1997)

[105]Fedler and Bender (1997), Dunwoody and Griffin (1993), Boykoff and Roberts (2007), Harbinson et al. (2006), Hilgartner and Bosk (1988, p. 62), Wilkins and Patterson (1987), Ereaut and Segnit (2006), Wilson (2000a)

knowledge about current climate state, causes, and consequences of climate change than environmental journalists, politicians, and laypersons. Most people know more about climate change causes than the current state or future consequences, and most also know more about weather and sea/glacier consequences than health consequences. Experts express more confidence in their own knowledge than journalists, politicians, and laypersons. Journalists are more likely than experts to adjust confidence in their own knowledge when confronted with actual knowledge.[106]

Journalists often lack the space or time to report complex detail. They must simplify for a general audience and use familiar and emotive terms in place of scientific ones. Journalists avoid some issues because they are too complex or lack attention-getting images. Media accounts that do provide more explanatory content about climate change can boost reader interest and understanding of the issue. Explanatory news text can significantly enhance reader interest and understanding of the content, compared with the traditional inverted pyramid news stories, even among readers who lack science expertise. Most journalists strive to write at a sixth-grade level to improve readability, but this can lead to the oversimplification of climate news and the omission of the complexities and consequences of energy choices.

Peak oil, the theory that oil production has or soon will reach its zenith and then enter into a terminal decline, is a complex story that gained prominence after 2005 but remained underreported and lacked clear, nuanced explanation. Newsrooms often avoid covering peak oil because it is not an event-based story and involves gradual accumulation of data that do not provide easy answers. They feel the story lacks good visuals and is not lucrative enough to justify the newsroom resources required to report on it properly.[107]

Surveys of print, radio, and television journalists from Honduras, Jamaica, Sri Lanka, and Zambia found that editors and journalists had little interest in covering adaptation because of low levels of knowledge on the issue, insufficient financial resources, and different priorities for news coverage.[108]

Sourcing

Most American reporters have autonomy in deciding how to cover a story and which sources to use. Sources are perceived to be more credible when they have established credentials, understand news production norms, are known to the public, and have the resources to continually meet the media's information needs. A source's assertiveness and quotability, as well as understanding of daily media routines, ability to provide credible information on a timely basis, and availability to produce

[106]Wilson (2002), Wilson (2000b), Bell (1994b), Sundblad et al. (2009)
[107]Kitzinger (2006), Yaros (2006), Plate (2009)
[108]Harbinson et al. (2006)

commentary or analysis also can affect his or her prominence in news coverage. Similarly, Meyer's credibility index uses five variables to assess the credibility of a communication source: fairness, bias, completeness, accuracy, and trust. News media organizations often fail to follow up on sources when covering climate change.[109]

Matthew Nisbet identified three groups of public intellectuals arguing for action on climate change, the elites who are frequently quoted in media coverage: ecological activists, smart growth reformers, and ecomodernists. Ecological activists like American writer and activist Bill McKibben "argue that climate change is a symptom of a capitalist society that has dangerously exceeded the carrying capacity of the planet. They are skeptical of technological or market-based solutions to the problem, urging the need for a global movement that dramatically re-organizes society." Smart growth reformers like former U.S. vice president Al Gore "agree that climate change poses catastrophic risks but argue that those risks can be avoided if political leaders adopt the right market-based mechanisms, enabling sustainable economic growth to continue." Ecomodernists like *New York Times* writer Andrew Revkin "argue for recognizing the biases in how we have conventionally defined climate change as a social problem."[110]

The specialist journalists who cover climate science in the British national press value journalistic professionalism and skill more highly than formal training in their area of specialization, apply conventional news values but emphasize relevance to the reader in selecting science news, and use elaborate routines for obtaining credibility, including actively cultivating mutual trust with sources and seeking more sources that are institutionally based and authoritative. Prospective interview sources representing different interests and agendas competitively try to influence the flow of information through media gatekeepers. Source credibility influences how environmental journalists choose interview sources from environmental groups in covering climate change. For example, in news coverage of an international climate conference, the Peruvian media relied mainly on government sources and gave limited access to dissenting voices such as environmentalists.[111]

Interview sources have a substantial influence over how news about climate change is framed, and politicians and government officials are big winners when it comes to the competition for public attention through the media. Journalists often rely on interviews with a small set of "authorities" without identifying a wider range of perspectives, especially when climate change coverage appears because of a looming or unfolding crisis. The public assigns the most credibility to political and expert sources in news coverage of climate change, and this public trust in authority figures can, in turn, influence climate policy decision-making.

[109]Detjen et al. (2000), Ryan et al. (1998), Stempel and Culberston (1984), Roscho (1975), Meyer (1988), Mooney (2009)

[110]Nisbet (2015)

[111]Hansen (1994), Flynn (2002)

Contrarians, environmental groups, and other nongovernmental claims-makers can gain traction for their ideas and shift public discourse through media coverage and thus can have a strong impact on public understanding. Over time, these claims-makers have increasingly replaced scientists as dominant interview sources. Those with the power to define the terms of the debate can determine the outcomes. In speaking out against consensus in climate science and through privileged media access, contrarians and other skeptics amplify perceived uncertainty about human contributions to climate change and construct the argument that human's role is negligible. Contrarians who can gain embedded power and leverage public legitimacy through the media can broadly convey the counterclaim that climate change is not problematic.[112]

In 2007, Fox News Corporation became "carbon neutral" and generally endorsed scientific warnings about global warming. Its CEO, Rupert Murdoch, announced not only that the media group held a corporate view about climate change but that its editorial coverage would change. From 1997 to 2007, opinion pieces produced by newspapers and television stations owned by News Corporation largely denied the science of climate change and dismissed those who were concerned about it. While the intensity of commentary about climate change varied across media outlets owned by News Corporation, its corporate view framed the issue as one of political correctness rather than science. Scientific knowledge was portrayed as an orthodoxy and climate skepticism as courageous dissent. In recent decades, corporate and special interests have developed numerous methods to manufacture doubt about climate science because it threatens their economic interests. When reporters cover rhetorical claims about scientific ignorance and uncertainty that actors use to discredit threatening science, they contribute to the social construction of ignorance in scientific controversies. Trade associations have issued rhetorical claims intended to sow public confusion about university studies that had threatened to undermine their industries' activities. Journalists' use of these claims appears to vary as a function of their perceptions of their journalistic roles and of their audiences, even though their knowledge of science also plays a role.[113]

Michael Mann, the scientist who helped author the well-known "hockey stick" climate change temperature graph, claimed that climate change denial groups stole his emails from servers at Britain's University of East Anglia, in an effort to discredit him. Deniers claimed the emails showed unethical conduct, while scientific organizations and academic panels defended Mann and the credibility of climate science. Mann believes news coverage about the campaign against him ultimately led the U.S. Senate to refuse to take action on carbon dioxide emission controls, even though the incident apparently did not compromise public belief in climate science.

[112]Boykoff (2007), Plate (2009), Miller and Riechert (2000), McManus (2000), Pidgeon and Gregory (2004), Lorenzoni and Pidgeon (2006), Trumbo (1996), McCright and Dunlap (2003), Leiserowitz (2005), McCright and Dunlap (2000), Freudenburg (2000)

[113]McKnight (2010), Stocking and Holstein (2009)

Scholars have identified three major counterclaims in media coverage of climate change: that the evidentiary basis of global warming is weak, uncertain, or flawed, that global warming will have substantial long-term benefits, and that climate policy action will do more harm than good. They found that dissenters collaborate with conservative think tanks, antienvironment movements, and carbon-based industry to disseminate messages that disempower top climate science in national and international discourse about the causes of climate change. Throughout the 1990s, the government officials who cited skeptics became the most frequently quoted interview source in elite press articles, surpassing scientists, who had been the most cited source in 1988.[114]

Environmental pressure groups such as Greenpeace, World Wildlife Fund, and Environmental Defense help to overcome social inertia and bureaucratic resistance to policy action but also can push media discourse beyond the parameters of what science can currently claim and frame issues as overly catastrophic or alarmist. Media coverage of climate change outcomes is necessarily speculative. If interview sources for these stories followed Gregg Easterbrook's "law of doom saying," they would predict catastrophe no sooner than 5 years from now but no later than 10 years away, soon enough to terrify but distant enough that people will forget if they are wrong.[115]

Attitudes about global warming generally are not strongly influenced by scientific evidence. However, the news media increasingly are important sources of scientific information about climate change. Scientists can be influential in shaping attitudes on a wide range of issues when they are quoted in news coverage, especially where scientific opinions are central to policy debates. Media coverage influences scientific opinion about climate change and its consequences. The vast majority of climate scientists in a variety of fields believe that human-induced global warming is occurring and that it poses a significant threat to the planet in the future. Scientists who foresee the most severe future global consequences are younger scientists, those who work in colleges and universities, and those most likely to believe that researchers understand the process of climate change relatively well.[116]

Science has autonomy from other social institutions in its pursuit of long-term questions that build knowledge incrementally, within a society that is basically impatient and pragmatic. While scientists are generally respected in the U.S.A., their voices are often marginalized in the arena of public policy, and they fail to engage the public directly. Scientists share a worldview that presupposes rationality and orderliness and believe answers to most empirical problems are eventually obtainable by posing the right questions and approaching them systematically. Most Americans are not comfortable with risk probabilities or long-term problems. Scientists' input on climate policy has been problematic.

[114]Bulletin of the Atomic Scientists (2010), McCright and Dunlap (2000, 2003), Wilkins (1993)

[115]Newell (2000), Hulme (2006), Ereaut and Segnit (2006), Will (2009)

[116]Brittle and Muthuswamy (2009), Wilson (2000), Farnsworth and Lichter (2009)

Scientists often fail to frame policy options, assign weight to them, make their input less technical, or take political considerations into account when serving as technical advisors to policymakers. When scientists do disagree with policy decisions, they must risk their professionalism and credibility by resorting to advocacy or silence. When news stories do frame policy options, they often do not assign proper weight to relevant science. Media accounts often refer to theory as something not proven, often give equal voice to scientific consensus and contrarians, and have difficulty putting risk and other uncertainties into an easily understood frame of reference. Science operates in a framework of decades or longer, while political pressures push resources toward popular or expedient solutions, not necessarily those with the greatest chance for long-term success.[117]

Scientific expertise has played an important role in media coverage of the policy process regarding climate change and ozone layer protection. Contrary to the IPCC's assumptions, scientific consensus is not necessary to achieve political goals. A climate of expectation, along with pressure from leader countries, can be more important than consensus in achieving change. While ambitious political regulations in the ozone case were achieved under greater scientific uncertainty, negotiations on climate change have been much more modest but based on a large scientific consensus.

Public opinion tends to move in the direction of elite consensus but polarize when citizens perceive that elites are divided. Perceived consensus among scientists has not prompted public engagement or individual action. There are variations in the strength of scientific evidence in media portrayals of scientific consensus and in the presence of political cues in news coverage of climate change. Specifically, the presence of political cues in newspaper articles about climate change activated ideological beliefs and made such beliefs a stronger predictor of concern, regardless of whether scientific elites were portrayed as agreeing or disagreeing. However, scientific agreement and evidence strength were not related to concern. British media reconstructions of scientific claims are strongly entangled with ideological viewpoints. Journalists use these ideas and values as a powerful selection device for deciding what is scientific news, what the relevant "facts" are, who is authorized as "agents of definition" of scientific matters, and which program of action has greatest legitimacy.[118]

Scientists often find themselves enveloped in furies triggered by skepticism about the global warming consensus. Historically, a scientific consensus will prevail until a diametrically different consensus comes along. For example, in the 1970s, a scientific consensus and media coverage predicted that the world faced potentially catastrophic cooling. In 1975, the New York Times reported that a major cooling of the climate was widely considered inevitable because the Northern Hemisphere's climate had been getting cooler since about 1950. While some media accounts at the time did hype a cooling scare, others suggested more reasons to be concerned about

[117] Yankelovich (2003)

[118] Grundmann (2006), Boykoff and Roberts (2007), Brittle (2005), Carvalho (2007)

global warming. During that time, between 1965 and 1979, the scientific literature emphasized greenhouse warming. Mooney also argued that it is misleading to draw a parallel between global cooling concerns articulated in the 1970s, when the field of climate research was relatively new, and climate change concerns today, when hundreds of scientists worldwide repeatedly ratify the conclusion that human activities are driving global warming.[119]

In general, people are no more concerned about climate change, even when the evidence is strong and scientists agree. They tend to ignore scientific evidence, which implies that scientists may have little influence in shaping public concern. People who already have high environmental concern are more likely to incorporate evidence into their attitudes, especially when scientists agree. Also, political cues in the news coverage seem to activate additional message processing among these individuals, perhaps by making them more anxious and attentive to evidence strength.[120]

International media coverage of the IPCC's work has greatly influenced the construction, global mobilization, and consumption of climate change knowledge around the world. However, the U.S. media continue to suggest that scientific consensus estimates of global climate disruption, such as those from the IPCC, are exaggerated and overly pessimistic. By contrast, the Asymmetry of Scientific Challenge suggests that such consensus assessments probably understate climate disruptions. Science tends to be self-correcting over time. U.S. climate change coverage generally appeared during two major periods: when the papers were overstating challenges to the then-prevailing scientific consensus and in 2008 after the IPCC and former Vice-President Gore shared the Nobel Prize for their work on climate disruption and before opinion polls showed the U.S. public to be growing more skeptical toward climate science again. During both periods, new scientific findings were more than 20 times as likely to support the ASC perspective than the usual framing of the issue in the U.S. media. Supposed challenges to the scientific consensus on global warming should be subjected to greater scrutiny and that journalistic balance should account for the scientifically legitimate view that global climate disruption may be significantly worse than has been suggested in scientific consensus estimates to date.[121]

Scientists use excessive jargon in communicating about climate change. When journalists interview scientists, they often qualify their findings in light of uncertainties in their research. Since uncertainties are difficult to translate into the clear language needed in policy decisions, journalists often omit discussion of uncertainties or translate hypotheses into certainties. Although scientific insights evolve over years, media only can take snapshots of this knowledge, which in turn provide limited interpretations. Sometimes, the finer points of a climate story are lost when a journalist tries to translate science into public information. Even a small reporting

[119]Will (2009), Mooney (2009)

[120]Brittle (2005)

[121]Hulme and Mahony (2010), Freudenburg and Musellia (2010)

mistake can discredit both scientists and the media organization that covers their work, and the consequences of the misinformation are difficult to roll back.

In 2006, reporters misinterpreted a scientist's point about melting Arctic ice. An Associated Press wire story and the *San Francisco Chronicle* sounded a false alarm when they claimed that sea ice was actually melting during both the winter and summer. Most previous AP and *Chronicle* stories had accurately reported the risks associated with sea ice melt, including global warming feedback effects and threats to polar bears. But an early press release from NASA had misconstrued a scientist's findings, which then led to misleading statements in the earliest news stories. The scientist also claimed he was misquoted. Some newspapers did provide spot-on reporting. For instance, the *Washington Post* lead stated, "The amount of ice being formed in the Arctic winter has declined sharply in the past 2 years, a finding that NASA climate researchers say significantly increases their confidence that greenhouse gases created by autos and industry are warming the Arctic and the globe."[122]

Sometimes, reporters unintentionally dramatize scientific findings. An example of recent news that sensationalized research was the coverage of ice sheet collapses. The IPCC deemed both the potential collapse in the Thermohaline Circulation (THC) and the collapse of the West Antarctic Ice Sheet (WAIS) to be equally unlikely events. However, the THC issue received more than three times more coverage than the WAIS issue. Representation of the THC as the "Gulf Stream" caused adverse reactions from some scientists. More than 80 % of newspaper articles covering the THC issue did not indicate the probability of collapse or contain contradictory probabilities. The relatively large amount of coverage about the THC issue, the absence of accompanying probabilistic statements, and the use of sensationalist headlines had a significant influence on public perceptions of the climate future.[123]

Scientists often struggle to translate uncertainties inherent in their research into ordinary language. When scientific uncertainty enters into public debate, it can inspire inaction. When elite U.S. print coverage of climate change emphasizes uncertainty, this serves as a boundary between the public and scientists. This emphasis has led to a deferential citizen acceptance of the need for more research. Coverage of climate contrarians amplified this uncertainty but did not explain that the counterclaims were marginalized within the climate science community. Greater contextualization in climate stories can help mitigate controversy stirred up through uncertainty.[124]

Climate scientists sometimes comment on the technical merits of proposed policy responses. Political cues in a news article can activate ideological beliefs and make such beliefs a stronger predictor of concern about climate change, regardless of whether the story portrays scientific elites as agreeing or disagreeing. People are no

[122]Harbinson et al. (2006), Weingart et al. (2000), Carvalho and Burgess (2005), Brainard (2006b)

[123]Jennings and Hulme (2010)

[124]Pollack (2003), Demeritt (2001), Zehr (2000), Wilkins (1993), Zehr (1999), McCright (2007), Schneider (1993), Dunwoody (1999), Corbett and Durfee (2004)

more concerned about global warming even when evidence is strong and scientists agree, because people tend to ignore scientific evidence when shaping concern about scientific topics. However, those high in environmental concern incorporate evidence into their attitudes when scientists agreed and political cues were present.[125]

Conflict and Balance

Journalists are expected to create "balance" by devoting equal attention to two sides of a given story, and this routine practice also can help reporters who lack requisite scientific knowledge or who are facing a tight deadline to produce a credible story. Journalists typically feel a story is balanced if it gives equal attention to scientific opinion and the opposite opinion in story about risk. Many news media organizations have been accused of cherry picking misleading bits of information, to provide the appearance of artificial balance, and failing to apply critical thinking to the weighing of evidence.[126]

The U.S. news media have consistently represented conflict and contentions, despite an emergent consensus view regarding anthropogenic climate science. Journalists often create a conflict frame in a story by pitting authorities against one another or by seeking sources to contest dominant opinions. This illusion of conflict leads to dramatization, personalization, as well as the pretense of balance needed to boost the story's credibility and objectivity. British coverage of controversial science issues often represents the government as undemocratic and beholden to powerful political and economic interests. As the science becomes a contested issue, coverage increasingly emphasizes the importance of deliberative and inclusive forms of science policy decision-making.[127]

In the U.S.A., political ideology plays a larger role in shaping adaptation concerns than any risk perception effects. American liberals tend to support mitigation and adaptation policies, while conservatives oppose them regardless of the framing used.[128] Many conservatives live in southern states and other areas that may experience more severe climate impacts.

In contrast, non-Western news coverage of climate change often emphasizes international relations while de-emphasizing conflicts and controversies. In the Mexican newspaper Reforma, the ecology/science and consequences frames have been the most intensely reported frames, while scientific conflict and U.S. conflict frames have received the least attention. International relations were the most frequently presented solution to global warming, and story frequencies peaked during international conferences. Scientists were the most frequent source of conflicting statements in broadcast news coverage of the continuous rise in

[125]Gushee (2004), Brittle (2005)

[126]Entman (1989), Dunwoody and Peters (1992), Kitzinger (2006), Mooney (2009)

[127]Boykoff and Roberts (2007), Cunningham (2003), Augoustinos et al. (2010)

[128]Moser (2014)

greenhouse gases between 2000 and 2005, but these stories more often quoted political or governmental sources. Most stories in U.S. elite newspapers give equal attention to the view that humans contribute to global warming and to the view that exclusively natural fluctuations explain the earth's temperature increase. Coverage significantly diverged from the scientific consensus from 1990 through 2002.[129]

Before 2005, most climate coverage tried to balance the view that humans cause climate change with the opposite viewpoint. Policy debate about mitigation has been framed as a conflict between skeptics and supporters. Artificial balance, most prevalent in the U.S.A., often arises from journalists' need to appear unbiased and tell a story from two sides. Critics contend that since conflict sells more than consensus, journalists have "balanced" the overwhelming scientific consensus with skepticism. This has confused and misinformed the public and delayed mitigation. Some critics have characterized the debate as a disingenuous pseudocontroversy because of inequitable resources, motives, authority behind the scenes, and extensive commercial and political interests trying to manipulate public information and mislead the public. Political polarization in the climate change debate has been amplified through the rapid rise of the public relations industry in recent years, as well as through claims-makers who use increasingly sophisticated media strategies.[130]

The U.S. news media have moved from an earlier era of false balance to a new phase of overdramatization, which skeptics can easily exploit to dismiss climate change as a problem. Audiences, in turn, filter such critiques through their preferred partisan lens and assumptions about liberal media bias. Although contradictory information about climate change can confuse audiences, it also can boost perceived issue importance. Conflict and immediacy in news stories can impart a sense of fleetingness to climate change issues, which in turn may inhibit public understanding.

By 2005, most British journalists stopped reporting on climate change by balancing expert vs. skeptic voices and by knocking the human-induced climate change argument through prominent coverage of an alternative theory. These changes in media treatment of climate change, which appeared in the British press but not the U.S. media, helped lay the groundwork for a dramatic shift in the depth and regularity of coverage, as well as in the quality of public debate on the issue. British journalists discovered the center of gravity of informed opinion on climate change after providing a decade of polarized coverage, even though the basics of the science had changed little since the mid-1990s. This delay may have occurred, in part, because of a well-intentioned preference for skeptical opinion, but this earlier reporting routine may have impeded public debate about the next political and economic steps to take.[131]

[129]Gordon et al. (2010), Kuban (2007), Boykoff and Boykoff (2004)

[130]Boykoff (2007), Shanahan (2007), Banning (2009), Anderson (2009)

[131]Revkin (2007), Boykoff and Rajan (2007), Lee and Yoo (2004), Andreadis and Smith (2007)

Investigative reporting has exposed vested financial interests among companies and politicians who tried to undermine science and subvert journalism. Financial conflicts of interest have been exposed among major media outlets, as well. For example, from 2007 to 2009, *Newsweek* sold advertising packages to the American Petroleum Institute – the oil and gas industry's largest trade group – to cohost forums on energy issues. *Newsweek*'s parent, The Washington Post Company, also planned but cancelled a series of closed-door "salons" in 2009 where lobbyists and interest groups would have paid for access to public officials and journalists. Atlantic Media, *The Wall Street Journal*, and *Fortune* also accepted corporate funding for conferences and other events, many focusing on energy issues. These events have served as important moneymakers for news outlets in a time of rapidly declining revenues but present potential conflicts of interest that can erode media credibility.[132]

The news media may have underreported several key climate issues, including the urgency of adaptation, costs of acting and failing to act, views of the poor, vested interests that resist change, and potential for action to address climate change to bring substantial benefits. One possible reason for inattention to critical issues may be the financial pressure for climate news to complement the advertising that supports it. In the U.S.A., car and fuel companies have threatened to withdraw advertising from radio stations after they reported on climate change. For many reporters, investigating American climate policy has proven more difficult than translating climate science for the public. Unraveling the Bush administration's approach on climate change policy was challenging for reporters, and some persevered for several years before discovering key paper trails. In 2007, *Rolling Stone* ran a 16-page report on "The Climate Crisis," following a long line of national magazines that published special sections about climate change. The report included an investigative piece, "Six Years of Deceit," about the Bush administration's campaign to deny global warming, cast aspersions on climate science, and allow polluters to shape climate policy. Similarly, *The New York Times* scrutinized oil and coal industry influence on Bush climate policy and unearthed evidence that the Bush administration had tampered with scientific reports about climate change shortly after the president's first inauguration. In 2005, the *Times* also exposed Philip Cooney, a top deputy of the federal Council on Environmental Quality, for heavily editing government climate reports to play up scientific uncertainties about climate change.[133]

Public Understanding of Climate Change

Polls show that public understanding of climate change is low and public action lower still. Maintaining public interest in global climate change through news coverage is necessary for the survival of the issue. Not only is the climate change

[132]Shanahan (2007), Columbia Journalism Review editors (2009)

[133]Shanahan (2007), Brainard (2007d)

issue widely perceived as diffuse and nonpersonal, it also has been framed in terms of false inferences. Most Americans do not understand the difference between weather and climate, and some news coverage, commentary, and media-sponsored polls have led people to believe they can draw inferences about climate change just by looking out their windows. Climate science has important things to say about the prevalence, distribution, and dangers of rainfall and flooding. However, the connection between reporting about high-profile flooding events and scientific understanding of climate change is often tenuous. Responsible climate coverage elucidates scientific details to promote intelligent debate and explains that climate change is a long-term threat with impacts that may not be seen immediately or discernibly.[134]

Public engagement with climate change issues may be required to spark climate change mitigation on any level. The public engagement model proposed by Collins and Evans consists of three waves of public engagement with a science issue over time: knowledge deficits, democratization of science and practice, and authorized expertise. In the first wave, poor choices and actions are attributed to a dearth of knowledge, reliance on "sound" science, and the need to eliminate uncertainty before taking action. In the second wave, democratic public engagement mitigates common "bads" and "goods" in a risk society. In the third wave, some groups and institutions are authorized to speak about climate change while others are not.[135]

People show the greatest concern, commitment, and optimism in the developing economies and the greatest indifference, reluctance, and fatalism in developed nations, even though global climate change coverage does not reach all people equally. Prime-time evening news on the main TV stations in China, India, Mexico, Russia, and South Africa made no mention of the IPCC report on mitigation when it was released in 2007. Meanwhile, the poorest, most vulnerable people in the world, those who have contributed least to the problem and have the least access to climate information, will suffer the most from its impacts. Climate change is a media-driven issue, in the sense that the media can easily make the issue salient in the public's thinking through news reporting. However, because climate change is an intangible issue, is difficult to explain to the average citizen, and is framed as a debate, the public is generally misinformed about the issue despite volumes of information and data generated over the last 30 years. Although the global energy crisis may have become too large and complex for the media to handle on its own, public apathy about the future energy economy is not solely the media's fault. Since news originates and disseminates into the public sphere before entering the private sphere of individual engagement, personal responsibility is diffuse. Although all humans contribute to greenhouse gas emissions through daily activities, some vulnerable human groups suffer concentrated impacts.[136]

[134]Miller (2004), Gavin et al. (2010)

[135]Shanahan (2007), McComas and Shanahan (1999), Brainard (2007e), Collins and Evans (2002), Beck (1992)

[136]HSBC (2007), Painter (2007), Shanahan (2007), Soroka (2002), Trumbo (1996), Plate (2009), Lowi (1972)

In working through science issues, the public opinion climate is complex, and the development of consensus policy can be problematic. In a science controversy such as the climate change debate, a spiral of silence can develop when visible dissent decreases, even as public opinion begins to appear hegemonic, because personal fear of social isolation inhibits people from expressing opinions perceived to be in the minority. A spiral of silence in public opinion about controversial science is more likely to develop when skeptical citizens are willing to speak among those who believe themselves to be more knowledgeable about science or among those who apply moral reasoning besides consequentialist and utilitarian arguments. Canadians are more likely than Americans to be ethical populists in a science controversy, in the sense that they believe ordinary people should make personal decisions about science issues based on ethical considerations. The most common group in each country is made up of utilitarians who believe risks or costs and benefits should be weighed in developing policy and this should be done by experts. Two other cluster groups, moral authoritarians and democratic pragmatists, exist in equivalent proportions in both countries. Most media coverage of climate politics emphasizes expert and elitist discourse while neglecting the interests, views, and voices of citizens. One reason citizens are left out of the deliberation is the ignorant assumption that "the environment" does not involve human action and society. The assumption that greater understanding leads to more positive attitudes has informed many practical initiatives in the public understanding of climate change. The media provide an important part of the social context through which citizens judge controversial science issues such as climate change.[137]

Learning about climate change through newspapers and television leads to increased understanding about the connections between fossil fuel use and climate change. In turn, increased understanding increases people's stated intentions to take action. However, climate change issues often lack the day-to-day relevance needed to motivate people to actually take action. As their specialized knowledge and concern increases, so does their compartmentalization of understanding. Climate change knowledge then can become relegated to an arena where "appropriate" action is seen as too problematic. Public perceptions of science are generally shaped by value predispositions, schema, and media use rather than scientific knowledge. Value predispositions related to social ideology, along with reservations about science, often serve as primary influences on citizen evaluations of controversial science issues. Ideology can have a strong effect on citizen understanding of climate science, and ideology can interact with other factors, such as college education that affect comprehension of information. As citizens' ideology shifts from liberal to conservative, concern for global warming decreases, and college education does not increase global warming concern among conservative ideologues. However, citizens with a college education and higher general science literacy do not tend to have higher concern for global warming. It is difficult for any media consumer to ever know how to recognize the real conclusions of climate science and how to

[137]Priest (2006), Beck (2010)

distinguish them from scientific-sounding spin or misinformation. When partisans wield vastly different facts, finding truth and common ground is difficult. Science journalist Chris Mooney argues that journalism should be constrained by standards of evidence, rigor, and reproducibility similar to the canons of modern science itself.[138]

Attention to newspaper coverage and certain entertainment television genres can influence citizen evaluations of science. Trust in university scientists, exposure to national television news, and familiarity affect perception of research benefits. When individuals read science or environment news, this attention predicts heightened global warming risk perceptions and stronger policy support, while attention to political news predicts lower risk perceptions and less support for climate policies. The internal consistency of individual attitudes toward science tends to be poor, and the links between attitudes toward science in general and attitudes toward specific areas of scientific research are weak. Understanding of science is weakly related to more positive attitudes in general, but it is also associated with more coherent and discriminating attitudes. Knowledgeable citizens tend to be more favorably disposed toward science in general but are less supportive of morally contentious areas of research such as climate change than those who are less knowledgeable. Ultimately, informed public opinion can actually constrain climate change research.[139]

Lack of public support for climate change mitigation may be linked to poor science literacy. Although the rate of civic scientific literacy in the U.S.A. has long hovered around 20 %, a strong and continuing public belief in the value of scientific research for economic prosperity and quality of life existed before 1999. Before that time, some concerns lingered about the pace of change caused by science and technology and the relationship between science and faith, but the public consistently reconciled these differing perceptions in favor of science.[140]

The "deficit model" of public attitudes toward science asserts that scientific knowledge predicts and explains citizen attitudes toward science. Knowledge is a strong determinant of attitudes toward science. Although the success of environmental policymaking depends on public participation, the scientific construction of environmental issues often means that such participation is difficult when the public lacks scientific expertise. Lay ideas are typically discounted as nonscientific, and educating citizens about environmental science does not guarantee that they can constructively participate in policymaking. The dominant assumption is that science literacy in climate change discourse is both the problem and the solution to societal conflicts. However, science communication initiatives can facilitate conversations with the public that recognize, respect, and incorporate differences in knowledge, values, perspectives, and goals.

[138]Stamm et al. (2000), Bord et al. (2000), Ungar (2000), Nisbet and Goidel (2007), Zia and Todd (2010), Mooney (2009)

[139]Evans and Durant (1995)

[140]Miller (2004)

The benefits of public engagement initiatives about risk-related policy issues are difficult to establish without a rigorous evaluation of engagement processes. These initiatives often are not evaluated at all, even though they are advocated as an antidote to deficits in lay knowledge and other policymaking problems. Participatory action research can be used to evaluate climate change campaigns. A grassroots organization can be transformed through personal and collective political power, through a process of double-loop learning. From inception to widespread grassroots endorsement and political awareness of a proposed bill, activist groups can contribute to legislative outcomes on climate change. Public concern about the impacts of climate change and the federal government's weak response was more pronounced because of increased media coverage.[141]

When citizens draw the line in a science controversy, they often discuss regulation and which conditions should be the subject of research. Ambiguities and tensions in lay accounts can enable, rather than stifle, greater democratization of science policy. Beyond the deficit model of science ignorance, lay people may hold technical, methodological, institutional, and cultural knowledge. When citizens do mobilize a stock of knowledge, it is influenced by their own social context and perceptions of relevancy. Identifying lay people as expert in, rather than ignorant of, the way science may shape their lives is a fundamental first step in moving toward greater citizen participation in policy discussions. When attributing responsibility for collective action, the media often avoid discussing scientific uncertainty, in the belief that it might undermine the demand for collective action. Reporters are typically responsive to the political setting in which they operate and tend to link local, national, and transnational risks. Many British governmental publications have advocated greater public dialogue and engagement in science issues. Moving beyond mere sloganizing about science and democracy requires strategic message development. Opinion-leader campaigns can catalyze wider political engagement on climate change and sustainable consumer choices and behaviors. Combining the recruitment of digital opinion leaders with traditional media strategies leads to significant trade-offs, in comparison with face-to-face initiatives. However, only in specific conditions are digital opinion leaders effective in strengthening online interactions and real-world connections.[142]

Effective public communication can engage audiences in low-carbon lifestyles by facilitating top-down public acceptance of regulation and by stimulating bottom-up, grassroots action through affective and rational engagement with climate change. Using communication to stimulate demand for regulation may reconcile these top-down and bottom-up approaches. Climate communication campaigns often require significant resources to promote attitudinal change, but research suggests that encouraging attitude change alone is not likely to be effective. The link between individual attitudes and subsequent behavior is mediated by social norms and other

[141]Sturgis and Allum (2004), Eden (1996), Nisbet and Scheufele (2009), Rowe et al. (2005), Hall et al. (2010)

[142]Kerr et al. (1998), Olausson (2009), Irwin (2001), Nisbet and Kotcher (2009)

influences. Introducing regulation that forces green behavior can promote mitigative behaviors, but government fears the loss of political capital. Conversely, communication approaches that advocate individual, voluntary action ignore the social and structural impediments to behavior change.[143]

The threat that global climate change poses to the health and well-being of human and nonhuman species has received relatively little attention in the press. Relatively few people hold clear top-of-mind associations between climate change and human health risks. Although international polls reflect that climate change lacks salience as a health issue, a survey of U.S. residents found that framing climate change in terms of public health can make climate change more personally relevant and emotionally engaging to segments of the public who are currently disengaged or even dismissive of the issue.[144]

Most people in the U.S.A., Canada, and Malta believe climate change poses significant health risks, and about a third believe people are already being harmed. More than a third of Americans and Canadians see themselves, their family, and people in their community as vulnerable to at least moderate harm from climate change. Many Canadians believe the elderly and children are at heightened risk of harm, while Americans see people in developing countries as being at greater risk than people in their own nation. When prompted, most Canadians and Maltese say climate change could cause respiratory problems, heat-related problems, cancer, and infectious diseases. Canadians also named sunburn and injuries from extreme weather events.

Substantive news attention to health threats associated with climate change can increase the capacity of communities to pursue mitigation and adaptation actions, but much of the current news coverage is not substantive. Health impacts such as extreme heat, disease, and respiratory problems and threats such as hurricanes are rarely mentioned, and most stories that do mention health threats simply react to heat waves, storms, and other naturally occurring events. Few stories include enterprise or explanatory reporting. News agenda–building strategies might be useful for generating substantive reporting about regional climate studies, regional public health meetings, and other localized topics.[145]

If the mass media could promote individual behavior change, this in turn could boost public engagement with climate change issues and contribute to health-related climate change mitigation and adaptation goals. Intersections between health communication and public health scholarship underlie an emergent research framework known as public health communication. Effective public health communication about climate change requires transdisciplinary theory and methodology. Communication interventions have considerable potential to promote population behavior change consistent with climate change prevention and adaptation objectives. Communication interventions can promote beneficial changes in behavior, either by

[143]Ockwell et al. (2009)

[144]Myers et al. (2012)

[145]Akerlof et al. (2010), Nisbet et al. (2010a)

directly targeting people already concerned about climate change and the people who influence them or by indirectly creating changes in the environments where people live and work. To optimize the influence of a climate change communication intervention, planners should identify opportunities to use media to target both people and places in ways that complement and extend existing programs. Although Americans are only dimly aware of the health implications of climate change, providing a human health frame of reference in news coverage could enhance public engagement with climate change.[146]

The success of proposed climate policy reforms such as cap and trade, carbon tax, and international climate treaties may depend on generating widespread public support and mobilization while countering partisan gridlock and the communication efforts of opponents. Public engagement is necessary for policy action but hinges on whether the media can reframe the relevance of climate change in ways that can reach more Americans. High-quality news coverage often reaches only a small audience of already informed and engaged citizens, while the rest of the public either ignores the coverage or reinterprets competing claims based on partisanship or self-interest.[147]

Fear-inducing representations of climate change are widely used in news stories and effectively attract attention to climate change. The popular film "The Day After Tomorrow" caused viewers to become more anxious about climate change and motivated to take action on it. It also made them less concerned about extreme events as a result of climate change, such as a possible shutdown of the North Atlantic thermohaline circulation, also known as the Gulf Stream. Fear is generally not an effective tool for motivating genuine personal engagement. Nonthreatening visual imagery and icons that link to individuals' everyday emotions and concerns in the context of climate change issues tend to be more engaging. In light of anchoring and objectification in social representations, verbal and visual representations often are attached to fear, hope, guilt, compassion, and nostalgia. Thus, emotional representations of climate change can enhance public engagement in the issue but also may draw attention away from climate change as an abstract, long-term phenomenon.[148]

Nisbet and colleagues argue that the global community will not take meaningful action on climate change until four cultures can collaboratively engage audiences through rigorous and accessible science, shared values, and personal relevance. The four cultures are (1) environmental sciences, which provide environmental data and predictive models; (2) philosophy and religion, which ground a society's discourse about what is good, right, and valuable; (3) social sciences, which provide theories and data about mental models, narratives, and frames of reference public audiences need to understand and make decisions about climate change; and (4) creative arts and professions, including nature and poetry writing, documentary filmmaking,

[146]Kreps and Maibach (2008), Maibach et al. (2008), Abroms and Maibach (2008)

[148]O'Neill and Nicholson-Cole (2009), Lowe et al. (2006), Höijer (2010)

multimedia design, and journalism, because they tell inspiring and emotional stories that shape human actions, provide different forms of learning, sponsor deliberation, and provoke action.[149]

Public Understanding and Engagement About Adaptation

Until recently, U.S. policymakers and scholars avoided discussing adaptation, out of concern that public awareness of adaptation could reduce policy support for mitigation.[150] Victor and colleagues[151] noted that "until just a few years ago, even discussing adaptation to climate change was taboo" (p. 119). The consequences of framing climate change as mitigation or adaptation could have important effects on public support for policy adoption and implementation.[152]

Learning about adaptation may "spill over" into attitudes toward mitigation. Negative spillover effects occur when adoption of one proenvironmental behavior reduces the likelihood of adopting another proenvironmental action.[153] This often happens when individuals feel morally "off the hook"[154] or believe the problem already has been dealt with.[155] Weber's work on single action bias found that farmers who adapted their cultivation practices, such as crop selection, or adopted off-farm adaptations such as investing in futures were less supportive of government intervention to mitigate climate change.[156]

Discussing adaptation does not necessarily reduce support for mitigation or concern about climate change. For instance, Carrico and colleagues[157] found that politically moderate individuals exposed to adaptation information rated climate change as a higher political priority and were more supportive of policy to subsidize mitigation technology than those who did not view any adaptation information. This may be explained by applying the risk salience hypothesis, which suggests that information about climate change adaptation may increase the salience of impacts and therefore increase mitigation support.

Even when individuals do support mitigation and adaptation policies, they consistently prefer mitigation actions (such as reducing energy use or using sustainable energy sources) over adaptation actions such as purchasing flood insurance,

preparing homes against flooding, or moving to another home. They feel others should take adaptation actions but are not willing to do these things personally.[158]

Research about place attachment and place identity provide useful implications for improving public engagement on adaptation issues.[159] Places are understood through the personal meanings instilled in them, as well as through the emotional experiences, learning and growth, family and other social ties, occupational and recreational practices, and spiritual practices enacted there. Ties to place help people develop a sense of belonging.[160] Adaptation actions that impact places can affect person–place intimacy. Disruption of these relationships or displacements can cause grief,[161] as well as resistance and defensiveness to change, such as reactions to a recommendation that residents retreat from a shoreline or floodplain.[162]

As values become anchored in places,[163] they give meaning to events, motivate behavior, influence perceptions of adaptation options, and guide interpretation of situations as they unfold.[164] For example, in coastal Louisiana researchers noted how the slow process of coastal land loss due to relative sea level rise forced a constant and heightened awareness of place attachment. The perceived fragility of the place was reinforced through political alienation from decision-making processes.[165] Place attachment evokes visible impacts on the places people hold dear.[166] Proactive adaptation could be enhanced when place identity is embedded in news coverage[167] because place identity motivates publics to act personally and civically.[168] Engaging place, place attachment, and place identity could improve adaptation messaging and reduce unproductive political disputes.[169]

Among public audiences, knowledge about how to prepare for or protect against climate impacts is often limited and socially conditioned.[170] However, past experience with extreme weather events is an important teacher.[171] Issue publics tend to be better informed and more willing to engage in discussions about adaptation.[172]

When the media invokes global risks or frames local impacts as unknown, overwhelming, or beyond individual control, audiences are more likely to want

national and local governments to take adaptation measures.[173] At least in principle, most people favor proactive government planning and preparation, as opposed to "wait and see" or merely cleaning up after disasters.[174] In reality, however, initial adaptation planning efforts at the local level often focus only on disaster preparedness and recovery, without addressing the changing climate. To communicate more effectively about adaptation, news organizations should help audiences appraise the risks they face from climate change and how they can alleviate the threat. Journalists also should present different scenarios and explain the uncertainties in understandable ways and with clear relevance to the implications for actions at different times.[175]

Moser recommends that news reports point to past experience or experience in other locations with similar adaptation approaches, such as relocation of communities out of floodplains, significant shifts in policy or regulatory environments, or creative financing and compensatory mechanisms. This coverage can familiarize audiences with the idea of adaptation and create a sense of continuity and stability in the midst of change.[176]

To justify proposed adaptation measures, stories can explain how long a given behavior or management approach will work in light of climate change (and other stressors) and identify points at which an objective can no longer be achieved with "business as usual." Then, the story can show how well adaptation alternatives may achieve the objective. For example, the Climate Vulnerability Monitor evaluates climate change impacts for a particular location, to produce a vulnerability factor for the year 2030.[177] Solid reporting should communicate the costs and benefits of adaptation options and outline different ways to reach each intended outcome. Media organizations ultimately can use news coverage to facilitate public deliberation about risks, adaptation goals, and the adaptation options needed to achieve them.[178]

Conclusions

Dominant framing of public understanding of climate science reflects the assumption that laypeople are defensive, risk averse, uncertainty averse, and unreflexive, while science is assumed to be the epitome of reflexive self-criticism. Although awareness of global warming is growing, the public has resisted coming to terms with the trade-offs involved in any serious solution such as an international regulatory treaty, investment in alternative fuels, or control of carbon dioxide emissions. Public engagement must transcend science literacy, because people do not need to become

amateur scientists to deliberate about policy choices. Moving people beyond awareness to judgment and resolution requires the public to actively deliberate and reconcile possible actions with their own beliefs and habits.[179]

Coverage reached a historic peak in 2007, and limited attention to Climategate in 2009 was followed by a quick return to relative nonattention. Climate change coverage may not return to 2007 levels again, unless a novel storyline emerges that defines the problem in ways that are more localized and personally relevant than long-term catastrophic environmental impacts, regulatory actions, and politics. Human health risks, economic growth from energy innovation, or energy insecurity might provide this news hook, if journalists could convey these risks using noncatastrophic frames. Local angles might play best in small and medium-sized newspapers, which in the past have typically provided only national wire stories that lacked details about regional impacts of climate change and regional policy initiatives.[180]

The future of climate change mitigation and adaptation likely will depend in part upon the effectiveness of news media content to motivate audiences to take action and support proactive policies. Media routines, including framing, balance, and sourcing, can in turn mitigate the flow of complex and politicized content about climate change science and policy. Scientists and policymakers should identify specific frames that can help journalists present climate change problems in ways that are more personally relevant, significant, and understandable to public audiences.

Economics for a Sustainable Planet

Arif S. Malik

Contents

Abstract

Sustainable development endorses the idea that social, environmental, and economic progress is possible within the limits of earth's natural resources. Sustainable development acknowledges that everything in the world is connected through space and time; hence, environmental pollution created in one part of

the globe disturbs the other part of the globe or decisions made by the present generation will affect the future generations. Sustainable development is the route to world's sustainable future. Therefore, to achieve true sustainability there is a need to harmoniously balance economic, social, and environmental sustainability factors. Environmental sustainability means that world's ecological limits are not transgressed. Economic sustainability requires that existing resources are used optimally so that a responsible and beneficial balance can be achieved over the longer term. Social sustainability is the ability of society, or any social system, to continually achieve a good social wellbeing. Yet there are policies and practices in social, political, and economic milieu that constantly promote unsustainability or are fundamentally in tension with the sustainable development notion. For example, sustainability and economic growth are fundamentally incompatible because the contemporary global economic system, which promote economic growth, assumes continuous expansion in consumption of material goods and resources, a phenomenon that conflicts with the environmental notion of a finite planet with limited resources. Similarly, the unfair economic structures in the economic system create great wealth inequalities, which could lead to social unsustainability and social unrest. Likewise, the solutions to world's political problems if enforced without considering the will and aspirations of the affected local population create social unrest and affect the global peace.

This chapter emphasizes on the need for a fair and just economic system to achieve sustainability. It shows that climate change, ecological degradation, population growth, poverty and the resource scarcity, the problems of failing financial markets, and economic recession are all intertwined with the present economic system, which has been responsible for transgressing the balance of nature. The chapter then reviews reforms and alternatives, proposed in literature, to the present economic system to promote sustainability such as steady-state economics; environmental economics, ecological economics; restorative economics; local self-reliance/alternative currency, etc. Existence of interest and discount rates, which are a given necessity of the world economic system, means that the future costs and benefits are less valuable than those in the present – a clear case of intergenerational inequity and injustice. The chapter, using the concepts of systems thinking, make a case against discounting the future and shows that the discounting practice is in conflict with the holistic approach to the environment. The chapter shows that all the reforms or alternatives to contemporary economic system proposed in the literature do not really address the root cause of all the problems, which is the built-in interest-based system, made possible with the paper currency, in the economy that creates great injustices. The chapter argues that solutions of science and technology to ecological problems are limited because of ecological shortsightedness and corporate greed. Finally, in the future directions a broad framework of "fair and just" economic system is laid out which if realized can lead to an ecologically sustainable future for the planet.

Introduction

How serious is the global threat to sustainability and the environment? This is the question one has to ponder if one truly cares about the planet he lives in. One way to judge is by carefully considering the present world predicament – by bearing in mind the present state of humanity as a whole – and where it is heading.

Human civilization as a whole is on a path to increasing world population pressure; rising poverty and hunger; an increasing gap between rich and poor among the nations and within nations; growing potential for social and political conflicts; escalating violence or terrorism in response to injustices (Milne 2001), or in the very least, to call attention to perceived wrongs or injustices; huge world military spending; accelerating climate change; food, water, and energy shortages; worsening industrial, urban, and agricultural pollution; nonstop destruction of the ozone layer (Environmental Protection Agency 2015); accelerating reduction of biodiversity; and continued loss of atmospheric oxygen (Bardi 2013). Humankind also runs the risk of global destruction through nuclear war, risk of mega disasters caused by nuclear accidents and leaking nuclear waste, devastating floods, storms, and cyclones due to climate change; and widespread health problems owing to natural catastrophes due to the accumulation of toxins, in soil, air, and water (Milne 2001; Environmental Protection Agency 2015; Bardi 2013; Capra 1983; Laszlo 2006). This, then, in brief is the dire state of the world humanity is in and if human civilization continues on the same trajectory, it is on a collision course with nature. How did it come to be as it is and how can the human race avoid this imminent disaster?

Unless this sickness is thoroughly understood, no cure is possible. This chapter will delve into the fundamental contributing factors that led to this pathetic situation and then suggest a future remedy to emerge from this state. After providing a brief introduction to ecology, economy and economic growth, and ecosystem concepts, the effect of economic activities on the global ecological situation is examined. Poverty and population growth are discussed as drivers of social unsustainability. The concept of sustainable development is then introduced and the compatibility of a market-based capitalist economic system with sustainability is reviewed. Several reforms/alternatives, proposed in literature, to the present economic system are reviewed to promote sustainability. The case of intergenerational equity and discounting the future is critically discussed in light of systems thinking. Recent advances in hierarchical systems approach concepts in systems theory are employed to argue against the economic growth imperative of capitalist economic system. Next, the cause of all the ills – the interest-bearing system of the capitalist economy – is discussed in rather detail. Before giving a prescription, the role of technology is critically reviewed. Finally, the concept of a "fair and just" economic system is introduced for sustainable development of humanity and future guidelines are provided for its realization.

Ecology and Ecosystem

Ecology is the science of relationships between living organisms and their environment. Ecology is also the study of ecosystems. An ecosystem is everything in a specified area – the air, soil, water, living organisms, and physical structures, including everything built or devised by humans. The living parts of an ecosystem – microorganisms, plants, humans, and animals are its biological community. Ecosystems can be of any size. A small pond in a forest is an ecosystem, and the entire forest is an ecosystem. A single farm is an ecosystem, and a rural landscape is an ecosystem. Villages, towns, and large cities are ecosystems. A region of thousands of square kilometers is an ecosystem, and the planet earth is an ecosystem. People affect ecosystems when they use resources such as water, fish, timber, and livestock grazing pasture. After using materials from ecosystems, people return the materials to ecosystems as waste (Marten 2001). The main driver behind the changes in ecosystems is human economic activity and the related economic growth.

Economic Growth

Economics is defined as the discipline dealing with the production, distribution, and consumption of wealth. Economic growth is then an increase in production and consumption of goods and services. It is a function of increasing population and per capita consumption and is typically expressed in Gross Domestic Product (GDP) or Gross National Product (GNP). When the economy grows, natural capital is either consumed as a nonrenewable resource or reallocated to humans as a man-made capital. Natural capital, in this context, is the stock of all environmental and natural resource assets, from oil in the ground to the quality of soil and groundwater, from the stock of fish in the oceans to the capacity of the globe to recycle and absorb carbon (Pearce et al. 1990). One fascinating character of natural capital is that, unlike man-made capital, it has the capability to maintain itself provided its "health" is not critically deteriorated. If critical ecological thresholds are crossed, ecosystems may not only lose their capacity to maintain, renew, and replenish themselves, but may also begin to deteriorate spontaneously (Blignaut and Aronson 2008).

Economic Growth and the Environment

The vast expansion of economic activity that occurred in the twentieth century and continues today is the predominant cause of the environmental decline that has occurred to date. This activity is consuming vast quantities of resources from the environment and returning to the environment vast quantities of waste products. The damages are already huge and are on a path to be ruinous in the future. Yet the world economy, now increasingly integrated and globalized, is poised for unprecedented growth. The engine of this growth is modern capitalism or, better, a variety of capitalisms (Speth 2008). Capitalism includes competitive markets, the price

mechanism, the modern corporation as its principal institution, the consumer society and the materialistic values that sustain it, and the administrative state actively promoting economic strength and growth for a variety of reasons. Inherent in the dynamics of capitalism is a powerful drive to earn profits, invest them, innovate, and thus grow the economy. The capitalist era has in fact been characterized by a remarkable exponential expansion of the world economy (Speth 2008).

However, these features of capitalism, as they are constituted today, work together to produce an economic and political reality that is highly destructive to the environment (Speth 2010). The worldwide commitment to economic growth at almost any cost; enormous investment in technologies designed with little regard for the environment; powerful corporate interests whose overriding objective is to grow by generating profit, including profit from avoiding the environmental costs they create; markets that systematically fail to recognize environmental costs unless corrected by governments; governments that are subservient to corporate interests and the growth imperative; rampant consumerism spurred by a worshipping of novelty and by sophisticated advertising; economic activity is so large in scale that its impacts alter the fundamental biophysical operations of the planet – all combing to deliver an ever-growing world economy that is undermining the planet's ability to sustain human life (Speth 2010).

The current ecological situation is radically different from anything humanity has ever been confronted with in its history. This is due to the fact that the dangerous transformation of the environment has become global. These changes have affected all the subsystems and components of the environment over the entire surface of the planet, extending as far as its poles, leaving untouched perhaps only the ocean depths, as has been confirmed by various scientific studies (Speth 2008; Danilov-Danil'yan et al. 2009). Below are some points summarized from (Laszlo 2006; Speth 2008, 2010; Danilov-Danil'yan et al. 2009) elaborating the current global ecological crisis that has occurred due to the economic activity of mankind:

- Sudden rise in the CO_2 in the twentieth century due to emissions from human economic activity (burning fossil fuels and land clearing). Anthropogenic carbon emissions in 2008 are estimated at nearly nine billion tons per year. Models for CO_2 indicate that the earth is only absorbing about half of the CO_2 generated by human activity and the remainder accumulates in the atmosphere.
- Increasing average global temperature predicted to rise in the range 1.5–4.5 °C in the twenty-first century.
- Destruction of ecosystems. At the turn of the twentieth century, territories with ecosystems completely destroyed or depleted by humans comprised only 20 % of the dry landmass, but by the end of the twentieth century they had increased to 63.8 %.
- Decrease in forest reserves. In the preindustrial period alone, according to various estimates, 30–50 % of forests were destroyed all over the Earth. Another 9 %, of which tropical forests comprised the majority, were eliminated in the last 200–300 years. Unfortunately, there is no indication that this process has declined in any manner today but increasing at alarming rate. Because of difficulties in estimating

tropical forest loss, yearly estimates of global tropical deforestation vary widely from 50,000 km^2 – roughly the size of Costa Rica or the U.S. state of West Virginia – to 170,000 km^2 – about the size of the South American country of Uruguay or the U.S. state of Florida. At such rates, half of the world's remaining tropical forests will be gone in 35–117 years, resulting in a dramatic loss and degradation of biodiversity and the ecosystem services it provides (Miller and Spoolman 2009).

- Quality of soil degradation. Soil mantle loss from erosion and degradation due to modern agricultural practices amounts to 60,000 km^2 per year. In addition, thousands of square kilometers are neutralized every year through the salinization and erosion of soils, which no longer remain available for the Earth's biosphere (Danilov-Danil'yan et al. 2009).
- Increased desertification. The rate of desertification is also increased through anthropogenic pressure on semiarid ecosystems, especially as a result of massive water diversion for irrigation.
- Degradation of quality of fresh water in rivers. Increased scale of water regulation (river canalization as well as the construction of dams and water reservoirs, etc.) is undermining the self-rejuvenating capacity of river water.
- Water environment degradation due to acidification and salinization of freshwater reservoirs. The direct cause of acidification is acid rain brought about by the emission into the atmosphere of sulfur and nitrogen oxides formed through the process of fossil fuel combustion. As they become absorbed by raindrops, these compounds settle on water and soil surfaces, often poisoning organisms.
- Depletion of underground water-bearing strata. This could lead to palpable fresh water shortages in certain world regions as early as the next 10–15 years. According to estimates from the International Water Management Institute, by 2025 a billion people will be living in countries with an absolute fresh water deficiency (less than 1,700 m^3 per person per year). These would include parts of the Near East and South Asia, almost all of Africa, as well as the North of China. As a result, there will be even more acute water shortages for agricultural needs in these regions.
- Biodiversity loss. The rate of biodiversity loss (biodiversity is the variation of life forms within a given ecosystem, or on the entire Earth) amounts on average to at least one species per day. And in case of vertebrates, since the early 1600s, the Earth has lost an estimated 23 species of fish, 2 species of amphibians, 113 bird species, and 83 mammalian species. Each extinct species constitutes a final and irreparable loss for the biosphere, and a far greater number of species is in danger of extinction.
- Rapid accumulation in the environment of waste from human economic activity, including the products of chemical synthesis with pronounced toxic characteristics, some of which are discussed below:
  (i) Most of the waste, especially its solid forms is generated through the relentlessly growing process of mineral raw material production. The volume of waste generated by economic activity is indeed truly daunting and defies the imagination. Thus, for every inhabitant of the Earth, 50 t of raw

materials are extracted and transported from mining to processing per year. However, only 2 t of this is transformed into finished products but even the 2 t of final product are essentially a form of waste generation, merely postponed into the future. Therefore, from an ecological perspective, almost everything produced by humanity in the material sphere is sooner or later bound to become waste.

(ii) Aerosols, minute suspended particles, containing both solid (dust, ashes, soot) and liquid components (dissolved sulfur and nitrogen oxides, ammonia as well as airborne hydrocarbons), with a diameter of 0.1 to hundreds of microns, are typical atmospheric contaminants caused by anthropogenic activities. These aerosols, also absorb many metals, lead in particular, and high molecular toxic compounds, which upon reaching human respiratory channels, act as direct irritants and allergens. Other compounds penetrate the blood stream and can provoke a generally toxic effect.

(iii) Dangerous waste and supertoxicants constitute a special category of pollutants, 90 % of which originate in industrialized countries. Less than seven drops of supertoxic chemical if given in a liquid form to a 70 kg human could be lethal (Miller and Spoolman 2009). These include dioxins, biphenyl, furans, etc., and are quite stable in the environment and are not subject to easy chemical and biological decomposition. In this manner, for example, dioxins, formed as a byproduct of many technological processes, have been found not only in the atmosphere, water, and soil, but also in food, including human and animal mothers' milk. The truly global extent of these pollutants is evident in their significant presence even beyond the Arctic Circle (Danilov-Danil'yan et al. 2009). Some of them affect the hormonal, neural, and reproductive systems, hence the term "supertoxicants."

(iv) The role of pesticides in the pollution of the soil and water environments is well known. In particular, it turns out that many pesticides, starting with previously banned DDT (dichlorodiphenyltrichloroethane), as well as polychlorinated biphenyls, dioxins, furans, and finally an entire series of metals (cadmium, lead, mercury), are responsible for disruptions in the human endocrine system, hormonally determined breast cancer and cancer of the prostate, lower sperm counts, infertility, congenital defects, and neurological anomalies in children (Miller and Spoolman 2009). Furthermore, substances in this category are very slow to decompose or to be excreted by the body and therefore tend to accumulate in the body. Thus, lead concentrates in bone tissue; resulting in nearly 1,000 times higher concentrations in bones of modern humans than in bones of those living 1,500 years ago. Chlorinated pesticides and biphenyls accumulate in fat tissue and penetrate into breast milk in fat droplets.

(v) As many as 100,000–200,000 (including synthesized) substances are circulating on the world market; 80 % of these are unknown (Danilov-Danil'yan et al. 2009) and are unlikely to ever be known completely nor how they act upon living organisms. All foreign chemicals can easily enter human body because these are present in the air, water, or food used on daily basis.

As seen from the above, the ecological crisis is immense and the past century witnessed unprecedented destruction mainly due to the economic activity of humankind. Another important factor contributing to the ecological crisis is poverty, which is largely a result of the growing inequity in distribution of wealth (Human Development 2014; Shah 2010a).

Poverty and Population Growth

Global poverty statistics are dismal. According to income-based measures of poverty, 1.2 billion people live with $1.25 or less a day. However, according to the UNDP Multidimensional Poverty Index, almost 1.5 billion people in 91 developing countries are living in poverty with overlapping deprivations in health, education, and living standards (Human Development 2014). Those living in extreme poverty and deprivation are among the most vulnerable. About more than 15 % of the world's people remain vulnerable to multidimensional poverty. Large disparities in income, wealth, education, health, and other dimensions of human development persist across the world, heightening the vulnerability of marginalized groups and undermining their ability to recover from shocks. At the same time, nearly 80 % of the global population lack comprehensive social protection. About 12 % (842 million) suffer from chronic hunger, and nearly half of all workers – more than 1.5 billion – are in informal or precarious employment (Human Development 2014).

Poverty and environmental degradation are inextricably linked (Danilov-Danil'yan et al. 2009). Due to the lack of sufficient income, people begin using and in turn overuse every resource available to them when their survival is at stake. As desperate hunger leads to desperate strategies for survival, many trees are harvested for firewood, timber, and arts and crafts. Most of the poor use this firewood as their source of income by selling it, and arts and crafts products are also used to generate income. The struggle of the poor to survive creates a range of environmental impacts where the poor themselves are often the primary victims. For example, Nepal and Bangladesh have suffered from various environmental problems such as increasingly devastating floods, often believed to be resulting from large-scale deforestation (Shah 2010a). Deforestation also causes the erosion of the soil, and the land the poor farmers cultivate becomes of low quality, thus reducing the overall yield. The high level of pollution in Developing World cities is also amplified by the inability of the urban poor to pay for environmental cleanup. As a result, a large portion of solid household waste is not taken away; therefore, it is in such locations that the world's highest level of water and air pollution is found. Consequently, in the Developing World, intestinal disease alone (caused by dirty water) brings about the deaths of around two million children per year (Danilov-Danil'yan et al. 2009).

Poverty encourages high birthrates because children help subsistence-level families garner the resources needed for survival. Population growth creates more poverty, and more people destroy more of the environment. Without eradicating poverty it is difficult to control the population growth.

As seen from the discussion above, the two main causes for the ecological crises are economic growth based on the economic system that supports it, and the abject poverty related to it is the population growth. In fact, poverty is largely the effect of a world economic system that creates great inequity in the distribution of wealth. As Pope Francis once said, "Human rights are not only violated by terrorism, repression or assassination, but also by unfair economic structures that creates huge inequalities" (The Guardian 2013). The link between poverty and economic system shall be discussed in the later part of the chapter but before that the world response to the growing ecological damage is reviewed.

The industrialized nations having destroyed their own natural ecosystems some time ago were the first to realize the ecological consequences for the rest of the world attempting to emulate their policies. By the 1970s, the ground had been laid for new perspectives on global development. In *Limits to Growth* (1972), Meadows and other MIT researchers modeled trends in global population, resource consumption, and pollution, and found that without policy changes of a drastic kind, they projected population collapse somewhere in the mid twenty-first century (Meadows et al. 1972). They advocated for an end to ever expanding growth, holding population at present levels, and maintaining the per capita industrial output (that is, the average amount of industrial products produced by each person) at the 1975 level; with goods recycled and pollution controlled, soil restored and consumer goods made more durable. After this, alarmist report a tide of literature on sustainability followed. Some even strongly criticized the industrial way of life and its ethos of continuous expansion. It is largely through the Report of the Brundtland Commission in the 1980s the term "sustainable development" entered the wider scientific vocabulary (Danilov-Danil'yan et al. 2009).

Sustainable Development

Among the several definitions of sustainable development, the most frequently quoted definition is from *Our Common Future*, also known as the *Brundtland Report*, which proposes (World Commission on Environment and Development 1987):

> Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs.

It contains the concept of needs, in particular the essential needs of the world's poor, to which overriding priority should be given; and the needs of future generations. Taking care of the needs of the future generations or as it is called "intergenerational justice" would be impossible to achieve in the absence of present-day social justice, if the economic activities of some group of individuals continue to jeopardize the well-being of individuals belonging to other groups or living in other parts of the world (The World Bank 2004). What this suggests is the interconnected nature of the world.

All definitions of sustainable development require that the world should be seen as a system – a system that connects in space and time. When the world is considered as a system connected in space, one becomes conscious that greenhouse gases emitted mainly by industrialized countries can lead to global warming and flooding of certain low-lying islands – resulting in the displacement and impoverishment of entire nations. When the world is considered as a system connected in time, one can understand that the economic, social, or environmental decisions taken now will affect the future generations.

The concept of sustainable development is rooted in this sort of systems thinking, which helps understand humanity better and gives humans a higher purpose of life in this world. After more than two decades, there seems to be consensus that sustainability assessments ought to (Gasparatos et al. 2008):

- Integrate economic, environmental, social, and increasingly institutional issues as well as to consider their interdependencies;
- Consider the consequences of present actions well into the future;
- Acknowledge the existence of uncertainties concerning the result of society's present actions and act with a precautionary bias;
- Engage the public;
- Include equity considerations (intragenerational and intergenerational).

Although writers on sustainability share the same basic concerns about the directions of global development, there are also several recurrent debates between them. One main rift is between those who maintain a faith in technology, scientific rationality, and economic growth and those who do not (Wheeler 2004). The former approach is advocated by a large body of economists and sits well with the politicians continuously beating the drum of economic growth. This approach also sits well with the mainstream conservation movement within industrialized nations and with large international development agencies and research institutes that are used to engaging in detailed scientific, economic, and policy-related analysis. They aim to achieve ecological goals by quantifying environmental impacts, analyzing economic policy options, fine-tuning regulation of private industry, and adjusting market incentives. In contrast, others believe that sustainable development is fundamentally incompatible with current capitalist economic structures, attitudes, and lifestyles (Capra 1983; Laszlo 2006; Danilov-Danil'yan et al. 2009; Czech 2000). These advocates are either environmentalists, or equity activists, or spiritually and ethically oriented writers. Environmentalists tend to be motivated by the threat of ecological crises. The ecological worldview, in contrast, acknowledges cultural diversity but seeks to ground the development of society in fundamental values that are shared by virtue of being human and sharing a small planet. This perspective emphasizes interdependence and views the world in terms of overlapping complex systems and organic unity, rather than as an atomistic collection of people and material things, as in positivistic science and neoclassical economics (Capra 1983). Equity advocates often focus on inequality, exploitation, and developed world overconsumption, and develop detailed analyses of how concentrations of

political and economic power lead to exploitation. Such individuals and groups often mobilize politically against economic globalization and to regain local control over economic activity. Spiritual writers and ethicists dwell on the need for a transformation of values and mindsets as a precondition to sustainable development. By reconnecting with the earth, each other, and human relations to the universe, this viewpoint suggests, humans will become better able to coexist with one another and the planet. Ecofeminist critiques of development follow a similar path, arguing that specifically male values, mindsets, and institutions are much of the problem (Milne 2001; Meadows et al. 1972).

David Orr, a distinguished professor on Environmental Studies and Politics, writes (Orr 2010) "The conversation arising now from the concern for the sustainability of humankind on Earth in many ways resembles that of the eighteenth century Enlightenment, which aimed to free humanity from superstition and tyranny in their many guises. The global conversation about sustainability, similarly, aims to free humankind from the superstition that we are separate and isolated from each other and nature and the tyranny arising from those who would exploit our ignorance of our deep interdependence." Sustainability then can be seen as one of the core values and goals of an emerging ecological worldview that weaves together recent developments in physics, ecology, psychology, and many other fields along with core elements of many of the world's great spiritual traditions (which support the importance of ethical action within an interdependent world). This cognitive outlook sees the world in terms of interdependence and coevolving complex systems, and supports values, ethics, and actions that likewise emphasize interdependence (Wheeler 2004). Environmental, equity, and spiritual or ethical perspectives on sustainability can all fit well with this worldview with the exception of the dominant economic worldview.

Sustainability and the Current Economics System

The prevailing market-based capitalist economic system is very good at regulating supply and demand, allocating resources, and providing incentives for entrepreneurship and innovation. It is also clearly good at generating wealth and a high level of material comfort for a minority (Wheeler 2004). However, the current capitalist economic system – both in theory and practice – has many flaws from a sustainability perspective, as listed below (Wheeler 2004; Chang 2012):

- Interest fees in capitalism cause equity disparities with the effect that the rich become richer and the poor become poorer. Less efficient small businesses cannot survive resulting in unemployment and large corporations are formed with concentration of wealth and monopoly of power, resulting in a new wealth and monumental increases in the material standard of living for a minority, but for the growing masses it brings deepening poverty and seemingly hopeless marginalization.

- Existence of interest and discount rates means that the future costs and benefits are less valuable than those in the present – a clear case of intergenerational inequity and injustice.
- Capitalist economics assumes continuous expansion in consumption of material goods and resources, a phenomenon that conflicts with the environmental notion of a finite planet with limited resources.
- Difficulty in placing a price on social and environmental goods (such as human health, equity, and environmental quality), with the problem of externalities, those enormous social and environmental impacts of production and consumption that are generally not incorporated into economic decision making.
- Demand and human "needs" are manipulated by corporations and advertising to increase the level of material consumption.
- Global trade distances consumers from the true costs of their economic decisions, making it difficult for them to understand these costs, while displacing social and environmental harm onto far-distant people and ecosystems.
- Economic power tends to subvert democratic institutions and shape cultures to meet its own ends, meaning that economic objectives constantly threaten to overwhelm environmental and equity goals (Perkins 2011).

These deficiencies of capitalist economics – and of economic analysis generally – undermine sustainability.

Unfortunately, sustainability is not currently the burning issue for most world leaders, whether politicians or business executives. Their immediate concern is to keep the global casino afloat. Issues of justice, equity or environmental degradation, or stories about unstoppable global ecological change are backstage to the everyday business of firing the boilers of the world economy (Adams and Jeanrenaud 2008). However, a number of alternative strategies have been proposed over the years to restructure capitalist economics to meet environmental, equity, and economic goals.

Alternative Economic Approaches to Promote Sustainability

Steady-State Economics: John Stuart Mill, a classical economist, first raised this issue in the mid-nineteenth century but the main advocate of this position since the 1970s has been US economist Herman Daly (Daly 2010). Under steady-state economics, human population and consumption are held at constant levels with a minimum throughput of resources, while qualitative, technological, and moral evolution occurs instead of quantitative increases in material production. The endless growth in material consumption, in other words, is brought to a halt. Daly has proposed progressive resource depletion quotas as a mechanism to push the economy toward this steady level of consumption. In this scenario, the government would set a maximum quantity of nonrenewable resources that could be consumed each year and then adjust the level downwards annually. From this point market mechanisms would do the rest. Prices would rise correspondingly, promoting

conservation and substitution of alternative materials. Some policy measures are discussed in (Daly 2010) to achieve a steady-state economy.

Environmental Economics: This approach first appeared in 1970s with the ambition to reconcile environmental and economic goals (Pearce et al. 1989). The focus of this approach is to include the externality costs of production and resource depletion into economic equations and a framework to reduce pollution. The approach does not fundamentally challenge any of the basic assumptions of capitalist economics.

Ecological Economics: It is distinguished from environmental economics, which is the mainstream economic analysis of the environment, by its treatment of the economy as a subsystem of the ecosystem and its emphasis upon preserving natural capital. The identity of ecological economics as a field has been described as fragile, with no generally accepted theoretical framework and a knowledge structure that is not clearly defined. According to ecological economist Malte Faber, ecological economics is defined by its focus on nature, justice, and time. Issues of intergenerational equity, irreversibility of environmental change, uncertainty of long-term outcomes, and sustainable development guide ecological economic analysis and valuation (Faber 2008). Ecological economists have questioned fundamental mainstream economic approaches such as cost-benefit analysis, and the separation of economic values from scientific research, contending that economics is unavoidably normative rather than positive (empirical) (Victor 2008).

Restorative Economics: In the book Natural Capitalism (Hawken et al. 1999), the authors argue for a restorative economics that uses the enormous power of markets to bring about environmental restoration rather than exploitation. Mechanisms to assist in this process might include higher prices for nonrenewable resources and waste disposal and green taxes to internalize the environmental externalities of productions (examples for such externalities are. . .). Problems such as pollution and social injustice may then be seen as failures to properly account for all forms of capital including human, manufactured, financial, and natural. This approach might be seen as an extended version of ecological economics, in which specific policy mechanisms are used to integrate economics into a broader framework including equity and the environment.

Local Self-Reliance/Alternative Currency Networks: There have been efforts toward local self-reliance since the 1960s. For example, India sought import substitution policies in the 1960s to promote locally produced goods and restricted imports from abroad (Wheeler 2004). These efforts were undermined by advocates of export-oriented countries and often did not work well because of the difficulty of producing a wide spectrum of goods locally in the face of international competition and political pressure. In the USA, there have been proponents of self-reliance who advocated local development strategies that promote locally owned businesses rather than large multinational companies (Morris 1983). More recently in his bestselling book *Deep Economy*, Bill McKibben has made a compelling case for moving beyond "growth" as the paramount economic ideal and pursuing prosperity in a more local direction, with regions producing more of their own food, generating more of their own energy, and even creating more of their own culture and

entertainment (McKibben 2007). He argues that attention should be redirected toward more traditional means of pursuing prosperity within communities, such as farmers' markets, community-supported agriculture farms, community-based radio stations, and mercantile cooperatives. Alternative currency networks such as Ithaca Hours have also attempted to promote local self-reliance through the dramatic strategy of introducing a new currency that can be used locally, with notes representing hours of labor instead of dollars (Wheeler 2004). Anyone receiving such a note as payment can then redeem it at other local businesses for other products or services. A similar suggestion is proposed by Thomas Greco, in his book *The End of Money and the Future of Civilization* (Greco 2009). The suggestion is about individuals, groups, and communities taking control of the monetary system at the grassroots level and creating an entirely new basis for trade than bank-owed debt. Greco discusses the large and growing worldwide "LETS" movement – Local Exchange Trading Systems, like the Ithaca Hours system in Ithaca, New York. The LET Systems that have proliferated in communities around the world use the credit clearing process, as do commercial trade exchanges. Credit clearing systems are, in essence, clearing houses – but their members are businesses and individuals instead of banks. Greco writes about national and international barter exchanges that involve over 400,000 businesses trading at an annual level of $10 billion.

Sustainability: Intergenerational Equity and Discounting

The emphasis on sustainability implies a greater concern for the future and for future generations. The past models of the development process have tended to assume that the "future will look after itself," whereas the sustainable development approach acknowledges that the ability of the future to do this can be seriously impaired by actions taken now. Discounting has been subject to numerous critiques due to its present bias, especially as the time period under consideration becomes longer. Because of climate change, the debate on discounting and discount rates has recently become vigorous.

Discounting

Discounting is a standard technique used for making intertemporal decisions in which the future is given less weight than the present; thus the process of converting monetary values backward in time to an equivalent amount is called discounting. Discounting procedures are fundamental to the theory and practice of cost-benefit analysis for evaluating proposed projects and public policies (Howarth 1996). When weighing the costs and benefits of large public projects, the selection of a discount rate on which to discount the future is a key consideration and often a source of controversy. A simple example demonstrates the general point. At a discount rate of 10 %, typically used for cost-benefit analysis, the value of $1 million 100 years from

now is the same as a mere $73 today. Thus it would apparently be justifiable to impose costs of up to $1 million on people 100 years from now in order to enjoy $73 worth of consumption today. By this logic, much resource depletion and environmental damage could be considered acceptable, and even optimal, according to a criterion of economic efficiency. It is because of this, the practice of discounting the future, a standard feature of the economic approach to inter-temporal decision making, is discussed critically in the following few sections here.

Discount Rate and its Effect on Project Selection

What is a social discount rate? The social discount rate is the rate at which society as a whole is willing to trade off present for future benefits (Atmospheric Administration 2007). When weighing the decision to undertake a project with long-term benefits versus one with short-term benefits and high capital cost versus low capital costs, the discount rate plays an extremely important role in determining the outcome of the analysis. Indeed, a number of project evaluation measures based on present worth criteria (e.g., net present value, discounted benefit-cost ratio, discounted payback period, return on investment) depend critically on the chosen discount rate.

All present worth criteria involves ranking alternatives according to their discounted profits and costs. For example, net present value (NPV) is calculated according to the difference between the present value of benefits and the present value of costs. Mathematically,

$$\text{Net present value} = \sum_{t=0}^{N} \frac{B_t - C_t}{(1+i)^t} \tag{1}$$

Where, B_t and C_t are benefits and costs streams in years $t = 0,1,..,N$ and i is the discount rate.

To illustrate the effect of the discount rate on project selection, let us assume that there are two projects, A and B, with annual costs and benefits streams as shown in Table 1. By using the streams of costs and benefits in Table 1 in Eq. 1, the net present value for each project is calculated for different discount rates. Figure 1 shows the effect, of changing the discount rate from 0 % onward, on the net present value of the two projects. It can be seen that Project A is more economical when the discount rate is below 8 %, whereas Project B has a better NPV beyond an 8 % discount rate. At a 20 % discount rate none of the projects, however, is economically feasible.

Rationale For and Against Discounting

Why is there a need to discount the future values? The usual and most common argument given is because a dollar received today is more valuable than one received in the future. There are generally three main reasons used for applying discounting.

Table 1 Cost and benefit streams

	Project A		Project B	
Year	Costs ($)	Benefits($)	Costs($)	Benefits($)
1	15,000	0	10,000	0
2	5,000	0	0	5,000
3	0	6,000	0	4,000
4	0	6,000	0	3,000
5	0	6,000	0	2,000
6	0	6,000	0	1,000
7	0	6,000	0	0
8 and beyond	0	0	0	0

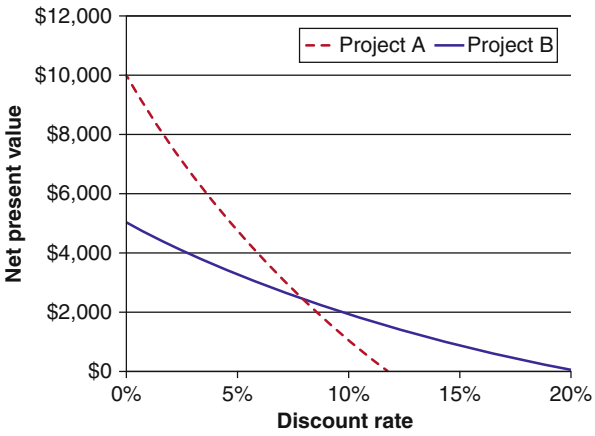

Fig. 1 Effect of discount rate on project selection

1. *Pure Time Preference*: humans are generally impatient and prefer instant gratification to waiting for long-term benefits.
2. *Opportunity Cost or Marginal Productivity of Capital*: money can be invested today, earning a positive rate of return.
3. *Risk*: there is uncertainty surrounding the ability to obtain promised future income. That is, there is the risk that a future benefit will never be realized.

All the three arguments are critically analyzed in the following paragraphs.

Pure Time Preference

Arguments in Favor: Empirical evidence suggests that humans value immediate or near-term resources at higher levels than those acquired in the distant future (Atmospheric Administration 2007). It is further argued that society, which consists of the sum of its living individuals, also prefers the present to the future. Furthermore, the dominant underlying value judgment of Western economic philosophy is that people's preference should count (Pearce et al. 1990). Hence it is difficult to argue with

the proposition that if people prefer the present over the future, then pure time preference indicates that discount rates are positive. Thus, discounting has been introduced to address the issues raised by the existence of this phenomenon, which is known as time preference.

Counterarguments: There have been arguments against the use of time preference to influence social discount rates. Firstly, that the individual time preference is not necessarily consistent with individual lifetime welfare maximization (Strotz 1956). There is a more general view shared by many economists that there seems to be no "ethical" justification for putting a utility discount into the social welfare function (Ramsey 1928; Pigou 1932). Secondly, the value judgment is improperly expressed. The argument is that it is tomorrow's satisfaction that matters, not today's assessment of tomorrow's satisfaction (Goodin 1986). Atleast this much is established in the literature.

But the question is whether any positive social discount rate used in a project that creates costs and benefits that are separated over a long period of time will discriminate the future generations and that is against the very spirit of sustainability; the definition of which says "meeting today's needs of development without compromising future generations' ability to develop."

Opportunity Cost or Marginal Productivity of Capital

Arguments in Favor: The opportunity cost of capital is the expected financial return foregone by investing in a project rather than in comparable financial securities. Theoretically, firms invest up to a point where the rate of return on marginal projects is equal to the interest rate. Consumer plans to save are brought to equality with producers' plans to invest and the ruling interest rate reflects both the time preference of consumers and the rate of return on capital (Kula 1997).

Counterarguments: There have been attempts to discredit the rationale of discounting based on the opportunity cost concept (Goodin 1986; Parfit 1983; Cowen and Parfit 1992). For example, Cowen and Parfit (1992) argue that the opportunity costs of consumption are determined by the marginal return to capital, which, in turn, depends on investment levels, which depend upon how high future benefits are weighted. If society as a whole valued all future periods equally, it would continue to invest until the rate of return on those investments (and, thus, the opportunity cost) was driven to zero. That opportunity costs are the result of valuing future outcomes less, not a reason for doing so. In other words, if the interest is removed from the society, the opportunity cost of capital will automatically fall to zero. But there is an argument against using a low or zero discount rate so that it will encourage more investment overall, and this will increase the demand for resources and environmental services. In the author's view, this argument is not valid as can be seen that in the case of national economic development, the investment portfolio would consist of all projects to be carried out within the capital budget constraint as determined by the availability of foreign exchange and local currency so the investment will only take place within the budget constraints and only those projects will be carried out that are economically justified and environmentally less harmful. As far as the private firms and businesses are concerned, the government can impose

resource taxes to discourage those projects that may harm the environment excessively.

On the contrary, it can be observed that high discount rates used in developing countries under the "prescription" of the World Bank and other lending agencies are a cause of much environmental degradation as the selection of such rates includes opting for short-term measures designed to satisfy immediate wants and at the expense of sustainable practices (Perkins 2011). In turn, poor prospects arising from environmental degradation actually assist in generating the poverty that causes high discount rates (poverty trap).

Risk

Arguments in Favor: Public projects involve uncertainty and risk. When public projects are undertaken there is a chance that future benefits will not be fully realized or realized at a higher level than estimated (there are also uncertainties associated with costs). The further out into the future these benefits are expected to be realized, the greater the risk that some unexpected event or factor will occur and diminish the value of the future benefit. This uncertainty is handled by adding a risk premium to the discount rate. For example, a 2 % "premium" attached to the officially recommended 5 % "test discount rate" has been used in the past in the UK (Treasury 1980).

Counterarguments: While adding risk premium to the discount rates it is assumed that the scale of the risk increases exponentially in time. There is no reason to believe that the risk factor takes this particular form and so the allowance for it through a single discount rate adjustment is invalid. This argument is widely accepted by economists (Dasgupta and Pearce 1972; Stiglitz 1986). Usually, the preferred method for dealing with uncertainty is to directly adjust benefits and costs (or to perform the analysis quantifying the uncertainty and explicitly considering it in the estimates of benefits and costs) and not to change the discount rate (Pearce et al. 1990; Atmospheric Administration 2007).

Controversy Over Social Discount Rates

As seen from the discussion above, debate already exists on the rationale for discounting but still a greater debate exists as to what the appropriate social discount rate should be. Various conceptual foundations have been proposed for the social discount rate, including the market rate of interest, the social opportunity cost of investment, and the consumption rate of interest (Guo et al. 2006). In an interest-based economy under ideal conditions, where there are no externalities, taxes or market imperfections of any description, these various rates will be identical and in equilibrium. However, no real economy satisfies these assumptions, so the debate exists on the conceptual foundations of the social discount rate. But there is a general consensus that the social discount rate should be based on the "social time preference rate" (STPR), which is the value society attaches to present consumption relative to future consumption. The Ramsey formula (Ramsey 1928) gives the expression for

the "socially efficient" discount rate to use for cost-benefit analysis (CBA). Letting i denote the social discount rate, the Ramsey formula gives the relation:

$$i = \rho + \mu g \tag{2}$$

where ρ is the "pure time preference rate" (PTPR), g is the growth rate of the economy, and μ is the income elasticity of marginal utility. The PTPR is the utility discount rate, which reflects society's preference for utility. The growth rate of per capita consumption, g, varies from country to country. The income elasticity of marginal utility, μ, measures the rate of change of the utility derived from an extra unit of income as society's income level increases. The literature suggests that this value is around unity (Guo et al. 2006). This implies that an extra dollar to a generation that has twice the consumption of the current one will only bring half as much utility to that generation. From a practical point of view, one only needs to specify values for the ρ, μ, and g to derive the discount rate. For instance, the UK government recommends a discount rate of 3.5 % for CBA (for use across all departments and all projects) based upon the following figures: $\rho = 1$ %, $\mu = 1$, and $g = 2.5$ % (Guo et al. 2006). The Stern Review (Stern 2007), another important UK government document on the economics of climate change, proposes a discount rate of 1.4 % using $\rho = 0.1$ %, $\mu = 1$, and $g = 1.3$ %. This low discount rate has already been criticized as being low in (Nordhaus 2007; Weitzman 2007).

It is clear from above that there is a lack of consensus on the value of the time preference rate and on the value of the growth rate of consumption. As stated in Jouini et al. (2010), there has never been consensus even among the experts on this subject. Different possible values for the parameters lead to very different values for the discount rate, which in turn lead to very different conclusions, as illustrated in Fig. 1 and shown by the following example. For instance, the present value of \$100 in 100 years' time is \$37 at a 1 % discount rate, \$5.2 at 3 %, 76¢ at 5 %, and only 0.007¢ at 10 %. This shows a small change in the discount rate has a large impact on policy outcomes, meaning that arguments about the "correct" number become weightier. Second, exponential discounting at even moderate discount rates implies that costs and benefits in the far future are almost irrelevant to decisions made today.

Moreover, this lack of consensus among experts about the right values for the growth rate and the time preference rate reveals another more fundamental problem, namely the fact that agents differ in their time preference rates as well as in their anticipation about the future of the economy. The Ramsey formula has been derived under the assumption of homogeneous agents (same time preference rate ρ and same anticipated growth rate of the economy g). This raises the question as to what extent the Ramsey formula remains valid once heterogeneity in time preference rates and heterogeneity in anticipation about the future are taken into account.

As far as the pure time preference is concerned estimates for individual rates are almost always positive for the simple reason that humans prefer good things to come earlier rather than later. Given the inevitability of death for individuals, a preference for benefits to accrue earlier rather than later is entirely sensible. However, at

individual level PTPR may reflect different levels of impatience. In a setting with long-lived agents that represent present and future generations, these rates reflect divergence of opinion about the importance granted to the welfare of future generations relative to the present. At the social level, the distinction is drawn and even it has been argued to use zero PTPR by philosophers and economists for decades. A positive PTPR involves placing a lower weight on the welfare of future generations, which is impartial and contrary to intergenerational equity. Cline (2004), for example, proposes to use a zero PTPR in evaluating climate change policies.

As far as the heterogeneity in anticipation about the future is concerned, agents (or experts) currently do not have a complete understanding of the determinants of long-term economic evolution. Long-term forecasts are subject to great errors, and forecasts for the next century or millennium are subject to potentially enormous divergence. The debate on the notion of sustainable growth is an illustration of the degree of possible divergence of opinion about the future of society. Some will argue that the effects of improvement in information technology have yet to be realized and the world faces a period of more rapid growth. On the other hand, those who emphasize the effects of natural resource scarcity will argue for lower growth rates in the future. Some even suggest a negative growth in per capita GDP in the future, due to the deterioration of the environment, population growth, and decreasing returns to scale (see for example (Wegner and Pascual 2011)). The debate among economists (and also among philosophers) on the notion of intergenerational equity, prompted by the challenges of climate change, biodiversity losses, and nuclear waste management, is an illustration of this possible divergence. These issues have spurred economists and policy makers to think more carefully about long-term intergenerational trade-offs. Some economists have advocated abandoning discounting altogether, proposing alternative methods to value the future (Wegner and Pascual 2011). Other economists conclude that although discounting (and cost-benefit analysis) is still very useful, it must be employed in a framework that guarantees intergenerational equity. A third view is that although conventional discounting is satisfactory for short-term decisions, it needs refinement before it can be legitimately used for long-term decisions (Cline 2004; Arrow et al. 2013). Yet another view is for zero discounting meaning that the future counts for as much as the present.

Heterogeneity in time preference rates and in anticipations about the future of the economy and issues coupled with intergenerational equity are critical features that render the debate on discounting and discount rates with virtually no consensus at all.

Cartesian Paradigm

Essentially all these approaches of finding an appropriate discount rate are based on reductionist philosophy. Reductionism is an approach to understanding the nature of complex things by reducing them to the interactions of their parts, or to simpler or

more fundamental things. Reductionist thinking and methods form the basis for many of the well-developed areas of modern science, including much of physics, chemistry, and cell biology. Classical mechanics in particular is seen as a reductionist framework. The atomic physicist Fritjof Capra has expressed this in a particularly lucid and eloquent way in his best-selling book entitled "*The turning point*," saying (Capra 1983):

> The triumph of Newtonian mechanics in the eighteenth and nineteenth centuries established physics as the prototype of a 'hard' science against which all other sciences were measured. . . . this tendency to model scientific concepts and theories after those of Newtonian physics has become a severe handicap in many fields, but more than anywhere else, perhaps, in the social sciences. (The social sciences deal with the social and cultural aspects of human behavior. They include the disciplines of economics, political science, sociology, social anthropology, and – in the view of many of its practitioners – history). The social sciences have been traditionally regarded as the 'softest' among the sciences, and social scientists have tried very hard to gain respectability by adopting the Cartesian paradigm (after Descartes, his mathematical methods, or his philosophy, especially with regard to its emphasis on logical analysis and its mechanistic interpretation of physical nature) and the methods of Newtonian physics. However, the Cartesian framework is often quite inappropriate for the phenomena they are describing, and consequently their models have become increasingly unrealistic. This is now especially apparent in economics. Present-day economics is characterized by the fragmentary and reductionist approach that typifies most social sciences. Economists generally fail to recognize that the economy is merely one aspect of the whole ecological and social fabric; a living system composed of human beings in continual interaction with one another and with their natural resources, most of which are, in turn, living organisms.

The author believes that with a fragmented worldview, there will never be a satisfactory solution to the problem of discounting which is essentially by nature a systemic issue (Malik 2011).

Systems Thinking and Discounting

McLaughlin and Davidson (1994) describe systems thinking as: "Seeing Whole Patterns. . . . It's time for us to make the next leap in consciousness to holistic thinking – to seeing whole patterns. In contrast with the prevailing linear paradigm, the New Paradigm sees everything as interconnected and interdependent . . . . Thus it is critical to keep the large picture – the whole system – in mind in order to create any kind of lasting solution and to avoid undue focus on effects, rather than dealing with causes that may be part of another system altogether.

Holistic thinking or ecological thinking – seeing how everything affects everything else – is finally beginning to influence other national policies, such as economics, where piecemeal solutions never work, since all sectors of a nation's economy are interrelated and interdependent with the world economy. The systems view sees the world in terms of relationships and integrated wholes whose properties cannot be reduced to those of smaller units."

It is challenging to find a clearer or more complete exposition of pure "Systems Thinking" than that contained in the above few lines. The depletion of the ozone layer or the increase in greenhouse gas emissions or the pollution of oceans is no more a concern of a single society presently living in any country. Similarly, society is no more a collection of living individuals whose preferences should count. The case of discounting based on "pure time preference" and "opportunity cost of capital" concepts should be investigated from the holistic viewpoint.

When the pure time preference argument is considered from a holistic viewpoint, a question can be asked: whose time preference is under consideration? Whose capital and wealth are linking whose time? Is it the present society living in USA or Canada or is it in some African country, for instance? And what about the generations to come? Who will take care of their time preferences? Therefore, from a holistic viewpoint, a pure time preference argument is ethically and morally indefensible in the selection of a discount rate.

Before analyzing the opportunity cost of the capital concept from a holistic viewpoint, first the practical implication of this concept for selecting discount rates in different countries is examined. Since the opportunity cost is linked to the prevailing conditions within a given country, the discount rate tends to vary, often significantly, from country to country. For developing countries, the discount rate used is much higher than for industrialized countries to reflect the scarcity of capital and the much larger profitability of new investment projects that compete for limited financial resources. Since there are different discount rates for different countries, a project considered "good" in the USA may not be "economically justified" in India. For example, a large-scale coal-fired power plant that generates millions of tons of greenhouse gases in its lifetime may be economically justified in one country but may not be a good project in another country because of the use of different discount rates for selection of the project. By considering the holistic approach, it becomes clear that the harm to the environment is the same whether such a project is carried out in the USA or India. So in this regard the discount rate should not be linked to opportunity costs of capital in a country but in the sustainability context to the environment.

It is clear from above that both the time preference and the opportunity cost concepts cannot override systems thinking. Both these concepts are also used as tools to support the institution of interest (Ahmad 1991), and the practice of discounting is just one of its obnoxious fruits. The practice of treating interest as an item of cost and ascribing it to the productivity of capital is based on the particular institutional setup of the capitalist society. In fact, it is the institution of interest that makes it possible for capitalist economists to ascribe a positive return to capital that is its value productivity, and not the other way round (Siddiqi 2001). The next section, using the hierarchical systems approach, emphasizes the need to change the present economic system so that renewable natural capital keeps functioning and maintaining itself and the global ecosystem may survive.

Renewal Cycle in Systems Theory and Capitalist Economic System

According to systems theory, the systems are not static, but evolve (more specifically economic, ecological, and social systems) as a combination of dynamically occurring renewals in their components (Voinov and Farley 2007). The renewal cycle has been observed in many natural and man-made systems. The renewal cycle assumes that a system goes through a series of stages, starting from growth, followed by conservation, then release or collapse and finally renewal. The phase of release does not necessarily mean loss or extinction of all components or species that make the system, but it implies that the systemic function that they perform is modified, at least temporarily. The released components may recombine to perform again as a similar system but the system itself will be different (Holling 2001). Examples of release phase can be observed in man-made and natural systems, e.g., bankruptcy of a company or forest fires. In bankruptcy of a company when employees are laid off, and assets are sold. It is the release phase and is the end of the company. It comes when the business as a socioeconomic system is no longer sustainable and can no longer extend the conservation stage. The components (human and material resources) may recombine in the form of another company (renewal), but that will be a different system. Similarly forest fires release organic material and nutrients thus ending a system. Forests may grow afterward in the same place, but these will be different forests: they may have a different spatial and species organization.

Any effort to sustain a system beyond its natural conservation phase, to avoid the release phase, has harmful effects on its next higher hierarchical system of which it is a subsystem. For example, efforts to sustain failing industries and even sectors would prevent capital from being reallocated to other or more dynamic ones in their growth stages. Inefficient enterprises if kept afloat by huge subsidies keeping human and material resources unavailable for recombination decreases the overall adaptive capacity of the socioeconomic system by making it vulnerable to disturbances that lead to its collapse. The Soviet Union is a societal example of accumulated rigidities that became vulnerable to societal discontentment and revolt against it, which ultimately resulted in a sudden collapse. Similarly in studying managed ecosystems, it has been observed that any attempt to manage a target variable for sustained production of food and fiber has resulted in less resilient and more vulnerable ecosystems (Holling 1996). The collapse in these cases is usually observed at the next higher hierarchical level, i.e., over landscapes.

The economic system itself is a managed sub-ecosystem of the sustaining and continuing global ecosystem (Voinov and Farley 2007). Human society is currently engaged in a global effort to sustain the growth phase of this subsystem. The integral feature of the economic system obsessed with growth and expansion is technological progress in an attempt to increase productivity.

The combined effect of technological and economic growth is that it has created an environment in which life has become physically and mentally unhealthy. Polluted air, irritating noise, traffic congestion, chemical contaminants, radiation

hazards, and many other sources of physical and psychological stress have become part of almost everyone's life. Obsessed with expansion, increasing profits, and raising productivity, the industrialized world has developed societies of competitive consumers who have been induced to buy, use, and throw away ever increasing quantities of products of marginal utility (Capra 1983). For example, in this consumption cycle, the total material flow still remaining in products or use 6 months after their sale in North America is just one percent. In other words, 99 % of the stuff that is harvested, mined, processed, transported and that runs through this system is trashed within 6 months (Leonard 2010). (This statement is not saying that 99 % of the stuff being bought is trashed. Think beyond one's household to the upstream waste created in the extraction, production, packaging, transportation, and selling of all the stuff he/she bought. For example, the No Dirty Gold campaign explains that there is nearly two million tons of mining waste for every 1 t of gold produced; that translates into about 20 t of mine waste created to make one gold wedding ring.) Excessive consumption and strong emphasis on high technology not only create massive quantities of waste but also require huge amounts of energy. Most of the world energy comes from nonrenewable fossil fuels that are declining with the passage of time resulting in an increase in energy prices. In their attempt to maintain, and even increase, their current levels of production, the world's industrialized countries have ferociously exploited the available resources of fossil fuels. Some industrialized countries have even used their military might by either directly to procure world natural resources or installing or supporting undemocratic regimes in some countries to dictate policies that suit their own economic and strategic objectives (Perkins 2011). The repercussions of these actions have created restlessness in the local populations and deep resentment against those industrialized countries involved in exploiting their resources directly or indirectly.

Economic growth conceived in terms of higher production not only ignores the ecological and social costs of development such as pollution and depletion of nonrenewable resources but also results in stresses and strains on individuals and families (Siddiqi 2001). The capitalist concept of development also ignores the fair distribution of wealth. How can the development of human society be conceived of in terms of amassing of wealth only, irrespective of whether this wealth is available to the bulk of its members or not. The enormous expansion of economic output throughout the industrial era has provided material benefits and more comfortable lives for a minority. Yet billions of others have been excluded and exploited in the process (Greco 2009). This distributive injustice condemns most of the world population to live in debt. The effect of debt is like a blood transfusion from sick to healthy. Each person born in Latin America owes already $1,600 in foreign debt; each child born in Sub-Saharan Africa carries the burden of a $336 debt interest, for something that their ancestors have long ago paid-off. In 1980, the debt of Southern countries amounted to $567 billion; since then, they have paid $3,450 billion in interests and write-offs, six times the original amount. Despite this, this debt had quadrupled by the year 2000 reaching $2,070 billion (http://www.henciclopedia.org.uy/autores/Laguiadelmundo/Usury.htm. Accessed 14 Dec 2014). The huge debt in under-developed and disadvantaged countries has made a poverty trap. For example,

in Pakistan and Tunisia, International Monetary Fund (IMF) bailout loans are being used entirely to repay old debts – in Pakistan's case, to pay previous IMF loans. In Portugal, the IMF and EU loans are simply paying off the reckless banks (Jubilee Debt Campaign 2013). There is more than abundant evidence that the repayment of loans of these poor countries is achieved at the cost of consumption of natural capital and the degradation of the environment (Shah 2010a; Perkins 2011; Jubilee Debt Campaign 2013).

Thus the present setup of the economic system is maintained only at the cost of higher hierarchical levels. Simply sustaining the present economic system will certainly threaten the global ecosystems. Collapse of these higher hierarchical levels is something that the human species, and indeed, many, many other species, cannot afford. In order to save the super hierarchical system (humanity as a whole and biosphere as a whole), the capitalist economic system compounded and nurtured by a system of interest must undergo the release phase to allow renewal through the emergence of a fair and just economic system so that humanity and global ecosystem may persist.

High Interest Rate: The Engine of Destruction and the Root Cause of Unsustainability

High interest rate causes injustice and major financial inequality in the society. It breeds greed and is the opposite of charity. The practice of high interest rates – lending money and accumulating financial gains on a loan – can be traced back 4,000 years (http://www.henciclopedia.org.uy/autores/Laguiadelmundo/Usury.htm. Accessed 14 Dec 2014). But it has always been despised, condemned, restricted, or banned by moral, ethical, legal, or religious entities. High interest rates in the modern banking system are made possible through the current paper money system in circulation. Money as has been claimed is not only a medium of exchange but a means of control. This is not the place to trace the development of all the changes which occurred in forming the present banking system but suffice it to say that the power has become rapidly concentrated into the hands of fewer and fewer financiers who control political affairs from behind the scenes, holding no social responsibility whatsoever for the millions of human beings who in ever greater numbers fall under their control (Bewley 2014a). One of the great studies of this process is described in *Religion and the Rise of Capitalism* by the English historian R.H. Tawney (Tawney 2000). Some brief history of formation of banking system can also be traced in (Greco 2009; Brown 2007).

The monetary and financial regimes that are spread around the world have the legal privilege to create virtually the entire nation's money by making a few bookkeeping entries and lending it out at interest (debt-money system). The imposition of interest on the debt by which the money is created causes debt to grow exponentially with the passage of time, if not paid back in timely fashion. Exponential growth can be observed by a simple example. Imagine a poor country has borrowed $1 at 10 % interest rate and is not able to pay it back, then after 50 years

the amount would grow to $117.4, after 100 years it would be $113,780.6 and after 200 years it would be $189,905,276, i.e., almost 190 million dollars. This is a ridiculous amount but true and that is the magic of compound interest.

Professor Thomas Greco in his book *The End of Money and the Future of Civilization* (Greco 2009) summarizes the money problem as: "the way in which money is created by the banking system today causes a debt imperative, which derives a growth imperative – this forces destructive competition for the available supply of money, which is never sufficient to enable all debtors to pay what they owe." As the debt grows in time, the money needed to pay this debt does not. Additional money comes into circulation only as the banks make additional loans. He describes three primary ways in which bank-created debt-money malfunctions. The first is artificial scarcity: there is never enough money to allow every debtor to pay what is owed to the banks, so someone must fail. Thus, debt continually mounts, and businesses and individuals are forced to compete for markets and scarce money in a futile attempt to avoid defaulting on their debts. Businesses must take measures to enhance revenues by increasing production, sales, and profits and reduce costs. This not only causes gross inequities and social strife, but it also promotes the destruction of the planet because the corporations do not internalize the externalities to cut their cost of production. A major reason corporations merge and consolidate and increase in size is so that they can gain synergies and also exercise both greater political influence and greater market dominance. Of the 100 largest economies in the world, 53 are now global corporations, larger than countries like Sweden and Norway, South Africa and Mexico, Belgium and Egypt, etc. The 200 largest global corporations now control nearly 30 % of global economic activity, but they employ only one half of 1 % of the global workforce, as monopoly and efficiencies of scale reduce employment and keep salaries down (Mander 2003). Capital wealth becomes even more concentrated in corporate conglomerates that must seek higher returns on their investments. They are driven to expand their markets and dominate economies, using support of governments to apply military power both overtly and covertly to ensure the continued flow of low-priced raw materials, the availability of low-cost labor, and access to markets in which to sell their products (Perkins 2011; Greco 2009).

The second factor of malfunction is the requirement that interest be paid, which causes a net transfer of wealth from the debtor class to the moneyed class or from producers to nonproducers. Those who must earn their livelihood by selling their labor and talents in the market are kept at a disadvantage relative to those who live off returns from their capital.

The third aspect of malfunction is that money created as bank credit is misallocated at its source. Much of it goes to finance government deficit spending for weapons, military interventions, and transfer payments to corporate clients. This money added to the existing supply enters the banking system where it becomes additional "reserves" that enable the banks collectively to lend many times that amount of money into circulation thus causing creeping inflation. This is the cruelest form of taxation as it eats away at the assets or wealth of all, particularly the moneyed class.

This entire system favors authoritarian governments, increasing concentrations of power and wealth, short-range planning, and the production of short-lived disposable junk over durable consumer products (Greco 2009). How long this system will continue is just a matter of time.

There is no person on the earth who does not now live and die in debt whether they know it or not and an ever increasing number know it only too well as their personal debts to banks and credit agencies mount and mount, causing terrible anxiety and stress and not infrequently leading to crime and sometimes suicide. The situation of national debt is notorious. Even the wealthiest countries in terms of natural resources are hopelessly in debt to supranational finance. For example by 2006, combined personal, corporate, and federal debt in the United States had reached a staggering 44 trillion dollars – four times the collective national income, or $147,312 for every man, woman and child in the country (Brown 2007). The United States is legally bankrupt, defined conventionally as being unable to pay one's debts, being insolvent, or having liabilities in excess of a reasonable market value of assets held. Local, state, and national governments are all so heavily in debt that they have been forced to sell off public assets to satisfy creditors (Brown 2007). The total national income of many poorer countries does not even cover the interest payments on the money they owe, much of which has been borrowed to finance vast megaprojects whose incalculable environmental damage to the earth's increasingly fragile ecosystem is becoming more and more evident day by day. This is just the tip of the iceberg of the detrimental effects of the world financial system. And it is all so that an infinitesimal percentage of the world's population, who are virtually unknown but who know all too well how to manipulate the situation, can skim billions off the top of the money mountain, and wield wealth and power to an extent never conceived of before in the whole of human history (Bewley 2014a).

One element in the elite plan is to further reduce the amount of control that national governments, particularly in the developing world, have over their economies and finances (Greco 2009). When a country cannot meet its debt obligation, the International Monetary Fund (IMF) imposes "structural adjustment" programs that favor western banks, wrest away control of national resources, and create hardships for local population. As detailed further below, the IMF and World Bank provide financial assistance to countries seeking it, but apply conditions such as (Shah 2010b):

- "Liberalization" of the economy and resource extraction/export-oriented open markets as part of their structural adjustment
- Minimizing the state role
- Encouraging privatization as well as reducing protection of domestic industries
- Currency devaluation, increased interest rates, "flexibility" of the labor market, and the elimination of subsidies such as food subsidies (Perkins 2004, 2011)
- Reduce or remove various regulations and standards to attract foreign investors

The impact of these preconditions on poorer countries can be devastating. This process leads to further misery for the developing nations and keeps them dependent

on developed nations. Poor countries must export more in order to raise enough money to pay off their debts in a timely manner but because there are so many nations being asked or forced into the global market place and told to concentrate on similar cash crops and commodities as others, the situation becomes like a large-scale price war. Then, the resources from the poorer regions become even cheaper, which favors consumers in the West. Governments of poor countries then need to increase exports just to keep their currencies stable (which may not be sustainable, either) and earn foreign exchange with which to help pay off debts. They must spend less, reduce consumption, remove or decrease financial regulations, and so on. Over time then the value of labor decreases, capital flows become more volatile, a spiraling race to the bottom then begins, which generates social unrest, which in turn leads to "IMF riots" and protests around the world (Shah 2010b).

These nations are then told to peg their currencies to the dollar. But keeping the exchange rate stable is costly due to measures such as increased interest rates. Investors obviously concerned about their assets and interests can then pull out very easily if things get tough, and in the worst cases, capital flight can lead to economic collapse, such as it is seen in the Asian/global financial crises of 1997/98/99, or in Mexico, Brazil, and many other places. When IMF donors keep the exchange rates in their favor, it often means that the poor nations remain poor or get even poorer (Shah 2010b).

While describing his job in World Bank of evaluating projects John Perkins writes in *Confessions of an Economic Hit Man* (Perkins 2004):

> The unspoken aspect of every one of these projects was that they were intended to create large profits for the contractors and to make a handful of wealthy and influential families in the receiving countries very happy, while assuring the long-term financial dependence and therefore the political loyalty of governments around the world. The larger the loan, the better. The fact that the debt burden placed on a country would deprive its poorest citizens of health, education, and other social services for decades to come was not taken into consideration.

Shaykh Abdalqadir As-Sufi, graphically sums up the present situation in his book, *Technique of the Coup de Banque* (As-Sufi 2000):

> We are tyrannized, enslaved, and indebted to entirely unelected elites whose names we do not even know. With hereditary titles abolished and with hereditary wealth made impossible for the masses through powerful taxation, the case of this elite remains an anomaly. Their wealth and their lands spiral up into almost incalculable statistics, beyond the dreams of Alexander. They have no racial loyalty. They have no class loyalty. They certainly have no national loyalty. Upholding humanism, it could be said that they have no human loyalty. Insisting on their compassion they uphold the Rights of Man, sure in the certainty that the upholding of that empty rhetoric will distract you from ever attempting to refrain from their monetary system and live without banking. They are an oligarchy. This is not to say they are oligarchic in the platonic sense, for it is in the nature of the modern social nexus that there is a dysfunction between them and the human species rather than that they are at the summit of human society as in the primitive model. All the crimes of all the criminals in the world added together do not amount to the enormity of this crime that they daily commit through their continued application of the [. . .] system. The pollution of the ocean is their

> achievement. The poisoning of the earth is the result of their programs. The toxic air of the world's megacities is the direct result of their existence. The millions of dead caused by the sporadic uprising across the globe of the poor driven from their land, who in abject misery turn on their neighbors, the world's poor scavenging on rubbish tips are to them an unfortunate side-effect of their monetary policies.

The current debt situation, with the major role that interest is playing in it, is potentially very devastating for the world as a whole. In 2000, the CIA made a prediction which reads more like a statement of the bleeding obvious (National Intelligence Council 2000):

> The rising tide of the global economy will create many economic winners, but it will not lift all boats. . . ...[It will] spawn conflicts at home and abroad ensuring an ever-wider gap between regional winners and losers than exists today. . . ...[Globalization's] evolution will be rocky, marked by chronic financial volatility and a widening economic divide. . . ... Regions, countries and groups feeling left behind will face deepening economic stagnation, political instability and cultural alienation. They will foster political, ethnic, ideological and religious extremism, along with the violence that often accompanies it.

So much for sustainability! The money in anyone's pocket is not the medium of exchange it pretends to be; it is precisely the financial instrument which has enabled the present situation to come about and which allow it to continue to proliferate. Societies' willing participation in the process is what keeps it going. Before discussing the alternative choice to out of control capitalism it would be worthwhile to ponder whether technology has the ability to solve the environmental problems without fundamentally changing or challenging the present economic setup.

Sustainability and Technology

World models have shown that if the world continues on its present course, i.e., business-as-usual, then disaster is imminent (Meadows et al. 1972, 1992; Bardi 2011). Although a general consciousness is emerging especially in the industrialized world that a lifestyle of consumption and squandering is part of the problem. Nevertheless, generally speaking, the belief in science remains that "science can save the future," that it has the ability to provide humanity with the knowledge to understand and manage earth's natural resources and that the effects of new technologies can be managed by doing proper cost/benefit analysis to maximize the benefits and minimize the costs that environmental damage from human activity can be minimized by doing environmental assessments, etc. The reason for this faith in science can be seen in the dazzling effusion of technological expertise which is put forward as the justification of the scientific method and as proof that present society is more advanced than any which has preceded it. The manifestations of technology tend to be viewed by people with awe, i.e., the airplane, the computer, the heart-transplant, the television, the neutron bomb, the credit card, the internet, the social media, and so on and so on. Optimistic materialism remains a powerful force in the

western way of thinking. People believe that technology is, on balance, beneficial. People define happiness in terms of their ability to accumulate new gadgets; the business community, anxious to sell merchandise, spares no expense in promoting a gleeful consumerism. Thus on the whole the belief in science and technology remains that it can solve the environmental problems and address sustainability issues.

It should be cautioned, however, that there are two problems with the way the technology is employed which limits its ability to attend to the issue of sustainability in a satisfactory manner. First, the essence of the technological process which has produced all these offspring is that it views the rest of existence as a standing reserve, as something that is there for no other reason than to be exploited for its own ends (Bewley 2014b). Everything else is seen as something to be brought under control and used. Nothing is seen as existing in its own right but only as a resource to be used up. The trouble is that man himself has become ensnared in the process (Bewley 2014b). Humans are seen as a workforce, as consumers, as a market, as human potential, etc.. People are no longer respected in their own right. The terrible end-result is that individuals then come to see themselves as a standing reserve. The second problem with technology is that it is difficult to anticipate all of the environmental consequences of technologies, however, beneficial they may seem; for example, consider the unanticipated scourge of DDT, plastics, and even cars. Who could foresee the real costs of even the most apparently benign innovations and inventions, such as antibiotics and television? For example, a journal article (Baker and George 2010) discussing the role of television in household debt concludes ". . . the empirical results suggest that greater access to television is associated with a greater tendency to maintain household debt and to borrow for durable goods, especially automobiles. Results also suggest that greater access to television is associated with higher levels of debt for durable goods. . ." This is just one side-effect of apparently benign technology.

Having understood the technological imperative and human limitations to understanding the environmental consequences of technology, it should be emphasized, however, that technology should not be rejected out of hand. One of the characteristics of technology is that once it is there, it is almost impossible to do without it; it makes itself indispensable. There is, therefore, a need for more research on cleaner fuels, alternative technologies that are more environmentally friendly and in harmony with the environment, and more public awareness. Those technologies whose environmental consequences are not fully known should not be adopted or adopted with caution with continued review of environmental assessment because there is a danger that instead of solving the problem of environment the future is mortgaged by opting for the immediate benefits of new inventions.

It should be reemphasized that science has been limited by its ecological short-sightedness and corporate greed. The question to be asked is if science is so full of promise to improve the welfare of society then why is the world beset with species extinction, poverty and starvation, atmospheric degradation, global pollution, desertification and deforestation? It may be remembered that the solutions to the

environmental crisis will not come from science and technology but will be political and socioeconomic.

Future Directions: Toward a Fair and Just Economic System

To summarize what has been said earlier. Neither "safe and benign" technology nor environmental regulations nor any amount of recycling alone can solve the sustainability problem as long as the present world economic system with its philosophy of economic growth compounded and nurtured by interest which creates greed and gross injustice is in place. The focus on increasing wealth has driven the planet's ecological system to the brink of failure, without making people happier (McKibben 2007). If Chinese ate the way Americans do they would use two-thirds of the world's grain harvest; if they drove as many cars as Americans do, they would use all the oil in the world currently produces plus 15 million extra barrels a day (Brown 2006). The economic model of fossil-fuel based, auto-centered, throwaway economy is not going to work in the medium and long term. Humanity has to dispel many old conceptions and beliefs such as: economic rationality; market distributes benefits; wealth and happiness are connected; economic ends justify military means; the cult of efficiency; technology is the answer; new is always better; jingoistic allegiance to one's country whether it is right or wrong; and future will look after itself (Laszlo 2006). People need to live more simply and not contributing more to the ecological and social worldwide catastrophe. In the short-term, local self-reliance and alternative currency networks mentioned in section "Alternative Economic Approaches to Promote Sustainability" seems to be part of the answer to limit the harmful effects of the current doing. However, the struggle should continue to challenge the system in place. Only a fair and just economic system can guarantee sustainability. ***Justice is the key to the future of sustainability.*** Humanity must devise an economic system:

- That takes on a holistic view and does not exploit the weak and oppressed;
- In which high interest rates are forbidden which focuses on distribution of wealth instead of growth;
- In which the distinction is drawn between public property and private property. The basic necessities of life especially water, air, and energy should be under public control (Owning a deep mine of minerals or petroleum fields is not the same as owning a house or a piece of land; neither is owning petro-chemical plants or various large energy generating units or a weapons manufacturing facility the same as owning a garment factory or a candy shop; and neither is owning a railway network similar to owning a car. On the recent Deepwater Horizon oil spill in the Gulf of Mexico, Costanza et al. in Solution Journal commented (Costanza et al. 2010): "The continuing oil spill from the Deepwater Horizon is causing enormous economic and ecological damage. Estimates of the size and duration continue to escalate, but it is now the largest in U.S. history and clearly among the largest oil spills on record. *One major lesson is that our natural*

capital assets and other public goods are far too valuable to continue to put them at such high risk from private interests." In (Wheeler 2004) the author writes: "*Developers, corporations, and ordinary citizens have maximized private benefit at the expense of shared public goods – including the quality of our cities and towns, not to mention the environment.* Individualism has triumphed over collective well-being. In a conservative era dominated by free market philosophies, there has been little political interest in recognizing that someone, usually the public sector, must stand up for the common good. Government, which exists in large part to protect and advocate for public interests, is routinely attacked by those who would like to privatize everything. Individualistic attitudes have been institutionalized through law, government policies, corporate practice, advertising, the media, and many other structural elements of our society. These structural forces also reinforce individualistic, consumption-oriented values, types of behavior, and modes of thought within individuals."); [emphasis added]

- In which big corporations do not exploit the world resources in poor and disadvantaged countries;
- Based on mutual welfare, trust and partnership in which both the supplier of capital and the user of capital become partners in profit and loss (equity financing instead of debt financing);
- In which business dealings are fair, free from speculations and not tied up to any particular currency. Any crisis in the dollar badly affects the currencies of other countries. Also paper currency is a form of exploitation and is part and parcel of present economic structure. To avoid such fiscal crises and be fair and just to all bimetallic coins of gold and silver medium of exchange should be adopted which have their own intrinsic value (Maloney 2008);
- In which businesses that exploit society in harmful ways should be banned.

What is clear from this is that that there is a need for a paradigm shift – a complete change in perspective. Awareness of sustainability has opened up discussion on many fronts and that necessarily includes economical and financial system in place. There is a need to engage meaningfully in understanding the harmful effects of current economic and financial system on the environment and indeed on the sustainability of the planet. While the full implications of the quantum change in perspective have yet to filter down to the level of general consciousness the forest has been cleared and the path is open. No doubt there may be reluctance due to powerful vested interests related to both cognitive belief systems and to the institutional position. But with courage and commitment the present growth-based economic system of exploitation can be challenged.

Remember by introducing a fair and just economic system in society the world is (Malik 2012):

- Reducing the environmental risk
- Reducing poverty in the developing world
- Reducing the gap between rich and poor
- Reducing the unemployment problem

- Reducing the problem of inflation
- Promoting a culture of charity and sacrifice and condemning the culture of greed and selfishness
- Doing justice to nature
- Increasing the economic efficiency

Safeguarding the interest of future generations; and so on.

Abstract

Climate change is being exacerbated by the emissions of globe-warming greenhouse gases (GHGs) as a consequence of economic activities associated with energy, industry, transportation, and land use. From an economic viewpoint, the Earth's climate is a *public good*, and pollution a *negative externality*; such change therefore constitutes *market failure*. Controlling air pollution by utilizing economic mechanisms represents an important change in environmental thinking – literally a paradigm shift away from historical command-and-control engineering systems. Today, this approach is being utilized to mitigate the emissions of GHGs, addressing the pollution externality by putting a price on carbon. The international carbon market, largely developed as a result of the Kyoto Protocol, had a total value of $176 billion in 2011, but it has decreased significantly in recent years. With the addition of China and other national and subnational programs, however, it is expected that it will once again increase, as a larger and larger portion of emitted GHGs come under such regulatory purview. Historically, the largest component of that market has been the European Union's Emission Trading Scheme (EU ETS), which represents a regional market designed first to assist Europe in achieving compliance with the Protocol's requirements, and now is a cornerstone of the EU's policy to combat climate change. It also has links to the Protocol's project-based mechanisms, the Clean Development Mechanism (CDM), and Joint Implementation (JI), which help minimize compliance costs. China's nascent market – currently seven pilot schemes, but expected to become a national program in 2016 – should ultimately become twice as large as the EU ETS. Other carbon markets created in numerous countries (e.g., the U.S., Japan, South Korea, etc.) as well as a voluntary market are also expected to make significant contributions. This chapter discusses the structure of these emissions trading carbon markets, the theory behind their development, their historical evolution, ongoing governance challenges, and future prospects.

Introduction

The issue of global climate change is as much an economic conundrum as it is one of science and regulatory policy. Climate change is exacerbated by the emissions of globe-warming greenhouse gases (GHGs) as a consequence of economic activities associated with energy, industry, transportation, and land use. Historically, polluters have not had to directly bear the social costs of emitting substances into the atmosphere – and therefore they have had no incentive to reduce such emissions.

In economics, the Earth's climate is considered a "public good," that is, a good that can be consumed by everybody in a society, where those who fail to pay for the good cannot be excluded from enjoying its benefits. An "externality" is the impact of an economic transaction on a party that is not a direct participant of the transaction, and the price therefore does not reflect the full cost of a certain good. Human-induced climate change, then, is a "negative externality," since the emitter of

GHGs does not pay the cost of detrimentally altering a public good (i.e., the Earth's climate). This means that climate change, from an economic viewpoint, is a market failure; in fact, the British government's *Stern Review*, a well-known economic analysis of climate change, called it a "market failure on the greatest scale the world has seen" (Stern 2006).

While the fundamental theory of public goods and externalities forms the basis of any economic approach, there are a few facets of global warming that make a market solution to the problem of climate change even more challenging: the climate change externality is global; the impacts are persistent and develop over time because some GHGs remain in the atmosphere for hundreds of years; since there is no accurate way of predicting the change in the climate system due to increases in atmospheric GHGs, there are considerable uncertainties and risks in developing a mitigation strategy based upon economic theory.

In standard economic theory, the marginal abatement cost (MAC) of pollution control should equal the marginal social benefit (MSB) of such abatement. This means that the goal of the economic control program should be to set a control level such that the next dollar spent on pollution control purchases exactly one dollar's worth of environmental amenities. Figure 1 illustrates the marginal abatement cost (MAC) and marginal social benefit curves (MSB).

Economists then offer two approaches to arrive at that point:

- A price-based mechanism also called a Pigouvian tax
- A quantity-based mechanism commonly referred to as emissions trading

The Pigouvian tax approach was first developed by Arthur Cecil Pigou (1877–1959), a British economist who was a professor at Cambridge. Pigou discussed the concept of externalities in his book *The Economics of Welfare* (Pigou 1920) and argued that a tax should be imposed on negative externalities such as pollution in order to discourage them. In the case of climate change, a

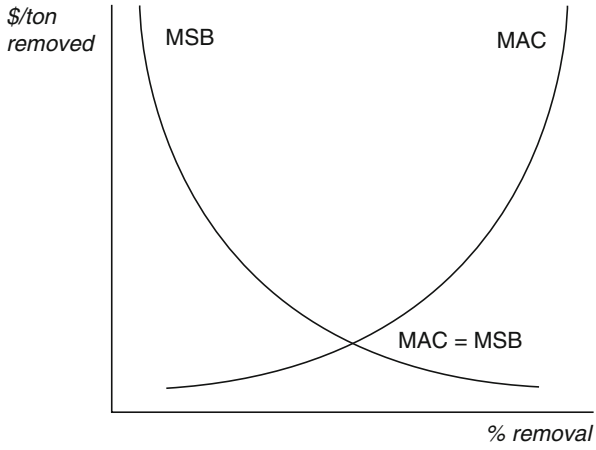

Fig. 1 The economists' idea of abating pollution

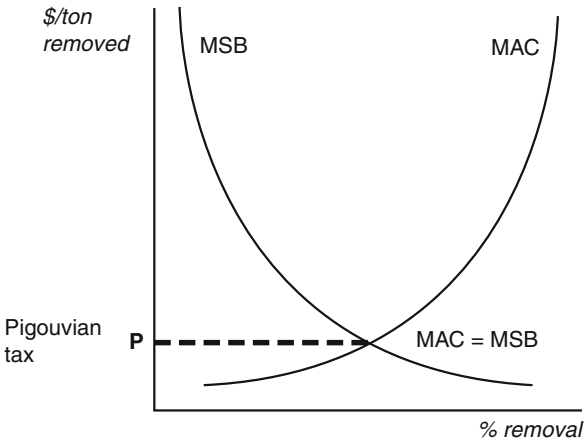

Fig. 2 A price-based approach to abate pollution: Pigouvian taxation

Pigouvian solution would introduce a tax on GHG emissions. If the MAC of a polluter is higher than the tax, the polluter will find it more cost effective to pay the tax and continue emitting. If the MAC is lower than the tax, then the polluter will try to abate the pollution as opposed to paying the tax (Fig. 2).

A Pigouvian tax is now considered a well-known and traditional means of bringing a modicum of market forces and therefore better market *efficiency* to economic situations where externalities exist. Such a tax will make it more expensive to pollute and will ensure a change in behavior by the polluting entity – forcing the polluter to either pay the tax or implement technologies to reduce pollution, whatever is more cost effective. Despite being an efficient solution to controlling pollution, taxes introduce a political dynamic that raises questions about wealth transfer from industry to government, the distribution of this revenue, lobbying of the government by special interest groups, polluters, etc. Economists have attempted to address this wealth transfer by linking the tax with subsidies (and utilizing the revenue generated by the tax to fund such efforts); by removing other taxes (so that there is tax neutrality); and similar schemes.

The quantity-based market approach, on the other hand, has an extensive background in the economics literature, but is perhaps most often associated with the work of John Dales, Professor of Economics at the University of Toronto, and his classic 1968 book *Pollution, Property and Prices* (Dales 1968). In that work, Dales proposed a new market-oriented policy instrument for tackling pollution problems. Dales' idea was to have an environmental authority issue a limited number of rights (or permits) to emit a specified pollutant and then leave the determination of the price of these permits to emitters within a market. Today, transactions in such markets are commonly called "emissions trading." A regulator sets an overall emission limit ("cap"), which is the total quantity of a pollutant that the participants in the scheme are allowed to emit. That quantity is then divided into a number of "allowances," and polluters are allowed to trade (i.e., buy and sell) such allowances in a market. Such "cap-and-trade" schemes have become quite popular over recent decades, and

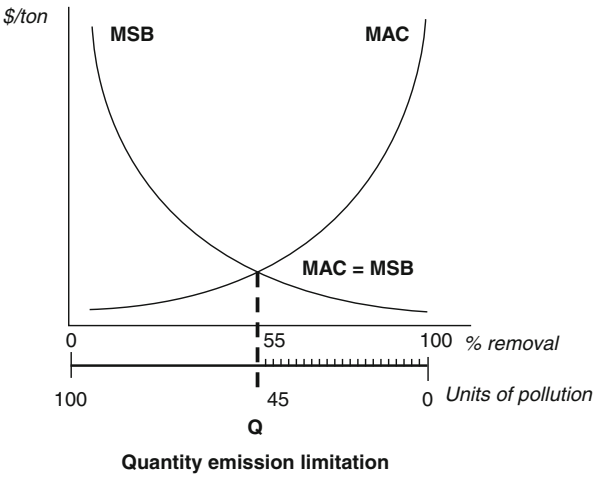

Fig. 3 A quantity-based mechanism to control pollution: Emissions trading

their success has led to the development of carbon markets under the Kyoto Protocol. In the figure above, a cap is set at the point where MAC = MSB, which is at the point where 55 % of the pollution is controlled. The "cap" of 45 units of pollution could be divided into 45 allowances, which could be bought and sold by polluters. Note that those with low marginal costs of control will put on control, rather than purchase such an allowance, and society will ultimately end up at the point where MAC = MSB; the figure also indicates that those with higher marginal costs should ultimately end up holding the allowances (Fig. 3).

There are several advantages to such "cap-and-trade" programs, the most obvious being that it is an economically efficient way to control pollution without the government having to worry about setting prices. It also has considerable flexibility in addressing the political issues associated with the wealth transfer noted above – allowance allocation schemes can call for 100 % auctioning (creating a transfer similar to that of a Pigouvian tax); or distribute the allowances for free to existing polluters (typically called 'grandfathering'); or utilize any combination in between. This gives the government considerable political leverage in addressing distributional concerns, and politicians can utilize, and have utilized, this to minimize political resistance to the pollution control program. Importantly, such quantity-based systems also limit the total amount of pollution, shifting the burden of dealing with growth on polluters. Under the "cap," individual emitters participating in the scheme have the flexibility of determining how best and where to deliver emission reductions.

A significant cap-and-trade program was introduced in the USA in the early 1990s for acid rain control, but this was not the first emissions trading program. Earlier, in the 1970s, a *baseline-and-credit trading* emissions trading system had been established. In baseline-and-credit trading, the regulator defines a specific set of acceptable conditions (the baseline) for an emission source. Depending upon preset

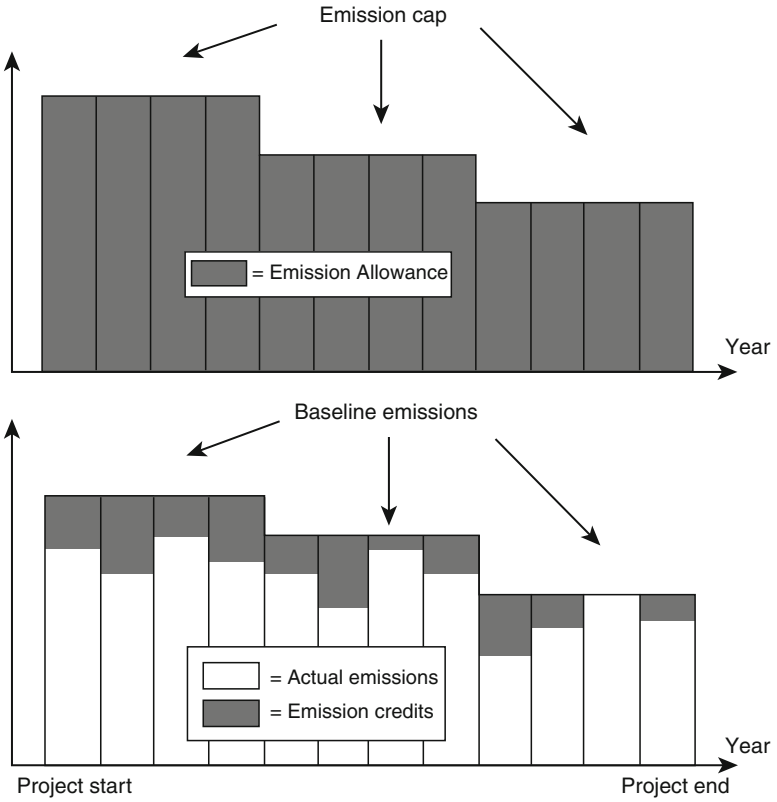

Fig. 4 Allowances versus Credit Trading (Source: Adapted from OECD 1997)

rules, improvements to this situation may qualify for "credits" (called Emission Reduction Credits [ERCs] in the US program) which could then be used for various purposes – to either offset new emissions, to reduce the control requirement on other units or be sold to others who might have trouble meeting their own baseline requirements. Figure 4 illustrates the difference between cap-and-trade and baseline-and-credit trading schemes. Later sections will make clear that both of these emissions trading approaches play an important role in the international carbon market.

The key aim of market-based approaches toward climate change policy is to ensure that those generating GHGs face cost for emissions that reflects the damage they cause (i.e., what economists call "internalizing the externality"). In ideal market conditions, both price and quantity-based mechanisms, if designed correctly, can be used to create such a price for carbon, and both approaches have the potential to deliver emission reductions efficiently.

This chapter seeks to analyze the role that quantity-based approaches play in mitigating climate change, and the resulting compliance and voluntary carbon markets that have been developed and are in operation around the world. The chapter

is organized in such a manner as to provide the reader a historical framework for the development of such market approaches – beginning first with traditional engineering approaches to pollution control, and then moving towards implementation of the economists' ideal, in order to see how carbon markets obtained their current structure. It then profiles the compliance carbon markets and the complementary, but increasingly important, secondary and related markets in operation today.

The Evolution of Emissions Trading

The development of markets to address environmental issues represents a strategic shift in the thinking behind environmental management. Pollution control has a long evolutionary history, beginning with traditional engineering approaches and subsequently developing into the economic realm with market-based approaches.

Historically, most governments have utilized "command-and-control" (CAC) types of regulations to address pollution problems. As the name suggests, the government would issue some form of "command" – typically a mandate for a pollution source to use some type of technology, or meet some specific pollution level. The government then faced the problem of ensuring that the command was actually followed out – and this required active "control." "Control" typically includes the monitoring, reporting, and verification (MRV) of emissions, as well as punishment for a failure to meet "commands." The absolute form of "command" is prohibition, which is used if the potential damage to the environment is severe and difficult to remediate. More frequently, however, technology-based requirements are employed, typically requiring polluters to meet some emission limit or performance standard for their equipment. Monetary fines, or perhaps imprisonment for egregious cases, are now the norms for "control."

In an 1874 amendment to Britain's Alkali Act of 1863, polluters faced a requirement to utilize the "best practicable means" (BPM) of pollution control. From an engineer's perspective, if everyone was utilizing BPM, then whatever happened to the environment simply happened – after all, everyone was doing the best they could with technology. An alternative regulatory approach was adopted in the USA in the 1960s, however. This alternative suggested that the goal of pollution control systems was not simply to use the best technology, but rather, to focus on achieving environmental quality. Technology was just a means of accomplishing such an end, not the goal itself. Environmental goals were thus developed in terms of *environmental quality standards*, and the technology-oriented requirements became recognized as the means to accomplish such goals. The resulting CAC programs developed in the 1970s therefore adopted the "traditional" (i.e., engineering) approach outlined on the left side of Fig. 5.

Economists had a different idea, however, as discussed earlier and as noted on the right side of Fig. 5. From their theoretical perspective, the goal is to develop a program where marginal costs of pollution abatement is equal to the marginal social benefit (i.e., MAC = MSB). All of the information used by the regulators to set environmental quality standards in the traditional approach would somehow have to

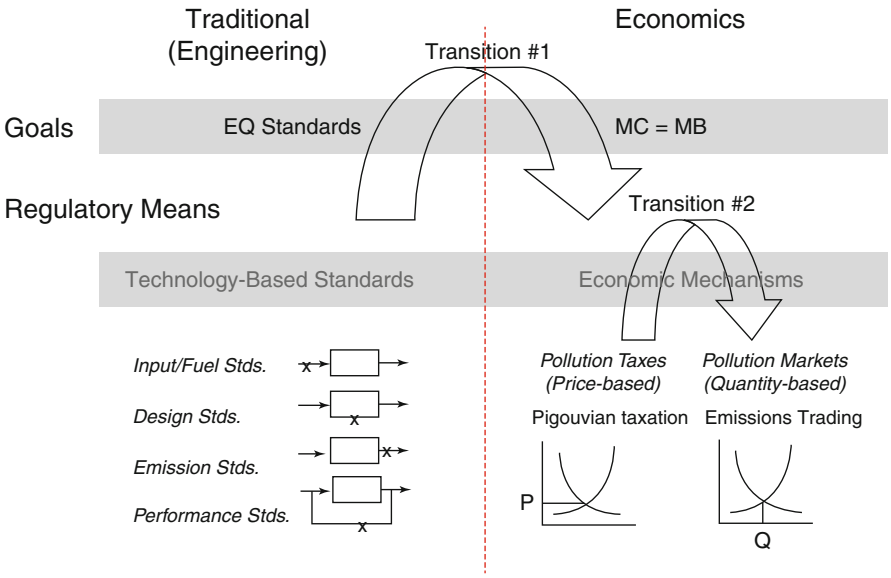

Fig. 5 Engineering versus Economic worldviews

be incorporated into the marginal social benefit curves outlined in the right side of that figure. This obviously would be a very difficult task.

Figure 5 suggests that two transitions are occurring today – a shift from an engineering to an economic worldview in environmental management and a secondary shift from price-to-quantity-based mechanisms. There are important caveats associated with both transitions, however. For the first, the transition is only occurring in the bottom portion of the figure – i.e., within the regulatory means, not environmental goal setting. Governments fully recognize the difficulties associated with developing accurate MSB curves, and thus tend to stay with environmental quality standards or depend upon political compromise to set goals. However, they increasingly recognize the strength of using the economic regulatory means (i.e., Pigouvian taxation and emissions trading) as tools to help accomplish such goals.

Any portend of a price-to-quantity shift within economic instruments must similarly be heavily qualified. Economists make choices about the appropriate price or quantity instruments to use based upon numerous factors, including the slopes of the MAC and MSB curves; confidence in the data used to estimate them; administrative simplicity (including the means of future adjustments); their visibility (explicit vs. hidden); second-best considerations; and a host of similar concerns. Certainly many governments – and economists – are more comfortable using price-based instruments, and it has frequently been suggested that these are a more appropriate tool for dealing with climate change. Nordhaus (2009, 2013), for example, has been a major proponent of carbon taxation, and notes that:

- The damages associated with GHGs strongly favor price-based policies, since GHGs are a stock pollutant, while control costs are related to the flow
- Quantity-based targets are difficult to set, and "are particularly troublesome where targets must adopt to growing economies, differential economic growth, uncertain technological change, and evolving science"
- A tax approach "may add less to the distortion caused by existing taxes" (i.e., second-best considerations), and is less susceptible to corruption and rent seeking behavior

Despite such efficiency considerations, the political economy and flexibility of quantity-based systems noted above, as well as the increasing difficulty faced by many governments in imposing taxation schemes, has led to such a longer-term shift over recent decades. Further, many believe that it is more appropriate for the government to focus on the physical goal (i.e., the quantity) and have prices respond than the converse. The EU has made cap-and-trade the predominant policy mechanism for dealing with its largest emission sources, and China has similarly chosen it as a key tool for reducing the carbon intensity of its economy. Prospective US regulation is likely following a similar path, as discussed below.

While this chapter focuses on the emissions trading (i.e., quantity) mechanism, the World Bank tracks both price and quantity instruments in its annual survey. It notes that "about 40 national and over 20 subnational jurisdictions are putting a price on carbon. Together these carbon pricing instruments cover almost 6 Gt CO_2e or about 12 % of the annual GHG emissions" (World Bank 2014).

Emissions Trading Programs

The US Environmental Protection Agency (EPA) introduced the concept of emission markets in 1976, as a means for new emission sources to locate in areas with unhealthy air quality (i.e., areas that did not meet the National Ambient Air Quality Standards). The new sources were required to use stringent control technology (i.e., Lowest Achievable Emission Rate), but were also required to "offset" the additional pollution they created by a ratio greater than 1:1. Thus, the new source would help clean up the nonattainment area even though it was adding new pollution. Some economists realized that this created a new asset: emission reduction "credits" from an existing source were now worth something to a new source hoping to locate within a nonattainment area (such as Los Angeles). This emissions trading scheme was expanded in 1979 to include existing sources as well as new ones through the "bubble" policy, which allowed sources to put an imaginary bubble over their facility, and then meet CAC requirements in the most cost-effective manner under the bubble (i.e., based upon their own determination of MAC rather than the government's embedded within the CAC requirements). Other mechanisms added that same year included "netting," a simplified-permit strategy which allowed sources to "trade" their old emissions for new emissions when replacing equipment and "banking," which provided firms the flexibility of storing their emission

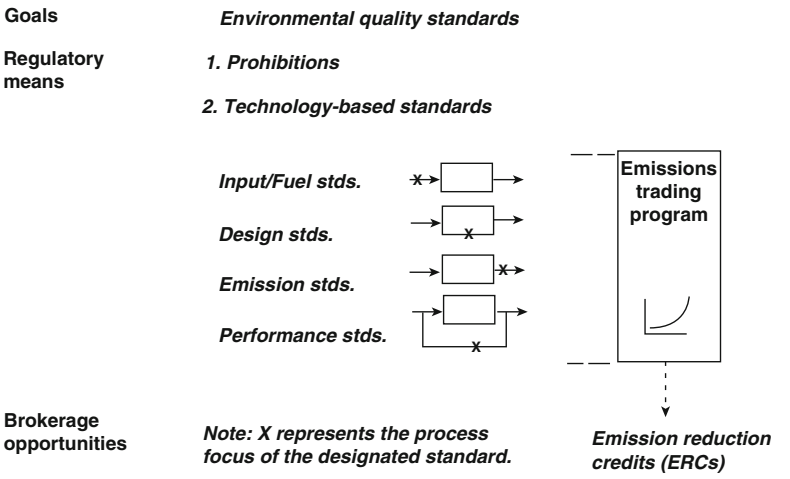

Fig. 6 The US EPA's Initial Emission Trading Program

reduction credits over time. These four regulatory provisions were collectively brought together in a draft Emissions Trading Program (ETP) in 1982, and finalized in 1986. The US EPA's ETP did not change the CAC requirements – it merely introduced a new and more flexible means for emission sources to meet them. The time and costs associated with completing a specific ERC transaction have been high, however, and while thousands of ERC trades have occurred, high transaction costs have hobbled this market. The resulting baseline-and-credit ETP is shown in Fig. 6, and remains in effect today.

The US Acid Rain Program (ARP)

The ETP laid the groundwork for a pioneering acid rain allowance trading program that is the predecessor of quantity-based trading programs in operation today. In 1980, rising concern about the extensive environmental impacts of acid rain (i.e., acid deposition) prompted the US Congress to establish the National Acid Precipitation Assessment Program, an interagency organization designed to study the causes, effects, and potential control of this environmental concern. With the Clean Air Act amendments in 1990, Congress addressed the control issue and sought to achieve major reductions of the primary components of acid rain: 10 million tons of sulfur dioxide (SO_2) and 2 million tons of oxides of nitrogen (NO_x) below 1980 levels by the year 2000. In doing so, the legislation established a new paradigm for environmental protection, since the resulting emissions control program was the first significant one utilizing the economists' idea of a quantity-based emissions trading mechanism.

The centerpiece of the Acid Rain Program (ARP) was a cap-and-trade system for SO_2. The NO_x reduction program initially took a command-and-control approach,

but in 1999 a cap-and-trade NO_x program was developed in the US Northeast (primarily for ozone-control purposes). A two-phased tightening of restrictions on fossil fuel-fired power plants was adopted: total emissions in 1995 (under Phase I) were 25 % below 1990 levels, and more than 35 % below 1980 levels (Burtaw et al. 2005). Phase II, which began in 2000, represented a significant 50 % cut from 1980 SO_2 levels (US EPA 2002).

A 2010 governmental analysis of the ARP estimated annual benefits of the program to be $122 billion, and costs to be only $3 billion (50 % of the figure estimated by the EPA in 1990) – a 40-to-1 benefit/cost ratio (US EPA 2010). Such numbers illustrate why *The Economist* (July 6, 2002) called it "probably the greatest green success story of the past decade."

Lately, however, the SO_2 market price has collapsed, and the clearing price in US EPA's March 2014 spot auction was only $0.35/t (and $0.04/t in the 7-year advance auction) (USEPA, 2014 Allowance Auction Results 2014a). The reason for this is that other regulatory initiatives (such as the 2005s Clean Air Interstate Rule, and its replacement, the Cross State Air Pollution Rule) have instituted further SO_2 reductions designed to tackle environmental concerns such as PM-2.5. Accordingly, as one prominent environmental economist noted, "the emissions constraint under the 1990 Clean Air Act amendment has become irrelevant, and the price of those tradable emissions allowances has fallen from several hundred dollars a ton to near zero." In that economist's view, this was indicative of an "institutional blind spot" in environmental economics – legislative actors were simply not capable of readily amending a statute to correspond to changing scientific information (Burtraw 2013).

While the current SO_2 market is essentially moribund, the ARP market design kept the existing ETP (with emission reduction credits) to protect local air quality and public health near the power plants, while superimposing a cap-and-trade scheme (with emission allowances) to deal with total loading of the pollutant. This dual 'baseline-and-credit' and 'cap-and-trade' market scheme was a forerunner of the international carbon market, which would similarly use both types of instruments to accomplish desired environmental goals.

Carbon Markets

The foundation for the international carbon market began at the "Earth Summit," in Rio de Janeiro, Brazil in 1992. The Earth Summit, formally called the UN Conference on Environment and Development, addressed a wide range of environmental and governance issues, including biodiversity, the management of toxic chemicals, and similar issues – but it is perhaps best remembered today for establishing the United Nations Framework Convention on Climate Change (UNFCCC). The UNFCCC committed the signatory governments to a voluntary, nonbinding effort to reduce GHGs with the goal of "preventing dangerous anthropogenic interference with the earth's climate system." The UNFCCC came into force in 1994, after 50 countries had ratified it, in accordance with the terms of the treaty.

Signatory countries of the UNFCCC agreed to "common but differentiated responsibilities" for addressing emissions, recognizing that the largest share of historical and current emissions was generated from developed countries (i.e., as a result of more than 150 years of industrial activity), and that the share of emissions from developing countries would need to grow to meet their social and developmental needs. This resulted in a division amongst the signatory countries into two principal groupings: Annex I countries, which are industrialized nations and nations with economies in transition such as Russia and Ukraine and Non-Annex I countries, which are the remaining (mostly developing) nations. [NB: There is also an Annex II grouping, consisting of OECD members and the European Union, which have a "special obligation" to provide financial resources and facilitate technology transfer to developing countries.]

The Kyoto Protocol was adopted on 11 December 1997 in Kyoto, Japan, during the third meeting of the UNFCCC (called the Conference of Parties [COP]), and, while it opened for signature on 14 March 1998, the Protocol only came into force on 16 February 2005. As of 2014, 192 countries and one regional economic integration organization (the European Community) are parties to the treaty. A major feature of the Kyoto Protocol was that it set binding GHG emission constraints for the Annex I countries (in Article 3 and Annex B). These were equivalent to an average 5.2 % emissions reduction from a 1990 baseline over the first 5-year commitment period (2008–2012). Thus, while the UNFCCC encouraged industrialized nations to reduce GHG emissions, the Kyoto Protocol committed them to doing so.

Even though the USA initially introduced the idea of emissions trading and was an ardent proponent of market-based mechanisms to address climate change (based upon its successful experience with the ARP), it never ratified the Kyoto Protocol. As a participant, the US would have been required to reduce GHG emissions by 7 % below 1990 levels. The USA experienced rapid economic growth during the late 1990s, however, and that 7 % reduction would have amounted to approximately 30 % in real terms for the 2008–2012 commitment period, as growth continued. The US disagreed with other parties about how the market-based "flexibility mechanisms" should be implemented, as well as other policy issues (e.g., the role of forestry "sinks") and subsequently withdrew from the process completely in March, 2001. The US did pursue a number of limited domestic initiatives to reduce emissions, but never joined the emissions trading markets created by the Kyoto Protocol.

Flexible Mechanisms of the Kyoto Protocol

The Kyoto Protocol remains a binding agreement today, in its second commitment period (2013–2020). In the first commitment period (2008–2012), it regulated six GHGs: carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), perfluorocarbons (PFCs), hexafluorocarbons (HFCs), and sulfur hexafluoride (SF_6). Emissions of these GHGs are primarily associated with the generation and use of energy, chemical and industrial processes, municipal wastes, and land-use activities such as

deforestation. A seventh chemical, nitrogen trifluoride (NF_3), used primarily in the electronics industry, was added in the second commitment period. For reporting and tracking purposes, the Global Warming Potential (GWP) in the atmosphere of each gas is expressed in terms of a CO_2 equivalent (CO_2e). Methane for example, has a GWP that is 25 times that of CO_2 (although the carbon market has employed an earlier estimate of 21). The Protocol set individual GHG emission-reduction targets for Annex I countries under the UNFCCC. These targets were specified in Annex B of the Kyoto Protocol. For the Annex I countries that ratified the Protocol, their assigned GHG emission amounts acted as a legally binding cap on emissions between 2008 and 2012.

Annex B countries could meet their emission reduction targets either through national measures (e.g., regulations, taxes or environmental markets), or through the use of three flexible market mechanisms incorporated into the Protocol. Described in Articles 6, 12, and 17 of the Protocol, these flexible mechanisms allowed Annex B countries to pursue opportunities to cut emissions or sequester carbon more cheaply in other countries than within their own domestic market.

Article 6 of the Protocol defines a mechanism known as *Joint Implementation* (JI), which allowed emission-reduction or removal projects in Annex I countries to generate *Emission Reduction Units (ERUs)*, which could then be used to meet the emission reduction or limitation commitments of other Annex B countries. Each ERU is equivalent to one ton of CO_2, and could be counted towards Kyoto target requirements. Article 12 defined the *Clean Development Mechanism* (CDM), which allowed similar carbon credits known as *Certified Emission Reductions (CERs)* to be generated from projects in developing (i.e., Non-Annex I) countries. The *International Emissions Trading (IET)* mechanism was outlined in Article 17 of the Protocol, and allowed Annex B parties to trade *Assigned Amount Units (AAUs)* in order to meet their commitments. Countries in Annex B that have spare (i.e., permitted but not used) AAUs could thus sell them to countries that exceeded their targets. As discussed below, these flexible mechanisms evolved over time. The CDM was the first to be implemented, since projects under the mechanism could start generating credits relatively quickly (i.e., before the first commitment period began). This was followed by the JI, and thirdly, IET. These latter mechanisms did not fully commence until the start of the first commitment period in 2008.

Thus, an Annex B country had several options to reduce emissions in order to comply with its Kyoto Protocol targets. Annex B nations could:

- Limit emissions through domestic policy, such as implementing direct regulation, Pigouvian taxation, or setting up domestic emissions markets (note: the role of regional markets such as the EU ETS is discussed below)
- Set up eligible projects in non-Annex I countries under CDM, and use the CER carbon credits generated from these projects
- Set up eligible projects in Annex I countries under JI, and use the ERU carbon credits from these projects and/or
- Utilize the IET program to buy/sell AAUs

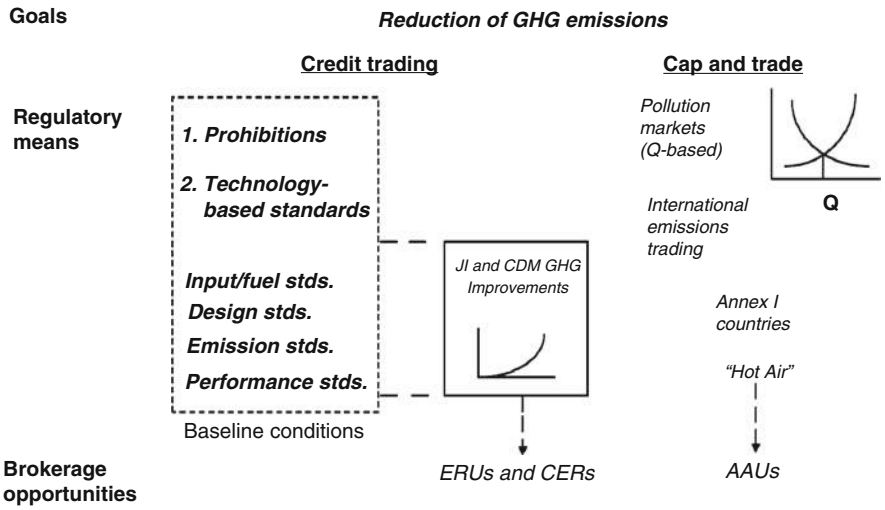

Fig. 7 The Kyoto Protocol flexibility mechanisms

As an example, Britain, which had a relatively high reduction target of 12.5 %, during the first commitment period could achieve this target by implementing a portfolio of domestic regulatory policies, such as improving building codes; employing price instruments such as a petrol taxes to reduce emissions from the transportation sector; and using emissions markets (in this case, the EU ETS) to reduce pollution from the power sector. Over and above such domestic efforts, the country could purchase AAUs from Russia or Ukraine, or invest in CDM or JI projects abroad (either through the EU ETS, or separately). The overall market framework for the Kyoto Protocol flexibility mechanisms is shown in Fig. 7. These mechanisms were indeed flexible, and countries were at liberty to employ one or all of these mechanisms, in any combination, depending upon their emissions constraints and economic situation.

Clean Development Mechanism (CDM)

Since climate change is a global problem and the physical nature of the pollutant makes the location of emissions reductions irrelevant, CO_2 emission reductions could be obtained anywhere – and usually at lower cost in the developing world. Article 12 of the Kyoto Protocol provides for such reductions, and the Clean Development Mechanism outlined in that article has two goals: to reduce GHG emissions and to foster sustainable development.

CDM is a project-based mechanism that allows public or private entities to invest in GHG-mitigating activities within developing countries, and to earn abatement credits for those projects. These credits, called CERs and equivalent to one ton of CO_2, can then be applied against their own emissions or sold in the marketplace. Buyers in other Annex I countries, for example, might purchase them to assist in meeting their own GHG reduction goals.

Prior to the generation of CERs from a CDM project, the developers of the project are required to go through a formal and rather complex process. They interact with three institutions: the CDM Executive Board (EB), which implements and supervises the mechanism; the Designated National Authority (DNA) of the host country which reviews and approves CDM projects, and provides country-specific guidance (e.g., for sustainable development criteria); and Designated Operational Entities (DOEs), which are independent private companies serving as auditors.

In order to qualify to receive CERs, projects have to have begun after January 1, 2000, and must submit a Project Design Document (PDD) which includes at least the following information:

- General description of the project activity (including location, technology, ownership, etc.)
- Application of a UN-approved baseline methodology for that specific activity. Baseline methodologies have now been approved for most standard renewable energy and energy efficiency applications, but any novel technology or application would first require such an approval
- Selection of a crediting period. Project developers can select either a fixed 10-year baseline period, or three 7-year baselines with adjustments at the end of the first and second periods (with the exception of afforestation and reforestation sink projects)
- Monitoring methodology and plan
- Estimation of GHG emissions and reductions
- Assessment and demonstration of "additionality" (i.e., that emissions reductions are above and beyond those that would have happened anyway – i.e., they are "additional" or "surplus"). Additionality is important because developing countries are not required to reduce emissions under the Kyoto Protocol and Annex I countries utilizing CERs from these countries will take credit for such reductions. This is usually the most difficult criterion for CDM projects to meet and document
- Documentation that the project meets the DNA's sustainability criteria for projects within that host country
- Other relevant data (e.g., contact information for project participants, stakeholder comments, information on the use of public financing, etc.)

The CDM project process is outlined in Fig. 8. Note that after the PDD is completed in the design stage, it is validated by the DOE, which will make a recommendation to the EB to register the project. Later, a second DOE will verify that the project has performed as expected, based upon the monitoring plan submitted as part of the PDD – and will recommend that the appropriate number of CERs be issued. Only if all of these criteria are met will the project then be issued CERs, which can be sold in the international carbon market.

As of October 1, 2014, 12,253 projects had submitted PDDs, and 7,562 of them had reached the registration stage. During the first commitment period, 1,491 million CERs (MCERs) were issued, and it was expected that 5,081 MCERs would be issued in the second commitment period. Seventy one percent of the CDM projects

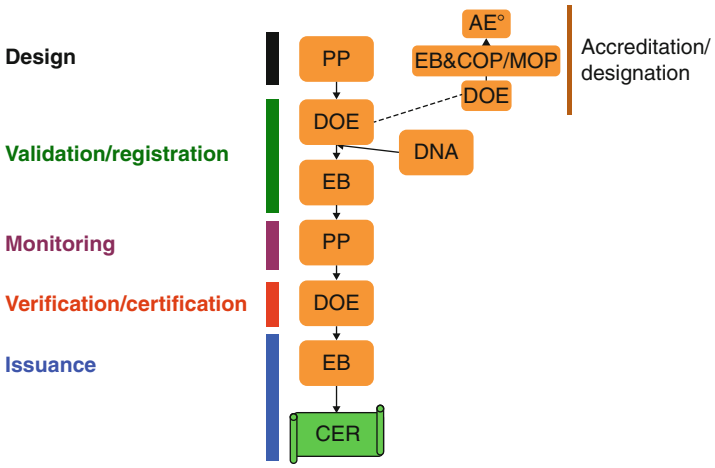

Fig. 8 Carbon credits from the Clean Development Mechanism of the Kyoto Protocol (Source: UNFCCC n.d.)

were associated with renewables in the first commitment period, but these represented only 34 % of the CERs. China has captured 59.9 % of the CERs issued to date, with the top five countries (China, India, South Korea, Brazil and Mexico) representing almost 90 % of the CDM market. Less than 3 % of the CDM projects were located in Africa (UNEP DTU Partnership 2014).

These figures do not make clear, however, the significant contraction which has taken place in the CDM (and Kyoto Protocol) marketplace in recent years. Prices for CERs have collapsed by 98 % over a 5-year period, to less than $0.50 per ton. Such prices do not even cover the transaction costs of issuance, let alone any project investment. As the World Bank noted, "since the second half of 2012 there has been a growing feeling in the CDM market that demand is saturated. With little prospect of a significant recovery, the biggest players have begun to leave the market, along with their skills and expertise"(World Bank 2014). One estimate suggests that the demise of CDM will require a write-down of $66 billion in asset value – over 40 % of owner's equity on average – primarily for developing country investors (CO_2 Spain 2013).

There are a number of reasons for the collapse in CERs prices, beginning with the fact that most demand was associated with the EU ETS – which saw its own significant price declines. As discussed below, the EU's "Linking Directive" created the largest demand for CERs, but the recession and economic contraction in Europe lessened demand significantly. Perhaps more importantly, however, Europe revised the rules of the EU ETS for CER usage in the second commitment period in a manner which had a profound effect upon the CER market.

There had already been considerable displeasure in Europe over the role that industrial gases had played in early stages of the carbon market. HFC-23 is a highly-potent and long-lived GHG that was one of the six gases originally included in the

Kyoto Protocol. With a global warming potential 11,700 times that of CO_2, every ton of HFC-23 destroyed produced 11,700 CERs for sale in the CDM market. The destruction of HFC-23 (a by-product of HCFC-22 [chlorodifluoromethane] production, which is used as a refrigerant) saw windfall profits created in several projects (especially in China). The NY Times reported that industrialized nations could end up paying $800 million a year to buy CERs, even though the cost of building and operating incinerators would only be approximately $31 million per year (NY Times 2006). In response to such windfall profits, China imposed a 65 % tax on CER revenue generated by HFC-23 projects (as well as a 35 % tax on N_2O projects), and set up a CDM Fund to utilize such revenues. So much potential revenue distorted the economics of new refrigerant facilities (Wara 2006), but when Europe tried to modify the approach for new facilities under Kyoto Protocol processes, it was blocked. It therefore unilaterally determined to eliminate the use of such CERs in Phase III of the EU ETS.

Given the magnitude of CDM revenue streams to China and other middle-income countries, the EU ETS also determined to purchase new-project CERs in Phase III solely from Least Developed Countries (LDCs). Thus, only projects registered before January 1, 2013 could provide CERs in Phase III (other than new projects from the LDCs). It put in another timing constraint as well: after March 31, 2015, only CERs generated in the second commitment period (i.e., after 2012) could be employed. These constraints on demand contributed to the price collapse noted earlier, and it is not clear whether the CDM can be resurrected in future COP negotiations– particularly given concerns about certain aspects of its design.

One such fundamental concern (or, as discussed below, what some consider a fundamental flaw) has been the determination of the "additionality" of a CDM project. Defined in paragraph 5c, Article 12 of the UNFCCC, emissions from a CDM project should be ". . .additional to any that would occur in the absence of such activities." This statement, however, is vague and has been subject to many different interpretations. The idea behind additionality is that the project should owe its existence to the prospective earnings from carbon credits sold in the CDM market, i.e., the emission reductions should go beyond what they would be in the absence of the CDM. In general, determining additionality has proven not only cumbersome, but has resulted in increased transaction costs, as well as liability and risk for investors. Friends of the Earth has estimated, for instance, that 75 % of all approved CDM projects were already up and running at the time they were approved by the CDM EB (Friends of the Earth and International Rivers 2009). David Victor, formerly head of Stanford's Energy and Sustainable Development Program, estimated that between a third and two-thirds of CDM offsets may not represent actual emission cuts (International Rivers 2008). In mid-2009, the CDM EB ordered an unprecedented review of a number of Chinese wind projects, to determine whether they satisfied additionality requirements. Now referred to as the "Chinese wind controversy," ten projects were rejected outright just before COP15 in Copenhagen, sending shockwaves through the CDM investment community. The resulting imbroglio was indicative of what He and Morse (2013) have termed the "Offsetters' Paradox": "On one hand, including domestic subsidies in the additionality

calculation creates perverse incentives for the host country by making projects less eligible for CDM and therefore discouraging policies that would jeopardize CDM revenues. On the other hand, ignoring these subsidies assures crediting for business as usual projects, which reduces the integrity of global emissions caps."

While CDM has thus suffered a number of critical blows in recent years, it has nonetheless served as the template for all baseline-and-credit trading schemes in the international carbon market. The procedures developed under CDM for generating, validating and verifying carbon reductions are now routinely employed in both compliance and voluntary markets around the world. As an example, China now issues Chinese CERs (CCERs) for use in its domestic carbon trading programs, utilizing procedures it learned under CDM.

Joint Implementation (JI)

Joint Implementation is a project-based mechanism under the Kyoto Protocol that assists Annex I countries in meeting their Kyoto commitments by participating in projects in other Annex I countries. Entities may partake in JI projects to generate emission credits, known as ERUs, in order to use them for compliance with their emissions targets or to sell in the international carbon market. Similar to the CDM, JI offers parties a flexible and cost-effective means of fulfilling part of their Kyoto commitment, while the host party benefits from foreign investment and technology transfer. Unlike CDM, however, projects could only begin generating ERUs in 2008.

To be eligible to qualify as a JI activity and to receive ERUs, projects must be undertaken between Annex 1 countries; must provide a reduction that is additional to any that would otherwise occur in the absence of the project; and must be supplemental to domestic actions to reduce greenhouse gas emissions. The lifecycle for projects to be eligible for JI ERUs similarly begins with the preparation of a PDD, following JI guidance established by the JI Supervisory Committee (SC). Then, an Accredited Independent Entity (AIE) determines if the emission reductions were correctly estimated, and if necessary procedures were established to monitor the project performance during its implementation. At this stage, the JI Supervisory Committee will consider the quality of the project and, after 45 days, the project automatically acquires a status of JI project. As with CDM, most countries involved in JI establish their own national Designated Focal Points (DFP) in charge of JI project approval. There are two main tracks by which projects qualify for generating ERUs: Track 1, where a host party meets all eligibility requirements and verifies that emission reductions from the project are additional to a baseline scenario (i.e., the project implementation is largely left up to the participating states); and Track 2, where a host party meets only a limited set of eligibility requirements (verified by an accredited independent entity) and verification of the emission reduction as being additional has to be done by the JI SC.

Ukraine (321 projects) and Russia (96 projects) have been the biggest JI suppliers, while countries such as The Netherlands, Denmark and Austria have been the most active buyers, through governmental purchase programs or participation in carbon funds. As of October 1, 2014, Track 1 has a total of 574 registered projects and Track 2 has 206 projects registered in the JI pipeline (UNEP DTU Partnership 2014).

Like CDM, the JI market has contracted severely in recent years, and is complicated by the fact that post-2012 ERUs cannot be created until AAUs for the second commitment period are assigned – an issue still under debate in COP negotiations. Further, even though Russia had a significant number of JI projects, it refused to accept any constraints during the second commitment period, and thus is not eligible to register new projects.

International Emissions Trading (IET)

The Kyoto Protocol provides for a quantity-based cap-and-trade scheme called International Emissions Trading that is limited to Annex B countries. The national allocations used in the emissions trading are expressed as levels of allowed emissions, or assigned amount units (AAUs). Although these are national allocations and commitments, in practice, individual countries devolve their emissions targets and requirements down to major industrial entities such as power plants and large emitters. Therefore, the ultimate market participants may be individual companies that expect their emissions to exceed their quotas. Russia, Ukraine, and the Central and Eastern European countries have an estimated 8–12 billion tons surplus of AAUs for the 2008–2012 Kyoto commitment period associated with the collapse of the former Soviet Union, which occurred after the Kyoto Protocol's 1990 base year. This surplus is often pejoratively referred to as "hot air." Annex I countries could theoretically achieve compliance by purchasing "hot air," but many buyers were reluctant to do so since that would merely represent payment for economic collapse which occurred nearly 20 years ago, with little ongoing environmental benefits. Green Investment Schemes (GIS) were introduced to address this "hot air" situation. Under GIS, revenues from the sale of surplus AAUs were invested in environmental improvements (or "green" activities) in the selling nation, even though such activities might not strictly qualify for carbon credits (e.g., training energy auditors, etc.). This way, purchased AAUs were linked to GHG mitigation efforts, and many GIS schemes began to mirror CDM and JI carbon credit mechanisms, paying detailed attention to additionality, sustainable development criteria, etc. (Tuerk et al. 2010). The total amount of "hot air" sold is estimated to be 453 million AAUs. ((UNEP DTU Partnership 2014). Negotiators addressed the "hot air" issue for the second commitment period at COP 18 (in Doha), removing the ability of countries to profit from the sale of such AAUs in that period. This primarily focused on Ukraine, since Russia declined to accept a second period constraint (Morel 2013).

International Cap-and-Trade Programs

As noted earlier, the 2014 World Bank survey indicated that there were 40 national and more than 20 subnational carbon pricing mechanisms in place around the world. That report (World Bank 2014) and a number of other documents (see, for example, (ICAP 2014a; IETA 2013; ICIS 2014); etc.) provide detailed information about the characteristics of individual programs around the world, and this chapter does not

attempt to duplicate such information. Instead, it outlines below some of the salient features of the largest existing international carbon market (i.e., the EU ETS), as well as emissions trading efforts underway within the two largest GHG-emitting countries (i.e., China and the US).

The European Union Emissions Trading Scheme (EU ETS)

Although the EU was initially skeptical about emissions trading, it has become a driving force behind its implementation on a worldwide basis. In January 2005, the EU ETS commenced operation as the largest multicountry, multisector GHG trading scheme worldwide. There are four phases in the Scheme: Phase I from 2005 to 2007, also called the trial period; Phase II from 2008 to 2012, coinciding with the first commitment period of the Kyoto Protocol; Phase III from 2013 to 2020, currently in progress; and Phase IV, from 2021 to 2028, which has not yet been clearly defined. Furthermore, a 2030 policy framework for climate and energy was adopted by the European Commission in October 2014. The center piece of this framework is a target to reduce EU domestic greenhouse gas emissions by 40 % below 1990 levels by 2030, and sectors covered by the EU ETS would have to reduce their emissions by 43 % compared to 2005 (EC 2014).

The EU ETS established a mandatory CO_2 cap-and-trade system, which addressed emissions from major sources throughout the EU; it covers about 45 % of the CO_2e emissions, from more than 11,000 heavy energy-using installations in power generation and manufacturing industry. Sources were first allocated a certain number of emission allowances, based on historic performance and other parameters. Specific national targets were established in Phase I and II by national governments in what were called National Allocation Plans (NAPs), which specified how many allowances would be awarded to emitters in each regulated industry, and the distribution of such allowances. As is characteristic of a cap-and-trade market, participants who reduced their emissions below their allocation could sell the resulting excess allowances. Those companies who found that reducing their emissions internally was cost-prohibitive could purchase allowances in the open market. Those who did not hold sufficient allowances to match their actual emissions at the reconciliation date were fined 40€ per ton of CO_2 emitted in Phase I, which rose to 100€ per ton of CO_2 in Phase II and III.

It is important to note that while the EU ETS was designed to meet the goals of the Kyoto Protocol, it is operated by the EU, and is independent of the UN. The EU has announced that it will proceed with Phase III and IV of the ETS, regardless of the actions of other countries in post-2012 and 2015 climate negotiations.

EU ETS Phase I

Phase I of the EU ETS (2005–2007) was established as a "trial" or "learning" phase, before the Kyoto Protocol's targets came into effect. It was designed to provide companies and governments with experience in developing, operating, and participating in carbon markets. Phase I covered CO_2 emissions from more than 11,000 installations in several major emission sectors across the 28 European Union Member States. The sectors included energy (combustion installations >20 MW, mineral

oil refineries, coke ovens); ferrous metals; factories making cement, brick, glass, ceramics, and pulp and paper. Tradable "European Union Allowances" (EUAs) were distributed to these installations (typically for free), with the sum of distributed allowances equal to the total cap. The amount of emissions allowed by the cap itself was determined on a country-by-country basis; each member state proposed a quantity of EUAs, which was reviewed and approved by the EU commission (Ellerman and Joskow 2008).

The transportation, chemistry and building sectors were excluded in Phase I. In cases of *force majeure*, such as exceptionally low winter temperatures, additional emission allowances could be issued by national authorities. Member states also had the flexibility of opting out individual facilities. A notable feature of Phase I of the EU ETS was that there was effectively no restriction on banking or borrowing of allowances within any given multiyear period, but this did not hold between trading periods. While each member state maintained its own registry to record the creation, transfer and surrender of allowances, a central registry, called the Community Independent Transaction Log (CITL) recorded transfers of EUAs among installations in different member states – in this way, the EU Commission would be able to block transfers from any member state that failed to gain approval of its NAP.

The Linking Directive

Another important design feature of the Emissions Trading Scheme is the *Linking Directive*, which was formally adopted in 2004. Up to a certain limit, it allows entities to comply with emission caps by submitting qualifying credits for emission reductions accomplished outside of the EU through the CDM (since 2005) and JI mechanisms (since 2008). Credits generated from certain CDM activities such as those from projects associated with nuclear power or CO_2 sinks were not allowed. Figure 9 illustrates the role of the Linking Directive.

The Linking Directive provided a strong stimulus for the development of CDM projects, and made their use an important means of compliance in the EU ETS. It helped to accelerate the carbon marketplace, i.e., the EU ETS provided demand in 2005, and the Linking Directive allowed the Kyoto Protocol's flexible mechanisms to provide supply. Thus, the carbon market was up in 2005–2006 and running well before the Kyoto Protocol's first commitment period.

As the EU ETS Phase I went into effect on January 1, 2005, a price between 8€ and 12€ a ton emerged for EUAs in the EU ETS market. Prices then climbed to over 30€ a ton for several reasons, including a cold winter spell in early 2005, a dry summer in southern Europe, and high natural gas and oil prices that made coal more attractive. Another reason was that companies with installations that were short allowances and needed to cover their emissions were disproportionately greater in number than those that held long positions (Ellerman and Joskow 2008).

In April 2006, however, within a span of a week, EUA prices fell sharply from over 30€ a ton to 20€ for Phase II EUAs and 15€ for Phase I EUAs. The precipitating event was the very first reporting of 2005 emissions by several member states, with emission levels that were significantly less than expected. For the trial period, allowances had been distributed based on an *estimate* of aggregate emissions, rather

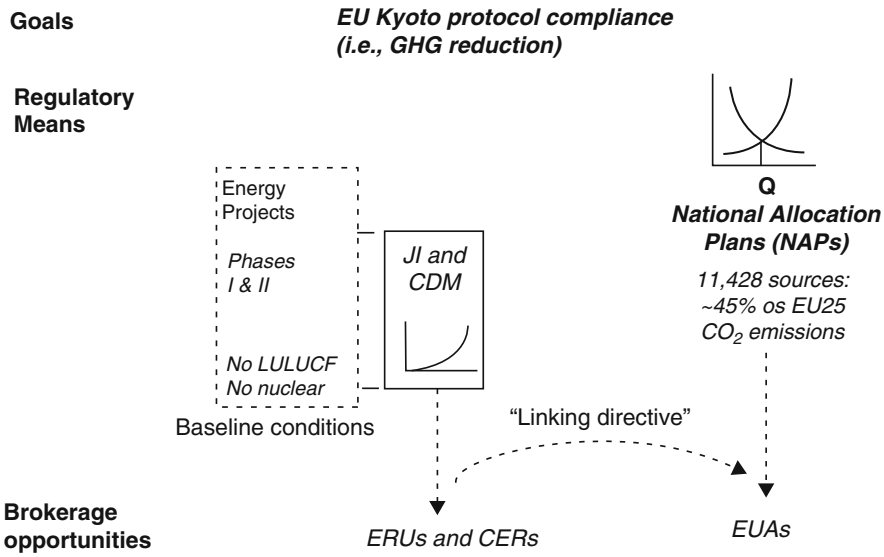

Fig. 9 The EU ETS linking directive

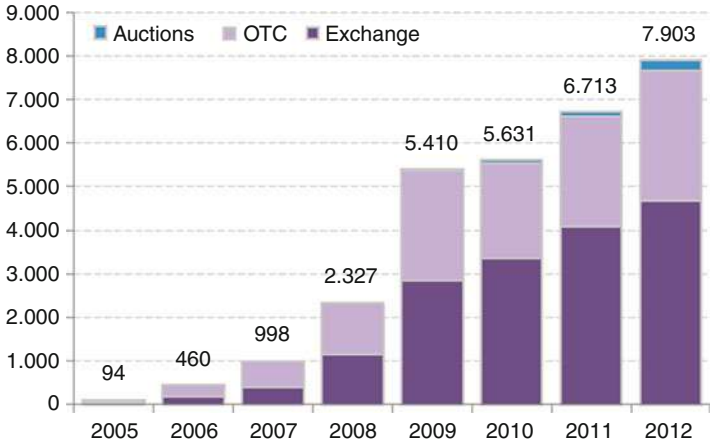

Fig. 10 Trading volumes in EU emission allowances (in millions of tons) (Source: EC 2013; Prepared by Bloomberg New Energy Finance, with data from Bloomberg, ICE, BlueNext, EEX, GreenX, Climex, CCX, Greenmarket, Nordpool; other sources include UNFCCC and Bloomberg New Energy Finance estimations)

than actual emissions. In addition, the restriction on trading between Phases I and II caused prices to decline sharply after September 2006, effectively making trading during the trial period self-contained. OTC markets were the dominant form of trading during the first years. However, trading in organized exchanges has gained popularity over time, and in 2012 it supported greater than three-fifths of trades (see Fig. 10).

From 2013, auctioning is the default method of allocating allowances within the EU ETS, and more than 40 % of allowances were auctioned in that year. Two auction platforms are in place: the European Energy Exchange (EEX) is the common platform for the large majority of countries participating in the EU ETS; a second auction platform is ICE Futures Europe (ICE) in London, which acts as the United Kingdom's platform.

Ultimately, the "learning by doing" phase did exactly what it was expected to do – it established the necessary infrastructure and created a carbon market for the free trade of emission allowances across the EU. There were several lessons learned from the exercise: the lack of verified emissions data caused difficulties in setting compliance targets; the free distribution of allowances resulted in windfall profits for several power companies, who received allowances for free, yet charged electricity consumers based upon their market price; and the haphazard release of emissions data by individual governments was problematical, since market positions could be affected by such information. The process for setting the cap made it difficult to ensure scarcity in the market, given the uncertainty about the emissions data, as well as the fact that national governments were under considerable pressure from companies not to be too stringent – after all, their competitors in the US, China, and other major economies were not operating under such constraints. The total EU-wide allocation in Phase I was estimated to be only 1 % below projected "business as usual" scenarios. In fact, during 2005, 2,088 million allowances were issued, but actual emissions were only 2,007 million tons resulting in 80 million surplus allowances (Baker and McKenzie International 2008). These issues were addressed in the design of subsequent phases of the EU ETS.

EU ETS Phases II and III

The EU ETS Phase II was in operation in 2008–2012 and coincided with the Kyoto Protocol's first commitment period. Phase II had a number of changes from Phase I; one of them was the inclusion of Norway, Iceland and Lichtenstein (1.1.2008).

Phase II removed the *force majeure* provisions, and raised the auctioning limit from 5 % to 10 %. The penalty for noncompliance increased from 40€ to 100€/t CO_2e. More installations were covered in Phase II, including hydrocarbon cracking units, carbon black, flaring, furnaces, and integrated steel works. Importantly, targets specified in the NAPs reflected actual 2005 reported emissions, as opposed to estimates (i.e., the case in Phase I). Moreover, in order to ensure that a significant portion of the expected emission reductions occurred within each country, the use of CERs and ERUs for meeting compliance requirements was limited within the ETS Phase II as a percentage of the allocation to an installation.

Despite the fact that the number of allowances was reduced by 6.5 % for Phase II, the economic downturn cut emissions (and thus demand) by an even greater amount. This led to a surplus of unused allowances and credits, which continues to weigh upon the carbon price (see Fig. 11).

Phase III of the EU ETS contained reforms designed to make it a more efficient, harmonized and a fairer trading system. Among the major changes in Phase III, NAPs were abolished in favor of an EU-wide cap, and a progressive shift towards

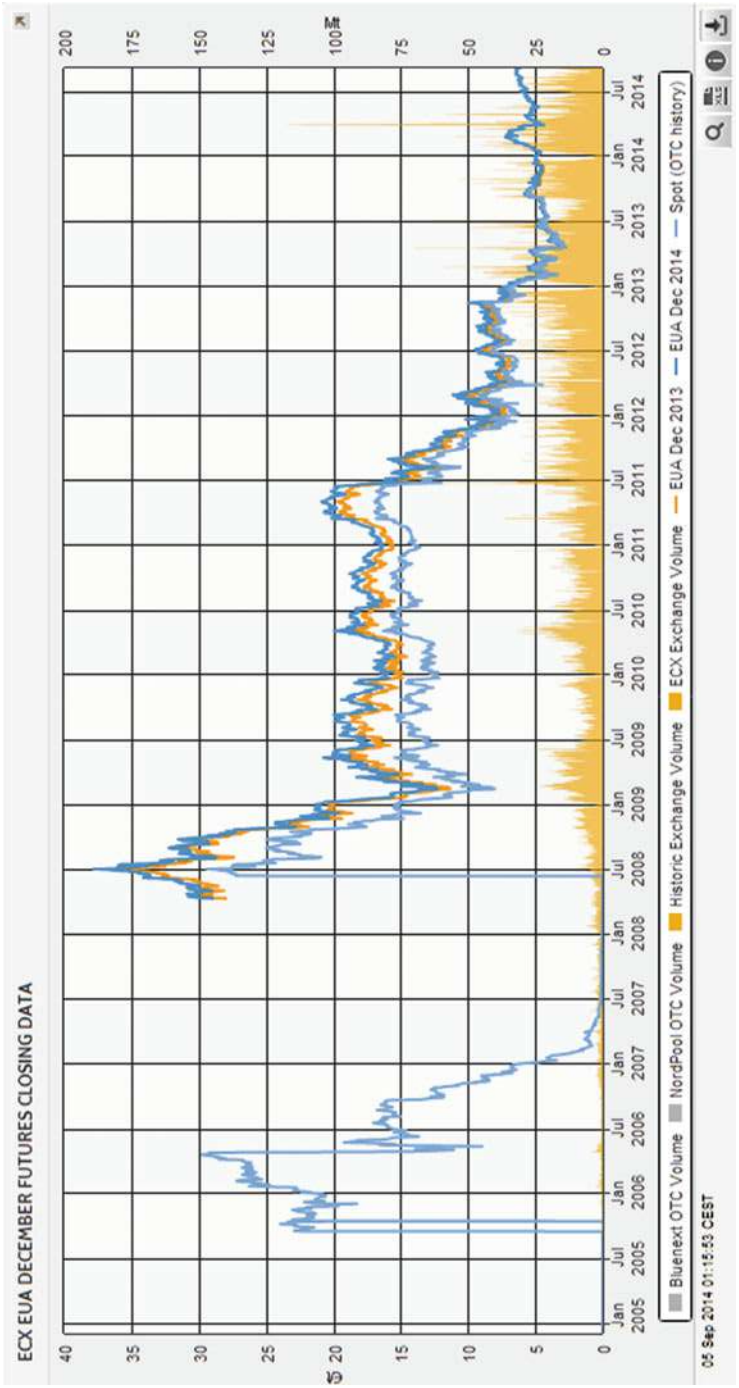

Fig. 11 ECX EUA December Futures Closing Data (Source: Point Carbon – Europe 2014)

auctioning of allowances has replaced cost-free allocation. In 2013 more than 40 % of all allowances in the system were auctioned. The EU legislation set the goal of phasing out free allocation completely by 2027. The cap currently decreases every year by 1.74 % of the average total quantity of allowances issued annually in 2008–2012. Thanks to this decreasing cap, in 2020 emissions from fixed installations will be 21 % lower than in 2005. Croatia joined the EU ETS in 2013, and, in addition to CO_2, nitrous oxide emissions from the production of nitric, adipic, glyoxylic acid, and perfluorocarbons from the aluminum sector were included in the scheme. Allowances for these sectors were given free in the same manner as other sectors already covered. Carbon capture and geological storage was also added. The power sector is subject to full auctioning, but may receive free allowances for district heating and high-efficiency cogeneration activities. For auctioning purposes, 88 % of the allowances are distributed on the basis of the member state's share of historic emissions under the EU ETS – but for purposes of solidarity and growth, 12 % of the total quantity is also distributed in a manner that takes into account GDP per capita and the achievements under the Kyoto-Protocol.

The EU ETS faced considerable problems when it tried to add the aviation sector, a sector not addressed until 2012. Initially all flights from and to EU-28 airports and Norway, Liechtenstein and Iceland (European Economic Area; EEA) were to be included in the EU ETS after January 2012, but this was met with fierce opposition from other countries. In November 2012, the EC therefore issued a "Stop the Clock" amendment, which exempted international flights to and from all EEA countries for a period of 1 year. This allowed time for the International Civil Aviation Organization (ICAO) to develop a global market-based mechanism, and present it to the General Assembly in October 2013. No agreement was reached in the ICAO meetings, however, and after further negotiations the European Council and Parliament decided in March 2014 to extend "Stop to Clock" until 2016. This limited aviation emissions covered within the EU ETS to flights operated solely within the EU for the period from 2013 to 2016. The European Parliament voted in favor of this extension on April 3, 2014, and it was published April 30, 2014 in the Official Journal of the European Union.

The overall use of CDM and JI credits was capped at 50 % of the EU-wide emission reductions over the period 2008–2012, and 50 % of the EU-wide reductions below 2005 levels of new sectors and aviation for the period 2013–2020. In November 2013 the EC set the maximum permitted use of international credits equal to 1,600 to 1,700 million international credits for 2008–2020. Facility operators used 1,059 million Kyoto credits in Phase II, and swapped 133 million Kyoto credits in 2013, leaving room for the use of 400–500 million international credits to meet their compliance obligations up to 2020. Given the low CER prices and the CER–EUA spread, most of the limit for international credits is expected to be used up in the beginning of Phase III. Since 2009 the EU ETS has experienced a growing surplus of allowances and international credits compared to emissions. By the end 2013, there was a surplus of 2.1 billion allowances in the market. This surplus significantly weakened the carbon price signal. EUA prices remained depressed, in the range of about US $5-9 (4–7€) in 2013, contrasting with US$18 (13€) in 2009–2010 (World Bank 2014).

The European Commission has undertaken an initiative to postpone (or 'back-load') the auctioning of 900 million allowances until 2019–2020 as an immediate first step. Back-loading does not reduce the overall number of allowances to be auctioned during Phase III, only the distribution over the period.

Phase IV and the 2030 Framework for Climate and Energy Policy

The 2030 policy framework for climate and energy proposed by the European Commission in January 2014 targets a reduction of EU domestic greenhouse gas emissions by 40 % below the 1990 level by 2030. This target is in line with European objective of cutting emissions by at least 80 % by 2050. EU leaders agreed on this 2030 policy framework in October 2014.

To achieve the overall 40 % target, the sectors covered by the EU ETS would have to reduce their emissions by 43 % compared to 2005. A sustainable solution to the imbalance between supply and demand requires structural changes to the EU ETS. The Commission proposes to establish a market stability reserve (MSR) at the beginning of Phase IV in 2021. This reserve would address both the surplus of emission allowances and the supply of allowances to be auctioned. To address the market imbalance a faster reduction in the EU ETS cap was proposed. The cap will need to be lowered by 2.2 % per year from 2021, compared with 1.74 % currently.

The EU ETS remains the largest carbon market compared to other markets (e.g., China's ETS) or market segments (such as the CDM and JI), accounting for over three-quarters of international carbon trading in 2013. In the EU ETS market, 7.9 billion allowances were traded in 2012 with a total value of 56€ billion (EC 2013). The economic recession in Europe and elsewhere in 2008 and 2009 led to lower demand for housing, cement, automobiles, steel, etc. As demand and commodity prices collapsed, cement and steel companies substantially cut back their production and power consumption. Emissions were therefore lower, as was the need to purchase carbon allowances. Higher supply and lower demand for allowances brought substantially lower prices for EUAs, and although there has been some rebound in 2010, prices remain well below pre-recession ones.

The EU ETS was the very first emission trading regulatory scheme for GHG emissions in the world. Today there are numerous other emission trading systems in place, learning from the EU ETS experience. It is clear that the difficult economic period faced in Europe after 2008 affected both quantities of allowances within the market, and the resulting low prices. Even as the EU ETS became more informed about emissions from the regulated entities (thanks to the registries), it was not able to respond quickly enough to changes brought about by shifts in the global economy. With the new back loading provisions, the CO_2 price should be stabilized during Phase III but at a relatively low price (below 10€/t CO_2). This price will not provide for important decarbonization investments necessary within the economy. With the proposed MSR mechanism, the hope (or fear, to some) is that higher CO_2e prices will become real – perhaps in the range of 48.3€/t CO_2 in 2030 (in nominal terms), according to one forecast (see Fig. 12) (Thomson Reuters Eikon 2014). One recent review of the EU ETS evaluated both the backloading and MSR mechanisms, and viewed both as positive contributions; but it noted that while incentives to abate

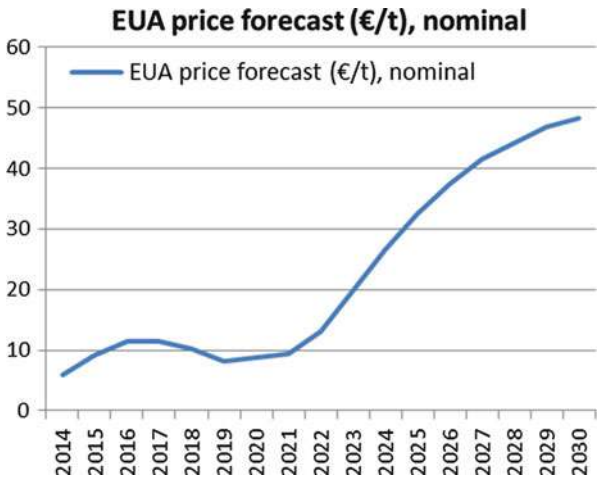

Fig. 12 2014–2030 EUA price forecast (€/t) (Source: IFPEN from Thomson Reuters Eikon 2014)

carbon are growing, they remain very weak. "The one over-riding, inescapably dominant feature of the ETS is its surplus" (Sandbag 2014).

China's ETS

Energy-intensive high-speed growth fueled by a coal-dominated energy mix has made China the world's biggest emitter of greenhouse gases. China has ratified the Kyoto Protocol; however, as a non-Annex I, developing country it is not obligated under the terms of the Protocol to set a specific carbon reduction target. Nonetheless, concerned about runaway emissions and already grappling with the effects of climate change (only projected to intensify), China has sought to take climate action by constraining its carbon emissions. China's 12th Five Year Plan (FYP) (2011–2015) set a carbon intensity reduction target of 17 % from 2010 levels by 2015. Under the leadership of the country's most powerful central government ministry, the National Development and Reform Commission (i.e., NDRC), which is responsible for leading national climate policy, China has begun developing a national market for carbon trading. The country has experience with emissions trading, having experimented with SO_2 trading in the 1980s and 1990s with US support. It has also been the world's leading supplier of CERs under the CDM. Nonetheless, the challenges involved in establishing a national carbon market within a still-developing country, in a rapidly growing economy still undergoing a transition from centralized planning towards a market-based approach cannot be overstated.

Rather than designing a carbon market from the top down through a unified national scheme, carbon market development in China has been initiated as a bottom-up and incremental process. To draw a parallel with the European ETS, China similarly began development of its carbon market with a trial process. Unlike Europe, however, carbon market development has centered on the implementation of experimental local markets, with trading to be scaled up nationwide only after all pilot markets have started accumulated experience (Kong and Freeman 2013).

The NDRC launched the development of carbon markets in China with its "Notice on Carbon Emissions Trading Pilots," announcing in October 2011 that it had selected seven diverse geographic locations across China. The seven pilot regions included two provinces and five cities. The goal of this first phase of China's carbon market development was to have trading underway in all seven pilot markets within approximately 2 years. Only after all pilot markets had begun trading in mid-2014 did the Chinese government commit to having a national carbon market in place by 2016 (Chen and Reklev 2014b). At the time of writing, China's ultimate national carbon trading scheme is still in the design process. There is limited information about what the national carbon market's design will look like, how it will be implemented, and what role the pilot projects will play in a scaled-up trading system. Certainly, the lessons learned during the pilot phases, and the effects of alternate designs, will influence the national program.

With NDRC encouragement, other regions have already begun the process of establishing their own local carbon markets (China Carbon 2014). One of the pilots, Guangdong, is considering linking to other regions, with the goal of designing an interprovincial market (Munnings et al. 2014). This suggests that China may opt for a national trading system that gives local governments the primary responsibility for administering and managing trading within their regions, with the central government setting national standards, including a national legal framework and exercising final authority over local allocation plans (Swartz 2013). Before a national trading system can be successfully established, however, a number of significant structural and policy factors will need to be addressed. If optimistic scenarios prevail, China's carbon market will be the largest in the world, with coverage estimated at 4 billion $MTCO_2$ and an aggregate value of USD 65 billion by 2020, according to NDRC projections (Bifera 2014).

China's ETS Phase I

The NDRC's pilot approach to developing a carbon market in China followed a tried and true approach associated with other significant reform initiatives in the country, as it has "marketized" its one-time command economy by beginning with local experiments. The seven pilots selected by the NDRC and announced in 2011 comprised the cities of Beijing, Shanghai, Tianjin, Chongqing, and Shenzhen, and the provinces of Guangdong and Hubei – locations representative of China's geographic and economic diversity. Estimates vary, but most indicate that the pilot regions cover roughly 1.3 billion $MTCO_2$ in aggregate. In accordance with a local decomposition of the national carbon intensity reduction goal, each pilot region set a different emission intensity reduction target for 2015 compared to 2010, ranging from 15 % of CO_2 for Tianjin and Shenzhen to 17 % for the same period for Hubei, 17 % for Chongqing, 19 % for Shanghai, and 19.5 % for Guangdong (Mao 2014). Local authorities in pilot regions were made responsible for undertaking all aspects of carbon market development, including distributing emissions allowances, creating registries for tracking allowances and emissions, and developing the monitoring and verification standards and procedures integral to a functioning market.

Absent a national standard, every pilot has followed its own path to establishing its market, with the result that each trading scheme has discrete features (see Table 1). Some of these differences reflect the diverse economies of the regional economies represented by the pilots, which vary significantly both in terms of economic structure and by level of development (see Table 2). For example, the share of the tertiary sector in the GDP of the coastal city of Shenzhen, the first of China's special economic zone (SEZs) opened in 1979, was about 52 % in 2012, but only around 36 % for the inland city of Chongqing. It is notable that the order in which trading got underway loosely mirrored the level of economic development of the regions. Shenzhen, with the highest per capita GDP of the group (at approximately USD 22,000 in 2013), launched trading in June 2013; the western province of Hubei and city of Chongqing, with per capita GDPs around USD 7,000 (Statistical Communiqué 2013), were the last two regions to begin trading in April and June 2014 respectively.

The diversity of market design across the seven regions was also reinforced by limited information sharing among them, as each competed to roll out a design that might potentially be selected as a national model or win designation as the central trading platform for a national scheme. There are differences among the local schemes along multiple dimensions. The percentage of emissions covered differs across regions, ranging from 60 % of total estimated regional emissions in Tianjin at the upper end, down to 35 % in Hubei. In addition, some pilots (Beijing and Shenzhen) have passed legislation to structure local cap-and-trade, while others rely on various types of administrative guidelines. There is also considerable variation in the way that the emissions caps are set and in the quantity and structure of offsets (which may be a percentage of emissions or allowances). Regions with relatively small industrial economies and substantial service sectors, like Beijing and Shenzhen, require some companies in the service sector to take part in carbon trading. Beijing includes major public buildings, for example; Shenzhen includes 197 large buildings. Compliance is also enforced by both penalties and incentives that vary across the pilots. Penalties may involve fines and or reductions in the number of free permits in the subsequent year. Incentives include such benefits to firms in compliance as priority access to national funding for low-carbon development, a strategy deployed in Guangdong, for example (Munnings et al. 2014).

The scope of "nonregulated" players able to take part in trading also varies across regions. Most pilot markets do not allow investors and other entities that are not covered by the trading scheme to engage in trading. However, this is not the case for Shenzhen and Tianjin, which do permit financial institutions and other entities not mandated to participate in the trading scheme to take part (Song and Lei 2014). Finally, most pilots do not mandate absolute emission reductions. Beijing is the exception, requiring absolute annual emission reductions for existing facilities in both the manufacturing and service sectors. Other pilots set other types of targets: firms in Shenzhen, for example, are required to reduce their carbon intensity per unit of Industrial Added Value (gross domestic product GDP due to industry) by 32 % below 2010 levels by 2016, keeping their absolute annual emissions growth to less than 10 %, with 2013 as the baseline (Song and Lei 2014).

Despite the variation among them, the seven pilots also share many fundamental features. All pilots include both indirect and direct emissions of carbon dioxide (ICAP 2014b). Most pilots use grandfathering as the principal method by which to allocate initial allowances (PMR 2014). Nearly all pilots distribute allowances for entities mandated to participate in the cap-and-trade system at the beginning of a compliance year without a charge. (In Shenzhen and Guangdong, however, a small number of allowances are also allocated via fixed-price sale or auction (King and Wood Mallesons 2014).) The majority of pilots allow offsets that may or may not include CCERs and other offset types (such as Hubei, which includes forest offsets from within the Province; Chongqing is also considering doing so). Finally, most, with the exception of Shenzhen, which bases its cap on a set of criteria, set their cap based on a minimum quantitative level of carbon emissions.

Carbon trading transactions reached approximately USD 140 million by September 2014 (Carbon Eight Group 2014). Every pilot region has its own carbon exchange; membership in the exchange is a prerequisite for trading. Allowances are tradable only in the regional exchanges. During the first year in which trading took place, price volatility was a feature of most of the pilot regions. Prices also varied considerably from one region to the next, not surprisingly, given the variation in design and economic structures among the pilot markets (see Fig. 13). Trading volumes have also been quite low. As one study points out, Shenzhen, which has been the most active of the pilot markets, traded just 4 % of the total allowances available in its market during his first compliance year (Munnings et al. 2014). Pilots have been experimenting with ways to boost liquidity. To date, Chinese authorities have prohibited futures contracts in carbon trading out of concerns that doing so would invite destabilizing speculation in its financial markets. However, Guangdong, Tianjin, and Hubei have allowed some investors to trade permits with entities bound by emissions limits. Shanghai allows registered institutional investors to trade permits; Shenzhen plans to allow foreign investors to do so, reportedly allowing trading in foreign currency (Chen and Reklev 2014b).

Fig. 13 Prices for Chinese ETSs, July 2013–October 2014 (Source: Bifera 2014)

China ETS Phase II

The announcement by a senior climate policy official from the NDRC in late August 2014 that China would launch a national carbon market by 2016, with regulations for a national market to be sent to the State Council for approval by the end of the year, was an unequivocal commitment by China's central authorities to scale up carbon market development (Chen and Reklev 2014b). Launching a national carbon market would be an ambitious undertaking for even the most developed economy; to implement cap-and-trade on a nationwide scale for a transitional economy the size and complexity of China's requires authorities to tackle numerous challenges. They must not only arrive at a functional design but also construct the institutions necessary to create a national market for buying and selling carbon. Doing so requires substantial numbers of technically capable trained personnel along with regulatory institutions that can set emissions caps, support an emissions trading registry, and monitor trading and enforce compliance. Pilots have taken on these challenges at the local level. However, as will be discussed below, the development of regional schemes has also revealed the challenges of designing an effective market in a political-economy in which transparency is limited. For a market to function, an accurate accounting of carbon emissions must be made in order for legitimate transactions to take place. China's official data collections systems are highly opaque, a feature that must be adjusted for cap-and-trade to work. Specifically, a national MRV system capable of inspiring confidence in trade for an intangible commodity must be developed (Kong and Freeman 2013). In short, on the institutional front, as China's proposal for market readiness observes, what is required is a "reliable statistical system, effective program management system and necessary laws and/ or regulations." (PMR 2013). The latter includes the passing by the National People's Congress of a national environmental law that defines carbon as a commodity and explicitly enables enforcement of compliance by regulated firms (Munnings et al. 2014).

In addition to institutional development and implementation, it is also necessary that the central government determine which specific sectors will be covered by the national carbon market, with an eye to future emissions trends, mitigation potential, and other factors such as international linkages (PMR 2013). China has already published monitoring and reporting guidelines for the national level, covering ten sectors: power generation, power transmission and distribution, aviation, cement, ceramics, flat glass, electrolytic aluminum, magnesium smelting, chemicals, and iron and steel. Among the considerations to be addressed are the development of policies to mitigate potential constrains on firm competitiveness and leakage from cap-and-trade; ways of encouraging liquidity without excessive risk to China's fragile financial system; and management of potential new entrants to ensure that increased participation does not add to carbon emissions (Munnings et al. 2014).

China ETS Challenges and Opportunities Ahead

China's bottom-up approach to carbon market development offers numerous lessons for the NDRC as it moves forward. However, the differences among the protocols established for measuring emissions among pilots alone reflects a heterogeneity which will pose challenges to future efforts at harmonization. The seven pilots applied different rules for monitoring, reporting, and verifying emissions; however, a national market requires a single set of enforceable procedures (Kong and Freeman 2013). Chinese authorities, led by the NDRC, are in the process of drafting a National Climate Change law that could provide a legal foundation for a national trading system. The NDRC has also published guidelines for some industries to date but a national registry for greenhouse gas emissions is still under development (Song and Lei 2014). Moreover, for a cap-and-trade system to function, China must develop a system for data reporting, and for collecting greenhouse gas emissions data about industrial sources that is transparent. In addition, China's lack of a well-developed legal system means that compliance by individual firms is heavily dependent on administrative enforcement, which in turn relies on the capacity and will of local authorities to do so. Currently, local officials' (cadres') promotion opportunities are closely linked to economic growth. China's central authorities will have to complete the retooling of China's "cadre evaluation system" to increase the effectiveness of local implementation, as they move ahead with legal development in the country.

Other key systems structuring China's economy also require reform and development for a national cap-and-trade system in China to function effectively. First, reforms are needed in how China manages power pricing. Currently, there are centrally-determined price caps on electricity in place that prevent power producers from passing on the cost of carbon to consumers. This explains why local pilots exclude the power sector or limit coverage to implied (i.e., emissions divided by activity) rather than direct emissions from power consumption. To fully bring the power sector– among the largest sources of carbon emissions in China – into the carbon trading system, difficult national policy changes in this area will be required (Kong and Freeman 2013). Second, China's financial system remains undeveloped and fragile. Concerned about risk, China's NDRC took futures trading off the table

of options for local carbon trading pilots' design. However, most experts see trading in derivative products as necessary for China's carbon market to have the liquidity to be an effective tool in reducing the cost of cuts to emissions (Song and Lei 2014). China's authorities are actively engaged in pushing reforms in the financial sector that will bring it into line with more mature economies; however, this process is a delicate one that will take time. Finally, national tools must be developed to mitigate against the potential for carbon leakage. This requires the ability to assess the risks of leakage accurately so that provisions can be made for regulated enterprises subject to this risk – something the European cap-and-trade system does through rebates in the form of allocations (Munnings et al. 2014). These are just some of the tasks ahead for China as it develops carbon trading on a national scale. Thus, while China's pilot markets mark significant progress toward the development of cap-and-trade, the country still has a long way to go to build an effective national carbon trading system.

US Carbon Trading Programs

While the US played a key role in introducing emissions trading through its ETP and acid rain regulatory programs, and also introduced the market-oriented approach into the Kyoto Protocol, the Bush Administration's withdrawal from the Kyoto process in early 2001 led to a significantly diminished role for the country. European countries, initially quite skeptical about emissions trading, assumed the lead with the launch of the EU ETS in January 2005.

The US did not pursue national carbon trading during the Bush administration, but expectations grew as the 2008 elections approached, because all three major candidates – Hillary Clinton and Barack Obama on the Democratic side and John McCain on the Republican one – espoused support for cap-and-trade legislation during the Presidential campaign. The build-up to the Copenhagen meeting thus assumed that the US would rejoin international efforts, and perhaps link its own national carbon market to ongoing EU ETS and Kyoto Protocol efforts.

Such enthusiasm was enhanced when the American Clean Energy and Security Act (ACES) passed the US House of Representatives less than 6 months after Obama's inauguration in January 2009. It contained an allowance-based program that required a 17 % CO_2 reduction by 2020 (from a 2005 base year) and an 83 % reduction by 2050. Often referred to as the Waxman-Markey bill (after its two principal sponsors), ACES provided for the use of international offsets and also included an allowance price floor. Very similar legislation, entitled the American Power Act (APA), was submitted to the US Senate by Senators Kerry and Lieberman in May of 2010 – but a special election in the State Of Massachusetts earlier that year meant that the Democrats no longer had a "filibuster-proof" Senate (i.e., a Senate able to pass legislation over the objections of Republicans).

The overwhelming Republican victory in mid-term elections later in 2010 ensured that such cap-and-trade legislation would not be enacted at the national level, and that party's efforts have since then focused on rolling back existing environmental legislation (and US EPA's budget) rather than passing new mandates. Prospects for new emissions trading legislation thus appear quite bleak; as one recent

article in *Foreign Policy* noted: "Congress will never pass cap-and-trade, at least until Miami starts flooding" (Galbraith 2014).

Despite such problems, market-oriented GHG control efforts continued at the state level (in California); at the regional level (in the Northeast's Regional Greenhouse Gas Initiative [RGGI]); and even at the national level, through previous legislation initially designed for CAC regulation. These three levels of programs in the US are described below:

California's Emissions Trading Program

California's cap-and-trade program is a result of the California Global Warming Solutions Act of 2006 (AB 32), which required the state's Air Resources Board to develop regulations and market mechanisms to cut the state's GHG emissions back to 1990 levels by 2020 – a reduction of approximately 25 %. Its emissions trading program is thus part of a larger regulatory effort (including a Low Carbon Fuel Standard as well as other energy efficiency standards) to achieve that target.

The market-oriented program went into effect in January, 2012, with compliance obligations beginning 1 year later. The first two compliance years focus solely on electricity and industrial sectors, but the program will expand after that to include transportation and heating fuels (see Fig. 14). It is thus the first multisector carbon trading plan in the US, and given its emissions coverage, is second in size only to the EU ETS.

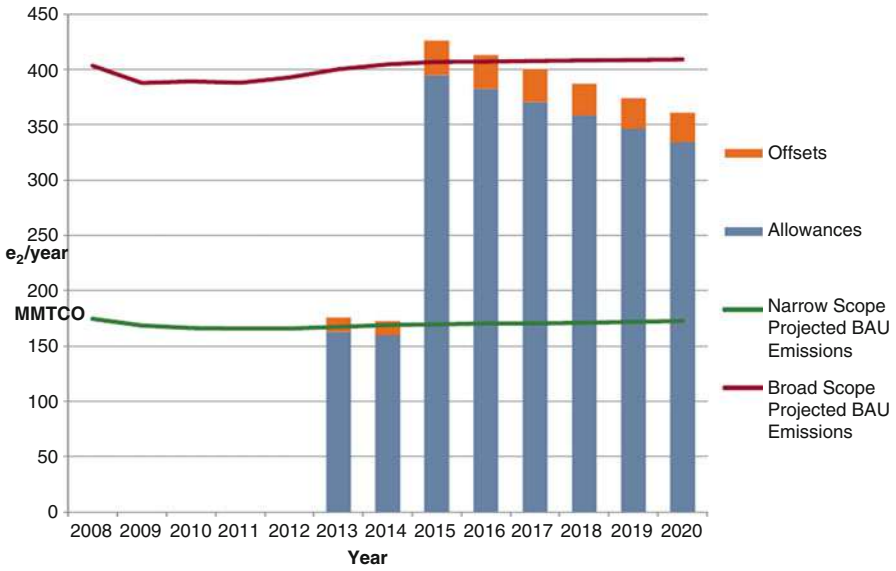

Fig. 14 California's GHG Cap compared with BAU projections (Source: Center for Climate and Energy Solutions 2014; adapted from CARB 2010)

The market covers the same six pollutants as the first commitment period of the Kyoto Protocol, as well as NF3 and other fluoridated gases. It covers approximately 350 business (with 600 facilities), and has been designed to link with similar trading programs in other states and regions.

The California market has several notable features, including both cost containment and market flexibility mechanisms. There is an auction floor price (starting at $10 per allowance in 2012, rising at 5 % above inflation annually) and a strategic reserve (rising from 1 % to 7 % over time, with higher tiered prices similarly rising at 5 % above inflation). There are thus both floor and ceiling mechanisms in place to contain prices (as long as there are sufficient allowances in the reserve).

There are three compliance periods: (a 2-year period [2013–2014]), followed by two 3-year periods [2015–2017 and 2018–2020]). At the end of every year, a source must provide allowances and offsets to cover 30 % of its previous year's emissions. Then, at the end of each compliance period, it must provide the remaining allowances and offsets. This provides sources with the ability to cover any annual variation in product output. If the source does not do so and is not in compliance, then four allowances must be surrendered for every ton not covered within the compliance period.

Offsets are allowed in the California program, but were initially restricted to US emission reduction projects from four targeted types: forestry; urban forestry; dairy digesters; and the destruction of ozone depleting substances. A linkage with Quebec's emissions trading scheme began in January 2014, and linkages with other systems are ultimately expected to occur as well.

Regional Greenhouse Gas Initiative

The Regional Greenhouse Gas Initiative (RGGI) was the first regulatory US cap-and-trade scheme addressing GHGs. It was designed to reduce CO_2 emissions from power plants in ten Northeastern US states – although this was subsequently reduced to nine states when the Republican Governor of New Jersey withdrew his state from the program in 2011.

RGGI is a regional program, but it is implemented through legislation adopted by each individual state. A "Model Rule" was drafted in 2006 and finalized in 2008, with requirements for individual facilities (i.e., fossil-fueled power plants greater than 25 MW generating capacity) beginning on January 1, 2009. RGGI initially sought to cap CO_2 emissions at a steady rate through 2014, and then drop them annually by 2.5 % – and thus achieve a 10 % reduction one decade later. A significant fuel shift towards natural gas at power plants in the region, however, coupled with lower electricity demand and increased levels of both nuclear power and renewables led to an overallocation of allowances. Prices reflected that, and the clearing price for allowances at RGGI auctions was often less than $2.

RGGI's target was revised when New Jersey left, and was then significantly changed as a result of a 2012 Program Review. The new cap called for a reduction of 45 % by 2020 (from 2005 levels), with a 2.5 % reduction occurring annually from the revised 2014 cap levels. This new Model Rule also introduced other provisions, including a Cost Containment Reserve (CCR), and an interim compliance period requiring sources to hold specific allowance levels in time periods before final

compliance dates (Bifera 2013). Most of the allowances in RGGI are sold through auctions, and the collected funds are dedicated for energy efficiency, renewable and clean energy, as well as bill support for low-income energy consumers.

RGGI allows offsets to achieve compliance, but only from five categories: (1) Landfill methane capture and destruction; (2) Reduction in emissions of sulfur hexafluoride (SF_6) in the electric power sector; (3) Sequestration of carbon due to US forest projects (reforestation, improved forest management, avoided conversion) or afforestation (for CT and NY only); (4) Reduction or avoidance of CO_2 emissions from natural gas, oil, or propane end-use combustion due to end-use energy efficiency in the building sector; and (5) Avoided methane emissions from agricultural manure management operations (RGGI n.d.).

Despite the significant drop in target levels in 2014, Fig. 15 shows that the actual emissions in recent years were not significantly above the new cap (i.e., 92 million short tons in 2012, just above the 91 million ton target in 2014). The cap will tighten in coming years, however, and it is not clear that the fuel shifts and other downward trends evident in recent years will continue. Thus, it is anticipated that the RGGI cap could become more binding in the future (EIA 2014).

The US EPA's Clean Power Plan

President George Bush promised to address CO_2 emissions during the 2000 Presidential campaign, but reneged on this shortly after taking office. In 2003, his Administration's EPA overturned a previous Clinton Administration decision, and declared that it did not have the authority to regulate CO_2 under the Clean Air Act – and further noted that it would refrain from doing so, even if it did have the authority. The State of Massachusetts and others filed suit against EPA for its failure to act, a suit which was subsequently decided in their favor in 2007 by the US Supreme Court. The Court ruled that EPA did have such authority, but the law required EPA to determine whether or not such emissions could reasonably be anticipated to endanger public health or welfare. In 2009, under the Obama Administration, US EPA issued such an "Endangerment Finding," and proceeded to issue new standards for light, medium and heavy duty vehicles in the following years. The Agency also proposed GHG standards for new power plants in 2012 and then revised and proposed them once again in September 2013.

On June 2, 2014, it proposed standards for existing power plants, under a program called the Clean Power Plan. Utility emissions are the largest source of carbon pollution in the US, accounting for roughly one-third of all domestic GHGs (EPA 2014b). The Clean Power Plan tackled this in two ways: (1) It set state-specific goals, which were based on achieving a level of carbon intensity in the state by 2030. This would have the effect of reducing CO_2 emissions from the power sector by 30 % (from a 2005 base) and (2) The EPA provided guidelines for the states in how they might achieve such goals.

Under the Clean Power Plan, states would have until June 2016 to submit plans to achieve these goals, with the possibility of a 1-year extension – or 2 years if states join together in a multistate plan. The states were also required to make "reasonable progress" in achieving such goals by 2020.

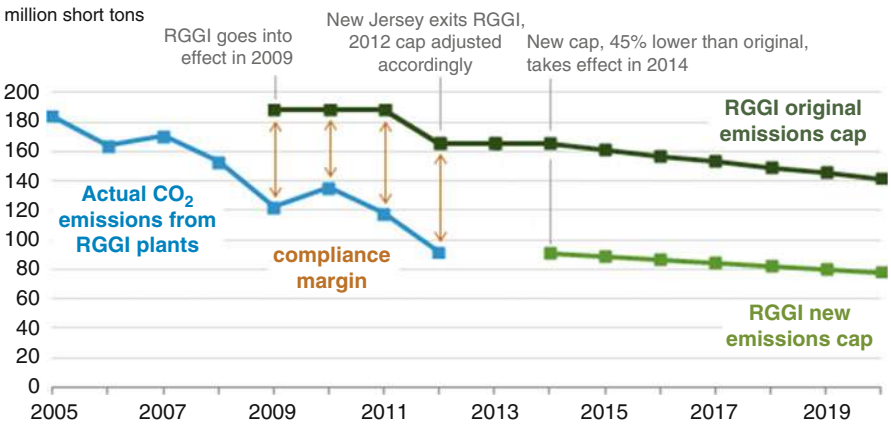

Fig. 15 Regional Greenhouse Gas Initiative CO_2 emissions cap vs. actual emissions (Source: EIA 2014)

Section 111(d) of the Clean Air Act requires US EPA to issue "standards of performance" reflecting the "best system of emission reduction" (BSER), and the Agency has used four "building blocks" of BSER to set the state-by-state goals: (1) heat rate improvements; (2) dispatch changes among affected units (e.g., coal to natural gas units); (3) expanded low- or zero-carbon generation (e.g., renewables and nuclear); and (4) use of demand-side energy efficiency, thereby reducing generation requirements.

US EPA has offered the states considerable flexibility in determining how they might meet their goals. They are able, for example, to:

- Look broadly across the power sector for strategies that get reductions
- Invest in existing energy efficiency programs – or create new ones
- Consider market trends toward improved energy efficiency and a greater reliance on lower-emitting power sources
- Expand renewable energy generation capacity
- Tap into investments already being made to upgrade aging infrastructure
- Integrate their plans into existing power sector planning processes
- Design plans that use innovative, cost-effective regulatory strategies
- Develop a state-only plan or collaborate with each other to develop plans on a multistate basis (USEPA 2014c)

Note that these last two options allow individual states to team up with other states if they choose – and also to employ market-based mechanisms to achieve their goals. Not only would this would allow them to accomplish their reductions in the most cost efficient manner – they will also get an extension on the time required to develop such an approach.

The Clean Air Act of 1970 is a piece of legislation now almost 45 years old, and its principal architecture was developed within the CAC framework. It was never

intended to tackle a problem as complicated and as comprehensive as GHG control. The failure of the political system to pass legislation (such as ACES or APA) means that it must now serve as the foundation for such control, given the fact that the problem is real (as indicated in the Endangerment Finding) and the courts have indicated that US EPA has the authority (and, indeed, the responsibility) to address it.

The US EPA has developed a creative regulatory approach that will allow states to utilize emissions trading, if they so choose – and to do so on a multistate basis. This plan will surely be modified in response to public comment, and must also survive the inevitable lawsuits when it is promulgated. Opponents have already attacked the Plan, based upon media reports that environmentalists played a key role in its development (Davenport 2014; Chait 2014). The final 111(d) rule is due to be released in June 2015, and while states must begin to make reductions by 2020, full compliance with the CO_2 emission performance level in the state plan must be achieved by no later than 2030.

Voluntary Carbon Market

In addition to the "compliance" markets discussed above, a corollary, voluntary market has developed that provides carbon trading opportunities for companies, individuals, and other entities not subject to mandatory limitations, but still wishing to offset their GHG emissions. As the name implies, the voluntary carbon market includes all carbon offset trades that are not required by regulation. Over the past several years, this market has not only provided an opportunity for consumers to alleviate their carbon footprint, but also provided an alternative source of carbon finance. The instrument of trading is called a Voluntary Emission Reduction (VER), although it should be noted that some market participants consider this acronym to mean "Verified Emission Reduction." While still very much smaller than the compliance market (<1 % in value), this voluntary carbon market has gained traction in recent years – although there was a downturn in 2013 in both market size and average price (World Bank 2014). Importantly, however, the voluntary market provided an outlet for forestry and land use–type projects that were excluded by the EU ETS.

The voluntary carbon market is not new – in fact, the world's first carbon offset deal was brokered in 1989, well before regulated carbon markets. AES Corp., an American electric company, invested in an agroforestry project in Guatemala to offset the GHG emitted by electricity production at one of their facilities in Connecticut. AES paid Guatemalan farmers to plant 50 million pine and eucalyptus trees on their land. The deal was voluntary and marked the beginning of this new type of carbon market (Bayon et al. 2007). Another early example was a program established in the late 1990s in Costa Rica to provide funds for reforestation and forest protection on private lands. This program sold carbon certificates called "Certifiable Tradable Offsets" (CTOs) to industrialized countries, and Costa Rica was able to pay thousands of private landowners to establish, protect, and manage

forest plantations on their lands. Nations such as Norway were invited to voluntarily purchase such CTOs for use in meeting their own compliance targets.

These programs were precursors to the provisions for afforestation and reforestation within the CDM. Two types of credits may be generated by Land Use Land Use Change and Forestry (LULUCF) within the CDM, specifically, afforestation and reforestation (A&R) projects. *Temporary credits (tCERs)* from such projects expire at the end of the commitment period following that in which they were issued, and must be replaced by the holder to ensure continuing carbon storage. *Long-term credits (lCERs)* expire at the end of the project's *crediting period*, as opposed to a tCER that expires at the end of the *commitment* period. The crediting period for an afforestation/reforestation project is the period for which net anthropogenic GHG removals by sinks are verified and certified by a DOE (CDM Rulebook 2008). Accordingly, the amount of tCERs issued equals the carbon stock of the whole project, whereas lCERs are only issued for incremental gains in the carbon stock. However, as noted above, the EU ETS' Linking Directive excluded CERs generated from forestry projects for use as offset credits within the Scheme. This is the primary reason that much of the forestry credits have been handled in the voluntary marketplace, rather than the compliance market. Offset credits from "Reduced Emissions from Deforestation and Degradation" (REDD) projects (and also REDD+ projects, which also include sustainable forestry management practices) have also found a home in the voluntary marketplace because they were not included in the Kyoto Protocol's first commitment period. There was a strong push for REDD and REDD+ projects to be included in the post-2012 agreement during COP15 in Copenhagen, but the prospect of a flood of credits from such sources has worried many carbon market proponents (see, for example, (KEA3 2009)). This issue remains as yet unresolved.

Buyers in the voluntary market are motivated by various reasons that are vastly different from those in the compliance market. Not having any binding emission reductions to comply with, companies in the voluntary market purchase credits to offset their carbon footprint for either Corporate Social Responsibility (CSR) reasons or for establishing better public relations with the community. Of the 100 largest economic entities in the world, 40 are corporations, not countries (Global Trends 2013), so voluntary commitments on their part are welcome. Firms in the retail or banking industry, for example, typically do not have a large carbon footprint, but have a high interest in demonstrating that they are socially responsible and "green." They are therefore major purchasers of voluntary carbon credits. Buyers also include individuals who are interested in being environmentally conscientious, and offsetting the carbon footprint of their lifestyles (including homes, cars, travel, etc.).

Voluntary markets initially had a "wild west" quality, and they experienced rapid growth that is now being tamed by verification/standardization. The verification and certification process is often the most important aspect of a product, since it determines the price that the VER from the project commands in the market. The generation of VERs for an offset project mimics the generation of CERs closely, and the quality of an offset project is usually evaluated based on the characteristics of

additionality, permanence (the project generates GHG emissions over a stated period of time), leakage (ensuring that the project does not transfer emissions to another location outside the project area), and co-benefits (benefits derived from the project over and above GHG reductions, such as habitat for biodiversity, contributions to local communities, etc.). In general, consumers prefer third-party verification to in-house verification for reasons of credibility. Major standards and certification programs used in the voluntary carbon markets are listed in the Carbon Offset Research and Education (CORE) website, a joint effort of the Stockholm Environment Institute and the GGH Management Institute (CORE 2011). Each standard has a slightly different focus in terms of project goals and addresses each of the above characteristics according to those goals.

The Verified Carbon Standard (VCS) is the most popular standard (VCS 2014), while premium carbon verification standards such as the Gold Standard tend to attract the highest prices for VERs accredited to them. VERs have typically sold at a discount to CERs or other compliance market project-based carbon credits, although the low prices across all instruments in the carbon market have led buyers to place additional focus on the co-benefits associated with their generation – a situation particularly relevant within the CSR-oriented voluntary market.

Voluntary carbon credits may be traded bilaterally, OTC, or in organized exchanges. Several exchanges throughout the world began with a focus on voluntary carbon trading, with the earliest one being the Chicago Climate Exchange (CCX). CCX was the world's first legally binding, rules-based GHG emissions trading system (Sandor 2012). It was important for several reasons, including the fact its owners spread the GHG carbon exchange approach to Europe (through its sister company, the European Climate Exchange [ECX]) and China (through a partnership with the municipal government of Tianjin and PetroChina in the Tianjin Climate Exchange). Members voluntarily joined the CCX, and agreed to a legally binding carbon reduction policy. It grew to include some 300 members, including 11 % of the Fortune 100 companies in the US, and 20 % of the country's largest CO_2 emitters. The CCX's unit of trade was the Carbon Financial Instrument (CFI), which represented 100 tCO_2e. CCX represented a significant fraction of the voluntary carbon market after the company's founding in 2003, representing more than 50 % of voluntary carbon trading volume in 2008. Its parent company (Climate Exchange Plc) was acquired by Intercontinental Exchange Inc. in mid-2010, however, and its emission reduction program closed at the end of that year. The CCX's offsets registry program has continued, however.

Many exchanges in developing countries began in the voluntary carbon market, with plans to become established and then play a much larger role in future compliance regimes. The China Beijing Environment Exchange (CBEEX), for example, is an environmental equity transaction institution authorized by the Beijing Municipal Government. In 2009, the CBEEX signed a deal with BlueNext to build a trading platform for carbon credits, and at the Copenhagen COP announced the Panda Standard, the first voluntary standard created specifically for the Chinese VER market. The CBEEX also traded the first VER transaction in China in August 2009. Today, as noted above, it is playing a key role in the country's compliance market.

Carbon Financial Derivatives

In anticipation of a price on carbon emissions and the associated market growth created by a cap-and-trade scheme, a number of financial instruments and derivatives based on carbon as a commodity have been developed. These have led to increased carbon trading activity in financial markets. While government officials are responsible for designing effective cap-and-trade systems, and polluters participate in the resulting market to comply with emissions constraints, carbon derivatives trading brings commodities traders, speculators, hedge funds, financial firms, and exchanges into the fray.

Derivatives are financial instruments whose cash flow is *derived* from an underlying instrument. There are several types of derivatives, including *future and forward contracts*, which are fundamental derivatives that represent an agreement to sell a certain commodity in the future at a fixed price; *options*, which are slightly more complicated derivatives where the buyer is given the right (but not the obligation) of purchasing the commodity depending on the price of the commodity in the future at a price (agreed upon at the present time), and *swaps*, in which two counterparties exchange certain benefits of one party's financial instrument for those of the other party's instrument.

Derivatives can be used for a variety of purposes. They can be used to hedge a transaction, (i.e., reduce risk exposure), and derivatives markets are thus risk transfer mechanisms. They facilitate the transfer of risk from those exposed to it but who do not wish to bear the risk (i.e., hedgers) to others not naturally exposed to it, but willing to bear the risk (i.e., speculators). Derivatives also contribute to price discovery; since individuals with information can buy or sell derivatives, their trades affect prices and these prices reflect their information. Derivatives may be traded bilaterally, or in the OTC market through brokers, or in organized exchanges such as the New York Mercantile Exchange (NYMEX).

Compliance carbon markets can also support the trading of such derivative products, including futures, options, and swaps. Currently, most carbon is sold in futures or forward contracts. These contracts contain promises to deliver carbon allowances or credits in a certain quantity, at a certain price, by a specified date. In the case of the EU ETS, the forward and futures markets have developed faster than the spot market. Approximately 95 % of the total volume in the European carbon market is seen in derivatives trades, with the remaining in spot trades. According to the ECX, this may partly be explained by the initial delay of national registries and final allocations in many of the EU member states, which prevented the execution of instant delivery for spot contracts. Another reason may be that in such a new and volatile market, derivative instruments are crucial tools to optimize the value of an emissions portfolio.

Carbon derivatives trading was severely affected by several factors in 2009. The economic recession slowed down manufacturing and other industries, causing reduced economic output, and hence lower emissions and a surplus of allowances. A large sell-off of EUAs started in September 2008, as companies realized that the allowances they had received at no charge could help provide liquidity, particularly

in the midst of a financial credit crunch. The EUA sell-off, mostly on the spot market, was followed by a discernible increase in trading of EUA options (more calls than puts, on average), showing the intent of some installations to hedge any anticipated 2008–2012 compliance exposure (World Bank 2010). Failure by governments to achieve a solid agreement on climate change negotiations in Copenhagen in December 2009 added to the downward trend of carbon markets, with carbon prices falling nearly 10 % (the biggest decline in 2009) immediately after the summit. The uncertainty about the future of emissions trading after the Kyoto Protocol's first commitment period expired in 2012, and the continued absence of a national cap-and-trade program in countries such as US, depressed prices even further. Reuters reported that the global carbon market would have reached $2 trillion by 2020 if nations had agreed to a new climate pact curbing greenhouse gas emissions and if the United States introduced its own federal cap-and-trade scheme (Reuters 2009). However, because neither case seemed probable, banks and investors started pulling out of the carbon market and emptying their carbon trading desks in early 2010 (Guardian 2010).

To make matters worse, the EU ETS was hit by a number of other significant controversies in Phase II. In December 2009, Europol announced that the EU ETS had been the victim of fraudulent traders over a period of 18 months, resulting in losses of approximately 5€ billion for several nations (Europol 2009). Traders would collect Value Added Tax (VAT) on carbon market transactions, but then not submit the collected revenue to national governments. They would then disappear without a trace, leading to the phrase "missing trader fraud" to describe the crime.

In early 2010, there were market disruptions because of the resale of two million surrendered CERs by the Hungarian Government. The Hungarian government first covered the CERs (which had been surrendered by Hungarian companies to comply with the emissions cap under the EU ETS) with AAUs because the CER price exceeded that of an AAU. They then signed a deal to sell those same CERs to a trading firm, and some of these "recycled CERs" eventually came back into the European market. A number of exchanges were thus forced to shut down, until the integrity of their CERs could be fully established and this loophole closed.

In 2010, there were also reports of "boiler room operations" that were selling emissions reduction credits (i.e., carbon offsets) as investments in the U.K. These are organizations that tend to target vulnerable or unsophisticated individuals with (often worthless) investment products using deceptive or especially aggressive sales tactics. The US-based Center for Resource Solutions has prepared a manual addressing such practices in the carbon market (Jones 2014).

The 2008 financial crisis caused by subprime mortgages and financial derivatives such as credit default swaps based on questionable risk profiles also raised other questions about carbon derivatives trading. For example, the potential for "subprime carbon" credits, i.e., relatively high-risk contracts to deliver carbon that might not mature to fruition (Chan 2009), was noted by some analysts. Carbon offset aggregators bundle small offset projects for buyers, and increased demand might give rise to exotic derivatives and structured products, similar to the situation in mortgage-backed securities. In November 2008, Credit Suisse announced just such a

securitized carbon deal in which credits from 25 offset projects were bundled. These were then securitized into three tranches of different risk levels and sold to investors. The 25 projects were at various stages of UN approval, and were spread across three different countries and five project developers (Chan 2009). Such off-balance sheet products, albeit profitable in the short-term, are highly risky and require close regulatory oversight. As the carbon market has contracted, banks and other financial institutions have withdrawn – and such arcane financial engineering has similarly declined. Regulators are also more diligent. China, for example, has limited its pilot projects to spot market transactions only in initial phases, in part to gain regulatory experience.

In May 2014, however, China General Nuclear Power Group announced that it would launch the first carbon-linked financial product, a debt note linked to the performance of carbon offsets on the Shenzhen Emissions Exchange (Chen and Reklev 2014a). The Shenzhen Emissions Exchange announced just a few months later (in August) that it would allow foreigners to trade on its exchange, although a date has not yet been set. Regulators thus face a challenge as carbon markets become increasingly sophisticated in emerging nations, to ensure that they offer stable and consistent financial systems, as well as ultimately satisfy the environmental objectives they are designed to accomplish.

Renewable Energy and Energy Efficiency Markets

While pollution presents policy makers with a *negative externality*, some energy technologies might be thought of as generating *positive externalities* because they are easily replenished and nonpolluting in nature, are decentralized, and can increase system resiliency, etc. While not the principal focus of this chapter, those interested in emissions trading should nonetheless be aware that a mirror image exists in the form of "positive externality" instruments. These typically provide support for renewable energy systems and energy efficiency and are growing in popularity.

Renewable Energy Certificates (RECs)

The market-based instrument employed in renewable energy markets is the Renewable Energy Certificate (REC), also called a *green tag* or *greencertificate*. It typically represents 1 MWh of electricity generated from a renewable energy source. A REC is an environmental commodity, and may be sold separately from the underlying electricity generated. Buyers can select RECs based on the generation source (e.g., wind, solar, geothermal), as well as the location of the renewable generator.

RECs may be used in both compliance and voluntary markets. In the US, compliance markets have been established by state Renewable Portfolio Standards (RPS), which require utilities to meet a certain quota of their electricity from renewable sources by a certain date. This quota is often increased over time, the converse of an emissions cap being lowered to reduce GHG emissions. An RPS

provides states with a mechanism to increase renewable energy generation using a cost-effective, market-based approach that is administratively and economically efficient. The goal of an RPS is to stimulate market and technology development so that, ultimately, renewable energy will be economically competitive with conventional forms of electric power.

Currently, 29 US states, the District of Columbia, and two US territories (i.e., Guam and the Northern Mariana Islands) have RPS policies in place, covering more than half of the electricity sales in the country. California, for instance, requires 33 % of its electricity to be generated from eligible renewable sources by the year 2020. Another nine states and two territories have nonbinding RPS goals (DSIRE 2014a). It is important to note that not all states permit REC trading for compliance with their RPS. An important feature of the REC compliance market in the US is that the goals differ from state to state; therefore, prices of RECs also differ. Compliance buyers are generally indifferent to the type of resource that created the REC, but are limited to the geographical area where the REC can be produced. The US Department of Energy's National Renewable Energy Laboratory (NREL) expects demand in the RPS market for renewable energies to grow from 22,296 GWh in 2008 to 156,527 GWh in 2015 (Bird et al. 2009).

European Union nations have established similar schemes to comply with an EU target of 20 % energy from renewable sources by 2020. In the UK, a scheme similar to the RPS has been set up where *Renewable Obligation Certificates (ROCs)*, each representing one MWh, are tradable green certificates issued to an accredited generator for eligible renewable electricity generated and supplied to customers within the country. Similarly, since January 2012 Sweden and Norway have had a common market for RECs. It was based on Sweden's "Electricity Certificate System" (established in 2003), and is designed to increase renewable energy production by a total of 26.4 TWh in the two countries between 2012 and 2020. The market is designed to be in place until 2035 (Energimyndigheten and NVE 2013).

There is also an active voluntary REC market, spurred by companies, government agencies and private consumers who have opted to support "green power" either by buying renewable energy directly, or through a variety of retail programs. In many cases, buyers purchase the "green attributes" of the REC associated with energy generation. Several factors motivate demand in the voluntary renewable energy market, including corporations seeking to differentiate themselves from competitors by environmental means, as well as environmentally-minded consumers of electricity. Although much smaller than RPS compliance markets, voluntary REC markets have been growing in the United States and in Europe.

The advantage of RECs in voluntary markets is that they can be sold unbundled from electricity, and so their market is national, while green power markets tend to be tied to local providers.

Prices of certificates from eligible renewable facilities under an RPS scheme (compliance RECs, or C-RECS) differ from RECS generated in the voluntary market (V-RECs) because the drivers of demand differ (Gillenwater 2008a, b), and prices can be considerably different (e.g., between $50 and $60 per MWh in the Northeastern US in 2011, versus less than $5 in Ohio and Texas). Prices for voluntary

RECs were below $1 per MWh for this same period, although RECs from wind projects in the West were somewhat higher (NREL 2012). Voluntary market purchases rely on certification programs to verify that the RECs were indeed generated by the renewable resource that is claimed, and that a REC is not sold to more than one buyer. The *Green-e* program is a nationally recognized standard that helps consumers identify environmentally qualified RECs.

The dynamics of linking renewable energy markets with emissions trading schemes brings up interesting questions and controversies. Because RES emit little-to-no pollutants, they are economically advantaged by any policy that puts a cost on emitting pollutants within the power sector. The issue of converting RECs to carbon offsets has produced heated debates in the voluntary carbon markets, especially in the US (Ecosystem Marketplace 2009). While the REC market essentially operates independently of the carbon market, RECs are sometimes viewed as tons of carbon dioxide avoided, and are sold into the voluntary carbon market as a carbon offset. The controversy in this practice revolves around the accuracy of carbon calculations, the additionality and ownership terms operating in different markets, and the potential for double counting in two markets with different (but often complementary) policy goals. Voluntary green power and GHG offset markets are not regulatory markets (by definition) and lack standardized commodities, resulting in a great deal of confusion for consumers wishing to offset their emissions associated with energy consumption. Because RECs are typically less expensive (mostly due to differences in additionality requirements) than offset credits, they are generally favored for purchase.

Renewable energy now represents more than 20 % of electricity production worldwide, and its share has been growing faster than conventional sources. RECs markets are therefore likely to play an increasingly important role.

Energy Efficiency Certificates (EECs)

Energy Efficiency Certificates (sometimes called *white tags*, or *whitecertificates*) are similar to RECs, except that they represent a unit of energy *not used*. White tags are usually created through energy conservation projects such as equipment upgrades, retrofits, combined heat and power (CHP), or cogeneration and demand-side management. A market for energy efficiency is created by setting an energy-saving obligation on entities in the energy supply chain, with preset rules for trading, monitoring, and verification. EECs are awarded to entities that create more energy savings than the target (typically in terms of electricity or oil equivalent energy units), and these EECs may then be sold or traded in the marketplace to those entities that are unable to meet their obligations.

Energy savings are usually cost-effective and efficient ways to reduce GHG emissions, in addition to providing energy security and independence. The process of measuring the energy efficiency savings requires establishing a baseline for energy use and/or demand before and after the implementation of an efficiency project. The approach to doing this depends on the specific market design rules, and can include “deemed savings” figures (i.e., standard figures for projects where the

expected savings are well understood), engineering calculations, and direct measurement. Many compliance markets require third party verification using a MRV protocol. The protocol may vary depending on policy decisions about program implementation cost, ease of compliance, and other factors. White tags are a type of offset credit instrument because they require the application of project-based accounting rules, with baseline, additionality, leakage, and ownership constraints. Currently, EEC markets exist in Italy, the UK, France, and several other nations in Europe. As of February, 2013, 20 US states have energy efficiency targets, typically through Energy Efficiency Resource Standards (EERS), and another seven have nonbinding goals (DSIRE 2014b).

India, now the third largest GHG emitter (after China and the US) launched the "Perform, Achieve and Trade" (PAT) scheme in July 2012, to comply with the National Mission for Enhanced Energy Efficiency (NMEEE), a part of the country's National Action Plan on Climate Change. PAT affects eight energy-intensive sectors (including thermal power plants, iron and steel facilities, cement plants, etc.). These eight sectors account for 25 % of the country's GDP and about 45 % of its primary energy consumption. PAT addresses the energy use of 478 industrial consumers, and creates a market in tradable white certificates called Energy Saving Certificates (ESCerts). One ESCert is equivalent to 1 MTOE (Metric Ton of Oil Equivalent), and PAT is expected to save the country approximately 6.6 million MTOE by the end of 2015. In addition to its PAT program, India also began a RECs green certificate market the previous year (i.e., 2011), and analysts have been studying whether a coordinated program (i.e., with fungible certificates) is feasible and/or appropriate (Ministry of Power and Government of India 2012; EDF and IETA 2012).

Such questions obviously arise as RECs and EEC markets are superimposed or run in parallel with emissions trading schemes. In 2008, the EU explored the potential for establishing a pan-European market in "Guarantees of Origin" to help meet its 20 % renewable energy goal by 2020, but ultimately decided that conflicts and interactions with the EU ETS warranted the more conservative approach of national indicative targets rather than binding quotas and trading. The Greenhouse Gas Protocol (the most widely used accounting tool for quantifying and managing GHG emissions) and carbon registries around the world face an exceedingly difficult task as the complexity of instruments, the potential for "double counting," and potential interactions increase.

Future Directions

The world now has almost four decades of experience with emissions trading, and much has changed during that period. It was introduced almost inadvertently in the US, as a means of dealing with problems associated with CAC regulation, and employed a baseline-and-credit scheme to deal with localized air quality. The resulting markets were very small, and – while offering some economic relief – were not designed to change environmental conditions (relying upon the CAC to do so).

There was considerably more success, however, when the US employed the economists' ideal of a quantity-based approach (called "cap-and-trade") in 1990 to cut sulfur dioxide emissions from the power sector in half. This success led to the subsequent adoption of such emissions trading mechanisms – both baseline-and-credit and cap-and-trade – within the Kyoto Protocol.

Today, SO_2 trading has collapsed within the US power sector, primarily because further controls were deemed necessary (to address PM-2.5, mercury, regional haze, etc.); the spatial characteristics of the control were recognized as significant (i.e., as opposed to the simpler "total loading" goals of the acid rain control program); and further economic analyses have made clear that essentially full controls for pollutants such as SO_2, particulate, and NOx are readily available and appropriate.

Carbon dioxide is a different matter, however. The technological options for pollution control (e.g., amine stripping, carbon capture and storage techniques, etc.) tend to be energy intensive and very expensive. The physical characteristics and impacts of the pollutant are also notably different. Humans exhale carbon dioxide, and toxic impacts only occur at extremely high concentrations – well above those normally occurring in natural systems. The pollutant mixes uniformly throughout the atmosphere, and the spatial characteristics are thus not significant (i.e., it doesn't matter where emissions occur, or where control takes place). Carbon dioxide is thus almost the perfect pollutant for an international market-based emissions trading approach.

Carbon trading in the real world, however, has similarly suffered its own downturns over recent years. The driving force behind the carbon market was the EU, not the US. The EU ETS was established to help European countries meet their Kyoto Protocol targets in an efficient manner, but that market was soon awash in allowances as economic contraction rather than new technology reduced emissions. Prices fell dramatically. The weak economy, lingering unemployment and the financial crisis, linked with real and perceived abuses in the financial markets, caused great suspicion in peoples' minds about the role of markets in general and trading in particular. Neither the USA nor China, the two largest GHG emitters, faced any comparable carbon constraints, and while China was able to receive considerable sums by selling carbon credits to Europeans, it continued to build coal-fired power plants at a rate which negated much of the impact of Kyoto. The 2009 COP was widely seen by Europeans as a failure, since the Copenhagen Accord, drawn up in the meeting's final hours by the US, India, China, Brazil, and South Africa (but not the EU), was viewed by many as a repudiation of Europe's strong, rules-based, global carbon market approach. Europe changed the rules for its own market after the first commitment period of the Kyoto Protocol ended, and demand for Kyoto's instruments (i.e., CERs, ERUs, and AAUs) plummeted and their prices similarly collapsed.

Today, there is some reason to be a bit more optimistic. China has developed seven pilot carbon emissions trading schemes, and is scheduled to develop a national program in 2016. Its success is by no means assured, but the country faces a severe environmental problem, and is devoting considerable resources and managerial attention to the issue. The USA has similarly decided to tackle GHG emissions

from its power plants, albeit in a rather circuitous manner, designed to circumvent strong political resistance by one of its major political parties. It relies on an environmental statute now nearly 45 years old, designed to provide CAC directives. However, the newly proposed regulations have been crafted in a manner that will allow emissions trading to flourish if individual states choose such an approach. There will be numerous lawsuits challenging these proposed regulations, and they will still face considerable political opposition – but nonetheless offer a progressive step forward from the current regulatory stasis in the country. Europe is also addressing some of the current concerns about the EU ETS, through its actions on backloading, its proposal for a market stability reserve system, and focus on more aggressive caps post 2020.

Just as in the buildup before Copenhagen, expectations are currently running high about the 2015 COP meeting in Paris, which is expected to lay down a framework for international post-2020 GHG control efforts. While many hope to see a world-wide emissions trading system like Kyoto, it seems much more likely that there will be numerous country-based efforts, coordinated in some manner by the UNFCCC. Negotiations are already well underway, and countries have been submitting their thinking about "New Market Mechanisms" (NMM) and the "Framework for Various Approaches" (FVA) to the UNFCCC. There seems to be relative agreement about such components as the registries infrastructure and the international transactions log, and the fact that only the international aspects of domestic trading programs would be addressed by the UNFCCC. However, significant issues concerning the role of the UN, the future of Kyoto-based mechanisms such as the CDM, and the linkage to the Nationally Appropriate Mitigation Actions (NAMAs) remain unclear.

As discussed earlier, there are essentially three means of controlling pollution: (1) command and control measures; (2) price-based economic instruments such as Pigouvian taxation; and (3) quantity-based economic instruments such as emissions trading. Given the scale of the environmental problem associated with GHGs, all three will be necessary in the future. They are likely to address different sectors of the economy, and each country is likely to employ a different mix.

Emissions trading's role in that future will continue to evolve. The possibility of linking up a diverse, robust mixture of "bottom-up" trading systems has appeal, even if the "top-down" post-Kyoto system sought by Europe cannot be developed over coming years. From an economic perspective, cost saving opportunities will be greatest in a situation where participants face very different marginal abatement costs. Linking emissions trading systems will tend to equalize abatement costs faced by companies around the world, thus significantly reducing costs as well as competitiveness concerns. There will be numerous difficulties associated with linking up emissions trading programs, however, including MRV concerns, enforcement, and the potential for fraud (such as that already seen in the world's largest carbon market, the EU ETS). In emissions trading, the integrity of these factors is magnified because the commodity being traded owes its very existence to governmental mandates.

The efficiency and distributive aspects of quantity-based schemes offer some very real appeal – and they have already been successfully implemented to tackle

environmental problems. The churning, volatility, self-interest of participants, and seeming chaos of dynamic markets can be uncomfortable, and can pose considerable regulatory challenges – particularly in externality markets specifically constructed by governments. But such markets are ultimately crucial in harnessing entrepreneurial skills for an energy technology revolution, and for delivering the scale of behavioral, technological, and social change being sought.

Climate change presents a unique challenge on a global scale to humanity in general and to economics in particular: the problem is global; it deals with long time horizons, has major risk and uncertainty at its core and requires unprecedented, immediate, collective action. Economics can provide a strong foundation for developing policies to guide action and reducing costs by providing flexibility on how, where, and when emissions are reduced. But pricing the pollution externality and developing robust carbon markets represent only part of the economic task involved in mitigating climate change. Policy frameworks that promote the development and deployment of new, cleaner technologies (i.e., what economists refer to as "induced technological change") and changing behavior in energy consumption (perhaps utilizing "behavioral economics" techniques) will be needed as well. One thing is for certain, the costs of reducing emissions enough to limit global warming to 2 °C may be high but doing so will provide certain obvious benefits that will clearly outweigh the costs. And the cost of not acting is likely to be very high indeed.

Carbon Markets: Linking the International Emission Trading Under the United Nations Framework Convention on Climate Change (UNFCCC) and the European Union Emission Trading Scheme (EU ETS)

Itziar Martínez de Alegría, Gonzalo Molina, and Belén del Río

Contents

Abstract

The trading of carbon emission permits is an instrument created recently to tackle the climate change problem. From 2005 onward, in particular, the volume and significance of different carbon emission trading schemes have increased spectacularly; despite the fact that new emission trading schemes are appearing, the

value of the market had fallen by the end of the Kyoto Protocol's first commitment period in 2012. One fundamental reason for this was the uncertainty as to whether a new global agreement or protocol would be reached in 2015. The main goal of this chapter is to offer an overview of International Emission Trading under the Kyoto Protocol together with the European Union Emission Trading Scheme (EU ETS), as the schemes at the core of today's carbon markets, exploring their basic structure, their main links, and their differences, including a carbon price analysis underlining their fundamental weaknesses and strengths.

Introduction

Broadly similar global carbon prices are considered to be an essential element of international collective action to reduce greenhouse gas (GHG) emissions. That price can, in theory, be created through internationally harmonized taxation or intergovernmental emissions trading, but neither is straightforward in practice (Stern 2007). Within the European Union (EU), a proposal for a harmonized carbon tax failed due to the concerns of some European industries about their competitiveness and to a lack of unanimity between Member States for its adoption (Martínez de Alegría et al. 2009; Brohé et al. 2009). This is a sign of the difficulties of adopting a carbon tax at the international level. On the other hand, as a result of pressure by the USA and some of its allies, emission trading in the form of carbon permits was included as a flexibility mechanism in the Kyoto Protocol to help the concerned parties to meet their commitments (Babiker et al. 2002; Walsh and Whalley 2008; Brohé et al. 2009). From then on, it has remained the main international policy instrument for addressing the climate change problem.

Trading in emission permits is a relatively recent instrument for dealing with environmental problems. The theory underlying such permits was first stated by Coase in 1960 (Coase 1960; Ellerman 2005; Brohé et al. 2009). A decade later, they were applied specifically to environmental problems (Ellerman 2005). Trading emission permits began to be applied on a large scale in the USA from 1974 onward, and by the end of 1997, six types of emission trading initiatives had been implemented there (Solomon 1999; Tietemberg et al. 1999; Ellerman 2005). There are currently a number of carbon emission trading schemes or low-carbon initiatives that generate emission permits. Each permit corresponds to the right to emit GHG into the atmosphere. All the emission permits generated under the Kyoto Protocol's International Emission Trading system (henceforth referred to as Kyoto Units) and from European Union Allowances (EUAs), i.e., the allowances generated under the European Union Emission Trading Scheme (EU ETS), are measured in units of one metric ton of carbon dioxide equivalent or $CO_{2eq.}$ The definition of CO_{2eq} is the amount of CO_2 emission that would cause the same radioactive forcing as an emitted amount of a well-mixed greenhouse gas or a mixture of well-mixed greenhouse gases, all multiplied with their respective global warming potentials (GWPs) to take into account the differing times they remain in the atmosphere (IPCC 2007).

According to the *State and Trends of the Carbon Market* reports, especially that of 2005, there has been impressive growth in the overall value of the global carbon market to the tune of around $159 by 2010 and $176 billion by 2011 (Linacre et al. 2011; Kossoy and Guigon 2012). EUAs increased their market share from 71 % of the global carbon market in terms of value in 2005 to 84 % in 2011 (Linacre et al. 2011; Kossoy and Guigon 2012). The sum of all emission permits generated by the Kyoto Protocol's International Emission Trading system (the so-called Kyoto Units) accounted for around 15 % of the total carbon market value in 2011. According to the data offered by Kossoy and Guigon, Certified Emission Reductions (CERs), i.e., the credits generated by the Clean Development Mechanisms (CDM), accounted for around 14 % of the market value in that year, while emission permit transactions outside the International Emission Trading under the umbrella of the Kyoto Protocol accounted for less than 1 % (Kossoy and Guigon 2012). The *Mapping Carbon Pricing Initiatives* report follows the same path as the aforesaid *State and Trends of the Carbon Market* reports but represents a fundamental change of scope in comparison to the previous reports. Instead of providing a quantitative, transaction-based analysis of the international carbon market (adducing that "current market conditions invalidate any attempt to undertake such an analysis"), it presents an overview of different carbon price initiatives around the world (including not only emission trading schemes but also carbon taxes). It asserts that "with limited support, prices reached historical lows and at the same time, several national and sub-national carbon pricing initiatives are emerging" (Kossoy et al. 2013). The *State and Trend of Carbon Pricing* report published in 2014 illustrates that 39 national and 23 subnational jurisdictions around the world have implemented or are scheduled to implement carbon pricing instruments (including emissions trading systems and taxes) (World Bank and Ecofys 2014). A total of eight new carbon markets opened in 2012 and another early in 2014. In total, the world's emissions trading schemes "are valued at about $30 billion" (World Bank and Ecofys 2014). This represents a remarkable reduction in scale compared to the figure estimated in 2011. In 2013, the cap for installations under the EU ETS was 2,084 million allowances, while the cap for the six pilot projects in China was 1,115 Mt CO_{2eq}, making the country the second largest carbon market in the world, after the EU ETS (World Bank and Ecofys 2014).

Based on a review of the most relevant literature and main legislative documents on the matter, this chapter gives an overview of the functioning of the Kyoto Protocol's International Emission Trading and the EU ETS, which represent the core of carbon markets between 2008 and 2012, as they were the main international emission trading schemes in that period. Section "Overview of International Emission Trading under the Kyoto Protocol" explores the basic elements of the International Trading Scheme under the Kyoto Protocol and its critical concerns. Section "Overview of the European Union Emission Trading Scheme (EU ETS)" focuses on the EU ETS, analyzing its basic structure and underlining its critical concerns. Section "Linking and Comparing the Two Trading Schemes" presents a comparative analysis of the two schemes, focusing on their main links and differences, including a supply–demand balance between different carbon emission

permits (subsection "A Supply–Demand Balance of Emission Permits and the Level of Ambition in the Trading Schemes") and a carbon price comparison (subsection "A Carbon Price Analysis"). Section "Conclusions" concludes.

Overview of International Emission Trading Under the Kyoto Protocol

This section provides an overview of International Emission Trading under the Kyoto Protocol. Firstly, its basic structure is analyzed; secondly, the main critical questions concerning its present and future as a carbon trading instrument are examined.

Basic Structure of International Emission Trading Under the Kyoto Protocol

The United Nations Framework Convention on Climate Change (UNFCCC) is a statement of aspirations, principles, goals, and the means to meet the commitment (IPCCC 2014) which seeks to achieve the "stabilisation of greenhouse gas concentrations (GHG) in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system" (UNFCCC 1992). The Kyoto Protocol (KP) was adopted in 1997 and came into force in February 2005, establishing individual, legally binding GHG emission limitation or reduction commitments for the 38 ratifying parties (ratification means formal approval, often by a Parliament or other national legislature, of a convention, protocol, or treaty, enabling a country to become a party; it is a separate process that occurs after a country has signed an agreement; UNFCCC 2015b) listed in its Annex B (henceforth called "Annex B countries;" see Table 2 in Annex). The protocol called on these parties, individually or jointly, to reduce their overall GHG emission level by 5.2 % below the 1990 levels in the first commitment period, i.e., from 2008 to 2012 (UNFCCC 1998). The main goal of the Kyoto Protocol is to contain or reduce emissions of the main GHGs in ways that reflect the underlying national differences in emissions, wealth, and capacity, according to the main principles agreed in the United Nations Framework Convention on Climate Change (UNFCCC) (1992), including the principle of "common but differentiated responsibilities" with the corresponding leadership by the richer and higher-emitting industrialized countries.

The Kyoto Protocol established the following Flexibility Mechanisms to help the Annex B countries to meet their commitments:

- The so-called bubble concept, which allowed European Union (EU) Member States to redistribute their joint 8 % reduction commitment between them as illustrated in Annex B to the Protocol (see Table 2 in Annex). This redistribution was stated by the Burden Sharing Agreement (BSA), which resulted, for instance, in 15 % emission growth for Spain, a 21 % reduction for Germany, etc. (Council of the European Union 2002).

- The so-called Kyoto Mechanisms or Flexibility Mechanisms, i.e., the International Emission Trading system, the Joint Implementation (JI) Mechanism, and the Clean Development Mechanism (CDM). These last two mechanisms are project-based mechanisms and have become the focal point for direct private sector involvement in the Kyoto Protocol. They state that a ton of GHG emissions saved, thanks to the development of a project or program, gives the right to emit a ton of GHG elsewhere. For the purpose of meeting their commitments, Annex B countries may transfer to, or acquire from, any other such party Emission Reduction Units (ERUs) which result from Joint Implementation projects, while the joint objective of the Clean Development Mechanisms is to assist developing country parties in achieving sustainable development and reducing GHG through the development of Clean Development Mechanism projects and to help Annex B countries in achieving compliance with their commitments. This last point is to be facilitated through the use of the aforesaid Certified Emission Reductions (CERs) generated by the cited projects. All Joint Implementation and Clean Development Mechanism projects must necessarily comply with the additionality rule. Using these two project-based mechanisms, any legal entity can participate in a Joint Implementation or a Clean Development Mechanism project to acquire Emission Reduction Units (ERUs) or Certified Emission Reductions (CERs), acting directly as a project developer or indirectly, for example, acquiring credits through the existing Carbon Funds. The objective of a Carbon Fund is to collect financial contributions from public and private sector entities and then use those funds to promote projects that reduce GHG emissions, in turn redistributing the Emission Reduction Units generated to the financing contributors according to their respective contributions (Carr and Rosembuj 2007).
- When Annex B countries have negative net emissions derived from land use, land use change, and forestry (LULUCF) activities (Art. 3.4 KP), those countries can receive Removal Units (RMUs). This type of carbon sink activities, i.e., activities that absorb CO_2, is expected to represent a relevant percentage of the different countries' commitments. The first Removal Units were issued in 2011 to those national registries that opted to print them annually (such as France and Australia, which received at least 23 million RMUs each; Russia, which held 4 million in 2011 and 462 million in February 2012; Hungary, which has received at least 3.9 million (Kossoy and Guigon 2012), but also Denmark, Monaco, Liechtenstein, and Switzerland. The rest of the Annex I countries opted to print their Removal Units after the "true-up period" (the "true-up period" or "additional period for fulfilling commitments" is the specific period of 100 days after provided by the Protocol that is to occur after the completion of the review of the final annual report for the commitment period in order for parties to continue making transactions for the purpose of "truing up" any remaining differences between the parties' total emissions during the commitment period and units retired for compliance; so during this period, each party is allowed to continue to undertake transactions of Kyoto Units) (UNFCCC 2008a, b).
- The possibility of carrying over (or banking) unused permits from the 2008–2012 period to the 2013–2020 period may be another relevant cause of flexibility in this

second period; however, that possibility is expected to be very limited (see subsection "Critical Concerns").

The Kyoto Protocol's accounting system is based on two parallel information streams: GHG inventories and the information regarding the operations linked to Kyoto Units. To manage this last information, a registration system has been developed which includes three types of registry: (i) the national registries of each of the Annex B parties which have ratified the Kyoto Protocol (including the EU) registry, i.e., the Community Independent Transaction Log (CITL) was replaced in 2013 by the European Union Transaction Log (EUTL) (see Table 1 in section "Linking and Comparing the Two Trading Schemes"); (ii) the Clean Development Mechanism (CDM) registry; and (iii) the International Transaction Log (ITL), which has been put in place and administered by the UNFCCC secretariat to verify the validity of transactions. Each of these registries is to operate through a link established with the ITL, which verifies the operations registered in real time to ensure that they are consistent with the rules agreed under the Kyoto Protocol.

According to the GHG emissions cap (established in Annex B to the Kyoto Protocol), an initial amount of Assigned Amount Units (AAUs) is allocated free of charge (this is known as grandfathering) to the Annex B countries at the beginning of 2008 (UNFCCC 2008b). Apart from these free allowances, the following Kyoto Units also give the right to emit one ton of CO_{2eq} to the atmosphere and may also be transacted under the International Emission Trading without restrictions, with the exception of the commitment period reserve (UNFCCC 2008a): Removal Units (RMUs); Emission Reduction Unit (ERU) credits (which are units converted from Assigned Amount Units or Removal Units on the basis of Joint Implementation projects (Art. 6 KP)); Certified Emission Reduction (CER) credits (given for emission reductions certified for a CDM project (Art. 12 KP)); and finally, tCER and lCER credits (derived from forestation and afforestation activities also developed under Art. 12). All the cited Kyoto Units represent the same compliance value in dealing with Kyoto commitments.

The Annex B countries have the following options to comply with their respective commitments under the Kyoto Protocol:

- To carry on internal abatement measures and obtain domestic GHG emission reductions
- To remove GHG from the atmosphere by increasing carbon sinks (LULUCF activities as mentioned above)
- To use the Kyoto Mechanisms mentioned above

The decision depends on the relative costs of each option at each moment, on the legislation in place, and, as explained by Grubb (2003), on the political objectives of each country.

Thanks to the aforesaid registry system, Annex B countries may add and subtract Kyoto Units from their corresponding national registries, reducing or increasing their level of Kyoto Units compared to their initial assigned amount (their total AAUs at

Table 1 Fundamental characteristics, links, and differences between the Kyoto Protocol's IET and the EU ETS

Period: 2008–2020	Kyoto Protocol's ET first commitment period (2008–2012); second commitment period (2013–2020)	EU ETS Phase I (2005–2007); Phase II (2008–2012); Phase III (2013–2020)
Parties involved	*FCP: 38 parties = 37 ratifying industrialized countries included in the Kyoto Protocol's Annex B + the EU **SCP: 34 (Russia, Canada, and Japan, which ratified the Kyoto Protocol and stayed out in the post-Kyoto 2012); the "Doha Amendment" still not ratified (status December 2014)	Operates in the 28 EU countries and the three EEA-EFTA states (Iceland, Liechtenstein, and Norway)
Sectors of the economy affected	Country focused	Company focused: European big industrial emitters of GHGs ***Phase II: the energy sector, iron and steel production and processing, mineral industry, and paper and board industry *[v]Phase III: new sectors (e.g., aviation, ammonia, and aluminum (EU 2009))
Type of GHG affected	FCP: CO_2; CH_4; N_2O; HFCs; PFCs; SF_6 (included in Annex A to the KP) SCP: NF_3 is included	Phase II: mainly CO_2 Phase III: new GHGs affected, N_2O and PCF
% of GHG emissions covered	FCP: with the ratification of Russia in 2005, at least 55 % of the world's GHGs were covered SCP: Japan, Canada, and Russia are out of the "Doha Amendment to the Kyoto Protocol," so only around 15 % of the world's GHGs are covered (see Table 2)	*2005–2012 period: around 40 % of EU emissions *2013–2020: around 45 % of EU emissions
Emission permits involved and their links	Kyoto Units: AAU; RMU; ERU; CER; lCER and tCER	Phase II: EUAs (which are converted from AAUs) + a limited quantity of CERs and ERUs that can also be used for accomplishment Phase III: EUAAs included
Registry system	Three types of registry: the 37 national registries; the CITL and the ITL (from 2013 the EUTL superseded the CITL; see next column). There is a direct link between the EU ETS registry system and the ITL as established by European Commission Regulation (EC) No 2216/2004	Between 2005 and 2012: 30 electronic registries + the CITL Phase III[i] the European Union Transaction Log (EUTL) is the successor of the CITL and is now the only registry operated by the European Commission
Targets	FCP: added together parties must reduce 5.2 % below the 1990 levels SCP: 18 % between 1990 and 2020	2005–2020: 21 % reduction target as stated by Directive 2009/29/EC; the Commission proposes 43 % lower by 2030

(*continued*)

Table 1 (continued)

Period: 2008–2020	Kyoto Protocol's ET first commitment period (2008–2012); second commitment period (2013–2020)	EU ETS Phase I (2005–2007); Phase II (2008–2012); Phase III (2013–2020)
Consequences of noncompliance	Disqualification from participating in the Kyoto Mechanism and a penalization by deduction from allowed emissions in subsequent rounds with a 30 % penalty factor (Grubb 2003)	Any operator that does not surrender sufficient annual emission permits to cover its verified emissions must pay a penalty of EUR 100 for each ton of $CO_{2\text{-eq.}}$ for which the operator has not submitted an emission permit and in addition must surrender the corresponding amount of emission permits
Flexibility to reach commitments	To help them reach their targets, Annex B parties can use (a) the bubble concept; (b) emission trading; (c) unlimited amounts of UREs, CERs, tCERs, and lCERs; (d) carbon sinks (with certain limits); and (e) the limited possibility of banking AAUs (as stated by EU, Australia, Norway, and Switzerland)	To help them reach their targets, EU ETS firms can (a) use emission trading; (b) use a limited amount of CERs and UREs; and (c) bank or carry over EUAs for 2013–2020

Source: Own work; *first commitment period (FCP), from 2008 to 2012; **second commitment period (SCP), from 2013 to 2020; ***Phase II of the EU ETS from 2008 to 2012; *^{v}Phase III of the EU ETS from 2013 to 2020

the beginning of 2008). To comply with the Kyoto commitments at the end of the first commitment period, these countries must send to their respective retirement accounts a number of Kyoto Units equivalent to their total GHG emissions in those 5 years. It must be taken into account that, due to the complexity of data collection, final GHG data are reported with a time lag of at least 2 years on their actual emission. This is why the period known as the "true-up period" is instated. The "true-up period" is a 100-day period after the final GHG emission data have been reported when parties have the opportunity to undertake any final transactions necessary to achieve compliance with their Article 3, paragraph 1 commitment (UNFCCC 2008a). 2014 is the year of the "true-up period."

Critical Concerns

The commitments between 2008 and 2012 were never intended to provide the definitive solution to climate change and "second and subsequent periods are likely to require more stringent emission commitments" (Grubb 2003). With a view to the 2013–2020 period, in order to maintain GHG concentration at a level of below 450 ppm CO_{2eq}, the Intergovernmental Panel on Climate Change (IPCC) highlights that the Annex I countries need to cut their GHG emissions by 25–40 % by 2020 compared to the 1990 levels and also that developing countries need to significantly

reduce their emissions (Gupta et al. 2007). As part of the Copenhagen Accord reached at the Copenhagen Conference of Parties (the COP-15), most Annex I parties formally submitted voluntary GHG emission reduction pledges. In addition, seven major emerging economies (China, India, Brazil, Indonesia, Mexico, South Africa, and South Korea) also sent in mitigation action plans (UNFCCC 2015a). Various studies indicate that the said pledges will not suffice to bring about the reductions needed to limit the increase in global warming to 2 °C, especially if the lowest-ambition pledges are implemented at a time when LULUCF accounting rules and the use of surplus emission units result in a net increase of emissions (Den Elzen et al. 2010a, 2011; Kartha and Erikson 2011). As stated in 2011 at the Durban Conference of Parties (the COP-17), Annex I parties must start the process for the development of a new protocol or another instrument with legal force under the UNFCCC, applicable to all parties, which should be adopted by the COP-21 (i.e., by 2015 in Paris), in order for it to come into effect and be implemented from 2020 (UNFCCC 2012a). Due to the need to increase the level of ambition with regard to GHG emission reductions, the Warsaw UNFCCC Conference of Parties agreed that there was a need to set more comparable targets together with a calendar from Warsaw to Paris (UNFCCC 2014a).

In the framework of the Kyoto Protocol, the possibility of using all the Flexibility Mechanisms and the corresponding Kyoto Units for the second commitment period, that is, from 2013 to 2020, is allowed by the 2011 Durban Conference of the Parties, serving as the meeting of the parties to the Kyoto Protocol (the CMP-7) (UNFCCC 2012b). The following year, the Doha Agreement (the CMP-8) stated that those Annex B parties taking commitments in the 2013–2020 period should reduce their overall emissions by at least 18 % below the 1990 levels in this second period (UNFCCC 2013a). CMP-8 includes an Annex called the "Doha Amendment to the Kyoto Protocol" (Annex A to CMP-8), which comprises a new list of limitation or reduction commitments for the Annex B countries of the Kyoto Protocol. However, apart from the United States (USA), a number of Annex I countries (notably Canada, Japan, Russia, but also Belarus, New Zealand, Norway, Switzerland, and Ukraine) decided not to participate in the second commitment period (UNFCCC 2015c), so the small proportion of world GHG emissions affected (around 12 %: see subsection "A Supply–Demand Balance of Emission Permits and the Level of Ambition in the Trading Schemes") is the main weakness of the post-Kyoto 2012 period.

Other relevant questions that determine the level of ambition as regards the 2013–2020 period within the Kyoto framework are linked to whether or not surplus Kyoto Units can be banked. Of course, mitigation efforts to 2020 could be reduced considerably if the total surplus of Kyoto Units is used and transacted with no limits. Although the "Doha Amendment" did not agree on any additional restrictions on the banking of AAUs for the next commitment period, major GHG emitters included in the amended Annex B (notably the EU, Australia, Norway, and Switzerland) have confirmed that they will not purchase or use carried-over AAUs transferred from other parties for compliance in the second commitment period (UNFCCC 2013a).

In regard to project-based mechanisms, between 2004 and 2013, over 7,300 project activities were registered under the Clean Development Mechanism in over

90 countries, over 1,500 component project activities were included in over 230 programs of activities registered in over 60 countries, over 1.4 billion Certified Emission Reductions were issued, and over USD 215 billion was invested; under the Joint Implementation Mechanism, 547 Track 1 projects and 52 Track 2 projects were implemented and 840 million Emission Reduction Units were issued for emission reductions generated before the end of 2012 (UNFCCC 2014b). For the 2013–2020 period, Warsaw decisions 3 and 5 by CMP-9 express concern regarding the difficult market situation currently faced by participants in Joint Implementation and the Clean Development Mechanism and the consequent loss of institutional capacity related to the mechanisms, which is threatening their value as a tool for parties to collaborate in achieving the objective of the Convention and its Kyoto Protocol (UNFCCC 2014b). Indeed, 2012 saw a dramatic increase in registrations, while 2013 saw a dramatic decline in the number of Clean Development Mechanism projects registered and a dramatic decline in the number of projects entering the Clean Development Mechanism pipeline as a result of diminished demand for CERs, tied ultimately to the level of ambition of parties to reduce GHG emissions (UNFCCC 2013b). According to the Joint Implementation Supervisory Committee (JISC), this mechanism is virtually at a standstill, while countries turn their attention to negotiating a new climate deal, due to be agreed in Paris at the end of 2015 and take effect in 2020. The Joint Implementation Mechanism is facing difficulty due mainly to low demand, ultimately tied to the countries' level of ambition to reduce greenhouse gas emissions. The JISC is also challenged critically by the fact that JI units are created by converting a portion of a country's total allowable emissions, the so-called Assigned Amount Units, which for the current commitment period of the Protocol have yet to be issued (Joint Implementation Supervisory Committee (JISC), 2014).

Scientific literature has detected the following critical concerns, which may have led to a decrease in the degree of confidence in Clean Development Mechanisms:

- *There are various methodological problems in determining baselines and the additionality* of Clean Development Mechanism projects (Gupta et al. 2007), such as the problem that although the Clean Development Mechanism's additionality toll is well respected, it does not guarantee that only additional projects are approved (Kollmuss et al. 2008). On the other hand, as stated by the Warsaw CMP-9 conference, work may be done on the simplification and streamlining of methodologies, with the aim of reducing transaction costs for all project activities and programs of activities, especially those in regions underrepresented in the Clean Development Mechanism (UNFCCC 2014b).
- As mentioned, the *coverage of forestry and forest-related projects* is another cause of uncertainty due to the problems linked to the impermanence of forests and leakage to other regions (Gupta et al. 2007).
- *The sustainability of the projects*. The Marrakech Accord, where the main rules for the implementation of the Kyoto Mechanism are provided, states the host party's prerogative in confirming whether a Joint Implementation or a Clean Development Mechanism project activity assists it in achieving sustainable

development (UNFCCC 2002). A number of publications can be found which deal with the question of the sustainability of Clean Development Mechanism projects, highlighting mainly the lack of guarantees concerning the sustainability of the projects carried out and the need to establish adequate indicators for their evaluation (Holm Olsen and Fenhann 2006; Kollmuss et al. 2008; Watson and Fankhauser 2009). Some significant initiatives implemented in an attempt to deal with these problems can be outlined, such as that of BlueNext, an emission trading exchange company which divides spot CER contracts into two: spot CERs (involving N_2O from adipic acid and nitric acid production and HFC-23 from HFC-22 production) and spot green CERs (involving wind, solar, energy efficiency, and other project types) (Bluenext 2012), and the Gold Standard certification, which is a standard for creating high-quality emission reduction projects mainly in the Clean Development Mechanism (CDM). It is designed to ensure that carbon credits are not only real and verifiable but that they make measurable contributions to sustainable development so some of the issued credits are called CER Gold Standard (Gupta et al. 2007; Kollmuss et al. 2008). Within the EU ETS, credits from all types of projects are accepted except nuclear energy projects (European Commission 2014a) and CERs from projects starting from 2013 involving the destruction of industrial gases (trifluoromethane (HFC-23) and nitrous oxide (N_2O)) (EU 2011).

Finally, the existence of an adequate, transparent accounting system that guarantees the correct functioning of Kyoto Unit transactions is fundamental for the proper functioning of International Emission Trading under the Kyoto Protocol. In this regard, several authors have pointed out the potential for double accounting of offsets as a major source of uncertainty and have estimated that this could account for 0 to +1.3 Gt CO_{2eq} (den Elzen et al. 2010a, b). In regard to Removal Units, tCERs and lCERs, as explained by Grubb, carbon sinks were one of most technically complex issues in the Kyoto Protocol's entire negotiations (Grubb 2003). The main criticisms related to the inclusion of carbon sinks have to do with the accounting of GHG fluxes and the risk of impermanence. Indeed, major criticisms regarding forestry-based compliance methods are linked to uncertainties regarding the net emissions from forests (IPCC 2007; LeBlanc 1999). According to IPCC estimates, uncertainties regarding the annual carbon flux in the 1990s may account for 5500 $MtCO_{2eq}$/year (IPCC 2007).

Overview of the European Union Emission Trading Scheme (EU ETS)

Basic Structure of the EU ETS

All parties to the UNFCCC (including developing countries) have a general commitment to adopt climate change mitigation policies that includes submitting reports on the actions that they are taking. In 2007, the European Council established the

"20/20/20 mandate" (i.e., to achieve by 2020 a reduction of GHG emissions by 20 % on the 1990 levels, to save 20 % of primary energy consumption compared to the forecasts for 2020, and to increase the level of renewable energy sources in the EU's overall mix of final energy consumption to 20 % (European Council 2007)). To achieve this mandate, a wide range of measures (legislative, technological, etc.) have been developed (Martínez de Alegría et al. 2009, 2012), offering an ambitious, integrated pack of measures. It is worth noting that EU legislation distinguishes between the following economic sectors:

- The so-called *diffuse sectors*, such as agriculture, services, buildings, and transport, which are affected by Decision 406/2009/EC, which sets a 10 % GHG reduction (average) for them below the 2005 levels for the whole of the EU by 2020, with different targets established for different Member States
- Big *industrial emitters (or EU ETS firms)*, which are included in the EU ETS

According to Directive 2003/87/EC, the EU ETS started functioning in January 2005 (EU 2003) and was inspired and generated under the umbrella of the Kyoto Protocol's International Emission Trading. "The EU emissions trading system (EU ETS) is a cornerstone of the European Union's policy to combat climate change and its key tool for reducing industrial greenhouse gas emissions cost-effectively. The first – and still by far the biggest – international system for trading greenhouse gas emission allowances, the EU ETS covers more than 11,000 power stations and industrial plants in 31 countries, as well as airlines" (European Commission 2014a).

The main source of information on the EU ETS is the Community Independent Transaction Log (CITL) (known as the European Union Transaction Log (EUTL) from 2013 onward), which is administered by the European Commission and has the task of checking and reporting all transactions taking place within this trading system. As mentioned above, European Union Allowances (EUAs) are specific allowances created within the EU ETS. Each EUA entitles its owner to emit one metric ton of CO_{2eq} into the atmosphere. The following types of account can be distinguished in the scheme: *the party account*, which corresponds to those Annex B parties which are included in the EU ETS, that is, the EU countries; *the operator account*, which is comprised by the EU ETS firms that hold allowances that correspond to AAUs previously converted into EUAs; and *the person account*, which corresponds to any natural or legal person that wishes to participate in the EU ETS (EU 2004).

- Directive 2003/87/CE distinguished between Phase I (2005–2007) and Phase II (2008–2012), when each Member State must develop a National Allocation Plan (NAP) (which must be approved by the European Commission), establishing the overall and individual cap for the affected EU ETS firms for each phase. According to the National Allocation Plans, EUAs were distributed mainly for free (grandfathering) among EU ETS firms (in Phase I and Phase II, at least 95 % and 90 %, respectively, of the allowances were distributed for free, while the rest went through auctioning). After each year, those firms must surrender enough

allowances to cover all their emissions; otherwise, different fines would be imposed. If a firm reduced its emissions, it could keep the spare allowances to cover its future needs or sell them to another EU ETS firm that needed allowances. During Phase II, the 30 participating countries (27 EU Member States, Iceland, Lichtenstein, and Norway) emitted on average around 40 % of the total emissions of the EU (European Environment Agency (EEA) 2012). In 2009, Directive 2009/29/EC was adopted, to be applied from 2013 (i.e., Phase III), establishing new rules and relevant changes such as the possibility of banking EUAs between Phase I and II. Other relevant new features in Phase III are: different national caps are replaced by an EU-wide cap system, to be established by the European Commission.

- *New relevant sectors and gases are included*. Initially, the focus was on CO_2 emitters (such as the electricity sector, the mineral industry, etc.). From 2013 the EU ETS scope was to be further extended to include new sectors as the ammonia and aluminum sectors (EU 2009) and the aviation sector (EU 2008) and gases, such as CO_2 emissions from petrochemicals, as well as N_2O emissions from the production of nitric and adipic acids and perfluorocarbon (PCF) emissions from aluminum production (EU 2009).
- The inclusion of the target of a 21 % reduction in GHG on the 2005 levels by 2020 for the EU ETS-covered sectors.
- An *auctioning system* was set in place.

Some critical factors in regard to these novelties are analyzed in more depth in the next subsection ("Critical Concerns").

Critical Concerns

According to various authors, within these types of emission trading scheme, an auction system is preferred to grandfathering because it tends to generate less market distortion (Grubb and Neuhoff 2006; Hentrich et al. 2009). However, other authors affirm that, considering the past experiences of auctioning, the sophisticated allocation rules applied, which are highly influenced by lobbying groups, are not in line with the desire for simplicity and transparency (Benz et al. 2010). The current experience in regard to the auctioning system established in the EU ETS will determine whether market distortion is weakened or reinforced.

As stated by Directive 2009/29/EC, in 2013 more than 40 % of allowances should have been auctioned and this share should rise progressively each year. Indeed, the Directive states that full auctioning should be the rule from 2013 onward for the power sector and only when the risk of "carbon leakage" is high will some allowances be allocated for free for a period of time. On the other hand, the Directive envisages a transitional system for those sectors deemed to be at risk of carbon leakage, for which free allocation will initially account for 80 % of the amount. Thereafter, free allocation should decrease each year by equal amounts resulting in 30 % free allocation in 2020 and no free allocation in 2027 (EU 2009). Sectors

deemed to be at risk of carbon leakage are those that may suffer a material competitive disadvantage against competitors located in areas outside the EU which do not have similar emission reduction commitments, which could in turn lead to an increase in GHG emissions. The Directive also states that allowances in the EU ETS must decrease by a linear factor of 1.74 % per annum, compared to the average annual total quantity for 2008–2012, leading to a reduction of just over 70 % in the ETS cap by 2050 (European Commission 2011). However, that linear factor seems not to be balanced by the necessary level of ambition within the EU (see subsection "A Supply–Demand Balance of Emission Permits and the Level of Ambition in the Trading Schemes"). In 2014, "in the light of the evidence and the experience of current policies the European Commission proposes a new reduction target for domestic GHG emissions of 40 % compared to 1990, to be shared between the ETS and the non-ETS sector (. . .) the ETS sector would have to deliver a reduction of 43 % in GHG in 2030 and the non-ETS sector a reduction of 30 % both compared to 2005. In order to bring about the required emission reductions in the ETS sector, the annual factor by which the cap on the maximum permitted emissions within the ETS will have to be increased from 1.74 % currently to 2.2 % after 2020" (European Commission 2014b).

According to Directive 2008/101/EC, the aviation sector is included in the EU ETS from 2012 onward. This entails the creation of European Union Aviation Allowances (EUAAs): special emission allowances that can only be used by airline companies for compliance purpose. From 2012 emissions from all flights from, to, and within the European Economic Area (EEA) (the 28 EU Member States plus Iceland, Liechtenstein, and Norway) were included in the EU ETS. However, in 2013, the International Civil Aviation Organization (ICAO) Assembly agreed to adopt a definitive agenda for a global agreement to tackle emissions in the aviation sector, and pending the possible adoption of international rules, the EU limited the coverage of the EU ETS to flights within the EEA for the period from 2013 to 2016 (European Commission 2014a).

Without doubt, the frauds detected within the EU ETS (e.g., VAT fraud and double accounting) (EU 2010; Linacre et al. 2011) have helped undermine the confidence in different agents in the scheme.

Linking and Comparing the Two Trading Schemes

This section presents a comparative analysis between the two trading schemes, focusing on their main links and differences and including a demand–supply analysis (subsection "A Supply–Demand Balance of Emission Permits and the Level of Ambition in the Trading Schemes") and a price analysis (subsection "A Carbon Price Analysis").

An emission trading scheme may be established as a climate policy instrument at both domestic and regional levels. Various national schemes (e.g., New Zealand (NZ ETS) and Australia) and regional schemes (e.g., the EU ETS) have been established under the umbrella of the Kyoto Protocol's ET. Any transfer of emission

permits between entities in different Annex B parties under such domestic or regional schemes is also subject to the Kyoto Protocol's rules (UNFCCC 2008a). In a major step toward the first full intercontinental linking of emission trading systems, the European Commission and Australia announced an agreement in August 2012 on a pathway for linking the EU ETS and the Australian emission trading scheme (European Commission 2012a).

There are two direct links between the emission permits allowed in the EU ETS, i.e., EUAs, and Kyoto Units. On the one hand, a link between the EU ETS and project-based mechanisms is established through Directive 2004/101/EC, which allows EU ETS firms to use a limited number of ERU and CER credits to meet their targets during Phase II (2008–2012). These firms used 1.058 billion international credits (European Commission 2014a). On the other hand, even though the EU ETS started functioning in 2005 and operated independently from the Kyoto Protocol's accounting system, in 2008 the two trading schemes were linked through the International Transaction Log (ITL), and between 2008 and 2012 Assigned Amount Units (AAUs) were converted into European Union Allowances (EUAs) before being allocated to different EU ETS firms. Later, once these firms had surrendered an amount of EUAs equivalent to their verified emissions to their corresponding national registry (within the Community Independent Transaction Log (CITL)), the EUAs were again converted and transferred to the retirement account within the International Transaction Log (ITL). The retirement account is the special account were each party must ensure that it has transferred a quantity of units equal to its total Annex A emissions for the commitment period by the end of the true-up period, so the compliance of an Annex B country at the end of 2012 is assessed by comparing the total amount of Kyoto Units in its retirement account to its total verified emissions for the commitment period (UNFCCC 2014c).

There are different ways of acquiring Kyoto Units. It has been common for different buying countries to acquire carbon credits (mainly CERs) through the participation in the aforementioned Carbon Funds and carbon allowances (especially AAUs) through bilateral agreements using Green Investment Schemes (GIS). In a Green Investment Scheme, revenues from emission trading are used to support investments in climate-friendly projects – that is, in projects that reduce emissions. These investments can be made in project reductions that are measurable and quantifiable ("hard greening") or in capacity building, such as emissions inventory development in the seller country, which is nonmeasurable ("soft greening") (Kossoy and Guigon 2012; Point Carbon 2009; Grubb 2003). It is estimated that the total Annex B government demand for Kyoto Units for the first commitment period was 547 Mt CO_{2eq} with the EU-15 accounting for around 75 % of the total and Japan for about 17 %. The main sellers of AAUs linked to these Green Investment Schemes were the governments of Ukraine, with more than one third of the total; the Russian Federation, with around 13 %; the Czech Republic with 8 %; and other EU-10 countries with 40 % of the total. Gross demand for private entities was expected to be around 1070 $MtCO_{2eq}$, while the demand of EU ETS firms, mainly for CERs and ERUs, accounted for 81 % of the total. However, these numbers correspond to the amount of AAUs that governments intend to sell,

which is much lower than the whole amount of excess AAUs, now estimated at more than 10 $GtCO_{2eq}$ over the first commitment period, with Russia accounting for half, Ukraine one quarter, and Poland one fifth (Kossoy and Guigon 2012). According to Point Carbon, there are also private sector entities and intermediaries engaged in the trading of AAUs. By 2009, approximately 147 million AAUs had been transacted. A further 50–60 million AAUs were reported to be under negotiation, with the Czech Republic and Ukraine as the largest sellers, with 68.5 and 44 million AAUs, respectively. The Japanese government and private companies appear to be the largest buyers, having bought most of the volume transacted by those two countries (Point Carbon 2009). 57.81 million tons of AAUs were transacted in 2010 and 47 million in 2011, with Estonia being the biggest seller and Lithuania the second biggest in 2011 (Kossoy and Guigon 2012).

Table 1 summarizes some fundamental characteristics, links, and differences between the Kyoto Protocol's International Emission Trading system and the EU ETS in the 2008–2012 and the 2013–2020 commitment periods. Apart from the number of countries, the GHG, and the economic sectors affected, which are of course much more significant in the case of the Kyoto Protocol's IET, there are other relevant differences to be remarked, such as the targets set, the level of ambition, the consequences of noncompliance, and the instrument of flexibility for reaching the targets.

Apart from those shown in Table 1, there are also other relevant similarities between these two trading schemes, such as the negative trend observed in the different carbon emission prices, which is closely linked with the number of GHGs affected and the caps established, and consequently the over-allocation of emission permits observed in the 2008–2012 period. These issues are analyzed in greater depth below.

A Supply–Demand Balance of Emission Permits and the Level of Ambition in the Trading Schemes

An overview of the supply–demand balance for different emission permits is fundamental in understanding the trends in their corresponding prices. When analyzing the demand and supply of Kyoto Units (especially AAUs) in the first commitment period, two types of countries can be distinguished: *Kyoto Unit seller countries*, that is, those countries that emit less than their "assigned amount," thus generating a surplus of Kyoto Units, and *Kyoto Units buyer countries*, such as Japan, Canada, Australia, and some EU countries (Grubb 2003; Kossoy and Guigon 2012).

As stated on the Kyoto Protocol, parties that represent at least 55 % of the total carbon dioxide emissions for 1990 included in Annex I of the UNFCCC must deposit their instruments of ratification, acceptance, approval, or accession (UNFCCC 1998). Accordingly, when Russia joined the Protocol, it came into force in February 2005. In regard to the level of ambition for 2008–2012, as affirmed by Grubb, the aggregate emissions of Annex I countries in the year 2000 were already below the aggregate Kyoto cap of 5.2 %, but with a huge east–west

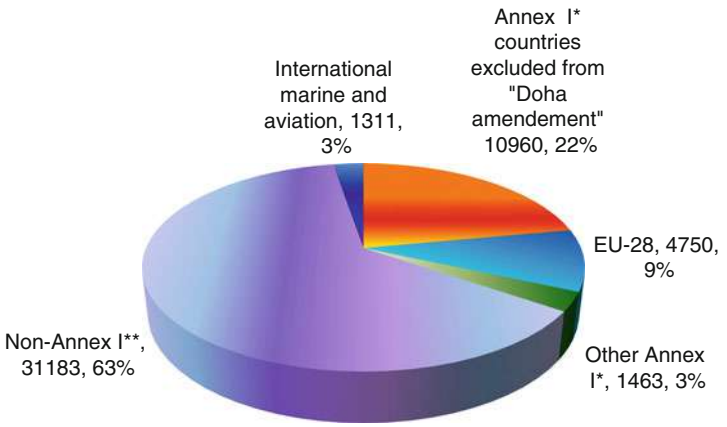

Fig. 1 GHG emissions in 2010 per group of countries (%). Annex I* excluding Turkey and excluding LULUCF. Non-Annex I** including LULUCF for the countries with a high share of LULUCFs, i.e., Brazil, Indonesia, Mexico, Chile, Colombia, Costa Rica, Papua New Guinea, and Peru (Own work using data from Hof et al. (2013))

discrepancy in distribution (Grubb 2003). As explained by this author, the three tumultuous events of 2001 were expected to have as a result a large potential supply against a radically reduced demand of emission permits: the withdrawal of the USA (by far the largest source of potential demand of permits), the expected surplus of AAUs from Russia, and the Bonn/Marrakech deal on carbon sinks (the named LULUCF activities). As a result, the modeling projections of the price plummeted after 2001 (Grubb 2003). It is estimated that most AAU surplus originate from the economic downturn in the "economies in transition" of Central and Eastern Europe and the former Soviet Union due to the so-called hot air problem. This "hot air problem" occurs when some governments are able to meet their targets with minimal effort and can then flood the market with emission rights, reducing the incentive for other countries to cut their own domestic emissions (UNFCCC 2015b). The total surplus of emission units at the end of the first commitment period was estimated to be between 9 and 13 $GtCO_{2eq}$ (Point Carbon 2009; Den Elzen et al. 2010a, b).

Figure 1 illustrates the percentage of GHG emissions by different groups of countries in 2010. As aforesaid, Canada, Japan, and Russia opt out of the "Doha Amendment to the Kyoto Protocol" and so do the USA, all together accounting for around 10,960 Gt CO_{2eq} in 2020. With the world's total emissions of around 60,627 Gt CO_{2eq}, the aforesaid countries amount to around 22 % of the total emissions. Non-Annex I countries emitted a total of 31,191 Gt CO_{2eq} in that year so as illustrated in Fig. 1; they account for around 62.8 % of total emissions worldwide. Finally, the commitment acquired by the countries which are involved in the "Doha Amendment to the Kyoto Protocol" represents only around 12 % the total emissions worldwide with around 6, 2013 Gt CO_{2eq} (Fig. 1).

In the EU-28, the total GHG emissions (not counting international aviation and LULUCF) in 2012 are already 19.2 % below the 1990 levels and 21.6 % below the

Kyoto base year levels. According to preliminary estimates, total emissions decreased by a further 1.8 % in 2013. This means that the EU-28 overachieves its targets by a total of 4.2 Gt CO_{2eq} in the first commitment period, and its emissions over the second commitment period are expected to be 23 % down from the 1990 levels (excluding international aviation and LULUCF) (European Commission 2014c). This means that unless a new accord is reached by the Paris Conference in 2015 a very low level of ambition is envisaged for the 2013–2020 period. However, it must be outlined that there are differences in regard to the potential level of fulfillment by the different Member States of their corresponding commitments to 2020. The European Commission Progress Report estimates that around half of Member States will need additional efforts to meet their 2020 targets domestically for non-ETS sectors, while the rest are forecast to reach these commitments with existing policies and measures (European Commission 2014c).

Within the EU ETS framework, GHG emissions by the firms involved are 5 % below their allocated allowances for the first commitment period, i.e., 5 % below their corresponding caps (EEA 2012). In any case, the over-allocation indicated may vary considerably depending on the sector analyzed, so the following distinction should be made within the EU ETS: on the one hand, *seller EU ETS subsectors* (e.g., Spanish EU ETS firms other than power generation firms) and, on the other, *buyer EU ETS subsectors*. According to the European Commission, the EU ETS has helped to deliver real GHG emission reductions in line with EU targets for 2020. However, partly due to the estimated surplus of almost two billion allowances at the start of Phase III and to record the use of international credits, serious imbalances are expected to emerge in the short term between supply and demand with potentially long-term repercussions which may profoundly affect the ability to meet the ETS target in future phases in a cost-effective manner (European Commission 2014a). This surplus of two billion allowances is due to several factors: auctioning of Phase II allowances and remaining allowances in the new entrant reserve, early auctioning of Phase III allowances, and sales of Phase III allowances to generate funds for the NER300 program (300 million allowances set aside in the New Entrants' Reserve (NER) to fund the deployment of renewable energy technology innovations as well as carbon capture and storage through the NER 300 program) (European Commission 2014a). In regard to the use of international credits, as indicated above, operators used 1.058 billion international credits in Phase II (2008–2012), and based on an earlier draft of the regulation on international credit entitlements, market analysts expect that a total of around 1.6–1.7 billion credits will be available for use in Phases II and III combined (European Commission 2014a).

In a 2012 report by the European Commission to the European Parliament, addressing the European Union Allowance (EUA) surplus problem for Phase III (2013–2020), two types of action are proposed (European Commission 2012b): (a) a review of the auction timetable as a short-term measure, postponing auctions of a certain amount of allowances (so-called back-loading), and (b) more *structural measures*, such as increasing the EU GHG target to 30 % by 2020, retiring a number of allowances, bringing more sectors into the EU ETS, access rules to international

credits and discretionary price management, and an early revision of the linear reduction factor. In regard to short-term measures, on 25 February 2014, the Auctioning Regulation was amended with the back-loading of 900 million allowances to the end of the trading period, i.e., 2020. However, as far as we know, no structural measures have yet been adopted. Moreover, in regard to the aforesaid reduction factor, Directive 2009/29/EC states that the total amount of allowances must decrease by a linear factor of 1.74 % per annum, leading to a reduction of just over 70 % in the ETS cap by 2050, but to be consistent with the EU's agreed long-term objective of 80–90 reduction by 2050 on the 1990 levels as set out in the 2050 Low-Carbon Roadmap (European Commission 2012c) and to achieve the target of a 40 % reduction from 1990 to 2030 as stated by the European Council in 2014 (European Council 2014), the European Commission affirms that this linear factor would need to be revised and lowered to 2.2 % per year (European Commission 2014a, b).

A Carbon Price Analysis

According to Kossoy and Guigon, in 2011 the average price reported per Assigned Amount Unit (AAU) is €5.1/tCO_{2eq}, while at the end of 2010, prices are in the range of €5–7/$tCO_{2\text{-}eq}$. This downward trend coincides with the overall trajectory for all carbon assets and is motivated mainly by lower than expected emissions and length in allowance supplies. However, there were also other contributing factors to explain this downward trend (i) the regulatory uncertainty surrounding surplus AAUs face to the second commitment period, and (ii) the fact that some Japanese private entities (who had been key AAU buyers since 2009), shifted their priorities elsewhere after the Fukushima incident (Kossoy and Guigon 2012). Meanwhile, the EU ETS showed significant price volatility during its start-up period (i.e., Phase I from 2005 to 2007). In late April 2006, prices were over €30, but they fell dramatically when the first EU ETS plant-level emissions data from different Member States were released (Ellerman and Buchner 2007; Ellerman 2009).

Figure 2 illustrates that the European Union Allowance (EUA) spot market price is higher than the Certified Emission Reduction (CER) spot market price throughout the first commitment period, and both prices show the same downward trend, from more than €23/tCO_{2eq} and €18/tCO_{2eq} in August 2008 to €7/$tCO_{2\text{-}eq}$ and €3.5/tCO_{2eq}, respectively, in May 2012. However, the difference between the EUA and CER spot prices increases especially since the end of 2010. Indeed, on 14 November 2012, the EUA spot price is €7.91 (with 421,000 allowances transacted), while the CER spot price is €0.78 (with 87,000 credits transacted) (so the difference was €7.13). Note that the price per tCO_{2eq} of the *green CER* is €1.03 (with 218,000 credits transacted), so the difference with the EUA totals €6.88. Finally, the Emission Reduction Unit (ERU) price at that time is as low as €0.54 (with 200,000 emission rights transacted) (Bluenext 2012).

This downward tendency in all the emission permit prices observed is linked to the aforesaid oversupply of emission permits in both emission trading schemes

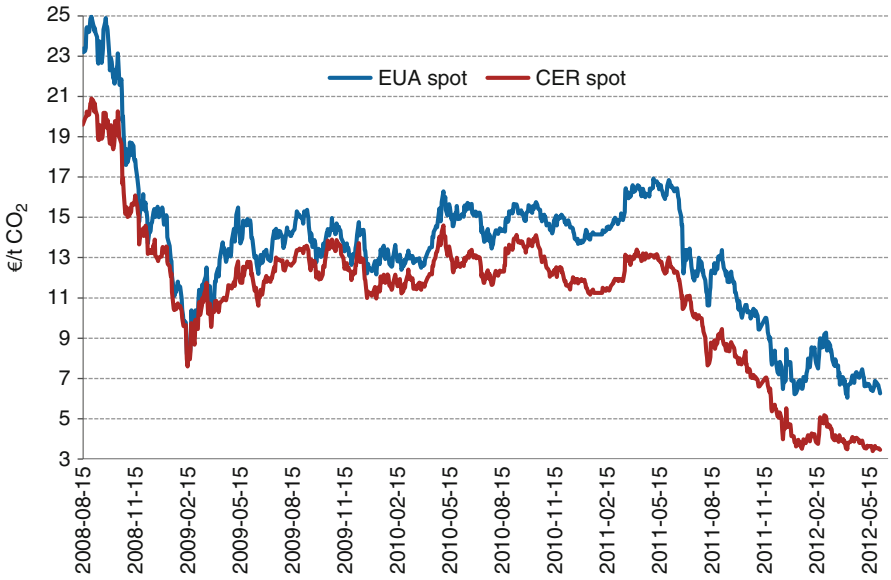

Fig. 2 Trend in EUA and CER spot prices in the 2008–2012 period (Source: Wind to Market, 2012)

(see subsection "A Supply–Demand Balance of Emission Permits and the Level of Ambition in the Trading Schemes"), and as illustrated, major differences exist between the different emission permits. In regard to the EU ETS, the European Commission affirms that from 2009 onward, a growing surplus of allowances and international credits became available on the carbon market, leading to a fall in the carbon price (European Commission 2014a). However, Ellerman affirms that a uniform price for CO_2 exists across the EU ETS system and is taken into account in operating and investment decisions by most owners of EU ETS firms. He also concludes that the EU ETS has shown itself to be an effective mechanism for limiting GHG emissions in the sectors covered and that it is being used to effect progressively more significant emission reduction (Ellerman 2009). By contrast, as shown, notable differences exist between the prices of the different Kyoto Units. According to Grubb (Grubb 2003), some of this discrimination may come directly from the private sector. Especially in this formative stage, the value accorded to emission units by the private sector is strongly affected by both reputational considerations (which make companies averse to large-scale and potentially controversial projects) and political risk considerations (which include the risks associated with uncertainty about what kind of units governments will ultimately accept). In this sense this author affirms that credits from project mechanisms may attract a premium over AAUs from trading, because they can be associated with actual project investment and also that direct trading of national emission allowances appears to be

subject to the greatest political risks and subsequently the greatest discounting (Grubb 2003). However, the trend in emission permit prices illustrates that the average estimated AAU price has been higher than the average CER spot price. This could be due to several reasons: on the one hand, there may be a problem linked to the delay of certain CER credits issued from different Clean Development Mechanism projects, which may have pushed some Annex B buyer countries to buy AAU allowances instead of CERs in order to reduce their degree of uncertainty; on the other hand, it is possible that what the author quoted has overestimated the political risk associated with the direct trading of AAUs, especially because a relevant amount of AAUs are probably being transferred through Green Investment Schemes, which means that the trading of AAUs could be associated with real project investments. Reputational risks may not be such a relevant factor, moreover, as the controversies in regard to the contribution to sustainable development of certain Clean Development Mechanism projects (see subsection "Critical Concerns"), which may have acted as a disincentive to demand for CER credits. Finally, as the transfer of AAUs occurs between countries that are both subject to legally binding constraints, it does not carry many of the political and technical complexities associated with the Clean Development Mechanism. This may be another cause for their lower demand. Indeed, it is probable that problems related to transaction costs due to the complexity of the methodologies established have also discouraged demand for CERs.

Conclusions

This chapter underlines the close relationship between the EU ETS and International Emission Trading under the Kyoto Protocol in the 2008–2012 period. The future of this International Emission Trading is now being called into question. Despite the fact that the countries signed up to the "Doha Amendment to the Kyoto Protocol" are able to use the Flexible Mechanism for the 2013–2020 period, the main weakness in regard to the future of the post-Kyoto 2012 period can be summed up as follows:

- The small proportion of GHGs included in the Doha Amendment, which accounts for only around 12 % of the worldwide total
- The low level of ambition of the countries involved, especially considering that the EU-28 group (which accounts for around 9 % of world emissions) had by 2012 achieved a 19.2 % GHG reduction below the 1990 levels

These weaknesses are robbing this trading instrument of relevance in tackling the worldwide climate change problem. The next UNFCCC 2015 meeting in Paris may be critical for the future of the International Emission Trading and also for the international policy against the climate change problem as a whole. It must also be underlined that, although the EU-28 has already overachieved the 18 % reduction target set by the Doha Agreement, major differences exist between Member States,

which means that there may be some Kyoto Unit buyer countries that will need to buy emission permits to reach their respective comments. However, considering current conditions, the most likely outcome is that they will have to pay a very low price for the units that they acquire.

Despite the critical situation faced by the International Emission Trading under the Kyoto Protocol and their links, the EU ETS still represents one of the most significant instruments for reducing GHG emissions in the EU. However, the problem of surplus allowances for 2013–2020 may also undermine its effectiveness as a trading instrument. It is still necessary to verify whether the EU will adopt the necessary measures to solve the surplus problem, whether the short-term measures adopted (the back-loading of 900 million allowances) will be effective, and whether more structural measures are still needed.

The downward trend observed in emission prices is closely linked to the oversupply of emission permits in both emission trading schemes. However, future expectations may be also fundamental to understanding different carbon price trends, especially at the end of the first commitment period, when the prices observed collapsed. The fall in Kyoto Unit prices is probably also directly linked to uncertainties regarding a possible future agreement in 2015 for an ambitious engagement of countries to face the climate change problem and the low level of significance of the Doha Agreement. These reasons are also relevant in understanding the current critical situation observed in the Clean Development Mechanisms and the virtual standstill of the Joint Implementation mechanism. Present chapter also outlines several reasons that may explain why the Certified Emission Reduction Prices are lower than Assigned Amount Unit prices, such as the delay of certain credits issued from some Clean Development Mechanisms projects.

Although a uniform price existed between 2008 and 2012 for European Union Allowances, notable differences were observed between the prices of different Kyoto Units, especially between Assigned Amount Unit (AAU) and Certified Emission Reduction (CER) credits. Questions linked with the existence of methodological problems when determining baselines and additionality, the coverage of forestry-related projects, the sustainability of the projects implemented, and other factors may have discouraged the demand for Certified Emission Reduction (CER) credits from certain Clean Development Mechanism projects, and that could largely explain the fall observed in average CER spot prices compared to average AAU estimated prices.

As illustrated, there are in addition other relevant factors to be considered, such as the necessity for robust, transparent regulations regarding the different emission permit transaction and accounting systems. Without doubt the frauds detected in the EU and the high level of complexity inherent in such trading systems (as may occur in regard to the recent complex auctioning system set up in the EU ETS) have probably increased the level of skepticism toward them as policy instruments.

Acknowledgment This work has been possible thanks to the collaboration of the Energy Working Group, which belongs to the Chair of International Relations (Social Sciences Faculty) of the University of the Basque Country (UPV–EHU).

European Union (EU) Strategy to Face the Climate Change Challenge in the Framework of the International Commitments

Itziar Martínez de Alegría, María-Azucena Vicente-Molina, and Cristian Moore

Contents

Abstract

Since climate change has become an international concern, most of the developed countries have attempted to adopt policies to mitigate global warming and its side effects in the last years. In this chapter, firstly the climate change framework for international action and policy development is analyzed. Likewise, due to the strategic importance of the European Union (EU) leadership in developing and

implementing new instruments and policies to mitigate climate change through energy efficiency and renewable energy sources, this work is mainly focused on its energy legislative instruments to face the climate change. The present energy model of the EU, which supports its economic growth and prosperity, is nearly 80 % dependent on fossils fuels and increasingly dependent on energy imported from non-EU member countries, creating economic, social, political, and other risks for the EU. From the 1990s, the key objectives of the EU have been energy security of supply, competitiveness, and environmental protection, making renewable energy sources and energy efficiency the basis for EU's new energy strategy. Accordingly, the EU has recently adopted new legislative instruments with the aim to become the world leader in the impulse of climate change mitigation through the employment of renewable energy sources and energy efficiency technologies. Therefore, this chapter presents and discusses the main legislative measures adopted recently, as well as their potential incidence on the EU's objectives to comply with climate change amendments under the Kyoto Protocol.

Introduction

In recent years, various local, state, federal, and international programs have been introduced, proposed, and adopted with the intent to implement measures to reduce the levels of carbon dioxide (CO_2) and other greenhouse gas (GHG) pollutants emitted into the atmosphere (See Annex 1), which are considered the main cause of climate change. Due to the need for consistent international evaluation of GHG emissions and to enable a universal standard of measurement for climate change impacts, GHG emissions are commonly referred to in terms of "carbon dioxide equivalents" or CO_{2eq}, because CO_2 is the most abundant among the mentioned GHGs (e.g., it represents around 80 % of the European Union's GHG). The definition of carbon dioxide equivalent (CO_{2eq}) is the amount of CO_2 emission that would cause the same radioactive forcing as an emitted amount of a well-mixed greenhouse gas or a mixture of well-mixed greenhouse gases, all multiplied with their respective global-warming potentials (GWPs) to take into account the differing times they remain in the atmosphere (IPCC 2007). Around 78 % of the total GHG emission increase in the period 1970–2010 has been due to CO_2 emissions from industrial processes and fossil fuel combustion (IPCC 2014). A specific global-warming potential (GWP) has been developed for each identified GHG. The global-warming potential is a measure of the impact of the emissions of the specific GHG's climate change influence relative to a similar amount of CO_2 over a consistent time frame (see Annex 1). The type of pollutant and its specific GWP is an important aspect in the planning of legislative and regulatory approaches to mitigate climate change.

As shown in Fig. 1, despite a growing number of climate change mitigation policies in place, from 1970 to 2010, total anthropogenic GHG emissions kept on growing continuously, with larger absolute increases toward the end of this period.

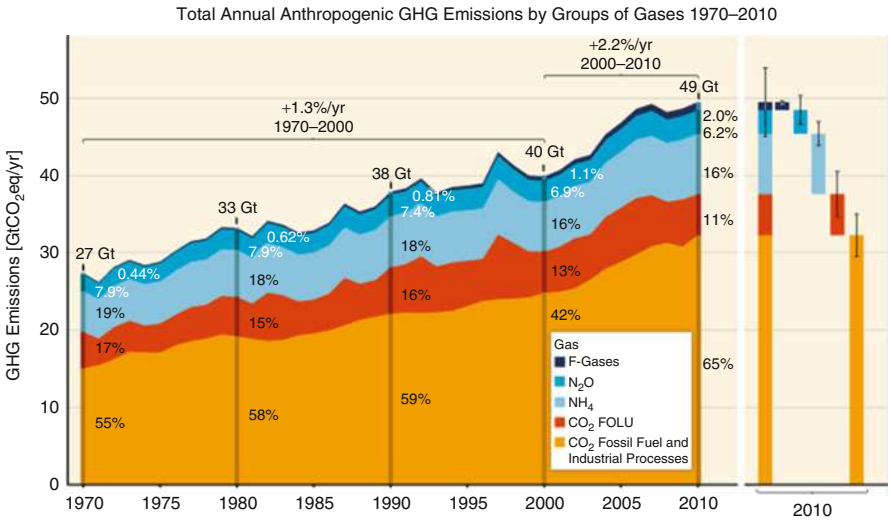

Fig. 1 GHG emissions by group of gases. *F-Gases* Fluorinated gases, *FOLU* Forestry and other land use (Source: IPCC 2014)

The most important drivers of increases in CO_2 emissions from fossil fuel combustion continue to be economic and population growth. Both drivers offset emission reduction due to energy efficiency. Accordingly, the International Panel on Climate Change (IPCC) prevents that emission growth is expected to persist driven by growth in global population and economic activities, unless additional efforts are taken to reduce GHG emissions (IPCC 2014). Figure 2 illustrates the main CO_2 emitter countries in 1995 and 2010.

Since fossil fuels are the first source of CO_2 emissions in the EU (IPCC 2014), which are, at the same time, the most common gases among the GHGs contributing to climate change, the EU has decided to reduce the use of these energy sources betting for this purpose on a strategy focused on renewable energy sources and energy efficiency increase. According to the European Council, the EU is committed to reducing GHG emissions to 80–95 % below 1990 levels by 2050 in the context of necessary reductions by developed countries as a group (European Council 2009). The EU's energy and climate strategy includes, on one hand, the implementation of an Emission Trading Scheme (the EU ETS from now) that focuses on the EU great CO_2 emitters (the EU ETS firms from now) and covers around half of the total GHG and, on the other hand, a wide number of policy measures that affect at the same time the aforesaid EU ETS firms and also the rest of sectors (referred as the diffuse sectors). The main objective of the present work is to offer an overview of the current climate change policy strategy carried out by the EU focusing on the legislation affecting the generation and use of energy. This is why a relevant amount of policies and regulation, which may have a fundamental impact on the future evolution of the GHG in the EU, have been kept out from the present analysis (specially that linked to

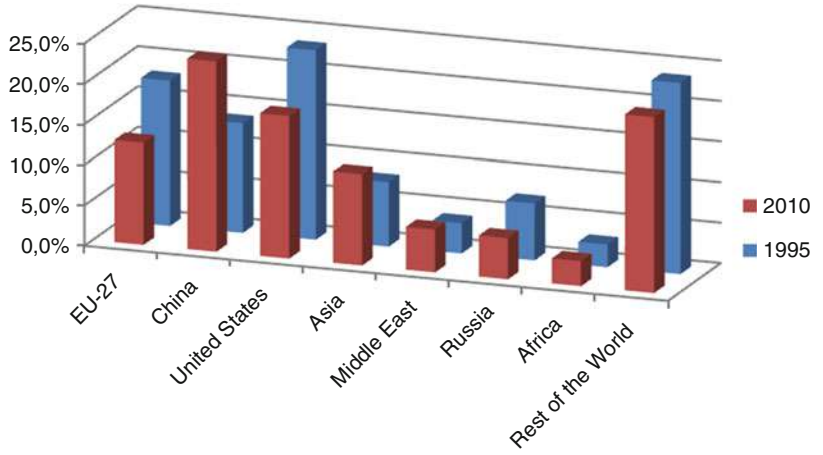

Fig. 2 Contribution to the world CO_2 emissions (%) by emitter countries or regions (Source: Elaborated with data from European Commission 2013a)

the agriculture sector that aimed at promoting carbon sinks or that linked with the nuclear energy). The legislation related with the fluorinated gases ("F-gases") (which are a family of GHG manmade gases used in a range of industrial applications whose global warming effects are up to 23,000 times greater than carbon dioxide (CO_2) and which are rising strongly and affect the sector of cars and vans (the MAC directive), the buildings' air conditioning, etc.), the legislation related with the completion of the internal energy market, and the financial measures destined to promote the climate change policy within the EU (such as the different R + D Frameworks Programs, the Intelligent Energy Europe Programme 2007–2013, etc.) are also kept out from the present study.

Figure 3 shows a synopsis of the most relevant binding targets established recently by the EU to face the climate change through GHG emission reduction and the main pillars of its "Climate Change Policy."

As illustrated in Fig. 3, under the UNFCCC framework, the EU committed to reducing its GHG emissions by 8 % (on average) compared to 1990 emissions by 2012 (as stated by the Kyoto Protocol in 1997). In 2012, the Doha Agreement included the objective to reduce GHG emissions by 18 % from 1990 to 2020 (UNFCCC 2013). In 2007, the EU committed to reduce GHG emissions by 20 % by 2020 (30 % in the case of an international agreement being reached) (European Council 2007). Unfortunately, no agreement has been reached in this regard till now. To reach this target, the EU established the so-called 20/20/20 mandate, upon which the EU has lately articulated its strategy against climate change, which is supported by three fundamental pillars: increasing energy efficiency (+20 %), use of renewable energy sources (20 %), and reducing GHG emissions (−20 %). Along this line, the EU distinguishes between big emitters (industrial and power sectors) and small emitters or diffuse sectors (e.g., citizens in their daily life activities, such as heating

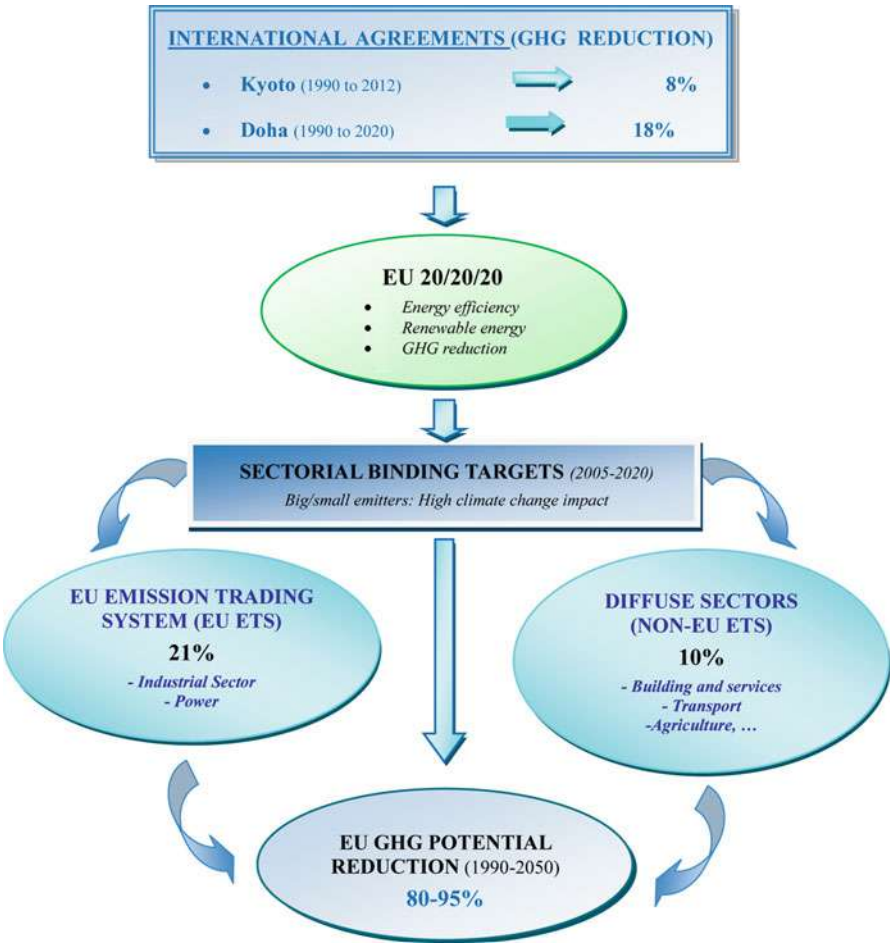

Fig. 3 Binding targets of European Union for climate change mitigation, GHG emission reduction

of buildings, etc.), whose GHG emissions have individually or in the whole an important impact on climate change. This classification serves as a guide in the development of a wide amount of EU legislative instruments, being the great emitters included in the EU Emission Trading System (EU ETS) in order to control their large individual impact on climate change. The rest of the emitters, who are not included in the aforesaid system, form the diffuse sectors and comprise building, services, transport, and agriculture (although only building and transport sectors are analyzed).

Following the scheme represented in Fig. 3, the present chapter is organized as follows: First, the international framework to face climate change and main accords reached (section "International Framework for Action and Policy Development

Toward Climate Change Mitigation") are briefly shown. Second, the EU policy strategy to face climate change is analyzed focusing on main legislative instruments, roadmaps, and policy guides adopted (section "European Union Strategy to Face Climate Change"). Section "European Union Strategy to Face Climate Change" is divided into two parts, which comprise a historical perspective of the EU's energy and climate strategy (section "Historical Perspective") and a sectorial analysis of the aforesaid strategy (section "Analysis of Climate Change Legislative Instruments from a Sectorial Perspective") including the analysis of the EU ETS sector (section "The EU ETS Sector"), the residential sector (section "The Diffuse Residential Sector"), and the transport sector (section "The Transport Sector"). Finally, section "Conclusions" concludes with a summary and an outlook.

International Framework for Action and Policy Development Toward Climate Change Mitigation

In the early 1980s, the United States directed the completion of a study of worldwide environmental challenges that included a detailed analysis of climate change impacts. Although no specific actions resulted from this study of climate change and related issues, in 1988, "because of the need of broad and balanced information about climate change" and "to provide the governments of the world with a clear scientific view of what is happening to the world's climate," the Intergovernmental Panel on Climate Change (IPCC) was established in order to (IPCC 2010)

- Prepare a comprehensive review and recommendations with respect to the current state of knowledge of the science of climate change
- Evaluate the current and projected social and economic impacts of climate change
- Determine possible response strategies and elements for inclusion in a potential future international convention on climate

The scientific evidence produced in the first IPCC Assessment Reports in the 1990s revealed the importance of climate change as a future topic of interest for environmental policy and planning. In the years following, the IPCC's work has been and continues to be a key work in developing policies to address climate change mitigation.

In 1992, the United States and 153 other countries signed the United Nations Framework Convention on Climate Change (UNFCCC), in Rio de Janeiro (Brazil), which committed all parties to voluntarily reduce GHG emissions to reasonable levels in future years, becoming the main multilateral forum focused on addressing climate change, with nearly universal participation. Following ratification of the UNFCCC, annual meetings of all included parties have been conducted in meetings generally referred to as Conferences of the Parties (COP). Major COP meetings to date are briefly summarized in Table 1.

Table 1 Summary of major UNFCCC Conference of Parties (COP) meetings

COP -No / Year Location	Main objectives and/or amendments
COP-1 / 1995 Berlin, Germany	This was the first meeting of UNFCCC COP. It established an assessment phase known as the Berlin Mandate to develop control options for countries and implemented a 2 year analytical and assessment phase to define specific climate change mitigation options for countries.
COP-3 / 1997 Kyoto, Japan	The Kyoto Protocol was adopted and specific emission reduction or limitation targets for developed countries (with an overall GHG emission levels reduction commitment of 5.2 % below 1990) were established. The United States signed the protocol; however, United States Senate resolutions blocked further action. Note that the Bush administration openly rejected the Kyoto Protocol in 2001.
COP-7 / 2001 Marrakech, Morocco	The rules for the implementation of the Kyoto Protocol were detailed, especially in regard to the Clean Development Mechanism and the Joint Implementation Mechanism. The United States continued as observers only and declined to be active in the negotiations amid hope that the United States would re-engage in the process.
COP-11 / 2005 Montreal, Canada	One of the largest climate change meetings ever held. Entry into force of the Kyoto Protocol. Discussion of the ratified Kyoto Protocol including discussion of emissions trading systems and other aspects of global emissions policy development. The meeting resulted in the Montreal Action Plan that extended the life of the Kyoto Protocol beyond the original 2012 expiration date with deeper GHG emission cuts planned.
COP-13 / 2007 Bali, Indonesia	Parties agreed on the Bali Road Map on implementation timelines and structured negotiation on post Kyoto 2012 timeframe.
COP-14 / 2008 Poznan, Poland	Agreements reached on financing to help poor nations cope with climate issues through adaptation and financial assistance. Approval of forest protection mechanism to combat climate change impacts in heavily impacted forest areas.
COP-15 /2009/ Copenhagen, Denmark	The original goal of COP-15 was to reach a global climate agreement for the period after the Kyoto Protocol expiration in 2012. The COP-15 expressed the environmental objective in terms of limiting increases in average global temperature of 2 °C above pre-industrial levels. It was agreed that developed countries should raise funds of $30 billion from 2010 to 2012 and a goal to raise $100 billion per year by 2020. After the summit, parties sent their corresponding GHG emission limitation or reduction pledges referred as the "Copenhagen pledges." These Accords were later ratified by the Cancun Agreement (COP-16).
COP-17 / 2011 Durban, South Africa	Annex I parties decided to start the process for the development of a new Protocol, or another instrument with legal force under the UNFCCC, which should be adopted by 2015 (to come to effect and be implemented from 2020). To this aim the Durban Platform for Enhanced Action was established.
COP-18 / 2012 Doha, Qatar	Adoption of the "Doha amendment to the Kyoto Protocol" to enable the continuing with the Kyoto Protocol through a second commitment period from 2013 to 2020.
COP-19 / 2013 Warsaw, Poland	An accord to establish more comparable targets face to the future Paris Agreement in 2015 and a calendar in order to establish more ambitious objectives were agreed.

(*continued*)

Table 1 (continued)

COP -No / Year Location	Main objectives and/or amendments
COP-20 / 2014 Lima, Peru	Nations concluded by elaborating the elements of the new agreement, scheduled to be agreed in Paris in late 2015, while also agreeing the ground rules on how all countries can submit contributions to the new agreement during the first quarter of 2015. These Intended Nationally Determined Contributions (INDCs) will form the foundation for climate action post 2020 when the new agreement is set to come into effect.

The Major Steps in International Climate Change Mitigation: From Kyoto to Paris

The most significant development resulting from all of the COP meetings since the inception of the UNFCCC (1992) was likely the Kyoto Protocol adopted in Kyoto, Japan, in 1997. The Kyoto Protocol required that "at least 55 % of the total carbon dioxide emissions for 1990 of the Parties included in Annex I" of the UNFCCC (see Annex 2) must deposit their instruments of ratification, acceptance, approval, or accession (UNFCCC 1998). Accordingly, with the adhesion of Russia, it entered into effect on February 16, 2005. The Kyoto Protocol is generally seen as an important first step toward a complete international GHG emission reduction program that will stabilize GHG emissions, provide the essential architecture for any future international agreement on climate change, and enable efficient mitigation and adaptation programs to be developed and implemented. The major achievement of the Kyoto Protocol is that it established binding GHG emission reduction targets for 37 industrialized nations and the European Community. These reductions amount to an average of 5.2 % against 1990 emission levels over the 5 year period from 2008 to 2012. The Kyoto Protocol places a larger burden on more developed nations under the principle of "common but differentiated responsibilities" based on the belief that developed countries are "principally responsible" for the levels of GHG emissions in the atmosphere and should assume a greater burden for mitigation of emissions (UNFCCC 2010a).

Under the Kyoto Protocol, countries are required to meet their GHG emission reduction targets primarily through federal and regional measures. However, the Kyoto Protocol offers them additional means of meeting their reduction targets by way of three market-based mechanisms (also referred to as three flexible mechanisms):

- GHG emission trading or international emission trading
- Clean development mechanisms
- Joint implementation

These three market-based mechanisms were established to help stimulate significant green investment and technology advancement while also helping all countries

meet their GHG emission reduction targets in an efficient and cost-effective manner. Each of the market-based mechanisms is defined in more detail below.

International Emission Trading

As noted previously, countries that are party to the Kyoto Protocol have agreed to targets for reducing their GHG emissions during the 2008–2012 initial commitment period (UNFCCC 2010b). Emissions trading, as established in Article 17 of the Kyoto Protocol, allows countries to sell excess GHG emission credits to other countries that exceed their committed target level of GHG emissions. Beyond actual GHG emission reduction credits, other units are available for trading under the program including

- A removal unit on the basis of land use, land use change, and forestry activities (LULUCF) (e.g., reforestation)
- An emission reduction credit generated by a joint implementation project
- A certified emission reduction generated from a clean development mechanism project

Under the Kyoto Protocol, each country's actual GHG emissions have to be accurately monitored and detailed records maintained of carbon market activity through carbon registries and other means. GHG emission trading schemes may be established in regional or national markets under the guidelines established in the Kyoto Protocol.

Clean Development Mechanism and Joint Implementation Mechanism

The clean development mechanism is essentially a global clearinghouse of acceptable GHG emission offset programs or projects that have been successfully implemented and are thereby certifiable for GHG emission credits. Designed to stimulate sustainable development and GHG emission reductions, this mechanism provides a means of added flexibility for industrialized countries to meet their GHG emission reduction targets and comply with associated limitations. This mechanism also allows emission reduction projects in developing countries to earn certified emission reduction (CER) credits. Each CER credit is equivalent to 1 ton of CO_{2eq}. These CERs can be traded and sold on the international market and utilized by industrialized nations to meet their GHG emission reduction targets under the Kyoto Protocol (UNFCCC 1998). Joint implementation, as defined in Article 6 of the Kyoto Protocol, allows a country with a GHG emission reduction or limitation commitment to earn emission reduction units from an emission reduction project in another country that is party to the Kyoto Protocol and to be counted toward the specific country's GHG emission reduction target. Joint implementation, thus, allows countries under the Kyoto Protocol the flexibility to invest in other countries through capital projects and technology transfer.

Country Classifications Under the Kyoto Protocol and UNFCCC

An important aspect of implementation of the Kyoto Protocol and planning under the UNFCCC is how each country is classified. On the one hand, the UNFCCC set the following classification: *The Annex I parties*, comprising industrialized countries that signed the UNFCCC (it includes the 24 original OECD members, the European Union, and 14 countries with economies in transition) (see Annex 2). *The Annex II* parties is a subgroup of Annex I parties with a special obligation to provide financial resources and facilitate technology transfer to developing countries (Annex II parties include the 24 original OECD members plus the European Union). The rest of countries are referred to as non-Annex I countries (see Annex 2). On the other hand, the Kyoto Protocol included two other new Annexes: *the Annex A*, which includes the GHG affected by the cited Protocol*, and the Annex B*, which includes a list of countries with their respective emission reduction or limitation commitments compared to their 1990 levels (see Annex 2). It must be noted that the United States, being comprised in the Annex B of the Kyoto Protocol and being currently the second biggest GHG emitter country after China (see Fig. 4), did not ratify the Kyoto Protocol for its first commitment period.

According to the UNFCCC, developing countries are not required to reduce GHG emissions unless developed countries in Annex II provide sufficient funding and technological investment. Developing countries may volunteer to become Annex I countries when they are sufficiently developed.

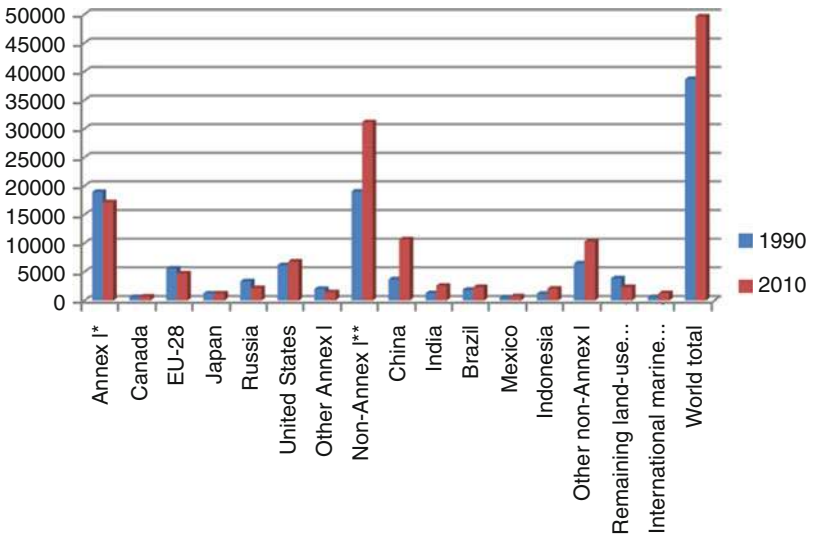

Fig. 4 GHG emissions 1990 and 2010, by Annex I, Non-Annex I and other main GHG country or regions emitters ($GtCO_{2eq}$). Annex I* excluding Turkey and LULUCF. Non-Annex I** including LULUCF for the countries with a high share of LULUCFs, i.e., Brazil, Indonesia, Mexico, Chile, Colombia, Costa Rica, Papua New Guinea and Peru (Source: Adapted from Hof et al. (2013) data)

Current Developments in the International Negotiations

As negotiated in the Bali Conference in 2007 (COP-13), by the end of the first commitment period of the Kyoto Protocol in 2012, an updated international framework that would deliver the GHG emission reductions that the IPCC had deemed necessary must have been developed, negotiated, and ratified. As explained by the UNFCCC, ratification means formal approval (often by the country Parliament or other national institution), of a convention, protocol, or treaty, enabling a country to become a party, so ratification is a separate process that occurs after a country has signed an agreement and must be deposited with a "depositary" (in the case of the Climate Change Convention, the UN Secretary-General) to start the countdown to becoming a party (UNFCCC 2015c). The UNFCCC meeting took place in Copenhagen (Denmark), during December 2009, became the focal point for the development of this new international framework. Although prospects looked dim early in the meeting for any type of agreement, near the conclusion of the meetings government leaders negotiated with focused intensity to reach a global agreement on climate change. In describing the newly touted Copenhagen Accord, United States President Obama commented that there was "a meaningful and unprecedented breakthrough here in Copenhagen." President Obama went on to comment that while the international community has come a long way, there is still a long way to go to reach consensus on climate change mitigation policy. Despite no "new legal agreement" being made, after the Copenhagen Conference, most of Annex I parties formally submitted their GHG emission reduction pledges. In addition, seven major emerging economies (China, India, Brazil, Indonesia, Mexico, South Africa, and South Korea) sent their mitigation action plans (UNFCCC 2015b). However, as most individual targets include high and low estimates, contain assumptions and conditions attached (which depend in many cases on future agreements), use differing base years and GHG gases, and include distinct approaches to the account of offsets and sequestration methods, it is a difficult task to compare various pledges. According to some studies, the cited pledges will not be sufficient to reach the necessary reductions to obtain a max. 2 °C temperature increase reduction objective, especially if the lowest-ambition pledges are implemented at the same time that the aforesaid land use and land use change accounting rules and the use of surplus emission units result in a net increase of emissions (Den Elzen et al. 2010, 2011; Kartha and Erikson 2011).

Later, in the Conference of Parties that took place in Durban in 2011, Annex I parties highlighted the significant gap existing between the aggregate effect of a party's mitigation pledges, in terms of global annual emissions of GHG by 2020, and aggregate emission pathways, likely to have a chance of holding the increase in a global average temperature below 2 °C or 1.5 °C above preindustrial levels. It was also decided to start the process for the development of a new protocol, or another "instrument with legal force" under the UNFCCC, applicable to all parties by 2015 (in order for it to come to effect and be implemented from 2020). To prepare this new Protocol or "instrument with legal force" face to 2015, the Ad Hoc Working Group on the Durban Platform for Enhanced Action was established also at the COP-17 (UNFCCC, 2011). Another major decision adopted in the Durban Conference of

Parties, as meeting of the Parties to the Protocol (UNFCCC 2012) and ratified later by the eighth Conference of the Parties held in Doha in 2012, was the "Doha Amendment to the Kyoto Protocol," which enabled the continuing with the Kyoto Protocol through a second commitment period from 2013 to 2020 (according to which parties may provisionally apply the aforesaid amendment pending its entry into force). The "Doha Amendment" meant the creation of a new Annex B of the Kyoto Protocol, converting the "Copenhagen Pledges" into new quantified emission limitations or reduction commitments for the affected Annex B countries (UNFCCC 2013). However, apart from the United States (USA), a number of Annex I countries (notably Canada, Japan, and Russia but also Belarus, New Zealand, Norway, Switzerland, and Ukraine) decided not to participate in the second commitment period (UNFCCC 2015d). As illustrated in Fig. 5, the world total GHG emissions in 2020 are estimated at around 60,626 $GtCO_{2eq;}$ therefore, the aforesaid countries plus the USA GHG emissions (that will amount to around 6,802 $GtCO_{2eq}$ in 2020) all together account for around 22 % of the world emission in 2020. Meanwhile, countries inside the Doha Amendment only amount to around 12 % of the total emissions worldwide.

In the Conference of Parties held in Warsaw (Poland), in 2013, it was agreed to set more comparative targets together with a calendar from Warsaw (the COP-19) to Paris (the future COP-21), in order to establish more ambitious objectives (UNFCCC 2014). However, in spite of the existing advances in regard to the international policy to face the climate change, the key question to be kept in mind is the level of ambition in relation to the new Agreement to be adopted in 2015. Not only, the final number of countries agreed, should a binding target be taken into account but also the real, absolute level of reduction or limitation of their corresponding GHG emissions, considering the potential flexibility offered by the market-based mechanisms and the land use and land use change activities.

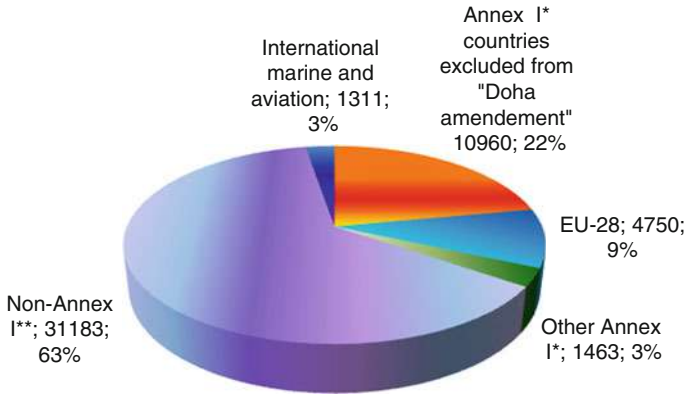

Fig. 5 GHG emissions (in $GtCO_{2eq}$ and %) by different groups of countries in 2010. Annex I* excluding Turkey and LULUCF. Non-Annex I** including LULUCF for the countries with a high share of LULUCFs, i.e., Brazil, Indonesia, Mexico, Chile, Colombia, Costa Rica, Papua New Guinea and Peru (Source: Hof et al. 2013)

As stated by the IPCC, under regime designs for low concentration stabilization levels (450 ppm CO_{2eq}), Annex I countries would need to reduce their emissions substantially during this century by 2020 (−25 % to −40 % below 1990 levels) and to still lower levels by 2050 (−40 % to −95 %), even if developing countries make substantial reductions. It was estimated that 450 ppm CO_{2eq} limit the temperature increase to 2 °C (IPCC 2007). The European Council and the Parliament endorsed these calls for emission reductions as an EU objective, in the context of necessary reductions according to the IPCC by developed countries as a group (COM 2011a).

European Union Strategy to Face Climate Change

In this section, the strategy of the EU to fight against climate change alongside to face the problem of security of energy supply and the increase of the European competitiveness is analyzed.

The EU objective to face the Kyoto Protocol was to reduce by 8 % its GHG emissions between 1990 and 2012. According to the European Environment Agency, a reduction of 19.2 % in GHG emissions was achieved by the EU-28 (without LULUCF), from 1990 to 2012 (EEA 2014). In the following paragraphs, the strategy chosen by the EU to achieve these positive results is shown.

Historical Perspective

The present European Union's model of economic growth and prosperity is around 53.8 % dependent on foreign fuels (European Commission 2013a). Since fossil fuels are the main source of CO_2, which is, at the same time, the most common gas among the GHG (IPCC 2014), this economic model is not environmentally sustainable. In addition, the EU economic model is increasingly dependent on energy imported from non-EU member countries (see Table 2), which creates economic, social, political, and other risks for the Union. Therefore, in the last decade, the Union has attempted to focus its growth on a low-carbon economy through legislative

Table 2 Gross Inland (GI) energy consumption, external dependence and GHG emissions for EU-27

Variable	1995	2005	2010
Energy consumption (Mtoe/year)	1,668	1,824	1,759
Variation rate compared to 1995	–	9.3 %	5.4 %
External energy dependence (All fuels)	43.2 %	52.5 %	52.7 %
GHG emissions (Mio ton CO_{2eq}/year)	5,429	5,445	4,907
Variation rate compared to 1995	–	0.29 %	−9.6 %

Source: Authors' own elaboration from data of European Commission 2012, 2013a

measures, where the increase of renewable energy sources and energy efficiency are key factors not only for energy security of supply but also for climate change mitigation.

As shown in Table 2, the EU Gross Inland energy consumption increased in the period 1995–2010 nearly 5.5 %, and the energy external dependence increased from 43.2 % in 1995 to 52.7 % in 2010. With regard to GHG emissions, from 1995 to 2005 there was an average increase of 0.29 %, while from 2005 to 2010 the trend changed and a reduction of 9.8 % was reached in these last 5 years. There was a 9.6 % reduction for the whole period, 1995–2010, which is a considerable reduction.

The need of promoting energy efficiency was already present in the European energy programs adopted during the 1980s, and in the 1990s the environmental aspects of energy gained importance. Since 1995, the following three key objectives are pursued by the European Energy Strategy: security of supply, environmental protection, and improvement of competitiveness. In 1997, the European Commission (from now on Commission) published a White Paper on Renewable Energy (COM 1997), which announced a target to double the European Union's renewable energy share to 12 % by 2010. The White Paper also announced a renewable energy strategy and action plan, highlighting the need to develop all renewable energy resources, create stable policy frameworks, and improve planning regimes and electricity grid access for renewable energy. A key element of the action plan was the establishment of European legislation to provide a stable policy framework and clarify the expected development of renewable energy in each Member State. In this regard, Directive 2001/77/EC (EU 2001) and Directive 2003/30/EC (EU 2003a) set indicative targets for 2010 for all Member States and require actions to improve the growth, development, and access of renewable energy. A Biomass Action Plan was also adopted in 2005 paying attention to the specific need for Member States to develop Europe's biomass resources (COM 2005). The objective of the EU was to change the increasing dependency on fossil fuels and energy import through the promotion of energy efficiency and the use of renewable energy sources.

In the domestic framework, in response to a request formulated by the 2005 Autumn European Council, the Commission worked on the following important tasks:

- The establishment of the basis for a **Common Energy Policy** that should be based on the following three pillars: sustainable development, increase of competitiveness, and security of supply (COM 2007). The three of them are directly related to renewable energy sources and energy efficiency.
- The elaboration of the **"European Strategic Plan for Energy Technology"** for the consecution of the three pillars. The final objective is the restructuring of the European full energy system, starting with competitiveness and passing through to technological processes. The Commission also highlighted that to reach this objective, and compared with the current situation, a higher quantity of resources (human and financial) would be needed.

In order to overcome the Kyoto Commitment of 8 % GHG emission reduction target, the commonly named "20/20/20" mandate was established, with the following ambitious targets for 2020 compared to 1990 levels (European Council 2007):

- Reduction in greenhouse gas (GHG) emissions by 20 % (and by 30 % in the event of a new global climate change agreement being reached and other developed countries committing themselves to comparable emission reductions and economically more advanced developing countries contributing adequately according to their responsibilities and respective capabilities)
- Saving 20 % of total primary energy consumption compared to projections
- Increasing the level of renewable energy in the EU's overall energy mix to 20 % (with a minimum target for biofuels of 10 % in transport consumption for each Member State)

The first of these targets was a clear sign of engagement and the "ethic leadership" of the European Union to face the Kyoto Protocol commitment, while the following two were internal objectives and constitute the best complement to reach the first one.

In 2008, the European Commission proposed what is being referred to as "Climate and Energy Package," which is a set of different legislative measures destined to reach the 20/20/20 mandate. It comprises four pieces of complementary legislation (adopted all along in 2009) regarding

(a) Carbon Capture and Storage Directive
(b) Measures destined to the big industrial GHG emitters or EU ETS sectors
(c) National targets and measures for non-EU ETS or diffuse sectors
(d) National renewable energy binding targets

(a) The Carbon Capture and Storage Directive (EU 2009a) creates a legal framework for the environmentally safe use of carbon capture and storage technologies. It involves capturing CO_2 emitted by industrial processes and storing it underground geological formations so it does not contribute to the global warming.

(b and c) The EU establishes a gradual and foreseeable trajectory of GHG emission reduction. The total effort for GHG reduction is divided between the sectors affected by the European Union Emission Trading Scheme, which covers around 45 % of the total EU's GHG emissions (European Commission 2014a), and the rest of sectors also referred to as the non-EU ETS sectors or "diffuse sectors." These diffuse sectors are a wide range of sectors that are made up of many small-scale GHG emitters, such as transport (cars and trucks), buildings (especially heat consumption), services, small industrial facilities, agriculture, and waste, that together represent large amounts of emissions. Each Member State must achieve a different objective of emission reduction from 2005 to 2020 *"based on the principle of solidarity between Member States and the need for sustainable economic growth across the Community, taking into account the relative per capita GDP of Member State"* (European Parliament and Council 2009a). As illustrated in Fig. 6, this

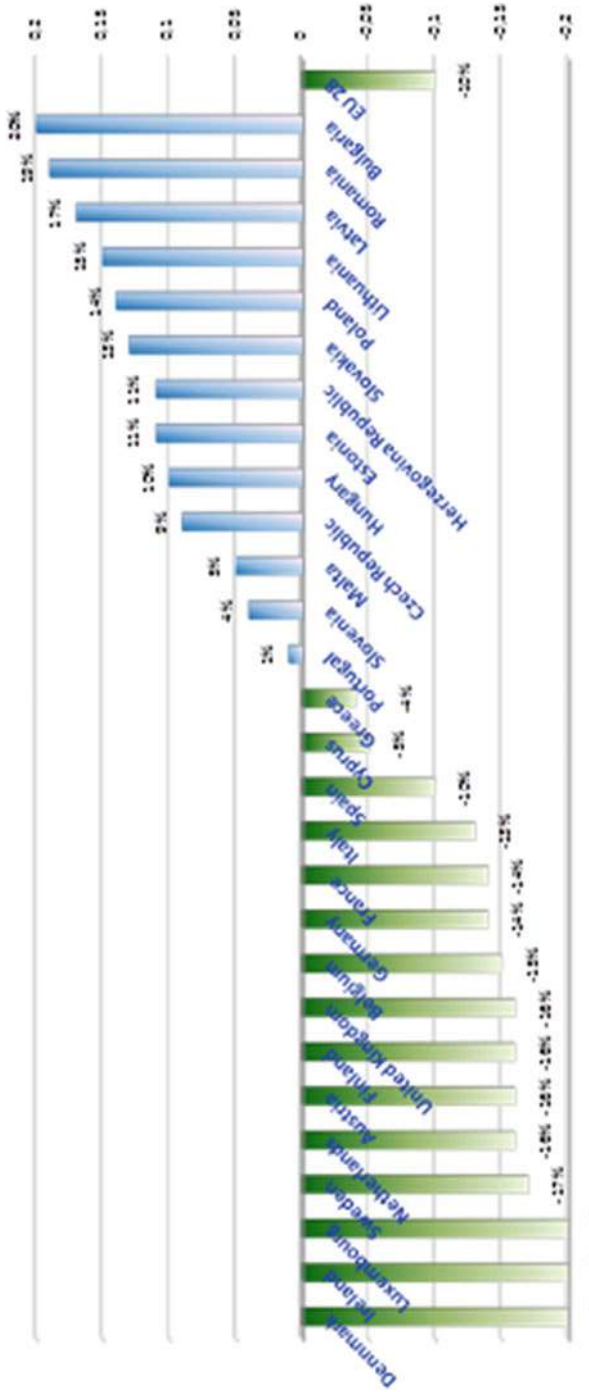

Fig. 6 Member State GHG emission limits in 2020 compared to 2005 levels (Source: European Commission 2014a)

objective represents on average an overall reduction of 10 %. The limits between Member States vary from −20 % to +20 % (e.g., −20 % for Luxembourg, + 20 % for Bulgaria, and −10 % for Spain) (European Parliament and Council 2009a). However, there are differences in regard to the potential level of fulfillment by the different Member States of their corresponding commitments to 2020. Member States are responsible for the fulfillment of this objective through the implementation of national measures. The most profitable way for both the EU ETS sectors and non-EU ETS sectors to perform their GHG reduction objectives (21 % and 10 %, respectively) is basically through the promotion of energy efficiency and the use of renewable energy sources (COM 2008; EU 2009a).

(d) The EU adopted in 2009 the new Directive on the Promotion of the Use of Energy from Renewable Energy Sources (EU 2009b), which does not distinguish between conventional and nonconventional renewable energy sources. A novelty of this Directive compared to previous Directives on the matter is that it establishes different nationally binding objectives for the Member States (from 8.5 % to 20 %), with an overall target of increasing the level of renewable energy in the EU's energy overall mix to 20 % (with a minimum target for biofuels of 10 % for all Member States). According to the Directive, all Member States had to notify the Commission by June 2010 about their national renewable energy action plans. These plans should include not only the share of renewable energy sources but also the information on policy measures (including public aid) adopted to fulfill their national objectives. The increased use of energy from renewable sources, together with energy savings and increased energy efficiency, constitute important tools to comply with the Kyoto Protocol, promoting at the same time the security of energy supply and the technological development and providing opportunities for employment and regional development, especially in rural and isolated areas.

It should be outlined that all the aforesaid legislation was adopted without a common legislative basis (Martínez de Alegría et al. 2009) until the entry in force of the Treaty on the Functioning of the European Union that contained for the first time the Article 194 (EU 2010a). This Article 194 established the framework and the objectives for the development of the EU's common energy policy; however, it must be taken into account that the Member States are still very active in regard to the development of their own energy sector and they still keep a great scope to develop their own energy policy strategy that may affect the trend in future GHG emissions (e.g., the type of energy infrastructures to be promoted in order to guarantee the security of energy supply, the type of incentives – or the lack of them – that are being set up to promote the renewable energy sources). Another element to be kept in mind is that the "Energy and Climate Package" does not address the energy efficiency target directly. As stated in 2011 by the Emissions Roadmap 2050, the EU was on track to meet two of the 20/20/20 targets, *"but with current policies, only half of the 20 % energy efficiency target would be met by 2020"* (COM 2011a). Instead, with full implementation of the 2011 Energy Efficiency Plan, the 20 % of GHG reduction objective could be surpassed in 2020 (European Commission 2011a). The 2011 Energy Efficiency Plan affirms that the energy efficiency is at the heart of the 20/20/20 mandate and declares that energy

efficiency is one of the most cost-effective ways to enhance security of energy supply and to reduce GHG emissions and could be considered Europe's biggest energy resource (COM 2011b).

In December 2012, the new Directive on Energy Efficiency (EU 2012) entered into force, its main objective being to ensure the achievement of the aforesaid 20 % of energy saving objective and to establish the path for further energy efficiency improvements beyond that date, helping to remove barriers and overcome market failures that impede efficiency in the supply and use of energy. It quantifies the EU energy efficiency target as the *"Union's 2020 energy consumption of no more than 1,483 Mtoe primary energy,"* which, compared to the EU-28's primary energy consumption in 1990 (of 1,667 Mtoe) (Eurostat 2014), would mean an energy consumption average reduction of around 11 % between 1990 and 2020. Such reduction is more or less equivalent to the aforesaid 20 % of energy consumption reduction target compared to projections by 2020. However, the directive does not establish individual binding objectives for different Member States; instead they had the obligation to set, by 30 April 2013, an absolute level of primary energy consumption and final energy consumption in 2020.

On the other hand, it is clear that technology and the efficient use of resources are also fundamental to reach the EU 20/20/20 challenge (COM 2009a). Indeed, the EU aspires to gain world leadership in the renewable energy sector (EU 2007). The European Strategic Energy Technology Plan (SET Plan) considers that the key factors to reach the mentioned leadership are to accelerate the availability of energy technologies into the market and, at the same time, to engage industry in the process. In other words, these targets are achievable if adequate technological strides are taken, but it is also necessary that these technologies are well introduced into the market. This is why the Council gave to the Commission two new mandates: on the one hand, the elaboration of the aforementioned "Climate and Energy package" of proposals linking the two areas; on the other hand, to elaborate a specific proposal for the development and execution of the aforesaid SET Plan. According to the Commission, "*the achievement of the goals of the European energy and climate change policy necessitates the development and deployment of a diverse portfolio of low carbon energy technologies (. . .) However (. . .) the EU will continue to rely on conventional energy technologies unless there is a radical change in our attitude and investment priorities for the energy system. In response, the EU has endorsed the European Strategic Energy Technology Plan (SET-Plan) as a vehicle to accelerate the development and large scale deployment of low carbon technologies"* (COM 2009a).

As affirmed by the European Commission in 2014, much has been changed from 2008. On the one hand, the economic downturn has negatively affected the EU Member States' capacity to invest. On the other hand, the fossil fuel prices remain high, which negatively affects their balance of payments, and based of current policies it proposes a new reduction target for domestic reductions of 40 % compared to 1990 by 2030 (COM 2014a). In line with this position, the European Council held in October 2014 adopts the following three targets (European Council 2014):

- A binding EU target of 40 % less GHG emissions by 2030, compared to 1990
- A target of at least 27 % renewable energy consumption
- A 27 % energy efficiency increase

Analysis of Climate Change Legislative Instruments from a Sectorial Perspective

The Energy and Transport sectors play a large role in climate change, as they are the two biggest emission sources (Eurostat 2009). The buildings account for around 40 % of total European Union's final energy consumption, and the sector is expanding (EU 2010b). Energy-related emissions represented approximately 80 % of total emissions in the EU, with the Energy Industry being the largest emitting source (40 % of energy-related emissions), followed by the transport sector (further 24 % of energy-related emissions) (Eurostat 2009). The potential CO_2 reductions for the different economic sectors are illustrated in Table 3.

The Energy Roadmap 2050 points out different scenarios that explore routes toward decarbonization of the energy system. Improvement of the energy efficiency and political commitment to very high energy savings is a priority in all decarbonization scenarios. The diversification of energy supply technologies is also fundamental (including high renewable energy sources' share of gross final energy consumption of 30 % by 2030 but also the use of Carbon Capture and Storage as well as the nuclear technology). The development of storage technologies is also crucial, as well as the development of the smart grids and infrastructures that improve interconnection which could reduce the need of energy storage. All scenarios show that electricity will have to play a much greater role than now (almost doubling its share in final energy demand to 36–39 % in 2050) and that it will have to contribute to the decarbonization of transport and heating/cooling, but to reach this last target, a structural change of the power generation system is needed. Decarbonization will also require, among other measures, a large quantity of biomass for heat, electricity, and transport (COM 2011a, c).

Table 3 Sectorial GHG reductions (%) from 1990 to 2005 (real), and potential to 2030 and 2050

Sector	2005	2030	2050
Electricity (CO_2)	−7	−54 to −68	−93 to −99
Industry (CO_2)	−20	−34 to −40	−83 to −87
Transport (incl. aviation excl. maritime)	+30	+20 to −9	−54 to −67
Residential & services	−12	−37 to −53	−88 to −91
Agriculture (non CO_2)	−20	−36 to −37	−42 to −49
Other non CO_2 emissions	−30	−72 to −73	−70 to −78
Total	−7	−40 to −44	−79 to −82

Source: COM 2011a

In the following section, the most recent and relevant regulation adopted by the EU toward the "low carbon energy model" is analyzed. The section offers a legislative analysis of most relevant CO_2 emitters distinguishing between the following economic subsectors: on the one hand, the big industrial GHG emitters or EU ETS sector; on the other hand, the non-EU ETS or diffuse sectors, including the Transport and the Residential and Services sectors. These last two sectors (Transport and Residential/Services) are the most important CO_2 emitters among the aforesaid diffuse sectors.

The EU ETS Sector

As mentioned, the Power and Industry sectors will play a fundamental role toward the decarbonization of the European economy. The Emissions Roadmap 2050 shows that these sectors reduced their emissions of 7 % and 20 % between 1990 and 2005 and a GHG reduction potential between 1990 and 2050 of around 99 % and 87 % has been estimated, respectively, by 2050 (COM 2011a) (see Table 3). As it is shown, the Power sector is the one with the highest reduction potential; however, as explained, the decarbonization scenario requires the higher penetration of renewable energy sources and the increase of the energy efficiency, but the development and penetration of a wide range of low-carbon technologies (e.g., smart grids, nuclear, carbon capture and storage, etc. after 2020), is also needed (COM 2011c).

Table 4 illustrates main legislative and policy instruments destined to reach the 20 % emission reduction objective by 2020 within these sectors. The first part of the Table 4 shows the specific legislative measures that establish the EU ETS framework focused on these big industrial emitters. The objective as stated by the directive 2009/29/EC is that these EU ETS firms meet their 21 % of GHG reduction objective from 2005 to 2020 (see below) mainly through the increase of their energy efficiency and the higher penetration of the renewable energy sources but also by the use of the EU ETS, which allow to these sectors that in the case that they do not reach their corresponding objectives, they can buy emission permits to balance out their excess of emissions.

The lower part of the Table 4 contains the transversal instruments affecting these big industrial emitters including (a) the main legislation destined to push the higher penetration of renewable energies alongside of promoting the increase of the energy efficiency within these sectors; (b) the fundamental roadmaps that set the pathways to reach the EU's GHG emission reduction objectives (see Fig. 3 and Table 3) including other policy instruments, such as information concerning public aids (which establish exceptions for enabling the promotion of renewable energy sources and energy efficiency).

The EU ETS is a cap-and-trade system that started functioning in January 2005 following the requirements established by the Directive 2003/87/EC (EU 2003b). Initially, the corresponding emission rights (The European Union Allowances) were allocated via grandfathering (for free). The mentioned Directive drew a distinction between Phase I (2005–2007) and Phase II (2008–2012) of the EU ETS when each Member State needed to draw up a National Allocation Plan for each phase setting up the total cap and allocating the individual caps for the EU ETS firms.

Accordingly, the EU allowances were distributed among the different firms. At least 90 % of allowances should be freely assigned in Phase II. As stated by Directive 2008/101/EC, the aviation sector is also included in the EU ETS from 2012, which involves the creation of European Union Aviation Allowances – that is, the special emission allowances that can only be used by airline companies for compliance purposes (EU 2008).

The new Directive 2009/29/EC (adopted in 2009 and which amended the previous Directive 2003/87/EC) establishes a gradual application of an auctioning system for the allocation of European Union Allowances (EUAs) for the Power sector from 2013, while there is a transition period for the rest of the sectors affected by the Directive. This Directive has improved and extended the GHG emission allowance trading scheme of the Community and regulates the allowance trade from 1st January 2013. The regime established by this Directive encompassed several important novelties with regard to the previous one (EU 2009c):

- It established an objective of a 21 % reduction of GHG below 2005 for the affected industries.
- In the previous Directive, the focus was on large CO_2 industrial emitters (such as the power sector, the mineral industry, etc.), which all together represented approximately 42.9 % of the EU-27 overall emissions (EEA 2009). However, from 2013 new relevant sectors such as fertilizers and aluminum industries emitting other GHGs (perfluorocarbons and nitrous oxide) are also included in the EU ETS. According to the European Commission, the EU ETS firms represent around half of the EU's GHG emissions (European Commission 2014a).

- The auctioning of allowances becomes the basic principle for allocation from 2013 (apart from exceptions and transitional provisions which will be applied in those sectors with a relevant risk of "carbon leakage," that is, with risk of delocalization).

The Commission establishes the overall emission volume to allocate among all Member States, which means that a Community view was established opposite to the national approach set by the former Directive. This system requires for the affected firms that for each tonne of CO_2 emitted, the emitting entity should present the necessary allowances that will have been previously acquired through auction (EU 2009c).

In order to address the European Union Allowance (EUA) surplus problem for Phase III (from 2013 to 2020), two types of action are proposed (COM 2012a): (a) a review of the auction timetable as a short-term measure, postponing auctions of a certain amount of allowances (so-called back-loading); (b) *structural measures*, such as increasing the EU GHG target to 30 % by 2020; retiring a number of allowances; bringing more sectors into the EU ETS; access rules to international credits and discretionary price management; and an early revision of the linear reduction factor. On 25 February 2014, the Auctioning Regulation is amended with the back-loading of 900 million allowances to the end of the trading period, i.e., 2020. However, no structural measures have yet been adopted. According to Directive 2009/29/EC, the total amount of allowances must decrease by a linear factor of 1.74 % per annum, leading to a reduction of just over 70 % in the ETS cap by 2050; however, to be consistent with the EU's agreed long-term objective of 80 % – 90 % reduction by 2050 on 1990 levels (as set out in the 2050 Low-Carbon Roadmap (COM 2011a)) at the same time that the target of a 40 % reduction from 1990 to 2030 as stated by the European Council in 2014 (European Council 2014) is achieved, the European Commission affirms that this linear factor should be revised and lowered by 2.2 % per year (European Commission 2014a; COM 2014a).

The Diffuse Residential Sector

As shown previously in Table 3, a 12 % GHG reduction was reached from 1990 to 2005, and there is a potential of GHG reductions from 88 % to 91 % by 2050, being the second sector with highest GHG emission reduction potential. Being responsible for around the 40 % of the energy consumption, and considering that the sector is expanding, the 2011 Energy Efficiency Plan states that the greatest saving potential lies in buildings. The key drivers for these reductions should be got through improved insulation in buildings, more use of (low-carbon) electricity, and renewable as well as more energy-efficient appliances (COM 2011b). As stated by the Energy Roadmap 2050, Renewable heating and cooling are vital to decarbonization. A shift in energy consumption toward low-carbon and locally produced energy sources (including heat pumps and storage heaters) and renewable energy (e.g., solar heating, geothermal, biogas, biomass), including through district heating systems, is needed (COM 2011a).

Source: Authors' own elaboration

As well as previous Table 4, Table 5 makes a resume of the current existing legislation destined to promote the energy efficiency together with the renewable energy sources in the Residential/Services sectors. Besides, the fundamental roadmaps that set the pathways to reach the EU's GHG emission reduction objectives (see Fig. 2 and Table 3) including other policy instruments, such as information concerning public aids (which establish exceptions for enabling the promotion of renewable energy sources and energy efficiency), are also included in this Table 5.

In regard to the energy efficiency of buildings, on 19 May 2010 a recast of the Directive on Energy Performance of Buildings is adopted (Directive 2010/31/EU) in order to strengthen the energy performance requirements and to clarify and streamline some of its provisions (EU 2010b). The recast Directive maintains the objective of the previous Directive which states that *"Member States must apply some minimum requirements as regard the energy performance of new and existing buildings, ensure the certification of their energy performance and require the regular inspection of boilers and air conditioning system."* However, the recast Directive includes the following novelties: (a) it requires that by December 2020, Member States shall ensure that all new buildings are nearly zero-energy buildings (NZEB) (and by December 2018 for public buildings) and (b) it states a set of minimum requirements for Member States to support the accomplishment of the cited NZEF objective.

Moreover, a large part of the Energy Efficiency legislation is oriented to establish minimum energy efficiency requirements or design standards and labeling systems to promote a more efficient consumption, especially in the residential and building sectors. These questions are addressed by the new Energy Efficiency Directive (Directive 2012/27/EC) and the aforesaid recast Energy Performance of Buildings Directive (EPBD) (Directive 2010/31/EC). However, as illustrated in Table 5, there

are also other legislation measures, such as the Ecodesign Directive (EU 2009d) or other instruments to promote these aspects (e.g., Lighting initiatives, see Martínez de Alegría et al. 2009) that specifically address this question and may be relevant to understand the improvements of the energy efficiency in this sector, including to reach the aforesaid objective that by December 2020, Member States shall ensure that all new buildings are NZEB. The new energy efficiency Directive 2012/27/EU, from January 2014, sets the obligation to renovate 3 % of buildings owned and occupied by the central governments and by including energy efficiency considerations in public procurement, so as to purchase energy efficient buildings, products, and services (EU 2012).

The financial aids (e.g., through the Structural Funds or the R + D Framework programs) may be determinant to promote the energy efficiency within the building sector. Without doubt, the social collective behaviors of citizens and public authorities in the choice of energy options in regard to streetlights, the cooling and heating of buildings, etc. are fundamental to reduce GHG emissions in the building sector. Some educational measures to improve these behaviors have been developed through the following initiatives:

- The Energy Star Program
- Smart Cities
- Covenant of Mayors
- Others

Finally, as aforesaid, heating and cooling is the most significant component of household energy demand, and for the first time, Directive 2009/28/EC promotes remarkably the use of renewable energies for heating and cooling.

The Transport Sector

In the last years, numerous specific legislatives have been adopted by the European Union for the transport sector, in order to achieve its GHG emission targets at the Union (COM 2008) and national level (European Parliament and Council 2009b), by 2020 and onward (COM 2014b). Those measures affect the transport sector in general, and the road transport particularly, vehicles and fuels being the main targets of these new legislative measures developed (see Table 6).

The transport sector should reduce its CO2 emissions by around 60 % of its 1990 level by 2050 to support the targets set out by the European Union Roadmap to a Low-Carbon Economy (COM 2011a) and the White Paper on Transport (COM 2011d). Recently, the Commission has proposed the 2030 Climate Policy Framework indicating that the objective for transport will be to reduce GHG emissions to around 20 % below their 2008 level by 2030 (COM 2014a).

Transport is a highly emitting diffuse sector associated with the economy and the users' habits, which are to be changed. Around a quarter of EU GHG emissions are generated by transport sector, making it the second biggest GHG emitting sector after energy (European Commission 2014b).

Source: Authors' own elaboration

European Union faces two key challenges regarding transport:

1. Transport system is heavily dependent on imported oil (COM 2013a). In 2010, transport was 94 % dependent on oil, and 84 % of it was imported, which represents an important problem for the Union trade balance (deficit of around 2.5 % of GDP) (COM 2013a).

2. GHG emissions, especially CO_2, have been increasing for most modes of transport in the last two decades despite the measures adopted by the European Union. While emissions from other sectors have been falling (around 15 % in some sectors), those from transport have increased more than 30 % between 1990 and 2007 (COM 2011c; European Commission 2014b). Changing habits in road transport is a real challenge for the EU, since road transport alone contributes about one-fifth of the EU's total emissions of carbon dioxide (CO_2) (European Commission 2014b).

The EU has so far put a wide range of policies to lower emissions from the transport sector and for breaking the oil dependence of transport. The Commission recognized in 2008 that measures adopted in transport were insufficient to reach both objectives, and since 2009 the transport sector has become the focus of new legislative measures. Some of the new specific legislative measures are

- A strategy for clean and energy-efficient vehicles
- A strategy for light-duty vehicles (cars and vans), including emission targets for new vehicles
- A strategy for high-duty vehicles (trucks, coaches, etc.) to measure and reduce GHG emissions
- A sustainable alternative fuels strategy to reduce the GHG intensity from fuels, as well as to develop the appropriate infrastructure
- The White Paper on Transport: a key specific legislative instrument that sets out the route for the transport sector
- Other measures, such as directives, regulations, etc.

Road transport is a complex sector, among diffuse sectors, because many small emitters (i.e., cars, vans, trucks, etc.) contribute to generate a large amount of GHG emissions, and individual behaviors of emitters are not easy to control and change. The level of complexity of transport, as diffuse sector, demands to deal with a plural view, in which social and economic aspects play an important role. Therefore, the transition to a more efficient and sustainable European transport system includes acting jointly on four main factors:

(a) Technology of vehicles and associated legislation
(b) Fuel technology and associated legislation
(c) Social collective behaviors of citizens in the rational and sustainable use of vehicles and transport means
(d) Integrating general political direction of all the previous factors

These factors are analyzed in depth in the following paragraphs.

(a) **Technology of vehicles and associated legislation**

From 1990 to 2007, GHG emissions of road transport increased by 33 %, but they have since fallen due to economic downturn growth (during the period 1990 to 2010,

GHG emissions from road transport increased by nearly 23 % (European Commission 2014b, c). That is, the whole increase during this period is lower than that from 1990 to 2007 (23 % and 33 %, respectively), what has been possible thanks to high oil prices, increased efficiency of passenger cars, and slower growth in mobility. This trend is expected to continue up until 2020 (COM 2014a, b).

Likely due to the fact of the high contribution of road transport to the EU's total emissions of CO_2 (around 20 %) (European Commission 2014b), many legislative instruments have been developed in the last years (2009–2014) for reducing their GHG emissions. It must be noted that the European Union's transport policy has also included some new legislative measures for maritime and aviation subsectors, although they are not the objective of this analysis for the aforesaid reasons.

One of the first decisions to change trends observed in road transport is the adoption of a Directive on the Promotion of Clean and Energy-Efficient Road Transport Vehicles (EU 2009e), aiming at a broad market introduction of environmentally friendly vehicles. This Directive is addressed to influence the market for standardized vehicles produced in large quantities such as passenger cars, buses, coaches, and trucks. Considering that clean and energy-efficient vehicles initially have a higher price than conventional ones, this directive attempts to create sufficient demand for such vehicles to ensure that economies of scale lead to cost reductions (EU 2009e). It also highlights that ensuring a sufficiently substantial level of demand for clean and energy-efficient road transport will encourage manufacturers to invest in and further develop vehicles with low energy consumption, CO_2 emissions, and pollutant emissions (EU 2009e). This Directive requires that environmental and energy impacts linked to the vehicles over their whole lifetime are taken into account in all purchases of road transport vehicles, as covered by the public procurement directives and the public service regulation.

Taking into account that reduction of consumption of energy in 2020, to comply with the so-called 20/20/20 mandate, might be achieved with more efficient and less emitting new vehicles that gradually replaced the old ones, Regulation of New Passenger Cars is adopted in 2009 as well (European Parliament and Council 2009b). The regulation objective is to set emission performance standards in order to reduce CO_2 emissions from light-duty vehicles (passenger cars) while ensuring the adequate functioning of the internal market. Therefore, it sets standards (average cap) to frame the CO_2 emissions of new cars sold in EU and also establishes the formulae for calculating average CO_2 emission target by manufacturer. The limit set by this Regulation is 130 g of CO_2/km from 2012, which is to be reduced gradually to reach 95 g of CO_2 by 2020. This means that the fleet average of CO_2 emissions to be achieved by each manufacturer of cars registered in the EU should be 130 g of CO_2/km, or less, from 2012 onward. Manufacturers that exceed their specific emissions target must pay an additional premium from 2012 (the penalty amount for light-duty vehicles is determined by different levels of violation over the minimum CO_2 emission target. For the period 2012–2018, the penalty settings are 5€ for the first g/km over the target; 15€ for the second g/km over the target; 25€ for the third g/km over the target; 95€ for the fourth g/km and subsequent. After 2019, violation per g/km will be 95€). However, in order not to introduce distortions in the

market for small manufacturers of cars, those manufactures that register fewer than 10,000 new cars in the EU could be excluded for accomplishing this emissions target, although they should apply for their exclusion to the Commission.

This regulation also attempts to encourage car industry to technological diversification for the development of new types of vehicles, such as the electric car (powered by batteries) or the hybrid and the plug-in hybrid cars. It sets out incentives for the development of new cars and investment in new technologies. To this aim, regulation determines how each new passenger car with emissions of CO_2 of less than 50 g CO_2/km should be counted in the average CO_2 emissions target, indicating that these cars count as 3.5 cars in 2012 and 2013 and as 1 car from 2016 in the calculation of the fleet average CO_2 emission of each car manufacturer.

In 2010, the European Strategy on Clean and Energy-Efficient Vehicles (COM 2010a) is presented by the European Commission as an integrating instrument for encouraging the development and uptake of vehicles with low environmental impact. Among other measures, it contains a commitment to present a set of technological rules which should be taken into consideration while preparing financial schemes for incentivizing the deployment of the clean and fuel-efficient vehicles.

As part of the strategy to reduce CO_2 emissions from light-duty vehicles (cars and vans), in 2011 the EU adopts the Regulation for New Light Commercial Vehicles (vans), which establishes similar rules to that for new passenger cars. Regulation establishes CO_2 emissions performance requirements for new light commercial vehicles that are registered in the Union for the first time. CO_2 emissions from these vehicles must not exceed the average level of 175 g of CO_2/km as from 2017 (the requirement will be introduced gradually as from 2014). From 2020, the level is not to exceed 147 g of CO_2/km, and manufacturers of light commercial vehicles shall ensure that its average specific emissions of CO_2 do not exceed its specific emissions target. These CO_2 emission levels represent a reduction of 3 % and 19 %, respectively, compared with the 2012 average (European Parliament and Council 2011). This Regulation actively promotes ecoinnovation and indicates that CO_2 savings can be achieved notably through improvements in vehicle motor technology and the use of innovative technologies in light commercial vehicles, including as well fuel efficiency progress.

In 2013, Guidelines are provided as a practical reference for the Member States on the implantation of demand-side measures (European Commission 2013b). Guidelines also identify best practices and encourage Member States to avoid unnecessary distortion of the internal market and maximize their supportive effect on the market uptake of clean vehicles.

Despite the economic importance of CO_2 emissions from high-duty vehicles (HDVs) – trucks, buses, and coaches – those emissions have been neither measured nor reported (COM 2014b). In this sense, the High-Duty Vehicles Strategy, adopted in May 2014, is a relevant step toward curbing such emissions and represents the EU's first initiative to tackle them. A key issue hampering action to reduce these emissions is the knowledge gap resulting from the fact that HDV CO_2 emissions are not measured and recorded when new vehicles are registered. However, there is a

significant potential, through employing existing technologies, to improve HDV performance and cut CO_2 emissions in a cost-efficient way. Therefore, the Commission intends to propose legislation in 2015 which would require CO_2 emissions from new HDVs to be certified, reported, and monitored with the help of a simulation tool developed ad hoc. This initiative will contribute to the adoption of more energy-efficient technologies, with effective reductions of at least 30 % in CO_2 emissions from new HDVs as suggested by studies carried out by EU (COM 2014b). The proposed strategy consists of short-term actions, such as filling the identified knowledge gap by measuring HDV fuel consumption and CO_2 emissions in order to provide the Commission and other stakeholders with righter information. Findings from short-term actions would serve as basis for medium-term actions, including the setting of mandatory CO_2 emission limits for new HDVs in order to support the implementation of the EU 2030 climate and energy policy framework (COM 2014a).

In April 2014, the Commission has reviewed the modalities of achieving CO_2 emission reduction targets for passenger cars in a cost-effective manner and has developed a new Regulation (European Parliament and Council 2014), amending some rules and articles of previous one. While this new Regulation holds on to the target of 95 g CO_2/km for the average emissions of the fleet (new cars) from 2020 onward, it establishes as main amendments to previous regulation the following (COM 2014a):

- Manufacturers responsible for fewer than 1,000 new passenger cars registered in the EU annually are directly excluded from the scope of the specific emissions target and the excess emissions premium, from 1 January 2012. This exclusion is due to the disproportionate impact on the smallest manufacturers resulting from the high administrative burden of the derogation procedure and the marginal benefit in terms of CO_2 emissions reduction from the vehicles sold by these manufacturers.
- Each new car with less than 50 g CO_2/km shall be counted as two passenger cars to calculate the fleet average of CO_2 emissions in 2020 (it must be remembered that the previous regulation set out that it should be counted as one car from 2016).

(b) **Technology of fuels and legislation associated**

The urgent need to break the overdependence of EU transport on oil has led to research of alternative fuel solutions. Although there are successful technological developments in alternative fuels, additional policy action is still required for their market acceptance.

It is broadly accepted that fuel quality rules are a key element in reducing GHG emissions from transport, since the quality of fuels affects the emissions. In this regard, the Fuel Quality Directive regulates the characteristics that the fuels must fulfill for the transport sector, and it sets a low carbon fuel standard in order to reduce the GHG intensity of fuels used in vehicles by up to 10 % renewables by 2020 (EU 2009f). Under this Directive, a notable reduction in the sulfur content of fuels

has been achieved, enabling the deployment of vehicle technologies to reduce greenhouse gas and air pollutant emissions.

According to the Directive for renewable energies, a binding 10 % minimum target for renewable energy in transport must be achieved by each Member State in 2020 (2009c). Biofuels might play a key role in this target, as they could be used as an alternative fuel, especially in heavy-duty trucks. However, an increasing demand of biofuels could also increase pressure on biodiversity and water management, and their production could contribute to the conversion of land (e.g., forests and wetlands) into agricultural land, leading to increase GHG emissions. Therefore, the EU considers that the introduction of criteria of sustainability for the biofuels destined to the transport is of great importance, in order to avoid the lateral environmental damages that the production and use of such fuels might produce. Thus, in 2012 the European Commission makes a Proposal amending the Fuel Quality Directive to include emissions from *indirect land use change* in the reporting of the GHG emission savings from biofuels under that Directive (COM 2012b). The Commission also proposes limiting the amount of food-based biofuels to 5 %, in the EU's target of reaching a 10 % share of renewable energy in the transport sector by 2020. This limit will allow non-food-based biofuels, as second- and third-generation biofuels produced from materials (e.g., lignocellulose, algae, straw, and various types of waste), which do not create an additional demand for land, to make a greater contribution to meeting the 10 % target. Moreover, the raw materials for biofuels cannot be sourced from land with high biodiversity or high carbon stock, what reinforces the need to advance in second- and third-generation biofuels (COM 2012b).

The Clean Power for Transport Package aims to facilitate the development of a single market for alternative fuels through two new legislative tools:

- The European Alternative Fuels Strategy (COM 2013a) provides a framework for the long-term substitution of oil as energy source in all modes of transport. It pursues to guide technological development and give confidence to consumers on the market development. The current high cost of innovative alternative fuel applications is largely a consequence of the insufficient market development of alternative fuels due to technological and commercial shortcomings, lack of consumer acceptance, and missing adequate infrastructure. Therefore, a coherent and stable overarching strategy was required in order to overcome these shortcomings and to show the paths for the deployment of alternative fuels.
- The Directive on the Deployment of Alternative Fuels (EU 2014) establishes a common framework of measures for the deployment of alternative fuels infrastructure in the Union in order to mitigate environmental impact of transport and its dependence on oil. This Directive sets out minimum requirements for the building-up of alternative fuels infrastructure, including recharging points for electric vehicles and refueling points for natural gas and hydrogen, to be implemented by means of Member States' national policy frameworks. Moreover, it provides common technical specifications for such recharging and refueling points as well as the way of fuel labeling at refueling points and on vehicles to ensure clarity in the consumer information on vehicle/fuel compatibility.

(a) **Social collective behaviors of citizens in the use of vehicles and transport means**

Some initiatives have been developed in the EU to educate people in a more responsible driving and a more environmental friendly use of transport means, such as initiatives related to road safety education, environmentally respectful driving behaviors, and behaviors of sustainability of municipalities and regions in terms of transport, etc.

In this regard, the Urban Mobility Package presents a basis for moving together toward competitive and resource-efficient urban mobility. Urban mobility in the Union is still heavily dependent on the use of conventionally fueled private cars and accounts for a high share (some 23 %) of all CO_2 emissions from transport (COM 2013b). This Package emphasizes that there is still a large potential for cities to move toward a low-carbon transport through the development of walking, cycling, public transport, and vehicles powered by alternative fuels. The Commission recommends a concrete set of measures to be taken on several relevant issues like urban logistics, urban access regulations, deployment of urban intelligent transport system solutions, and road safety and encourages cities to participate in specific actions that will be carefully monitored to measure results.

The Europe 2020 Strategy for Smart, Inclusive, and Sustainable Growth (COM 2010b) highlights the importance of a modernized and sustainable European transport system for the future development of the Union and stresses the need to address the urban dimension of transport. This Strategy aims to reinforce the support to European cities for tackling urban mobility challenges and ensure that goals for a competitive and resource-efficient European transport system are met. It also points out the need to overcome fragmented approaches and develop the single market for innovative urban mobility solutions by addressing issues like common standards and specifications.

Other European initiatives related to transport and mobility are

- Ecodriving program
- CIVITAS
- Smart Cities
- Covenant of mayors
- Others

(b) **Integrating general political direction of all the previous factors**

There have been several legislative pieces that have attempted to integrate – partially or totally – the diverse factors that affect the GHG emissions of transport and the dependence on oil of EU's transport system. However, the most important legislative instrument to integrate political direction of all aforesaid factors is likely the White Paper on Transport.

In 2011, the European Commission launches the White Paper on Transport, which establishes the EU's general policy in transport and the route toward 2020

and later. The White Paper not only provides a combined set of measures to increase the sustainability of the transport system but also highlights that technological innovation can help the transition to a more efficient transport system by acting on three main factors: vehicle efficiency through new engines, materials, and design; a cleaner energy use through new fuels and propulsion systems; and initiatives to educate citizens in the responsible and environmental use of vehicles and transport means and infrastructure (COM 2011d).

The main goal of transport legislation adopted during the period 2009–2014 is to ensure that CO_2 emissions from vehicles continue to be reduced, while giving the automotive industry the certainty it needs to carry out long-term investments and develop innovative technologies. The sector-specific state aid adds incentives which include the use of structural funds in order to devote a greater part to finance investments in a more efficient and sustainable transport system. Other economic incentives are reduction of tax registration and circulation for fuel-efficient vehicles and low emitters, reduction in VAT, especially for products and fuel-efficient vehicles and low emitters, aids to encourage consumers to purchase fuel-efficient vehicles, etc.

Summarizing the main driver for reversing the trend of increasing GHG emissions in the transport sector is likely to remain improved efficiency of both fuels and engines. Securing affordable mobility and reducing emissions from roads below 1990 levels in 2020–2030 can be possible in combination with measures such as refueling and charging infrastructure, improving public transport, pricing schemes to tackle congestion and air pollution, and intelligent city planning. Better demand-side management, fostered through CO_2 standards and smart taxation systems, should also facilitate the gradual transition toward large-scale penetration of cleaner vehicles in all transport modes, including plug-in hybrids and electric vehicles. The synergies with other sustainability objectives such as the reduction of oil dependence, the competitiveness of Europe's automotive industry, as well as benefits for health are enough reasons for the EU to step up its efforts to accelerate the development and early deployment of alternative fuels and propulsion methods for the whole transport system. In this respect, it is not surprising to see automotive industries in the USA, Japan, Korea, and China, making efforts to develop and/or improve electric, hybrids and fuel-eficient vehicles in order to lead this market.

The Union aviation sector should collaborate with the International Civil Aviation Organisation (ICAO) in order to create by 2016 a global market-based mechanism that will operate from 2020. The maritime sector will be integrated in the EU's GHG reduction strategy while the Commission works with the International Maritime Organisation (IMO) on a global approach to achieve the necessary emission reductions through the most appropriate measures (COM 2014b).

Conclusions

Although the Doha Agreement makes it possible to use the Flexible Mechanisms (i.e., the International Emissions Trading, the Clean Development Mechanism, and the Joint Implementation Mechanism) to face the 20013–2020 period, there are two

main factors that undermine the level of ambition of the aforesaid Agreement: first, only around 12 % of the world GHG emissions are concerned; second, the EU-28 has already reached around a 19 % GHG emission reduction by 2012. By 2015, a new Protocol (or other legal instrument) should be adopted by the Annex I Parties in order to face the climate change problem; however, more comparable targets are needed to face the aforesaid 2015 Agreement, and apparently, most Parties are waiting for this 2015 Conference to reveal their respective positions. Meanwhile, all the UNFCCC process to reach real and effective measures to face the climate change problem is suffering a period of real uncertainty.

In the EU framework, the threats of the conventional energy model (environmental problems, exhaustion of fossil sources, possible inflation process and loss of competitiveness, dependency toward energy export countries, etc.) have forced a change in its traditional energy strategy where the key objectives include also the increase of the European competitiveness and the environmental protection, making Renewable Energy Sources and Energy Efficiency its fundamental basis. The "Energy/Climate Change Package" complements the previous existing legislation on climate change and Renewable Energy Sources and Energy Efficiency and constitutes a fundamental set of tools for achieving the 20/20/20 mandate.

An important novelty of the new Directive 2009/28/EC for the promotion of Renewable Energies comparing with previous legislation is the establishment of different nationally binding targets, with an overall target of 20 % in the EU's energy overall mix by 2020; however, differences in regard to the level of consecution of their corresponding targets may be obtained between the EU-28 members. In regard to the energy efficiency, a notable improvement on the energy consumption patterns has been observed within the EU, with an average reduction of 9.8 % of the total primary consumption between 2005 and 2010. However, considering that this reduction has occurred in a period of economic downward development, in the case of the recovery of the European economy, the 20 % energy efficiency objective may be under question, which could put at risk the consecution of the two other 20/20 mandates (specially the objective of 20 % of renewable energy by 2020).

The most relevant measure adopted for the nondiffuse sector is the establishment of the EU ETS. Though this emission trading scheme may have contributed to delivering real GHG emission reductions for this sector in the past, the estimated surplus of emission permits may generate serious imbalances in the future. It is feared that these imbalances may profoundly affect the ability to meet the EU ETS targets by 2020.

In regard to the promotion of the Energy Efficiency in the building sector, the recast of the Energy Performance of Buildings Directive (EPBD) and the new Energy Efficiency Directive (Directive 2012/27/EU) follow the path of previous legislation, reinforcing the existing market-based instruments, especially the energy labeling instruments. The most relevant novelty of the aforesaid new Energy Efficiency Directive is that it establishes a quantitative target to reach an EU-28 gross energy consumption reduction target (of around 11 % between 1990 and 2020, which is more or less equivalent to the target established by the mandate 20/20/20), however without

establishing individual binding targets for each Member State, which could have as a consequence a different level of consecution between Member States. The recast of the Energy Performance of Buildings Directive (EPBD) requires that by December 2020, Member States shall ensure that all new buildings are nearly zero-energy buildings (NZEB) (and by December 2018 for public buildings). However, the real consecution of the cited target for different Member States is also uncertain.

In the transport sector, numerous legislative measures have been adopted to achieve 2020 objectives, although some more legislative instruments are still needed to address the challenges of the sector in a 2030 perspective and beyond. In line with the White Paper on Transport and the Alternative Fuels Strategy, efforts have been made on improving the efficiency of the transport system, further development and deployment of electric vehicles, second- and third-generation biofuels, and other alternative sustainable fuels as part of a more holistic and integrated approach. The improvements observed in passenger vehicles in recent years will have to continue; while in other transport modes there will be a need for a significant acceleration of current efforts to tap the significant unexploited potential. Additional reduction of emissions from transport will require a gradual transformation of the transport system toward a better integration among modes, greater exploitation of the nonroad alternatives, improved management of traffic flows through intelligent transport systems, and extensive innovation in and deployment of new propulsion and navigation technologies and alternative fuels (COM 2014b). Moreover, Member States should consider how fuel and vehicle taxation can be used to support GHG reductions in the transport sector.

Acknowledgments This work has been possible thanks to the collaboration of the Energy Working Group, which belongs to the Chair of International Relations (Social Sciences Faculty) of the University of the Basque Country (UPV-EHU). Special thanks must be given to Gonzalo Molina Igartua for his inestimable help and collaboration.

Annexes

Annex 1

The key GHGs under consideration in the most common legislative strategies are

- Carbon dioxide (CO_2) from fossil fuel burning, wood and other fuel burning, chemical manufacturing, and mobile source fuel combustion
- Methane (CH_4) from the production and transport of coal, natural gas, and oil; livestock and other agricultural practices; and decay of organic waste in municipal solid waste landfills
- Nitrous oxide (N_2O) from agricultural and industrial activities and combustion of fossil fuels and solid waste

Table 7 Global warming potentials of key GHGs

Type of GHG	Global warming potential
Carbon dioxide (CO_2)	1
Methane (CH_4)	21
Nitrous oxide (N_2O)	310
Hydrofluorocarbons (HFCs) and Perfluorocarbons (PFCs)	140 to 11,700
Sulfur Hexafluoride (SF_6)	23,900

Source: IPCC 2007

- Hydrofluorocarbons (HFCs) from industrial processes
- Perfluorocarbons (PFCs) from industrial processes
- Sulfur hexafluoride (SF_6) from industrial processes

In what is being referred to as the "Doha amendment" of the Kyoto Protocol, the following GHG was included in the Amended Annex A of the Kyoto Protocol:

- Nitrogen trifluoride (NF_3).

The GWPs for the key GHGs (assuming a 100 year time frame) are summarized in Table 7 below.

For example, in a 100 year time frame, 1 ton of nitrous oxide will impact climate change 310 times more significantly than 1 ton of carbon dioxide.

Abstract

For over half a century, society has relied on the products of the organic chemical industry to supply the clothes we wear, the food we eat, our health, housing, transportation, security, and other commodities. Approximately 92 % of organic chemical products are derived from oil and gas. In addition, these same resources are generally used to provide the large quantities of process heat and power needed by the industry. In the modern petrochemical industry, oil and gas inputs for both raw material and process energy compose around 50 % of the operating costs.

Not only is the chemical industry (including petrochemicals) the industrial sector with the highest emissions worldwide, it is also very vulnerable to variations in fossil fuel prices and, potentially, climate policies. Efficiency has long been a major factor in determining competitiveness in petrochemicals, and the sector has a high success rate in reducing its energy intensity. Yet, while global use of oil for energy grew globally by 12 % between 2002 and 2012, the use of oil for chemical feedstocks grew 21 %. It now represents 9 % of total global oil use and 6 % of total global gas use. Reducing greenhouse gas (GHG) emissions in an industry that is so dependent on fossil fuels presents a significant challenge.

This chapter introduces the history of the modern chemical industry and the establishment of its close relationship with the oil industry. This relationship has recently come under strain as new sources of oil and gas are increasingly exploited, and growth in hydrocarbon demand for chemical products outpaces that for energy from these sources. It goes on to describe some of the major chemical processes, their GHG emissions, and their geographical variations. The benefits and challenges of several technological mitigation options are discussed. These are recycling, efficiency gains through cogeneration, CO_2 capture and storage (CCS), and feedstock switching via biorefining.

Introduction

Many of the chapters in this book describe the potential for renewable and low-carbon technologies to reduce the rate of emissions of greenhouse gases from human activity. Other chapters address key components in these efforts, recognizing the energy sector as the major source of greenhouse gases (GHG) worldwide, the crucial role of energy efficiency and carbon capture technologies, and the importance of individual consumption patterns. However, all of these components impact (and are impacted by) the petrochemical industry. It permeates our daily lives and is one of the global economy's most important industrial sectors. Moreover, it faces implications from climate change not only in terms of its energy consumption and greenhouse gas emissions but also in terms of its very feedstock. The petrochemical industry's complex integration with fossil fuels is uniquely challenging in the climate change landscape and must be understood in its own right.

The chemical industry has for many decades been highly integrated with the prevailing energy system. In general, the organic chemical industry derives both its

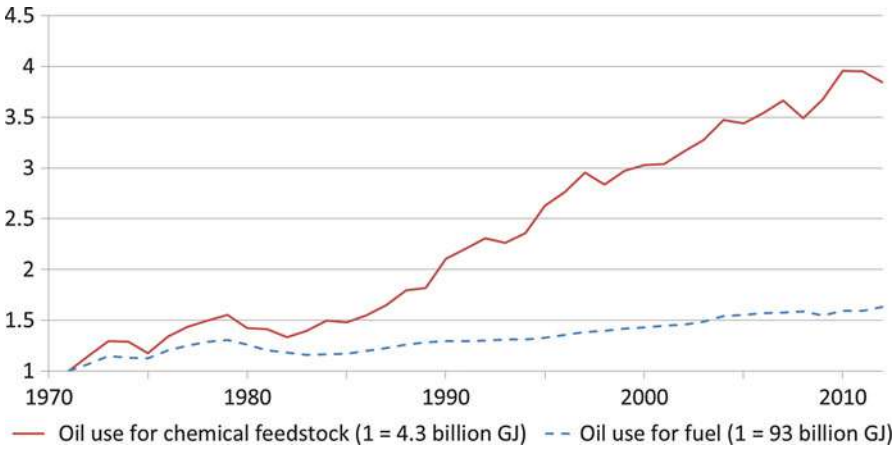

Fig. 1 Global growth in oil use for chemical feedstocks and energy, indexed to 1971 (IEA 2014b)

energy requirements and its raw materials from petroleum, making it both a heavy emitter of GHG and also highly dependent on fossil fuels: in the modern petrochemical industry, around 50 % of the operating costs are due to oil and gas inputs for both raw materials and process energy.

Overall, approximately 97 % of chemical products are produced from petroleum (including natural gas), while coal delivers 0.4 % of chemical feedstock globally, by energy content (IEA 2014b). The amount of oil used for chemical feedstocks continues to grow globally, at a rate of 4 % per year, representing an increasing proportion of growing global oil (total global oil use has grown at a rate of 1.4 % per year) (Fig. 1). The primary product from the petrochemical industry is plastics, and as plastics consumption has increased with gross domestic product (GDP) per capita, worldwide demand for plastics is expected to rise rapidly as the average wealth increases, particularly in emerging economies with very large populations (De Vries et al. 2006; Andre et al. 2014). Demand for petrochemical products has not yet reached saturation point, and the industry is expected to grow for some time yet.

Indeed, the diversity and high functionality of petrochemical products have resulted in their use across our daily lives. Some have simply replaced existing materials in society, taking the place of wood or metal. Others have created new opportunities, now essential to our modern lives. Over the last 50 years, society has become reliant on the products of the organic chemical industry to supply not only plastics but the clothes we wear, the food we eat, health products and pharmaceuticals, secure housing, transportation, security, and numerous other commodities (Wittcoff and Reuben 1980).

In addition, derivative products from petrochemical feedstocks are also pervasive throughout the industrial economy. Products generally undergo numerous stages of processing and are each transferred between firms within the value chain for further processing, such that the industry as a whole consumes more than a quarter of its own production. Petrochemical products can be divided into categories of “bulk”

and "speciality." Bulk organic chemicals are generally commodity products that are produced in large volumes and compete with one another on price. They include the major platform chemicals such as ethylene, propylene, and benzene and each of their immediate derivatives. Methanol, ethanol, and commodity polymers (including many fabrics and plastics) are also considered bulk products. Meanwhile speciality chemicals cater to specific custom markets and generally compete on the basis of technological expertise that can provide a greater added-value to their products. These end products typically include speciality high-performance plastics, fabrics, paints, pigments, and cosmetics.

While chemical production does not dominate the fossil industries, it does account for a significant share of the fossil resources. In the United States, approximately 3.4 % of a barrel of oil is used for chemical products, while nearly 20 times that amount (70.6 %) goes to fuel uses (Marshall 2007). This ratio is slightly higher for Europe, where 9 % is used for chemical feedstocks, as oil (naphtha) dominates natural gas for bulk chemical production in this region (IEA 2014b). Despite the differences in production volumes, the values of the two industries are comparable, due to the higher retail value of petrochemical products relative to oil-derived fuels.

However, the industry is changing. High oil prices at the beginning of the twenty-first century have combined with the shifts in the global economy to accelerate the petrochemical industry's migration eastward, from Europe and North America toward the Middle East and Asia Pacific. The former, in particular, offers opportunities to exploit low-cost liquefied petroleum gas (LPG) feedstocks, which are an associated by-product of oil refining and therefore widely available where oil production costs are low. Recent economic growth in Asia Pacific meanwhile has seen rapidly changing ownership structures of petrochemical companies and investment in new plants, with this region rapidly increasing its global share of the petrochemical sector (Lewe et al. 2012). Additionally, the shale gas "revolution" in the United States has seen North American natural gas prices decouple from global oil prices, leaving European naphtha-based chemical production increasingly exposed. Such changes are not entirely without precedent, and concern about volatile feedstock costs and potential oil supply constraints instigated a debate about the sustainability of petroleum-based products years ago (Hodges 2009; Koopmans 2006). Furthermore, growing concern about climate change and increasingly stringent GHG regulations are now driving the organic chemical industry to revise its energy use for the future and assess its process routes. Economic motivation, greenhouse gas reduction, and supply security are all acting as drivers toward greater energy efficiency and renewed interest in use of alternative feedstocks.

This chapter introduces the history of the modern chemical industry and the establishment of its close relationship with the oil industry – a relationship that has recently come under strain. It goes on to describe some of the major chemical processes, their GHG emissions, and their geographical variations. The main focus of the chapter is a discussion of the benefits and challenges of three main technological mitigation options: efficiency gains, CO_2 capture and storage, and feedstock switching. The interaction of these options with the main climate policy instruments in Europe, and worldwide, is considered.

The concept of "biorefining" for bio-based chemicals is given particular prominence for its potential to deliver renewability, low CO_2, and energy/feedstock security in the long term. However, establishing new production routes based on biomass in Europe is shown to face considerable social, technical, and economic obstacles to reaching a scale that can contribute valuable emission reductions.

The Chemical Industry Value Chain: From Feedstocks to Final Users

Organic chemicals are those that contain a structure based on carbon, usually in combination with hydrogen. Although there is no official definition, organic chemicals are widely understood to be the carbon-containing compounds associated with life (such as sugars and proteins) or the hydrocarbons present in fossil fuels. Oil, gas, and coal contain largely pure hydrocarbons with a carbon backbone of varying length, dependent on the source, and without a high prevalence of heteroatoms, such as oxygen, nitrogen, or metals. This gives them high energy densities and also makes them particularly suitable for chemical production.

Extracted hydrocarbon feedstocks first undergo pretreatment or fractionation, before being processed to produce targeted chemicals and products. Overall, the seven organic chemicals with the largest production volumes can be divided into three groups: olefins (e.g., ethylene, propylene, butadiene); aromatics, based on a six-carbon ring (e.g., benzene, toluene, xylene); and methanol, being the most basic alcohol. Global production of benzene alone in 2012 was 43 million tons (Mt) with current aromatics production amounting to 115 Mt each year; 2012 saw ethylene and propylene production reach 220 Mt, and methanol production in 2012 (most of which was used to make other chemicals) was around 58 million Mt (IEA 2013a). Some of the petrochemical industry's key molecular structures are shown in Table 1. Each of these can then be processed again and sold on, either to final consumers or to new industries for further processing.

Production of one chemical, such as acrylonitrile butadiene styrene (ABS) rubber, can be used to exemplify the complexity of such a value chain and highlights the many stages between fossil fuel and final product (Fig. 2). The fundamental building block for this material is 1–3-butadiene, which is used to make polybutadiene. Hydrocarbon feedstock (such as LPG or naphtha) is first cracked to provide the unsaturated olefin platform chemicals: ethylene, propylene, and butadiene. This production of bulk chemicals will typically occur at an integrated petrochemical and refining site. The crude butadiene is then separated using solvent extraction. This can take place remotely, in which case the crude butadiene is shipped or piped to an extraction unit; however, most extraction units are located close to the olefin cracker since butadiene is gaseous, meaning that significant energy is required to liquefy and transport it. Butadiene monomer is then polymerized to polybutadiene, which is subsequently copolymerized with styrene and acrylonitrile to make ABS resin. ABS resin is then sold to manufacturers who wish to take advantage of the thermoplastic's lightness, rigidity, insulating properties, and recyclability. These properties are

Table 1 Formulae and structures of the main hydrocarbons used in fuel and chemical production (with the exception of methane, only carbon–carbon bonds are shown as lines. Hydrogen atoms are omitted)

Group	Example hydrocarbons	Formulae	Structures
Natural gas	Methane	CH_4	Olefins	Ethylene, propylene, butadiene	C_2H_2, C_3H_6, C_4H_6	LPG	Ethane, propane, butane	C_2H_4, C_3H_8, C_4H_{10}	BTX	Benzene, toluene, xylenes	C_6H_6, C_7H_8, C_8H_{10}	Gasoline	Octane, plus a variety of saturated and unsaturated hydrocarbons	C_8H_{18}, other C_4 to C_{12}	Diesel	Cetane, plus a variety of saturated and unsaturated hydrocarbons	$C_{16}H_{18}$, other C_8 to C_{21}	Coal	60–90 % carbon	Approximately $C_{135}H_{96}O_9NS$	
valued across many sectors, and ABS is used for a wide range of final products for sale to end users: from car parts, drain pipes, and electronic products to Lego bricks and even tattoo inks.

From this example, it is clear that the industry's supply chains are varied and complex. Firstly, the downstream users of butadiene, polybutadiene, and ABS are usually very different firms to the major petrochemical companies that extract fossil resources and produce the primary bulk chemicals (Morrow 1990). Secondly, it should be noted that styrene and acrylonitrile are both produced from olefins: styrene from ethylene and acrylonitrile from propylene. Each of the value chain steps is

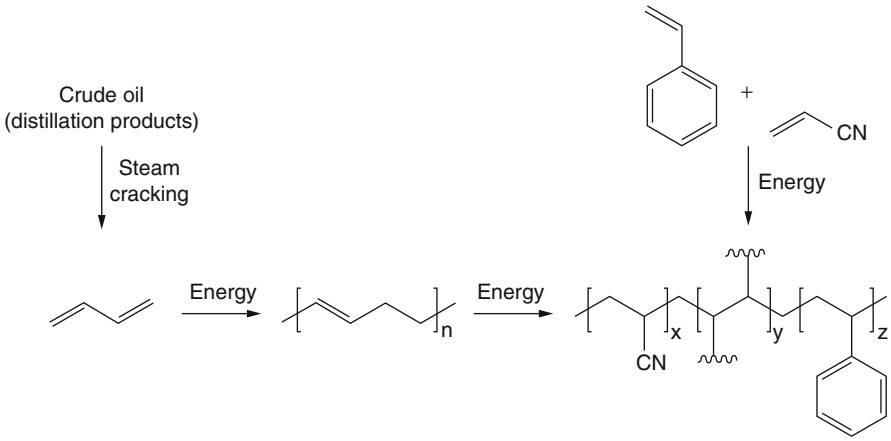

Fig. 2 Synthesis of ABS

highly integrated with one another, and as such there are inherent complexities in influencing change in any one step: they cannot be treated in isolation. This also indicates the large amount of process energy required for petrochemical production, most of which also comes from petroleum sources. Overall, one kilogram of ABS requires approximately two kilograms of petroleum in both feedstock and energy. Petrochemicals are doubly connected to the petroleum industry, and while this chapter deals with each of these relationships in turn, it is important to note that they are very closely integrated.

Feedstocks: Fossil History and Biomass Contenders

Oil

Oil is a relatively easily handled liquid comprised of a number of different lengths of hydrocarbon chain, and it is the main feedstock used for petrochemical production. In 2012, 396 million tons (Mt) of oil products were used for chemical feedstock worldwide, representing 9.4 % of the oil used for energy (IEA 2014b). A similar amount was also used by the petrochemical industry for processing energy, although exact figures are unavailable, due in large part to the integrated nature of refinery and petrochemical processes, and the difficulties in allocating energy balances between the various processes. However, all these numbers are projected to increase significantly. The World Energy Outlook 2014 considers that chemical feedstocks will be the fastest growing use of oil until 2040, at which point oil use for chemicals will reach a quarter of that used for transport (WEO 2014d). As this chapter will describe, the history of petrochemicals is closely linked to oil, and this relationship is expected to continue for some time.

After crude oil is extracted, it is distilled to separate the major components, most of which are further processed to deliver liquid transportation fuels. In terms of tonnage, the primary energy products are diesel (31 %), gasoline (25 %), jet fuel (6 %), and residual fuel oil which is often used in power generation (15 %). The proportions of the different products are determined by the nature of the oil – whether it contains mostly short or long chain molecules – which varies between locations and between oil wells. However, refinery operators have some flexibility to manipulate these values to meet demand, as is evident from a brief consideration of the history of oil demand and supply.

History

In 1850, when James "Paraffin" Young first patented his method of oil distillation, it was the illuminating properties of the kerosene product that ensured his technology a bright future (Redwood 2009). The early US oil-refining business continued to target the production of lighting, and throughout the supremacy of Standard Oil, liquid kerosene lamp fuel determined how refineries were designed. Kerosene was the only valuable product of otherwise dirty and unpleasant crude. The development of the internal combustion engine had demonstrated a use for one of the other distillates, but motoring did not take off until the 1920s and 1930s at which point there was not enough by-product to meet the demand (Levingston 2006). The story of the oil refinery is one adjustment to new technologies that maximizes output of products for the most attractive markets. The development of thermal cracking increased the petrol yield, and its replacement with catalytic cracking then opened the way for selling higher purity coproducts to the chemical and electricity industries, among others (Nguyen et al. 2005).

The use of oil for chemical production began in the United States with the manufacture of ethylene derivatives for solvents, in particular ethylene glycol and tetraethyl lead, whose functions as antifreeze and antiknocking additives went hand-in-hand with the manufacture of gasoline during the huge expansion in automobile ownership through the 1920s. The feedstock for this was primarily refinery off-gases, which were in plentiful supply adjacent to the oil refineries on the Gulf Coast of the United States (Spitz 1988). Since that point, the history of petrochemicals has been one of close interaction with the oil refining industry. At each turn, innovative chemists have found ways of tailoring fuel products to meet the needs of new engine technologies, such as production of high-octane fuel for military aircraft in the 1930s (Ogston 1997), and they have increasingly found new outlets for unused distillation fractions as chemical products. Early ethylene-based products built on existing acetylene lighting technology and targeted existing product families like solvents, surfactants, and lubricants. These product families were expanded to integrate other olefin raw materials and were based predominantly on small reactive molecular entities. For example, isopropyl alcohol from olefinic propylene was Standard Oil's first petroleum-based chemical product in 1920 (Mann 1966).

The mid-1930s saw major breakthroughs in the field of polymer science, causing a major revolution in organic chemical production. The theory developed by Hermann Staudinger revealed that small, reactive chemicals could be purposefully

joined together to synthesize products with known, useful properties. Indeed he suggested that it "is not improbable, that sooner or later a way will be discovered to prepare artificial fibres from synthetic high-molecular products" (Staudinger 1936, p 99). Confirmation of this theory was then delivered by DuPont's commercialization of nylon in 1938. Nylon (aliphatic polyamides) and polyethylene played highly significant roles in driving petrochemicals into markets where they could displace natural products, such as rubber, wood, and metal. The demonstrated effectiveness of these materials during World War II opened up the prospect of an almost limitless demand for olefins and fundamentally altered the economics of refining, ensuring that petrochemical complexes would be built alongside refineries in the United States from the 1940s onward.

However, the experience in Europe was markedly different, and European petrochemicals production did not catch up with the United States until the 1950s. Before North Sea oil and gas were discovered in the 1960s, Europe did not produce oil to fuel its vehicles but imported gasoline from North America, Russia, and the Middle East, meaning that there was not a ready supply of olefin by-products available. Furthermore, the two major energy-using European nations, Germany and the UK, had well-developed technology based on their coal reserves and were reluctant to exchange their leadership in coal-based technologies for reliance on imported fuel and feedstocks (Reader 1977). Decisions to support coal-to-oil conversion, alcohol motor fuel, and overseas oil exploration were influenced heavily by governmental attempts to steer technology change toward particular policy priorities: securing energy supplies, supporting troubled industries, and addressing unemployment. This was accompanied by industrialists' attempts to steer policy priorities toward maintaining or developing their own preferred technologies (Bennett and Pearson 2009). In 1927, Alfred Mond, the Chairman of the UK's Imperial Chemical Industries (ICI), expressed his belief that "not only oil, but the whole field of organic products will be based upon coal as a raw material in the near future" (Reader 1975, p. 84). Consequently, when ICI decided to invest in petrochemicals after the War, they did not do so in collaboration with BP – the major British oil company that was simultaneously moving some refining operations from Iran to Scotland – but as a stand-alone chemical plant near their existing coal-based operations. For cracking to olefins, ICI instead chose to import naphtha, a liquid by-product of oil refining that can be transported by ship. This was a novel approach and reflected the value that ICI and the British government placed on maintaining independent industrial enterprises. This allowed the UK to continue to lead Europe in petrochemicals, especially as Germany remained committed to its indigenous coal reserves as it rebuilt its economy after the War. European crackers continue to operate on naphtha today, a configuration that partly reflects this history.

Now

The story is different still for the Middle East, in particular Saudi Arabia, where the exploitation of abundant sources of LPG (liquefied petroleum gas: propane and butane) for chemicals has been a relatively recent development. This is because petrochemicals production requires sizeable investment in local infrastructure, requiring a more complex industrial strategy than the rapid returns delivered by

investment in oil production and export. Combined with a lack of local demand for high-value chemical products, this led to delays in investment. Today, the continued shift of refineries eastwards is threatening to relegate European naphtha crackers to become marginal suppliers of ethylene and propylene, and as long-term projections of oil prices indicate an increase over the coming decades, the dominance of LPG in the Middle East is expected to become further entrenched (Hodges et al. 2008).

In summary, the current utilization of petroleum as the major organic chemical feedstock and its options for greater sustainability must be understood in the context of the petrochemicals industry's codevelopment with fuel-orientated oil refining. The close integration of these two industries has resulted in highly efficient manufacturing complexes, with designs that have evolved over five decades. It is generally expected that this relationship will continue to determine the technologies, product mixes, and the economics of organic chemical production for some time to come.

Gas

Natural gas is an increasingly important feedstock and energy source for the petrochemical industry, with 183 Mt of natural gas used for chemical feedstocks in 2012, representing 6.4 % of that used for energy (IEA 2014b). The primary component of natural gas is methane, though ethane, propane, and heavier hydrocarbons may also be present in much smaller quantities. The carbon-hydrogen covalent bond in methane is exceptionally strong and requires a lot of energy to break, which to some extent limits its use as a building block for organic chemicals. However, natural gas is the primary source of hydrogen worldwide, through the steam reforming processing of methane to yield hydrogen and carbon dioxide. Hydrogen produced by this method is widely used in the chemical industry, in particular for the production of ammonia via the Haber process. Indeed, of the 50 Mt of hydrogen produced each year, approximately half goes to ammonia production, of which 80 % is then further processed to fertilizers (Da Rosa 2009; DOE 2013). Steam reforming of methane in this way releases large quantities of CO_2, which means that ammonia production is a significant emitter of CO_2, especially when the energy intensity of the Haber process is also considered. Depending on feedstock and process, CO_2 emissions have been estimated to vary from around 1.1 t of CO_2 per ton of ammonia in Spain to 1.3 t in the United States and 3.4 t in Belgium (Bosch and Kuenen 2009).

Due to the costs of transporting gases, the use of gas has historically been limited by local availability. However, natural gas is seen to occupy a different market niche to oil, and where it is readily available, natural gas can be an attractive source of carbon for organic chemical feedstocks. When compared to LPG or naphtha feedstocks, its use is often associated with lower CO_2, and it benefits from being relatively independent of the markets for other petroleum refinery products. Research into chemical conversion of natural gas is ongoing, and the advent of shale gas (discussed later in this chapter) has renewed interest into the economic conversion of methane to useful longer chain hydrocarbon building blocks, such as olefins (Ren and Patel 2009; Barteau and Kota 2014).

History

Gas has had a very different history to oil, since the cost of compression or pipeline construction for transportation historically precluded international trade. This has led to innovation in gas to chemical production in certain remote locations with abundant gas but little local demand for energy. In New Zealand, for example, following the discovery of natural gas, two plants were established in the early 1980s to convert methane to methanol. The first step of this process used steam reforming of methane to give carbon monoxide and hydrogen. Up to 6,700 t crude methanol was produced each day. Part of this was upgraded to gasoline via the Mobil process, and part was exported as chemical grade methanol for further processing in the main foreign petrochemical facilities (Dry 1988; NZIC 1988). At the time, this represented the world's largest methanol production capacity, and the two plants found a crucial market niche for chemical production from natural gas in an area with relatively low energy demand.

In addition to use as a feedstock, the petrochemical industry also uses natural gas to provide the process heat and electricity that power petrochemical facilities (Table 2). Heat is used in nearly all petrochemical processes, and there has been considerable interest in replacing the fuels used to heat petrochemical plants and refineries – typically crude oil and waste petroleum products from the conversion processes – with more efficient natural gas, which can reduce process costs and energy-related carbon emissions. Petroleum fuel products can then instead be used for feedstock or for higher-quality energy products.

Table 2 Fossil fuel consumption figures for the world and OECD in 2012 (IEA 2014b)

	Total primary energy supply (billion GJ)	Energy used by chemical industry (incl. petrochemicals) (billion GJ)	Used as organic chemical feedstock (billion GJ)	Percentage of total primary energy supply used by chemical industry (incl. petrochemicals)	Percentage of total primary energy supply used as petrochemical feedstock
World					
Oil and oil products	176.2	2.0	16.6	10.5 %	9.4 %
Natural gas	119.1	4.0	7.7	9.8 %	6.4 %
Coal	162.1	2.9	0.1	1.9 %	0.06 %
OECD					
Oil and oil products	79.8	0.8	8.9	12.2 %	11.1 %
Natural gas	56.3	2.4	1.4	6.8 %	2.5 %
Coal	42.4	0.5	0.04	1.2 %	0.09 %

Now

Use of natural gas has grown steadily over the last few decades. In part this is due to the increase in economically viable transport and use of liquefied natural gas (LNG), which has allowed much wider use of the fuel without the need for pipelines. Construction of LNG terminals has grown at a rapid rate in recent decades: from a capacity of around 55 million tons per annum (mtpa) in 1990 to more than 220 mtpa in 2010, with a slower rate of growth in recent years as 2013 saw LNG trade of around 240 mtpa (Wood 2013). The shipping of LNG has opened up new markets for natural gas and facilitated its use in regions without natural gas resources. Nevertheless, there still remains considerable interest in conversion of natural gas to methanol, dimethyl ether (DME), and especially gasoline for export. Perhaps the most notorious case is that of Qatar, where methanol production is proceeding alongside LNG and gasoline production from natural gas.

In addition to the new opportunities from LNG, the shale "revolution" in the United States has helped to trigger new interest in the use of this feedstock for chemical production. The boom of shale gas discoveries has lowered the price of natural gas in the United States, and there has been significant investment in optimizing olefin production from readily available, low-cost shale gas sources. Use of shale gas for ethylene production in particular is lowering prices and reinvigorating North American chemicals production (Platts 2013).

Switching from oil or coal to gas for heat and power provision can be particularly attractive in the petrochemical industry due to the sector's consistent demand for heat and power in numerous processes requiring a higher energy quality, including pumps, instruments, and motors. In addition, there has been increasing attention paid to the concept of heat integration in recent years. Provision of heat and power via heat cogeneration, or "combined heat and power" (CHP), plants (IEA 2014c) offers a particular opportunity for cost and carbon reduction: through heat integration, CHP can be 50 % more efficient than supplying steam and electricity separately. Thus, as a consequence of higher fuel costs and ever more stringent environmental legislation, CHP is increasingly being incorporated into petrochemical sites. At present, Europe's largest gas-fuelled CHP plant is capable of generating 1,240 MW with a thermal efficiency over 70 % while providing steam and power to the petrochemical and refining processes at Immingham in the UK. The role of CHP is addressed in more detail toward the end of this chapter.

Coal

Coal is typically higher in oxygen content and has a lower H/C atomic ratio than petroleum or gas. Additionally, unlike oil or gas, solid coal must undergo conversion through gasification or other processes before it can be used for further chemical manufacture (Speight 2012). However, this processing can be justified when there are abundant local resources or when access to oil and gas is limited. Particularly in coal-rich countries, such as China and Indonesia, coal feedstock continues to play an important role in the petrochemical industry.

History

Coal was the original energy source and feedstock for the organic chemical industry when it evolved from the early British coal tar pigment industry in the late nineteenth century. Indeed, it has been remarked that the synthetic dye industry became the "synthetic-everything-else-industry" (Belt 1987, p. 136). In addition to the aromatic chromophores (naphthalene, anthracene, and benzene derivatives) that were obtained from coal tar, coal was gasified to yield acetylene and synthesis gas (syngas) which could be upgraded to produce some basic synthetic chemicals. By the end of the 1930s, German and US coal-based chemistry had developed to a stage where liquid fuel, rubber, plastics, solvents, lubricants, and many other chemical products were commercially manufactured from coal. Coal-based chemistry laid the foundations for the modern petrochemical industry, often via carbon monoxide as an intermediate. In 1938, DuPont claimed that "in the field of carbon monoxide chemistry," they had "an answer to anything the oil companies can do from hydrocarbon gases" (Reader 1975, p. 321). However, by this time, coal had already been replaced by petroleum as the primary organic chemical feedstock in the United States and was about to be overtaken in the UK. Figure 3 shows the transition from coal to oil-based chemicals in the UK. This mirrors the substitution of coal by oil and gas in primary energy use, and although starting later, the overturn of the raw material base was even more rapid, reaching 50 % penetration 20 years earlier than as energy source. Coal was finally displaced by oil in the 1960s, when technologies for producing aromatic chemicals, such as benzene, from petroleum were

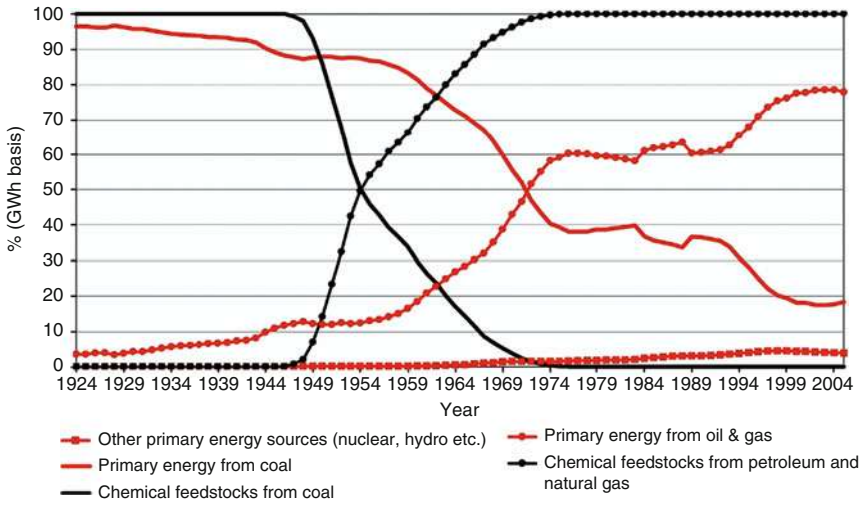

Fig. 3 Transitions from coal to oil and gas in UK primary energy (*red*) and chemical feedstocks (*black*) 1924–2005 (5-year rolling averages from UK official energy statistics. Nonfossil feedstocks are excluded from this diagram due to a lack of reliable data. They are thought to account for a shrinking proportion (from a high of up to 15 % in the 1930s to less than 3 % today.) (Bennett and Pearson 2009)

commercialized. Until that point, aromatics – crucial for so many applications – had remained the preserve of the coal-based chemical industry.

Petroleum-based processes began to out compete coal-based chemistry in 1940, and since then coal feedstocks have thrived only under severe resource pressures. This was seen in Germany during World War II, where, deprived of access to reliable oil supplies, chemists focused their energies on products from syngas: in particular gasoline and synthetic rubber. This technology was subsequently applied by the South African oil and chemical giant Sasol, who had restricted access to international oil markets but allowed access to large domestic coal deposits. By 1974, Sasol was operating its first integrated fuel and chemical plant based on coal gasification, and by 1982 (just before a significant drop in the global oil price), it was producing 80 different chemicals for about 700 clients, with its sales of chemicals representing 16 % of total sales (Hodge 2000). Most of this was produced from olefins, which were generated by cracking the naphtha fraction of the Fischer–Tropsch liquid fuel manufactured from syngas. Still today, Sasol produces around 2 Mt of olefins from coal each year for the South African chemical industry.

Now

Of all the sources of chemical feedstock or process energy, coal gives rise to the largest amount of CO_2 emissions, estimated at between 8 and 11 t of CO_2 per ton of high-value chemical produced (Ren and Patel 2009). By comparison, oil-derived process routes emit around 4 t CO_2 per ton of product, and natural gas routes are slightly higher at 4–5 t (due to the additional energy requirements of producing syngas from methane). However, despite these high CO_2 emissions and an increasingly stringent greenhouse gas regime, coal-based chemistry continues to be favored in certain locations. In large part, this stems from local availability: most notably in China, where indigenous coal is far more abundant than other fossil fuels, about 20 % of the domestic chemical industry is based on coal as a feedstock (Yang and Jackson 2012). This chemical production is largely based on traditional "low-tech" processes such as coking, processing of coke and coal tar, and carbide chemistry. Future developments in China are likely to see growth in coal-to-liquids, coal-to-methanol, and C1 chemistry based on syngas, such as is used by Sasol (Xie et al. 2010). Indeed, significant investments into research of coal to olefins technology have been made in recent years, with a target in the 12th five-year plan to have 20 % of China's olefin consumption to come from coal, and it is expected that by 2020, China will be 62 % self-sufficient in ethylene production, most of which could come from coal (Horncastle et al. 2011). As technology improves and learning effects lower plant costs, coal-derived chemicals are expected to become increasingly competitive with imported petroleum-based routes. Multiple plants are already in operation, and there are a number of international collaborations underway, which share expertise and finance for new technological ventures. There have been a number of collaborations between South Africa's Sasol and China's Shenhua group, and recently Shenhua also partnered with Dow Chemicals for the Yulin Integrated Chemicals project: a US $3.9 billion coal to many chemical plants, scheduled to launch in 2016 (Zhao 2013).

Biomass

Concern about climate change and sustainability of fossil resources has driven renewed recent interest in biomass. While it is not a petrochemical in the same way as oil, gas, or coal, biomass also consists of hydrocarbon chains, which can be extracted and processed in very similar ways to fossil feedstocks.

Biomass refers to vegetation or other plant material that can be converted industrially into useful energy, fuel, or materials. At present it is estimated that around 5 % of current global chemical sales are produced from biomass, with biomass additionally supplying about 10 % of global primary energy (IEA 2013b). Most of the biomass that enters the chemical industry's value chain is either in traditional bulk processes that have never been fully displaced by petrochemicals or in smaller quantities of speciality products that harness specific natural properties of biomass. The former category includes products such as cellophane, produced from wood cellulose, vegetable oil components in soap, pine resins in paint, and use of castor oil to produce polyurethane. The latter category, meanwhile, includes speciality products such as cosmetics, food additives, dyes, and medical products, including specialist materials that can biodegrade in the body. Companies such as Croda, a UK company founded in 1925 to manufacture lanolin from sheep's wool, is today a speciality chemicals firm that obtains 70 % of its raw materials (and 24 % of its energy) from renewable resources (Croda 2014). The company produces personal care products, as well as crop care, polymers, and coatings, and achieved a revenue of £1.08 billion in 2013. In addition, there are other firms, not historically linked to biomass utilization, who are now looking to biomaterials to diversify their feedstock dependence and increase resilience. With new technological developments and increasing environmental awareness among consumers, bio-based chemicals may be entering a new era of technological and economical competitivity.

History

In many ways, the history of the petrochemical industry is one of replacement of biomass by synthetic products. Wood, for example, has been replaced in a wide variety of furniture applications by plastics, while synthetic fibers such as nylon have now superseded cotton for certain fabric products. In addition, there are now numerous more sophisticated synthetic materials from bio-based chemical feedstocks, which have a more complex relationship with fossil-based chemicals.

While fossil chemicals have dominated in recent years, use of biomass for chemicals has a history at least as long. Indeed, the early stages of the chemical industry's development saw strong competition between biomass and fossil feedstock-derived pathways. Between World War I and World War II, Europe and America showed great interest in industrial use of fermentation ethanol, with support schemes operating in Germany, France, Italy, the UK, and the United States, among others (Bernton et al. 1982). There were various reasons for these policies, in particular relating to concerns about the security of supply of oil for motor cars, the need to provide farm support during and after the depression, and, particularly in the European context, a lack of convincing evidence that petrochemistry was truly

superior or cheaper than biomass routes. In the UK, the added incentive of adding value to the molasses obtained from sugar plantations in the British Empire led to significant tax relief for industrial alcohol production, known as the inconvenience allowance (Reader 1975). As a result of the inconvenience allowance, and the partly related lack of UK refineries, British chemical companies first deployed the ethylene-based chemistry that was being developed in the United States by dehydrating ethanol produced by ex-whisky producers such as the Distiller's Company (Weir 1995). As such, in 1938 when the first polyethylene plant was developed, it was based on bioethanol, not fossil feedstock.

Around this time in the United States, a movement based around the Farm "Chemurgic" Council advocated harnessing agricultural production for soybean plastics, corn-based rubber, and Agrol (gasoline–ethanol blends) to relieve farm poverty and dependence on powerful oil companies (Finlay 2004; Hale 1930). In 1941, Henry Ford unveiled a car that ran on Agrol and had a soybean plastic body. The notion of separating plastics production from the oil industry was revisited following the oil shocks in the 1970s when ICI began the development of Biopol, a polymer made from fermented glucose (Bennett 2008). As oil prices dropped, the prospect of commercially competitive Biopol production receded, but the development work undertaken by ICI provided the foundations for a new generation of bio-based chemicals.

While petrochemical feedstocks have dominated the latter part of the twentieth century, biomass has not been forgotten, and ongoing research into this feedstock has been driven by interest, circumstance, and economics. For example, one of the first demonstrations of aviation biofuels came in 1979 when a group of amateur flying enthusiasts developed alcohol fuels in an attempt to mitigate the impacts of the gasoline crisis (Bernton et al. 1982).

Now

Recently, climate change is one of the concerns that have generated renewed interest in using biomass as a chemical feedstock. Biomass is a renewable resource that has the advantage of sequestering CO_2 from the atmosphere as it grows. If the biomass is then used as a chemical feedstock, then atmospheric CO_2 is incorporated into products. Depending on the end-of-life disposal of the product, the carbon is either locked up indefinitely and kept out of the atmosphere or returned to the atmosphere upon degradation or incineration, but still creating lower net emissions than the equivalent fossil-based product. A lower carbon footprint has been calculated for a number of synthetic materials from bio-based feedstocks, such as for polylactic acid (PLA) and Mater-Bi plastics, and fibers made from corn starch by NatureWorks in Nebraska, United States, and by Novamont in Terni, Italy (Madival et al. 2009; Murphy et al. 2008; Uihlein et al. 2008).

Most bio-based plastics are still more expensive than their petrochemical counterparts, and so commercial production is generally limited to those with specialist properties (such as biodegradability) where niche markets can be accessed.

However, the landscape is changing. Increasingly, "green" product premiums are growing the market for bio-based goods, as consumers become more aware of the

environmental footprint of their products and the marketability of (and willingness to pay for) green credentials increases. In addition, continued research and technological progress are lowering the costs, and bioplastics in particular are becoming increasingly competitive (Golden and Handfield 2014).

Major companies are increasingly investing in biomass-derived routes, for economic and technical reasons as much as environmental motivation. The Lego company, large-scale consumers of ABS, have instigated research into alternative, biomass-based plastics to replace this petroleum component of their children's toys with a target of achieving full feedstock switching by 2030 (Miel 2014). Focusing on the technical and potential economic advantages, the Toyota car company have set a target of replacing 20 % by weigh of all fossil-based plastics with bioplastics by 2015, with many of their cars already making use of bio-based polyesters, PET, and PLA-blends (FNR 2014). Several other investments have been triggered by concerns about resource availability. Projections of butadiene shortages in the coming decades led the tire company Michelin to initiate the Bio Butterfly project, a €52 million research program, to develop butadiene production from biomass. Additionally chemical companies such as Mitsui, DuPont, Dow Chemicals, and Braskem have all invested in new bio-based polymer routes, with a wide variety of applications. As biochemical markets develop, the output and diversity of bio-based facilities is scaling up and further reducing costs. One such plant is the BioAmber plant in Sarnia, Canada, due to commence operation in 2015, which will see production of 50,000 t of bio-based succinic acid per annum.

For details on bio-based plastics, see the respective chapter in this handbook.

However, as with fossil feedstocks, the full environmental impact of biomass is not entirely straightforward. While carbon is captured during plant growth, crop cultivation and biomass processing still has impacts on water use, gaseous emissions, and uses resources, including fossil resources. A life cycle assessment (LCA) approach has been developed to take these impacts into account and to compare the benefits of different process routes. Full LCA analysis is particularly important for biomass, as at present it is a more limited resource than oil, gas, or coal. It is frequently advocated that its use should be directed to those functions with the greatest environmental gain, which does not currently match the greatest economic gain. Resource availability is discussed in more detail in the context of biorefineries, toward the end of this chapter.

Future Trends

Concerns About Resource Sustainability

Because of the reliance of the organic chemical industry on fossil fuels, especially oil, for both feedstock and energy, the sustainability of oil supply is of utmost importance. If the global oil market becomes disrupted or tight, competition for available oil supplies raises the production costs of petrochemicals more than for other commodities. This could benefit other feedstocks if they can be deployed

rapidly enough to take advantage of the imbalance between demand and supply of oil. Alternatively, total demand for organic chemicals could be reduced. While there are numerous political and economic factors that can lead to volatility in oil prices, long-term oil prices could be influenced by geological supply constraints. This notion that such constraints could lead to a peak in oil supply is commonly referred to as "peak oil."

The two men most associated with the ideas behind peak oil concerns are William Stanley Jevons and M. King Hubbert. Both looked at a finite fossil fuel resource and noted that the production rate of that resource, which had initially risen exponentially, would reach a maximum point long before the resource became exhausted. Jevons correctly predicted that UK coal supply would be unable to keep up with demand in the early twentieth century. Hubbert correctly predicted a peak in US oil production in the mid-twentieth century. For both resources, the growth rate of supply was checked at approximately half of the total reserve. Although British coal and American oil could subsequently be replaced by alternative fossil energy sources, mainly through imports, what was recognized by these theorists was that if there is no alternative supply source that can be used as a substitute at similar cost, then the inevitable decline in production will cause intense competition between consumers if their levels of demand are inflexible due to existing infrastructure and expectations. Peak oil proponents predict that after the global peak in the rate of production, price rises would accompany sharp declines in production rates unless demand were rapidly reduced, thus the key date would be the extraction of half the conventional oil resource and not the date of total exhaustion.[1] While concern was high in the early 2000s that rapid price rises could mean an end to decades of economic growth based on cheap access to oil, the addition of substantial oil production from unconventional sources has relieved many of these concerns in the last few years.

Conventional oil refers to crude oil, condensate, and natural gas liquids, which are usually relatively easily extracted from subsurface oil fields and require relatively little upgrading to liquid fuels. By contrast, unconventional oil refers to tight oil sands, shale oil, and extra-heavy oil, which are not found in a usable form and require more treatment to yield liquid fuels. To unconventional oil can be added synfuels (coal-to-liquids, gas-to-liquids, and biofuels) (IEA 2013c). Unconventional liquids are generally more expensive to produce than conventional oil, but their production is nevertheless increasing, partly due to higher than historical oil prices.

The date and severity of peak oil remains unresolved. It not only depends on the total remaining conventional oil resource but also the costs of extraction, the elasticity of oil demand, the availability of substitutes, and the rate at which demand is suppressed by market saturation and efficiency policies in various countries. Figures 4 and 5 show the global trends in oil reserves and production. It can be seen that oil reserves are increasing, reflecting a mixture of technological progress

[1]Studies suggest that most of the world's major fields have peaked at between 30 % and 40 % of their total resource (Hökök et al. 2009).

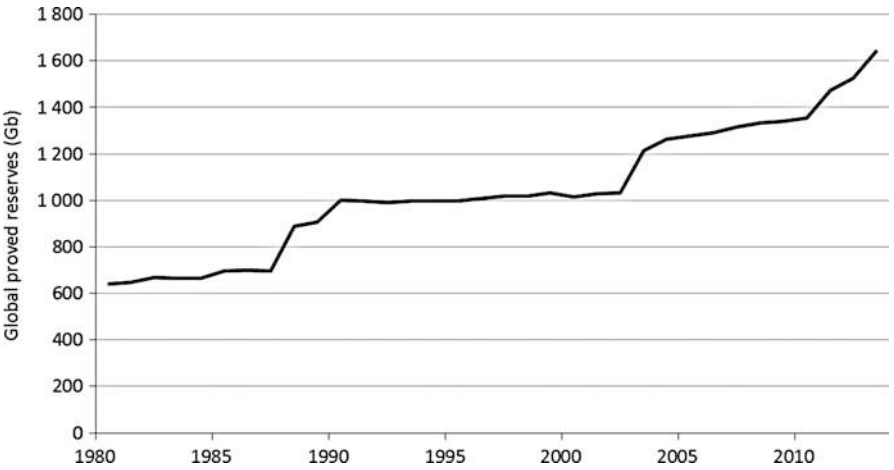

Fig. 4 Global trends in proved conventional oil reserves (EIA 2014a) (Proved reserves of crude oil are the estimated quantities of all liquids defined as crude oil, which geological and engineering data demonstrate with reasonable certainty to be recoverable in future years from reservoirs under existing economic and operating conditions. They are thus subject to changes in technology and oil price) Gb = gigabarrel

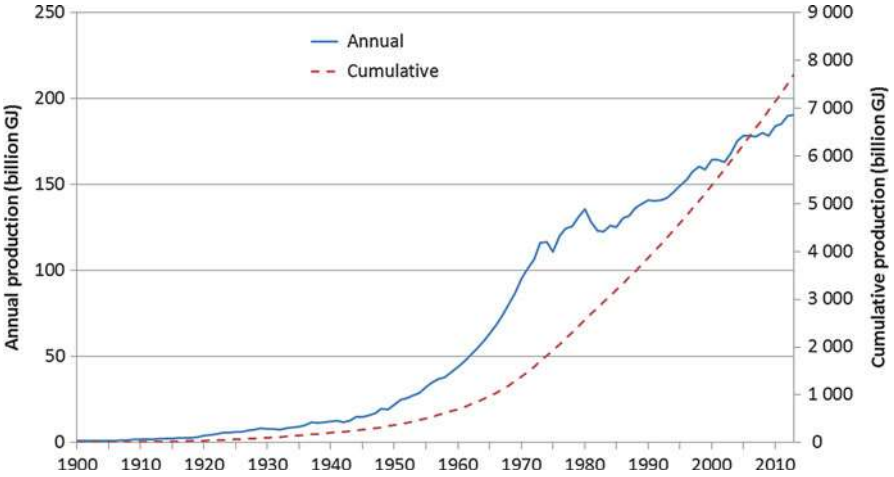

Fig. 5 Global trends in oil production (EIA 2014b; Emetad and Luciani 1991)

that reduces extraction costs of resources that are more difficult to access and oil prices above the long-term average that make higher-cost oil economic. Production growth has slowed, reflecting some consumer response to higher oil prices but also changes in consumption patterns in major economies such as the United States, Europe, and China. Fuel efficiency standards and fuel switching to less polluting fuels are having an impact. Yet, despite these trends, reserve additions are not

keeping pace with production. Recent years have seen relatively strong rates of exploration drilling; however, the discovered volumes have dropped since 2013, and the total number of discoveries per annum has fallen by 50 % between 2008 and 2014 (IHS 2014).

In a review of the evidence for a peak in conventional oil by 2030 by Sorrell et al. (2009), it is noted that although there are around 70,000 oil fields in the world, 100 fields account for half of production and up to 500 fields account for two-thirds of cumulative discoveries. Most of these giant fields are well past their peak of production or will begin to decline in the next decade. Their analysis indicates that just to maintain production at current levels, three million barrels per day of new capacity must be added each year – equivalent to a new Saudi Arabia coming on stream every 3 years. This means that in order to prevent production from falling, more than two-thirds of current crude oil production capacity may need to be replaced by 2030. Yet there appears little chance that new giant fields will be discovered and discoveries of new smaller fields are not currently at the levels needed.

While the likelihood of high future oil prices may have positive outcomes in terms of demand reduction and CO_2 emissions reduction, this needs to be balanced against the implications for economic activities such as petrochemical production, which is currently configured to take advantage of available and conventional oil at prices that have historically made production profitable. In a world that takes strong action to mitigate climate change, unconventional oil sources might comfortably substitute for declining conventional oil production. If demand does not decline due to climate action, however, the availability of synfuels and biofuels, including their public acceptance, will be more important.

For details on bio-based fuels, see the respective chapter in this handbook.

Unconventional Oil

Global oil production is expected to increase from 89 million barrels per day in 2013 to more than 104 million barrels per day in 2040 (IEA 2014d). The proportion of conventional oil will fall, with the proportion of natural gas liquids and unconventional oil increasing. It is also notable that OPEC's share of production is expected to increase somewhat, as well as increasing production from Brazil, Canada, Kazakhstan, and the United States. The increasing share of unconventional substitute fuels will also determine what resources are available for use in the chemical industry. This is already being seen in the United States, where the availability of shale gas is leading to its increased use as chemical feedstock.

Unconventional fuels primarily consist of oil sands, shale oil, and other heavy oils, shale gas, gas-to-liquids, coal-to-liquids, and biofuels. Each of these unconventional resources is itself a limited resource of differing proportions, and none is anticipated to offer a sole solution. Unlike for crude oil, production of liquid fuels from these resources do not generally produce by-products – such as LPG or naphtha – that are highly suitable as chemical feedstocks. Olefins, aromatics, or syngas can all be produced from unconventional liquids, but they would compete for the raw

material with fuel users, who may be willing to bid high prices if the available resource is constrained. Integrating unconventional feedstocks into the petrochemical industry could also require costly changes to the upstream infrastructure, which could be very costly.

Moreover, in terms of emissions, unconventional feedstocks often require more energy-intensive processing methods to yield fuels and feedstocks, such as gasification, hydroconversion, or steam injection. This additional energy consumption adds cost and will leave the chemical industry even more exposed to volatile energy prices than it already is. Furthermore, an increase in process energy will increase the carbon footprint of the industry, a factor which is becoming increasingly pertinent. Extraction of unconventional oil is predicated on the condition of economic as well as technical viability – it must be possible to make money from the process. However, the global economy is increasingly taking note of the concept of a "carbon budget": a finite, maximum total amount of CO_2 that can be released into the atmosphere if the planet is to stay within globally agreed temperature limits. To stay below a 2 °C increase, it is currently estimated that between 60 % and 80 % of proven fossil fuel reserves will need to remain in the ground. This has led organizations such as the Carbon Tracker Initiative to monitor and highlight the potential risk of investing in fossil fuel assets, some of which could become unexploitable if demand is curtailed by carbon pricing or regulation (CTI 2013). In such a situation, unconventional oil could be the most severely affected if its production cost (including any carbon price) were more expensive than the marginal oil price. Use of unconventional oil for chemical feedstock may therefore be more vulnerable to climate mitigation policy than other feedstock options and suffer from any reduced investment in unconventional oil production for fuel purposes.

Impacts of Energy Use by the Petrochemical Industry

The previous section explored the dependence of the petrochemical industry on fossil feedstocks. However, the sector is doubly dependent on fossil fuels, as it is also a massive consumer of process energy for heat and electricity. Many chemical processes are highly energy intensive, and the volumes of production mean that the petrochemical sector is one of the major consumers in the global energy landscape. Most of this energy is supplied through combustion of fossil fuels; as has been described, the modern petrochemical industry largely emerged as a corollary of primary fuel refining, and most petrochemical facilities continue to be located in close proximity to these sites if not integrated within the same complex and ownership structure. As a consequence, the fossil source for feedstock is often used for energy production too, supplying some of the 15 billion GJ/year used by the chemical and petrochemical industry for processing, not including the additional energy required to produce the feedstock (IEA 2012). While the many processes, products, and feedstocks make this a complex landscape, this section explores the main implications of climate change for the petrochemical industry as an energy consumer.

Primary Sources of Greenhouse Gases

The global industrial sector accounts for 21 % of direct greenhouse gas emissions. When indirect emissions (including those from electricity consumption) are included, industry's share rises to 32 % of global total GHG emissions, making it the primary source of GHG, above even the combined emissions from agriculture, forestry, and land use (IPCC 2013). The vast majority of this comes from energy use, and the chemical and petrochemical industry uses more than 30 % of the total industrial energy use worldwide, giving rise to very high volumes of GHG emissions. Overall, CO_2 emissions are found to account for the majority of these, accounting for around 99 % of greenhouse gas emissions from the petrochemical industry (Benchaita 2013), and while emissions of chlorofluorocarbons, methane, and nitrous oxides should be reduced wherever possible, the biggest implications are for CO_2, which is the focus of this section.

Data on the energy efficiency and GHG emissions from the global petrochemical sector are not readily available, for a number of reasons. Firstly, the diversity and complexity of the sector mean that there are a vast number of processes, products, and feedstocks that must be accounted for. This also leads to difficulties in allocating emissions between the heavily integrated processes on site, and without a global obligation to record and report CO_2 emissions, there are serious limitations to and discrepancies within the data that is available. Lastly, intellectual property and antitrust issues can prevent full disclosure of CO_2 figures. The world total GHG emissions attributed to chemical and petrochemical processes amounts to 1,240 MtCO2 equivalent annually. GHG emissions of the 18 largest volume chemicals are 960 MtCO2 equivalent per year, or more than 75 % of the total (IEA 2013a). This does not account for all emissions from power generation or energy recovery from petrochemical products during disposal, but does include both inorganic and organic chemicals production.

However, the situation is particularly complex for the petrochemical industry as compared to other industrial sectors. Much of the energy is used as feedstock, which then is locked up in products until the end of their lifetime and in many cases for a long time after their disposal. This makes the industry an effective "store" of fossil carbon in chemical products – carbon that would otherwise have been burnt for fuel and released to the atmosphere. It is estimated that carbon storage in plastics worldwide is around 477 Mt of CO_2 equivalent per year, and growing as plastic consumption rises (IEA 2007). With only 30 Mt of plastics incinerated annually at the end of their lifetime, the rest of the carbon continues to be locked into the plastic product. Furthermore, when considering the full lifecycle of the product, chemical industry representatives note that not only should end-of-life disposal be taken into account but also the contributions that use of the product made during its active product life. Carbon-containing products can contribute significant efficiency gains during their life: for example, the replacement of metal panels with carbon fiber reduces the weight (and therefore fuel consumption) of vehicles, and the use of polymers for insulation saves more in carbon dioxide via reduction in energy consumption than was generated during their production (Cefic 2006). Indeed, it

Table 3 Energy requirements for steam cracking for three different feedstocks (IEA 2007)

Feedstock	GJ/t ethylene
Ethane	15–25
Naphtha	25–40
Gas oil	40–50

has been estimated that in the food packaging industry, the replacement of materials such as metals, glass, or cardboard with petrochemically derived plastics has resulted in GHG reductions, as the plastics require fewer raw materials and less energy, as well as transport emission savings resulting from lighter weight plastics (IEA 2013a). However, it is difficult to create transferable metrics for the different stages of the product life, and it is likely that a robust carbon price, applied to all CO_2 emissions throughout the economy, would be the only way to effectively do this.

The vast majority of CO_2 emissions from the petrochemical industry stem from its energy consumption, which is used to power energy-intensive production processes. A typical petrochemical plant includes three types of energy consumption: about 60 % is due to fuel consumption, 35 % due to steam energy consumption, and 5 % fuel to power consumption (Benchaita 2013). Steam cracking to produce olefins is highly energy intensive, and it is used extensively, making it the major energy-consuming process worldwide. The energy used in steam cracking depends on both the technology used, and the choice of feedstock, with lighter feedstocks such as ethane cracked at lower temperatures, and the final ethylene yield decreasing (and so per-product emissions increasing) as the molecular weight of feedstock increases. One ton of ethylene can be produced from 1.25 t of ethane, 2.2 t of propane, or as much as 3.2 t of naphtha (Table 3).

In addition to the previously mentioned challenges for securing energy data, it must also be noted that the petrochemical industry is highly diverse, and it would be extremely challenging to develop separate indicators for each product. In response to this challenge, the IEA proposed an aggregate product indicator, composed of 49 products, which together account for more than 95 % of the total energy consumed by the industry (Tam and Gielen 2006). The five most energy-intensive processes are production of acetic acid (34 GJ/t), production of benzene via steam cracking (27 GJ/t), production of xylene by steam cracking (26 GJ/t), production of toluene by steam cracking (24 GJ/t), and production of toluene diisocyanate (22 GJ/t). Accounting for production volumes, it becomes clear that the three largest energy uses are for the processes that yield ethylene (1.3 million GJ per annum), propylene (0.7 million GJ per annum), and benzene (0.6 million GJ per annum). Considering the aggregate product indicator for the 49 products, it is found that efficiency savings just from implementing the best available practices and technologies in the core chemical processes could save around 14 % of this energy each year (excluding electricity), or more than 21 % when including electricity (IEA 2014a). However, the magnitude of the emissions from the top energy consumers clearly shows that targeting savings from these processes alone would yield significant climate change mitigation benefits.

Emissions also arise from the transport of chemical products, for further processing and for final sale. While many processing units are integrated with or sited near each other and near the refineries themselves, this is not always the case, and large volumes of chemicals (often gaseous or unstable, thereby requiring liquefaction or compression) must be transported to other locations. As with all industries, greater transportation leads to higher costs and GHG emissions from transport. Therefore, the economies of scale associated with large-scale petrochemical sites must be balanced with the increased demand for transport to sites of product consumption.

Calculations of the impact on the climate from organic chemicals should be undertaken with an understanding of the life cycle impact of a particular product or application. Such an approach could place appropriate emphasis on downstream users of chemical products to demand chemical commodities and synthetic materials that have a lower carbon footprint.

There is no space in this chapter to look in depth at particular products. Instead, the later sections on climate change mitigation options consider the potential for improvement of some of the most energy-intensive petrochemical processes.

Geographical Variations

The main petrochemical-producing regions are Europe, the Middle East, and the United States, although there has been significant growth in China during the last decade. Each of these regions relies to a large extent on different raw materials, meaning that their GHG emissions vary. Ethylene is one of the most important olefins, with production growing at an annual rate of 4.5 % each year (Benchaita 2013). Figure 4 shows the percentages of ethylene production capacity in different regions that are based on the six main feedstocks. This shows that while ethane dominates in the Middle East, naphtha and heavier fractions dominate in Europe. The United States is mainly reliant on LPG and some naphtha, while Asia Pacific is dominated by naphtha: indeed in 2013, 80 % of ethylene production facilities in China were naphtha based (Kalkman and Keller 2012). While the capacities vary between regions, the core technology designs are similar and are based on the steam cracking process developed in the United States in the early 1940s. The steam cracking process is energy intensive and globally accounts for more than 39 % of the chemical and petrochemical industry's final energy use. The energy used by each facility however depends on a number of factors, with feedstock being a key element since lighter feedstocks (such as ethane) are cracked at lower temperatures (IEA 2007) (Fig. 6).

The distribution of CO_2 emissions in Table 4 reflects these regional differences and also the emission intensities of the processes. Thus, the top countries in the table are those with high energy costs and therefore incentives to operate highly efficient, integrated plants and those that use lighter "cleaner" feedstocks.

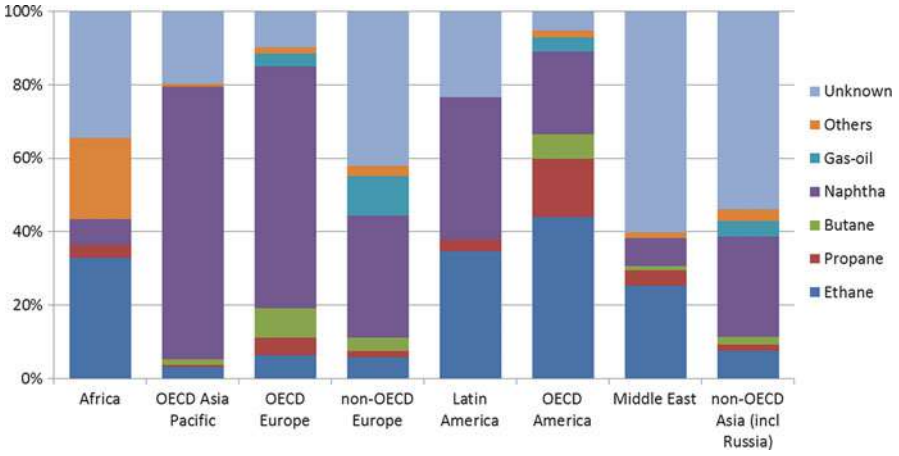

Fig. 6 Ethylene plants by feedstock and region (Oil and Gas Journal 2014)

Table 4 Total CO_2 emissions from national chemical industries, in reverse order of their estimated emissions intensity (IEA 2007)

Country	Million tons of CO_2 per year in 2004 (Mt CO_2/year)
Netherlands	22.7
Saudi Arabia	53.1
Japan	120.1
United Kingdom	19.4
France	24.3
India	51.0
Germany	46.8
Italy	10.1
United States	275.0
Brazil	13.6
China	51.0
Chinese Taipei	13.4

Future Trends in Geographical Variations

The main influences on GHG emissions from the organic chemical industry are feedstock costs and climate change regulation.

The high oil prices experienced in 2007–2008 gave an indication of how the industry could develop if investment decisions are made in the belief that oil supplies will be tight in the next decades. Middle East producers of olefins from ethane were the most advantaged under these conditions due to the low cost of both feedstock and manufacture from this feedstock. European naphtha-based crackers became the marginal producers and were able to continue operation only due to continued

integration with local refineries. However, prices of both naphtha feedstock and process energy increased sharply for these producers and caused a delayed downturn in demand. This was compounded by the greater damage done to demand for petrochemicals by the credit crunch and ensuing global recession.

Long-term increases in oil prices would be likely to cause a marked shift in basic petrochemical production to locations where light crude oil is plentiful, especially Saudi Arabia and the Middle East. Although the use of LPG as a basic feedstock is accompanied by lower CO_2 emissions, the increasing exploitation of LPG as a chemical feedstock in affluent oil-producing nations means that the carbon intensity of olefin production has decreased; this is more than offset by the rise in production and the use of heavier feedstocks elsewhere in the industry.

Nevertheless the nature of the industry is such that minimizing energy costs (for feedstock, heat, steam, and power) is a major factor in plant design worldwide. The development of shale gas in the United States has led to renewed investment in the nation's chemical sector. Through exploitation of relatively cheap shale gas, US organic chemical companies have been able to compete internationally for capital and markets. European companies, meanwhile, may find it necessary to return to a level of vertical integration that allows them to absorb price volatility in the value chain and focus on high-value-added products. Large plants and multinational companies have always been the status quo in the petrochemical industry, and this is not foreseen to change.

Another outcome of the oil price spike in 2007–2008 was the growth in interest in coal and biomass feedstocks. Coal has most interest in China, the United States, Australia, and South Africa for reasons of indigenous supplies and technological expertise. However, it must be noted that increased use of coal as a feedstock for ammonia and methanol production would lead to higher CO_2 emissions.

Overall, an eastward shift in chemical production appears to be an inescapable trend for the near future. Aside from raw materials costs, this relates to lower capital and operating costs in China, India, and Brazil, less costly regulatory environments, and the higher rates of demand growth in these regions. In the OECD, the main markets for bulk chemical products are largely saturated. Investment in new capacity in Europe is likely to continue to focus on speciality products and infrastructure considered to be of strategic importance.

Chemical plants in regions subject to GHG emission regulations have a very strong incentive to implement mitigation technologies. Although the timetable is unclear, there is a broad expectation that GHG emissions will be costly for chemical producers in most regions of the world in the coming decades. Investments today will therefore consider measures such as extensive heat integration and CHP as competitive advantages, as well as the use of biomass to provide a proportion of the heat and power requirements of a chemical site, perhaps through co-firing.

Another macroeconomic trend with possible impacts on the petrochemical industry's emission intensity is that of changes to refinery output. Modern refineries are capable of adjusting their output to meet demand by cracking and upgrading the different distillation fractions to meet fuel requirements. For example, heavier fractions can be cracked and reformed to produce more high-octane gasoline. As a

consequence, because of the high levels of integration between the fuels and chemical industries, changes in the – much larger by volume – fuel industry could impact on the fractions of crude oil that is available for chemical feedstocks. In the near-to-medium term, most of these changes to the current balance of products would most probably lead to a larger amount of processing in order to continue to supply the existing infrastructure. More processing generally indicates more CO_2. Plausible changes in refinery configurations could result from, among other things, a global trend toward diesel-powered cars; the emergence of a highly competitive market for LPG fuel; a substantial increase in the proportion of electric, hybrid, and biofuel-powered cars worldwide; and a trend toward "heavier" crude oils. This last change appears unavoidable: oil sands, coal-to-liquids, and other unconventional and difficult-to-access sources of liquid fuels will be needed to replace the depleted supplies of conventional light crude oil. Moreover, if demand continues to increase, these unconventional fuels will become increasingly cost competitive (assuming no carbon price). It should be borne in mind, however, that complex industries that have evolved together over many decades will only reorient their supply chains to radically new technologies on the scale of decades, as the inertia in the infrastructure is very great.

It is worth considering these future trends as they could all impact negatively on the ease with which the organic chemical industry can mitigate its impact on the climate. In the next section on mitigation options, the main focus will be on long-term options that offer serious emission cuts. Incremental efficiency improvements will also have a role to play, but they may be insufficient to offset trends that lead to higher emission intensities.

Implications of and Response to Climate Change

The previous parts of this chapter have described the extent to which the petrochemical industry is closely integrated with fossil resources. This section looks specifically at the climate mitigation options that have the potential to increase the sustainability of the chemical industry.

It must be acknowledged that the most obvious route would be to reduce consumption of petrochemical products or at least to slow the rate of growth. This would benefit both resource sustainability and climate mitigation impacts. However, the continued rate of growth in demand for chemicals, fibers, and plastics in particular appears unlikely to slow in the near future: indeed it has been suggested that it would only plateau once average wealth is in excess of USD 15,000 per capita, which is a long way from the current global economic reality (Andre et al. 2014). In addition, if reduced production were enforced, it may withhold many of the lifecycle benefits associated with use of some petrochemical-derived products. The transition to a climate conscious regime will require the technical qualities of specialist plastics, lightweight carbon fiber structures, and a multitude of other petrochemical products. Chemical products can thus contribute to GHG savings in downstream markets, something that demands a life cycle approach to understanding costs and

benefits. However, this section assumes that the products of the petrochemical industry will continue to be produced globally on a similar scale today to meet the material demands of a modern society with a growing population, and therefore, its emissions from chemicals manufacture will require attention.

The second most impactful route would be to decarbonize the electricity supply and electrify existing chemical processes. However, the challenges of moving domestic electricity networks to renewable energy have proven considerable, even without expanding electricity demand to include vehicular transport and industrial manufacturing. Nevertheless, even if it is unlikely that the fossil fuel-dependent petrochemical industry will shift to low-carbon electricity for heat and power in the near future, there will be many instances where installing local renewable energy sources to power certain processes may be economic. The extent of this switch will depend on local conditions and available government support.

However, there are a number of impactful technical measures that the chemical industry can take to reduce its emissions. This section considers a number of routes for the chemical industry to adjust moving forward: efficiency gains, focusing on combined heat and power (CHP), plastics recycling, carbon capture and storage (CCS), and feedstock switching, which focuses on the concept of the biorefinery. Each of these options and technologies has their own merits and opportunities, and they can complement one another. Indeed, a carbon-conscious future is likely to see the implementation of several of these technologies together.

Efficiency Gains and CHP

Efficiency Gains

Efficiency gains in energy and resource consumption can both reduce climate impact and costs for the petrochemical industry, as it both mitigates the economic impacts of climate regulation and reduces vulnerability to volatile fossil resource prices. These two drivers have been effective in provoking significant improvements in energy and resource efficiency within the petrochemical industry, and there is a long track record of such improvement.

High efficiency is a natural pursuit of any business that is highly exposed to the cost of energy, and consequently many of the key industrial processes in the chemical industry have improved their performance year on year. The oil price shocks of the 1970s offered a notable impetus to this efficiency focus: while early naphtha crackers consumed approximately 38 GJ per ton of ethylene produced, the 1970s saw extensive process redesign, which lowered the energy requirements by 40–50 % (Gielen et al. 2006). Today, furnace and product separation at new plants operate at around 18–25 GJ per ton as a norm. Continued improvements have been seen and are most apparent in Europe, where the energy efficiency of steam crackers improved by 10 % between 1999 and 2003 alone, with improvement in North America of just 3 % during the same time period. This stems in large part from the differential pressures from using imported naphtha in Europe, where other regions utilize local LPG resources which require less furnace and separation energy in

cracking. In the future, the battle for efficiency is likely to be due to both the costs of GHG emissions and energy.

There remain improvements that could be made to crackers in developed and developing countries alike. Higher-temperature furnaces, gas turbine integration, advanced distillation columns, and combined refrigeration plants are possibilities that have been identified as potentially leading to savings of up to 3 GJ per ton of ethylene. Other options, such as fluidized catalytic crackers (FCC) and new deep catalytic cracking processes, have milder temperature and separation requirements, although they are limited either by feedstock availability – FFC generally uses refinery gases – or by the impact on other integrated processes. For instance, deep catalytic cracking yields are generally achieved at the expense of gasoline yields. With rapid growth in production capacity occurring in areas heavily dependent on naphtha feedstocks, reduction of the energy intensity of the steam cracking process in particular (steam cracking currently accounts for 30 % of all chemical industry energy consumption (Ren and Patel 2009) will be necessary to reduce GHG emissions, potentially contributing a 143 Mt CO_2 equivalent saving, and research is ongoing into catalytic cracking approaches.

Efficiency improvements can offer the major petrochemical firms an important competitive edge, as well as leading to GHG savings, and they are expected to be realized wherever they are profitable. Where there is a shift to lower-cost regions of production, the savings may be realized faster than the expected 30-year infrastructure replacement cycle. After all, many of the plants built in the Middle East and Asia are made to cutting-edge designs, for example, the methyl methacrylate plant commissioned in 2008 by British firm Lucite in Singapore.[2]

Overall, improvements to the environmental performance of existing processes are encapsulated by the 12 principles of Green Chemistry (Table 5). Green chemistry is an approach to chemical production that stresses the environmental impacts of all process steps and encourages a holistic view of all processes, inputs, and outputs. It encourages industrial producers to use processes that meet as many of the 12 aims as possible, with "increase energy efficiency" as principle 9. The Presidential Green Chemistry Challenge Awards have been awarded annually since 1996 by the American Chemical Society, supported by the US Environmental Protection Agency (EPA). In 2009, the Greener Synthetic Pathways Award was won by Eastman Chemical Company for a novel route to the production of esters. The old process used strong acid catalysts at high temperatures; using enzymes eliminates the need for harsh conditions and thus significantly reduces energy use. It reduces the overall requirements for feedstock and solvents. It is also a cheaper process, which was only made possible by taking a holistic approach to the industrial process.

The European Chemical Industry Council (Cefic) considers that energy efficiency improvements will continue to contribute the greatest GHG reductions from the chemical industry (Cefic 2013). As an industry body, they also note that unlike other options, such an approach would reduce the costs of the industry in the near term,

[2]Lucite was subsequently subject to acquisition by Mitsubishi of Japan.

Table 5 The 12 principles of green chemistry (Anastas and Warner 1998)

1	Prevent waste
2	Design safer chemicals and products
3	Design less-hazardous chemical syntheses
4	Use renewable feedstocks
5	Use catalysts, not stoichiometric reagents
6	Avoid chemical derivatives
7	Maximize atom economy
8	Use safer solvents and reaction conditions
9	Increase energy efficiency
10	Design chemicals and products to degrade after use
11	Analyze in real time to prevent pollution
12	Minimize the potential for accidents

making it particularly appealing for the European context where recent years have seen stiff competition from production in regions where energy costs are much lower. This is also highly promising in terms of climate mitigation: implementation of best practice and best available technologies, in particular – increased development and use of catalysts – could reduce energy intensity for key products by up to 40 % by 2050, saving around 1,000 $MtCO_2$ equivalent per year in 2050, as compared to a "business-as-usual" scenario (IEA 2013a). This is particularly important in European and North American plants, where the majority of apparatus was designed and built more than two decades ago and efficiency is often considerably lower than plants built more recently (Benchaita 2013). However, currently available technologies can only go so far, and to achieve deeper energy and emission cuts, larger technological changes will also be needed.

Combined Heat and Power (CHP)

At present, there still remain efficiency gains that have not yet been realized (Fig. 7). As well as implementation of best practice technology and process intensification, CHP is particularly important to consider across all regions due to the massive demand for process heat in the chemical industry. Because heat is a low-grade energy product, its dedicated production can be considered to be a low-value use of resources anywhere where it could be recovered from other processes that generate excess heat, e.g., the production of electricity or even chemicals themselves.

Thus, by making use of the "waste" heat produced as steam in electricity production, CHP increases the overall efficiency of a power plant. A petrochemical facility has a high demand for both power and high-temperature steam, for processes such as steam cracking.

Industry is already one of the largest users of CHP. In 2011, industrial CHP facilities generated 26 % total global electricity generation from CHP (IEA 2014c). In the United States, 23 of the total 82 GW of installed CHP capacity was in the chemical sector in 2013, with estimates suggesting a technical potential for a further

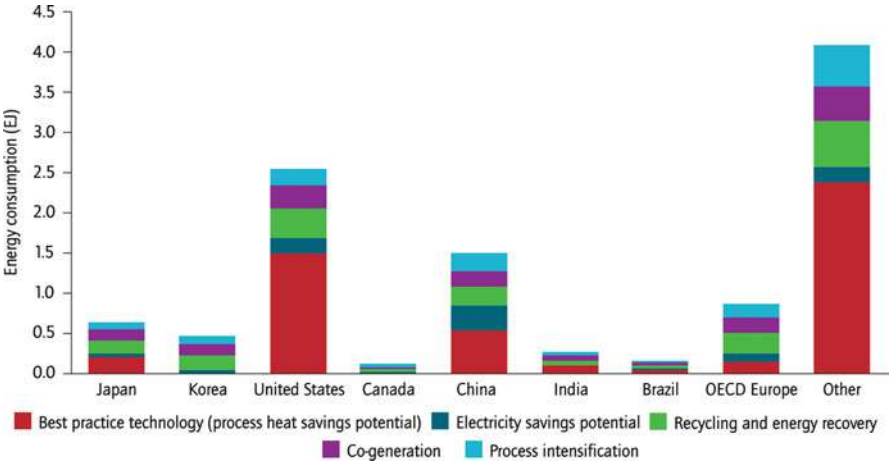

Fig. 7 Energy efficiency potential in the chemical and petrochemical industry (IEA 2013a)

25 GW capacity in chemical production alone (Gowrishankar et al. 2013). The EU meanwhile has specifically incorporated cogeneration into its energy policy through the CHP Directive and the Energy Efficiency Directive. Numerous refineries and chemicals sites have already installed CHP systems – including Immingham in the UK (1,240 MW), which is one of the largest CHP installations in Europe and operates with approximately 70 % thermally efficiency.

CHP is a technology that could be applied at nearly all chemical sites worldwide and could realize considerable GHG emission savings. It has the advantage of being possible to retrofit without redesigning and investing in new process infrastructure, unlike the huge theoretical energy savings that are actually distributed among many different process improvements. GHG emissions can be reduced still further by using sustainably produced biomass fuel. Two challenges face the expansion of CHP for the organic chemical industry, however. Firstly, the technology needs to become more economically viable at smaller scales than it is at present (e.g., below 50 MW). Secondly, policies for supporting renewable energy need to be aligned with those for CHP to incentivize the use of biomass with CHP and realize the maximum benefit from this technology.

Recycling and Waste Management

Another aspect of resource sustainability that must be considered is that of waste management and recycling. Waste management is important for managing the environmental impact of organic chemical products at the end of their life, including the GHG emissions. As well as a solution to the waste management problem, recycling also has major benefits in terms of reducing the need for fossil raw materials.

Taking plastics as an example, global production of plastics was around 288 million metric tons in 2012, of which only around 10 % was recycled. There are large geographical variations in recycling rates, however, and in the United States, Japan, and Europe, the proportion is much higher than this. In addition, post-consumer plastic waste is also increasingly being incinerated for energy recovery. Most plastics have relatively high energy contents, comparable to other hydrocarbon energy sources. Polypropylene, for example, contains 46 MJ per kg, which is equivalent to that of kerosene. On average household-mixed plastic waste contains around 32 MJ per kg, which is favorable compared to coal (approximately 25 MJ per kg). Hence, energy recovery from plastics can partially substitute fossil fuels in heat or power production, offering a sizable, secure, and competitive energy source. If even half of the global waste plastic resource was used for energy recovery, this would be a significant resource. With landfill taxes being employed in many countries for reasons of space constraints and waste management, this resource is increasingly attractive.

The climate story around energy recovery is slightly different. As mentioned earlier, the use of fossil fuels as plastics feedstocks effectively locks up the carbon, which breaks down only very slowly in landfills. (It should be noted that where it does break down, it may yield methane, a much more potent GHG, although this can be partially dealt with by landfill gas collection for energy use.) Use of plastics as an energy source creates CO_2 emissions that can be considered as deriving from fossil carbon. If this displaces coal combustion, then the climate benefit would be small but useful. If it replaces natural gas combustion, then the climate impact would be unfavorable. Therefore, while energy recovery is attractive in terms of conservation of fossil fuels, it is unlikely to be attractive for reduction of GHG emissions. Recycling, on the other hand, offers both energy security and climate benefits.

Reducing the amount of fossil (or bio-based) feedstock necessary for chemical production can have a positive effect on the available energy supplies. Perhaps, more importantly, recycling can reduce the energy demand, and therefore the GHG emissions, of plastic manufacture by about 0.6 t of CO_2 equivalent per ton of plastic recycled compared to landfilling (Wrap 2010). Maximizing recycling is therefore a vital tool in the pursuit of sustainability in the chemical industry from economic, social, and environmental perspectives.

To conclude this short overview of recycling, it is necessary to briefly distinguish between thermoplastic recycling and so-called feedstock recycling. Thermoplastics are polymers that become liquid when heated and can be reset as plastics when cooled and put to a new use, and most recycling today is thermoplastic recycling. Meanwhile feedstock recycling generally refers to the use of plastic waste as a raw material for thermochemical conversion to new feedstocks. This can either be achieved by pyrolysis to liquid fuel or, as is more usually promoted, by gasification to syngas and then use in similar chemical processes to those fed by natural gas or coal; this could be, for instance, production of ammonia, liquid fuels, methanol, Fischer–Tropsch olefins, or dimethyl ether. Because feedstock recycling to chemicals requires energy-intensive conversion of the plastic waste to syngas, it offers a solution primarily to the problem of resource sustainability, but is less

favorable as a climate mitigation tool. It may only yield GHG emission reductions when compared to coal gasification processes or if it provides exceptional savings in downstream uses of the resulting products.

However, one potential advantage of feedstock recycling is the hydrogen-rich syngas produced in comparison to that from coal. This could be advantageous in the future in which syngas is widely used for production of hydrogen, fuel, or chemicals, suggesting a possible role for "co-gasification" of plastic, coal, and biomass.

Carbon Capture and Storage (CCS)

CCS offers the unique ability to separate fossil fuel use from climate harm. By capturing CO_2 at source, transporting it, and sequestering securely underground, it could be a powerful tool in the fight against climate change. Without CCS, few climate scenarios are able to achieve the carbon reduction targets compliant with 2 °C warming, and the latest IPCC projections assume CCS to contribute a sixth of the CO_2 emission reductions required by 2050 (IPCC 2013). While other chapters of this book consider the technical details and policy context of CCS in more detail, this section explores the applicability and potential importance of CCS for the chemical industry.

CCS is really a collection of technologies rather than a single procedure. At each stage of the process, there are several technological options: CO_2 separation can take place pre-combustion, post-combustion, or via oxy-fuel combustion; transport can occur through pipelines or potentially through shipping; and there are a range of geological storage options, including depleted fossil fuel reservoirs, saline aquifers, and even coal seams. The different choices of technology will depend on the particular context. Post-combustion capture can be retrofitted to existing industrial facilities or power stations, whereas integrating pre-combustion capture can increase the efficiency of the overall process. Similarly, the captured CO_2 can be stored locally if a suitable aquifer or depleted hydrocarbon reservoir is nearby, or it can be piped (or potentially shipped) offshore for underground injection.

Each of the individual technological components is well demonstrated. CO_2 capture from flue gases was first commercialized in the 1970s for sale of CO_2 to the chemical and food industries, and for decades CO_2 has been transported over many hundreds of kilometers by the American oil industry for the purposes of enhanced oil or gas recovery (EOR/EGR). On the storage side, plants such as Sleipner in the North Sea have seen over a million tons of CO_2 per year stored since 1996.

However, the full chain of CCS, with capture from industry or the power sector, and geological storage with monitoring to verify storage permanence has never been integrated at a commercial scale. This is primarily due to the absence of markets that can absorb the capital costs. CCS plants generally have costs in the range of hundreds of millions, or even a billion, of dollars. In addition, the cost of investment in pipeline infrastructure, upfront storage identification, and long-term monitoring and verification to satisfy untested regulatory procedures all add upfront financial risks.

A strong business case is needed for CCS implementation, which in the longer term may be based on strong climate policy, but in the early stages has been dependent on the use of CCS for EOR/EGR.[3] At present, the majority of operational large-scale CO_2 capture plants use the captured CO_2 for enhanced oil or gas recovery (EOR/EGR), which has been a driver of technology development for CCS. Where these sites are able to demonstrably store CO_2 permanently and not raise overall oil and gas demand, they could also demonstrate CO_2 emission reductions.

CCS is often discussed in terms of its ability to decarbonize the power sector. However, dependent on the pace of climate policy development, the roll out of CCS in the power sector has been slow: with the first large-scale-integrated CCS project in the power sector only coming online in October 2014 (Boundary Dam, Canada). However, CCS is also particularly relevant for non-power applications such as gas processing, refining, cement and steel industries, and, in particular, chemical production.

The production of hydrogen, methanol, and ammonia offer significant promise for reduction of CO_2 via CCS. Many of these industrial applications generate CO_2 streams with higher purity than are seen from the power sector, and so could offer lower-cost abatement options. Capture from natural gas processing is already used in large-scale commercial projects, such as Sleipner in Norway and the upcoming Gorgon plant in Western Australia. Production of chemicals such as ammonia, hydrogen, methanol, and coal-to-chemicals has also been used to source CO_2. The Air Products Port Arthur project in the United States has captured CO_2 from hydrogen production since 2013, as will the Quest project in Canada, due to commence operation in 2015. These projects demonstrate the cost competitiveness of CO_2 capture from chemical processes and are together gradually building a base of demonstration projects from which future projects will learn.

Where coal is used a chemical feedstock, CCS offers relatively low-cost mitigation options to avoid emissions from highly carbon-intensive processes. Coal gasification to syngas is usually followed by separation of hydrogen and carbon monoxide (syngas) from carbon dioxide as a normal part of the process. This is a similar principle to integrated gasification-combined cycle (IGCC) power plants, which can be integrated with hydrogen production. Syngas is already widely used in the chemical industry. Integration of CCS with industrial syngas "hubs" could enable these alternative feedstocks to be utilized in a manner that is compatible with a low-carbon economy. With a strong carbon price or climate regulation, syngas, electricity, hydrogen, and CO_2 could all have value in a single, large industrial site similar to those that have been proposed in China (Fig. 7) (Fig. 8).

[3]It may seem incongruous that CCS, a climate change mitigation technology, be used to enhance the production of oil, yet while CCS passes through its technology development stages, this link with oil revenue can reduce the cost of project financing, a cost that otherwise often falls on the public purse. This use of CCS for EOR/EGR, combined with increasing climate change awareness have driven CO_2 capture technology toward reducing costs, potentially allowing application in larger (and lower margin) markets.

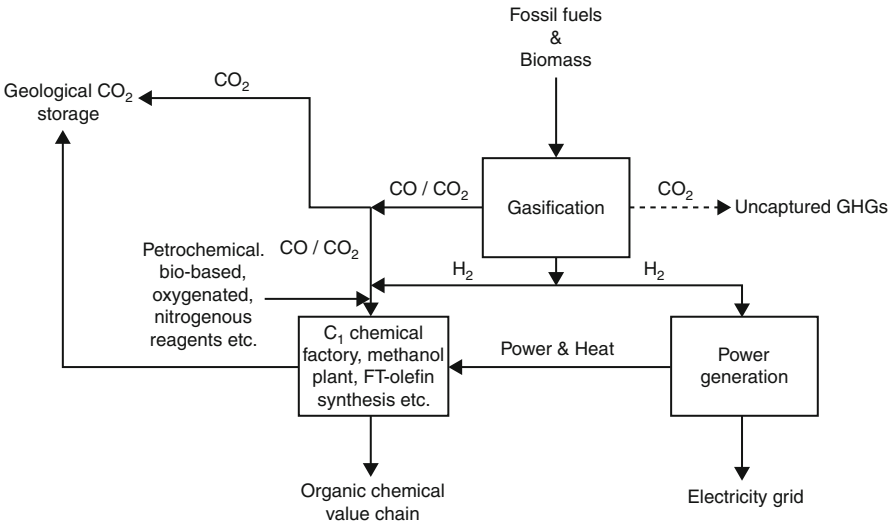

Fig. 8 Schematic representation of a gasification-based chemical complex with CCS

For some highly emitting processes, such as coal-to-chemical production, CCS may offer the only route to continue operation in a carbon-constrained future. However, for most petrochemical sites, the marginal costs of capture from all CO_2 sources will be similar to the power sector, and the smaller source sizes from the chemical industry (often less than 1MtCO_2 per year) mean that integrating transport and storage could be more complex and not benefit from economies of scale. Coordination with other emitters will help overcome this challenge through the development of industrial CCS hubs or clusters. CCS could this be well suited to the chemical industry. GHG emissions from petrochemical manufacture tend to be concentrated upstream in coastal areas of heavy industry, refining, and oil and gas production. These factors offer potential for linking emission sources together and accessing suitable offshore, or onshore, storage sites.

The White Rose CCS project in Yorkshire, UK, has been proposed as part of such a configuration. The proposed plant will capture CO_2 from a 426 MW coal power plant, with the concurrent construction of the "Yorkshire Humber CCS Trunkline," an oversized transportation system that will be able to accommodate local industrial emissions at a later date. This will then enable the next, much larger, tranche of CCS plants to plug into the already existing pipeline networks and utilize the same storage sites. This will greatly reduce costs. However, it should be noted that government intervention may be vital here to coordinate the development of such industrial hubs or clusters.

Above all, the chemical industry is particularly vulnerable to the pressures of international trade. Unlike the power sector, it does not have captive domestic markets: trade of chemicals and goods is global and increased costs from CCS will

disadvantage chemical industrial producers. This trade exposure of the chemical industry makes the costs of deep decarbonization highly risky and unattractive (ZEP 2013). Charting a policy course in this area will be extremely challenging, and certainly in the near term, carbon pricing is unlikely to be sufficient to facilitate this. In the absence of a global CO_2 price, asymmetric carbon pricing between regions will be compensated for by mechanisms such as free allowances that can reduce a sector's incentive to mitigate (Bennett and Heidug 2015).

Captured CO_2 from flue gases in the chemicals and power sectors has been used for chemical production since the late 1970s, primarily for soda ash and urea manufacture. Recycling CO_2 within the chemical industry could potentially reduce emissions and generate economic value.[4] Unfortunately, these remain limited. Due to the strength of the chemical bonds in CO_2 molecules, it often requires more energy and generates more CO_2 to convert a quantity of CO_2 into useful products than can be saved, even if the energy is derived from renewable energy (Ademe 2014; Bennett et al. 2015). Research into lower energy routes and potential uses of CO_2 remains an active area. Furthermore, to help mitigate climate change, potential uses of CO_2 will need to demonstrate a life cycle benefit compared to other value chains. CO_2 locked up in products can in some cases act as a carbon store, but incineration or decomposition of the products will release CO_2 at the end of life. If uses can be found whose life cycles can demonstrably prevent the emission of significant volumes of CO_2, both upstream and downstream, then chemical utilization of CO_2 may yet have a role to play in climate change mitigation.

Realizing widespread CCS requires governments and companies to develop shared visions of how the future chemical industry might look in a carbon-constrained world. The IEA has indicated that 18.5 Mt per year of CO_2, or 11 % of all captured CO_2, could be from the chemical industry in 2020 as part of a lowest-cost path to stabilizing CO_2 levels at 450 ppm. Plants capturing CO_2 from sources such as ammonia and fertilizer production offer near-term, low-cost opportunities. At present, climate policies do appear likely to be strong enough to support such a rollout of CCS this decade, and its future post-2020 will depend not only on climate policy but also any public opposition to CCS. Public opposition has already been observed in Europe where CCS has been connected to coal use in the power sector.

This chapter has mentioned numerous technologies that can partly address the fossil fuel dependency and climate impact of the global organic chemical industry. CCS on its own can do very little about the former, but could be a very potent weapon against the latter.

[4] CO_2 is today used in the agriculture industry to enhance crop growth and in the food industry to carbonate drinks and decaffeinate coffee (among other uses), but these also suffer from short-term net storage and limited markets.

Biorefineries

As described earlier in this chapter, the coevolutionary history of the organic chemical industry and the petroleum fuels industry has led to a highly integrated modern production system. While the majority of each barrel of oil is used for fuel, certain fractions are used to make higher-value chemicals such as plastics, thereby contributing to the economic advantage of oil in the energy mix. Worldwide there are only about 700 oil refineries, but their products underpin almost every aspect of modern society, and their integrated business models continue to dominate the fuel and chemicals sector. Indeed the synergies of this by-product relationship make it more difficult for either sector – fuels or chemicals – to individually make the switch to alternative, cleaner resources. However, there is an emerging alternative, based on the same refinery model, but with a renewable resource for fuel and feedstock: the biorefinery. This concept aims to maximize biomass raw material utilization and potentially offers a way to harness integration as a means of improving cost-effectiveness.

The term "biorefinery" covers a wide range of concepts, with various combinations of potential feedstocks, processes, and end products that can be targeted by an individual system. There is not a clear definition of a biorefinery, but it is generally considered to include the processing of various biomass sources to produce a "spectrum" of products, such as value-added chemicals, fuels, and agricultural products (Peck et al. 2009; Koutinas et al. 2007), just as a petrochemical refinery yields different fractions for different purposes. By also utilizing renewable biomass energy to power its chemical and biochemical processes, a biorefinery can reduce the overall consumption of fossil fuels and GHG emissions in the production of organic chemicals. Feedstocks range from cane or beet sugars, to oilseeds, to lignocellulosic materials from woods and grasses. An olive factory in Spain is even pursuing the route of chemical production from olive stones, to make the most of the available resource. Conversion technologies meanwhile can be thermal (such as gasification), chemical catalytic (including Fischer–Tropsch synthesis), enzymatic, or biochemical fermentation. The relatively low energy density of biomass means that large volumes are needed, and this can increase the costs of chemical processing significantly.

As with a petroleum refinery, the composition of the feedstock will determine the products and process routes to an extent, but adjustments to the chemical processing can target different production routes. This can add resilience to the system, by providing the flexibility to respond to feedstock changes and market signals.

Many biorefineries produce both lower-value bulk fuels and platform chemicals in combination with some higher value speciality chemicals. Platform petrochemicals are the olefins and aromatic BTX (benzene, toluene, and xylenes) that form the basic building blocks for most derivative chemicals in all organic chemical market segments. One approach for a biorefinery is to simply replicate these with bio-based products. For example, ethylene from bioethanol is chemically identical to that from fossil feedstocks, and its production is already economically competitive with ethylene from conventional routes. However, while Braskem produces 200,000 t ethylene each year from cheap Brazilian cane sugar-based ethanol (Braskem 2007),

and bio-ethylene capacity in India is rapidly expanding, overall bio-ethylene still only accounts for about 0.3 % of total global ethylene capacity (IRENA 2013). The disadvantage of producing bulk platform chemicals is the immediate exposure to competition with established fossil fuel routes. However, as consumers become increasingly interested in the environmental credentials of their goods, a market niche for bio-based platform chemicals is beginning to emerge. Companies such as Coca-Cola are seeking to source bio-ethylene for their product bottles, and long-term contracts on a multinational scale could help develop the competitiveness of this industry. Already, DuPont commercially produces 1,3-PDO from corn feedstock, and myriad routes to other platform chemicals are being widely explored.

There is also particular interest in the development of aromatic platform chemicals from lignocellulosic feedstocks, which could potentially be used to complement the development of chemicals from shorter-chain shale gas (Chemweek 2014; Golden and Handfield 2014). Global demand for aromatics is increasing by 5–10 % each year, and while the old joke that lignin can be used "to make anything but money" still has some truth, developments in lignocellulose enzyme technology (Teter et al. 2014) suggest that it may yet become a valuable source of aromatic platform chemicals. 2013 saw the opening of the largest cellulosic ethanol project in the world in Crescentino, Italy. Using local straw residues, this plant will produce up to 40,000 MT of ethanol per year and potentially marks a step change in the lignocellulosic material use. Indeed, plans have already been announced for a similar plant in Fuyang, China, which will target a capacity four times this size by the end of 2015.

However, not all bio-based platform chemicals are able to replace their fossil counterparts so easily. Biomass-derived platform chemicals tend to be more oxygenated than their petrochemical counterparts, and thus require more processing to yield materials of equal performance. In addition to the increased climate impact associated with more processing, this can lead to greater complexity in developing product lines for their derivatives, and overall leads to cost increases and lower competitively.

An alternative approach is for biorefineries to target new products, which could be accessed more directly from the complex molecules present in biomass. This strategy is often adopted by smaller chemical firms, keen to exploit the market insulation afforded by occupying a "green" product niche. Bioplastics and in particular biodegradable polymers are good examples of this (Harmsen and Hackmann 2013). The bioplastic polylactic acid (PLA) was discovered more than 80 years ago, but even though it has only been produced commercially since 2002, it is currently the most common bioplastic in use. PLA is used for medical implants and compostable mulch films for agriculture, and as research improves the ability to tailor the rate of biodegradability, it is increasingly being used for a broad portfolio of packaging applications. One of the things people generally find convenient about plastics is that they do not degrade during the time that people are actively using them, and accommodating these properties has been a challenge for some bio-based routes.

As with CO_2 utilization, calculation of the environmental impact of biorefineries is rather more complicated than simply subtracting the emissions of a comparative fossil fuel product. Where biomass is cultivated for a biorefinery (e.g., as opposed to agricultural waste), significant land use change will occur. Agriculture is a major emitter of GHGs, with high energy demand associated with fertilizer production, irrigation, and crop transportation. It is vital to conduct a full life cycle analyses for each new biorefinery configuration in order to ensure that there is a net environmental gain associated with the production route. Otherwise, while development of biorefineries can improve resource security, the climate impact can potentially be worse than fossil fuel production routes, and local environmental impacts (such as local biodiversity) can create negative impacts on a large scale. PLA is a case in point: while LCAs confirm that there is a net environmental gain from this production route, much of the carbon reduction relative to fossil fuel analogues is in fact offset by the energy intensity of the corn feedstock cultivation. Due to high capital costs and risk associated with the early stage of technological development, biorefineries are likely to require public financial support as the industry develops. It will therefore be important to consider the full LCA and target those concepts that can deliver the greatest carbon reduction overall.

There are also important scaling issues that need to be considered. Biomass offers the potential to replace both fossil fuels and petrochemicals with low-carbon, renewable alternatives, but the scale at which this can be achieved must be approached with caution. Biomass material is less carbon dense than oil or coal and requires both space and time to grow. While estimates for the size of the total resource volume vary (Slade et al. 2011), replenishment of the resource is unlikely to be able to match the rate at which mankind has been able to produce petroleum during the last 50 years, unless yields can be improved dramatically. In current circumstances, however, cultivation of biomass for biorefineries is highly likely to compete with forestry and other uses of agricultural land. The "food-versus-fuel" debate that has emerged from this prospect has led bodies such as the European Commission to revise subsidy regimes and research objectives such that they now overwhelmingly focus on second- and third-generation biorefinery concepts, which use biomass feedstocks such as forest residue or food waste and do not directly compete with food production. While in depth analyses by Ecofys, among others (Hamelinck 2013), indicate that increased biofuel production need not impact on food security (and the lower production volumes of the chemical industry mean that biofuels for chemicals will have even less impact), the debate remains controversial and will influence policy and exclude some options.

In summary, it is clear that while many of the products may be the same, biorefining is a different prospect to oil refining. Oil refineries are based on a fixed set of principles and a relatively fixed set of hydrocarbon distillation products. Biorefineries, because of the diversity of designs, raw materials, products, and scales will not be able to benefit from "by-product" relationships to the same extent. Thus, it may take a lot longer to approach the kind of standardized biorefinery designs that can be licensed and propagated worldwide.

The climate mitigation benefits of biorefining will be determined by individual biorefinery configurations and could potentially be improved by innovations in industrial arrangements. These could perhaps include gasification processes or localized processing of biomass before shipping the lighter, more valuable components for further processing; however, these opportunities will only become known as the industry develops. In any case, continued research into the effects of land use changes and the overall biorefinery LCA will be crucial to securing the optimum climate benefit. Limitations around feedstock production and techno-economic viability are likely to limit the rate at which the industry can grow. The technological development needed combined with the land use requirements mean that this industry will not radically arrive in a fully developed form. Biorefineries are beginning to emerge where there are feedstock opportunities or market niches that can be monetized, but the scale of biomaterials production remains extremely low. Long-term visions of a "bioeconomy" where biorefineries supply all consumer chemicals in all their forms are still a long way off. While mandates and policy support encourage production of biofuels worldwide, there is no similar subsidy for biomaterials. Without financial support, early applications will rely on one off subsidies and downstream demand for green products. Though this demand is observed at present, the historical overview of the petrochemical industry offered in this chapter clearly shows that current attitudes are not always indicative of future trends.

Future Directions

This chapter has sought to introduce the organic chemical industry as a highly energy-dependent sector of the economy. Presently, the industry is dominated by petrochemicals and a manufacturing system that is almost entirely reliant on fossil fuels, especially oil, for both raw materials and large amounts of process energy. This situation can be understood as the consequence of almost 80 years of "coevolution" of organic chemical production with liquid fuel production, based around the oil refinery and the platform chemicals that are produced in the refining process. This process of close integration was especially pronounced during the periods of very rapid expansion during the 1950s and 1960s in Europe and North America. It has bequeathed a network of petrochemical clusters that feed the world's manufacture of plastics, synthetic fibers, solvents, lubricants, medical products, and cosmetics. The efficiency of large-scale, integrated production continues to drive growth and innovation among the small number of multinational firms. As a result, this pattern of fossil fuel use, and thus GHG emissions, can be perceived to be somewhat "locked in," making it potentially more difficult for new low-carbon technologies to break into the chemical value chain.

The chemical industry continues to be responsible for 30 % of industrial energy use and about 5 % of global CO_2 emissions. This chapter proposes that to seriously address climate change, GHG emissions from the chemical industry need to be severely reduced and that to do so will require a thorough understanding of the

integration between the oil and chemical industries and the ambiguous nature of fossil carbon storage in chemical products. Truly sustainable solutions will therefore need to address the future trends in petroleum resource availability and overcome the barriers to market entry raised by the economics of the by-product relationship of olefins production and oil refining.

In addition to greatly increased global recycling, three options have been introduced that could have the potential to either "green" the existing production paradigm or disrupt it through radical innovation based on biotechnology. These three technology areas – efficiency savings through CHP, carbon capture and storage, and biorefining – could furthermore be combined to enable long-term organic chemical production that is compatible with deep GHG emission cuts. In addition, demand reduction and green chemistry are clearly identified as vital complements to the introduction of new technologies. However, as the industry moves closer to a world in which its use of carbon is tightly regulated, new tools that are able to account for the full lifecycle impacts of organic chemicals will need to be developed and established as international standards. For instance, there can be environmental benefits to locking up carbon in nondegradable plastics but only if they are not subsequently burned for energy recovery without CCS. Likewise, if biomass resources are limited, then there could be an argument for directing them to where they can have the greatest impact on GHG emission reductions. This calls for a major role for lifecycle assessment or policies that fully integrate carbon prices into the world economy. The challenge appears to be immense and one that requires committed and enduring action from industry and government.

Abstract

"Cleantech" is being widely used to replace "Green Technology." It describes a group of emerging technologies and industries, based on principles of physics, chemistry, biology, and resource efficiency, new paradigms in energy, and water conservation. The scope of this field includes large-scale infrastructure projects as well as innovative technologies. The term Cleantech is also often associated with venture capital (VC) investment. A goal of this chapter is to provide readers with an overview of the scope and trends in venture capital-funded innovation in Cleantech, where and how to seek VC funding, and Cleantech implications on world climate change.

This chapter addresses the basics of venture capital and the dynamic field of Cleantech. Subjects covered are as follows: **(1) VC investment trend** based on the volume of funds invested and the number of projects funded; **(2) the scope of Cleantech** encompassing renewable energy, energy efficiency, green building, transportation, smart power, smart grid and energy storage, air, water, and waste; **(3) Cleantech technology trend** detailing 2014 Cleantech top 100 companies – a barometer of the changing face of global Cleantech innovation; **(4) Cleantech investment in Silicon Valley** assumed a leading role in the global competition to develop renewable energy and other clean, green technologies; and **(5) Cleantech investment in emerging nations** addressing the status in China and other developing nations.

The **Concluding Remark***discusses* multidiscipline for Cleantech and the key to the deployment of Cleantech innovations. The **Appendix** provides a brief introduction of how and where to find information and seek for VC funding.

Introduction

In recent years, the term "Cleantech" is being widely used to replace "Clean Technologies" and "Green Technology." It describes a group of emerging technologies and industries, based on principles of physics, chemistry, biology, and resource efficiency, new paradigms in energy, and water conservation. The scope of this field includes large-scale infrastructure projects as well as innovative technologies.

The term Cleantech is also often associated with venture capital (VC) investment. In 2002, the Global Cleantech VC investment was US $0.9 billion and grew to the peak of $9.3 billion in 2008. After the financial crisis of 2009, its investments were gradually reduced, fluctuated, and then recovered to around $9 billion in 2013. This chapter addresses the dynamic field of Cleantech in the following four sections:

1.0 **Venture Capital Investment Trend** addresses the basics of venture capital and provides an analysis of the historical venture capital investment trend in terms of funds invested and the number of projects funded.
2.0 **The Scope of Cleantech** lists the scope of Cleantech encompassing renewable energy, energy efficiency, green building, transportation, smart power, smart grid and energy storage, air, water and waste, big data, and resource sharing.
3.0 **Cleantech Technology Trend** provides an overview of the key technologies that received venture capital or corporate investment. This is accomplished through a detailed discussion of 2014 Cleantech 100 – a barometer of the changing face of global Cleantech innovation and knowing where venture capitalists and corporate investors are interested to invest. These 100 Cleantech companies are selected from 5,995 companies across 17 countries and 17 technology sectors.
4.0 **Cleantech in Silicon Valley** has assumed a leading role in the global competition to develop renewable energy and other clean, green technologies. Cleantech is poised to be the valley's next great wave of innovation after semiconductor, information technology, biotechnology, and Internet-related technology.
5.0 **Cleantech in Emerging Markets** discusses Cleantech investment in development countries and gives examples of VC investment and start up in the fast-growing emerging markets.
Concluding Remark discusses the integration and deployment of VC-funded innovation in Cleantech and its implications on world climate change.

Venture Capital Investment Trend

Venture Capital

Venture capital (also known as VC or venture) (Venture Capitalist 2014) is provided as seed funding to early-stage, high-potential, growth companies and more often after the seed funding round as growth funding round (also referred as series A round) in the interest of generating a return through an eventual realization event

such as an IPO (initial public offering) or trade sale of the company. To put it simply, an investment firm will give money to a start-up and growing company. The growing company will then use this money to do research, build infrastructure, develop products, advertise, etc. The investment firm is called a venture capital firm or company, and the money that it gives is called venture capital.

The venture capital firm makes money by owning a stake in the firm it invests in. The start-up company that a venture capital firm will invest in usually has a novel technology or creates a business model. Venture capital investments are generally made in cash in exchange for shares in the invested company. It is typical for venture capital investors to identify and back companies in high-technology industries such as semiconductor, biotechnology, IT (information technology), Internet, and now Cleantech.

The source of funding of venture capital typically comes from institutional investors, endowment funds, and high-net-worth individuals and is pooled together by dedicated investment firms. Venture capital firms typically comprise small teams with technology backgrounds (scientists, researchers) or those with business training, financial management, or deep industry experience.

A core skill within VC is the ability to identify novel technologies or business models that have the potential to generate high commercial returns at an early stage. By definition, VCs also take a role in managing entrepreneurial companies at an early stage, thus adding skills as well as capital (thereby differentiating VC from buyout private equity which typically invests in companies with proven revenue) and thereby potentially realizing much higher rates of returns.

Inherent in realizing abnormally high rates of returns is the risk of losing all of one's investment in a given start-up company. As a consequence, most venture capital investments are done in a pool format where several investors combine their investments into one large fund that invests in many different start-up companies. By investing in the pool format, the investors are spreading out their risk to many different investments versus taking the chance of putting all of their money in one start-up firm.

Venture Capitalist

A venture capitalist (2014) is a person or investment firm that makes venture investments, and these venture capitalists are expected to bring managerial and technical expertise as well as capital to their investments. A venture capital fund refers to a pooled investment vehicle, often an LP (limited partner) or LLC (limited liability corporation), that primarily invests the financial capital of third-party investors in enterprises that are too risky for the standard capital markets or bank loans.

Venture capital is attractive for new companies with limited operating history that are too small to raise capital in the public markets and have not reached the point where they are able to secure a bank loan or government small business loan. In exchange for the high risk that venture capitalists assume by investing in smaller and less mature companies, venture capitalists usually get significant control over company decisions, in addition to a significant portion of the company's ownership.

Young companies wishing to raise venture capital require a combination of extremely rare yet sought-after qualities, such as innovative technology, potential for rapid growth, a well-developed business model, and an impressive management team. VCs typically reject 90–98 % of opportunities presented to them, reflecting the rarity of this combination. The general rule of thumb for the success rate of VC-invested start-up is about 60 % start-up failed and 30 % existed for 5 or more years with little or no profit; only about 10 % start-ups go to IPO or acquired by larger corporations as a separation business unit or merge into an existing operation of a larger corporation.

Venture Capital Investment Review

Traditionally, the venture capital industry has been focused on information technology, Internet, wireless and broadband communications, and biotechnology. All projects related to innovation of energy generation, energy saving, waste management, and environmental impact were grouped into a general industry category, and the investment funds were relatively small. In recent years, however, Cleantech investment has become a separate category and played a major role in the VC portfolio.

In 2014, venture capital funding (VC 2014) hit its highest annual mark since 2001 as venture investors participated in $47.3 billion across 3,617 deals. Even versus 2013, the past year was huge as venture capital skyrocketed 62 % year over year due to multiple $500 M+ mega-rounds, while deal growth was more modest, climbing 8 %.

A mix of traditional VC money coupled with corporate VCs, hedge funds, private equity investors, and even sovereign wealth funds created a potent cocktail in 2014 lifting funding levels to the highs seen during the dot-com boom. 2014 ended with a bang on the funding front as VC-backed deals hit $7.1B in the final month of the year. The massive funding figure was largely driven by mega tech deals to companies including Uber and Snapchat.

Although there were 738 VC-backed exits in 2014, the IPO picture was a bit mixed. The healthcare IPO market continued its momentum from 2013 with 64 US companies going public in 2014, up to 68 % year over year. Venture-backed tech IPO activity stalled a bit after Alibaba's IPO in September but did finish up versus 2013 and closed out with a strong December.

California and Massachusetts took 62 % of the US-headquartered venture-backed IPOs in 2014. California saw a whopping 45 % jump in venture-backed IPOs on a year-over-year basis. New York grew its number of IPOs significantly versus 2013 but remains a distant third to Massachusetts.

New Enterprise Associates is 2014's most active VC firm. As it targets a new $2.5B fund, New Enterprise Associates topped all venture investors by unique company deals in 2014. Andreessen Horowitz, which ranked first by deal count in 2013, again ranked in the top 2, followed by fellow mega-fund Kleiner Perkins Caufield & Byers. A list of the top 100 most active venture capital investors in 2014 by unique company deals is at appendix.

Global Venture Capital Investment in Cleantech

The following table lists venture capital investment in Cleantech from 2002 to 2014.

Year	Investment (billion US$)	Deals
2002	0.9	164
2003	1.3	301
2004	1.3	333
2005	2.0	381
2006	4.4	458
2007	6.42	564
2008	9.27	653
2009	6.23–7.5	557–691
2010	8.28–9.45	715–823
2011	9.61–10.8	243–829
2012	6.46–8.25	236–704
2013	6.75–7.35	175–1007
2014	3.98 (US only)	316 (US only)

From 2002 to 2005, Source: Cleantech Group (Global Cleantech Innovation 2014)
From 2006 to 2013, Source: Cleantech Group (Global Cleantech Innovation 2014) and San Jose Mercury News (MoneyTreeTM Report-Q3 2014) dated 03 Jan 2013
2014, Source: Cleantech Group (Global Cleantech Innovation 2014): San Jose Mercury News (MoneyTreeTM Report-Q3 2014)

Concurrent with the apparent decline in share of Cleantech venture capital in North America, the US government has invested around $16 billion a year and plans to increase investment to $50 billion annually by 2020. Part of the funding, about $15 billion, will come from tax credits and other fiscal measures. The rest will be derived from rate-payer increases for electricity and other energy. This spending should lead to very large investments in wind, solar, and carbon capture. In addition, the bill would bring into existence the first nationwide system of building codes, which would be further tightened every year through 2030. These codes will lead to considerable demand for green building technologies.

We can see venture capital investment in Cleantech is a smaller portion of the total investments by including government funding, but these VC-supported projects are often the most creative and full of scientific innovations.

The Scope of Cleantech

The scope of Cleantech encompasses a broad range of technology categories, including renewable energy, energy efficiency, green building, transportation, smart power, smart grid and energy storage, and air, water, and waste. The following lists (Clean Tech Open Defines Clean Technology) provide examples of technologies within each of the major categories:

Renewable Energy

The *renewable energy* category includes innovations that use, enable, and accelerate the migration to renewable energy. Renewable energy encompasses technologies that use waste streams to directly produce energy. Examples include low-emission power sources, such as solar, biofuel, wind, wave and tidal energy, and hydropower. Example technologies include:

- Solar for energy production
- CIGS
- Thin film solar manufacture
- Concentrating solar PV
- Coatings for solar panels
- Polysilicon supply and manufacture
- Residential-scale solar deployment
- Ethanol
- Bio-based fuels
- Tidal energy
- Wave energy capture
- Landfill gas to energy systems
- Agricultural waste to energy systems
- Hydropower
- Turbine blade design
- Advanced fluid flow designs
- Wind power aerodynamics
- Wind power conversion efficiency

Energy Efficiency

The *energy efficiency* category comprises technology that can significantly reduce wasted energy (including natural gas), driving toward the common goal of saving the equivalent of "a power plant a year." Examples include advanced light sources and controls, smart/user-friendly energy management systems, energy-efficient water heaters and other appliances, high-efficiency industrial process systems, motors, pumps, and advanced space heating and cooling systems. Example technologies include:

- Pumps for water/material
- Industrial process improvements
- Natural gas monitoring and control (industrial or residential)
- LED lighting
- Advanced lighting controls
- Water heating
- HVAC solutions

- Heat pumps
- Waste heat management
- Efficient heat transfer
- Utility-scale natural gas controls
- Display systems for energy management
- Materials used in microelectronics manufacturing
- Deposition and sputtering processes
- Alternatives to heat-intensive processes
- Cooling solutions
- Glass material production
- Pure manufacture techniques for fuel cells

Green Building

The *greenbuilding* category focuses on reducing the environmental impact of building construction or operation through improved design or construction practices, new or innovative use of building materials, or new hardware or software applications. Technologies are applied directly to the built environment. (Building energy efficiency submissions will be considered in the energy efficiency category).

Examples include improved site planning, water management systems, reduction of hazardous materials in building construction or operation, use of new environmentally friendly or recycled materials, systems to improve indoor environmental quality, and systems for improved waste reduction or disposal. Example technologies include:

- Insulation materials
- Cement alternatives
- Cement production techniques
- Building-integrated PV (BIPV)
- Indoor air filtration systems
- Modular housing
- Disaster relief housing
- Architectural designs for thermal management
- Office environment
- Low VOC carpeting and flooring
- Water-saving toilets, showers, and plumbing
- Residential heat pumps
- Recycled materials for use in building material
- Design improvements to commercial environment

Transportation

The *transportation* category encompasses transportation and mobile technology applications that improve fuel efficiency, reduce air pollution, reduce oil consumption, or reduce vehicle travel (not limited to automobiles). Technologies are applied

directly to transportation systems or vehicles. Examples include new vehicles and new types of transport services and infrastructure, efficient batteries, fuel cells, bio-based transportation fuels, and use of information technologies.

Example technologies include:

- Fleet management hardware and software systems
- Routing and data solutions for public transportation operators
- Logistics management
- Carpooling solutions
- Hybrid motor systems
- Storage of energy specifically applied to vehicles
- Plug-in hybrid vehicles
- All electric vehicles
- Fuel cell vehicles
- Biodiesel applications
- Intermodal tracking and monitoring
- NOX/SOX reductions for ocean-going vessels
- Cold-ironing systems
- Diesel particulate matter filters for locomotives
- Combustion designs
- Fuel blends
- Flex fuel engines and applications
- Drive train conversion kits
- Route management via GPS networks
- Exploiting GPS and location information
- Monitoring and control of driver behavior

Smart Power, Green Grid, and Energy Storage

The *smart power*, *green grid*, *and energy storage* category promotes links between information technologies and electricity delivery that give industrial, commercial, and residential consumers greater control over when and how their energy is delivered and used. It includes improvements in all forms of energy storage, from battery technology for consumer-scale products to large chemical, metal, biological, or other approaches to storage of utility-scale energy, as well as methods for controlling or increasing the efficiency of energy storage or energy transmission.

Examples include wireless metering and use of real-time pricing information, intelligent sensors, batteries, fuel cells, flywheels, and advanced materials or systems for energy transmission, such as hardware and software controls. Example technologies include:

- Advanced metering
- Network architecture for power management
- Cloud computing, applied to grid

- Batteries
- Novel battery chemistry
- Nickel-metal hydride improvements
- Hydrogen storage
- Li-ion cells
- Form factor improvements
- Improved cycle life for batteries
- Depth of discharge for batteries
- Solid oxide fuel cells
- Novel catalysts in batteries and fuel cells
- Advanced fuel cell membranes
- Methanol fuel cells
- PEM fuel cells
- Flywheels
- Grid-scale hardware and infrastructure
- Power storage for intermittent, renewable resources
- Monitoring and deploying power generated from renewables
- Transmission efficiency
- Electrical engineering and controls for power distribution
- Novel metals and alloys for power transmission
- Superconducting power transmission
- Real-time power monitoring

Air, Water, and Waste

Entries in the *air*, *water*, and *waste* category focus on improving resource availability, conservation, and pollution control. With respect to waste, the category focuses on cradle-to-cradle approaches to reduction, reuse, and recycling technologies, as well as innovative business models and approaches to material usage.

Air examples include services, instruments, and equipment related to emission control, treatment, or reduction technologies. Also included are creative approaches to greenhouse gas reduction, including carbon conversion and sequestration. **Water** examples include treatment, storage and monitoring, recycling, and conservation technologies. **Waste** examples include waste management equipment; sorting; resource recovery processes; pollution prevention, control, and treatment technology; as well as waste reduction through innovative recycling processes and new recyclable materials, such as bio-based plastics. Example technologies include:

- Water monitoring – on-site in situ real-time water monitoring for pathogens
- Cooling solution
- On-site wastewater recycling – industrial and commercial applications
- Advanced water metering
- Storm-water and flood control and rainwater harvesting
- Smart irrigation

- On-site water disinfection
- Membranes for water treatment
- Advanced filtration without membranes
- Produced water (from oil exploration and drilling)
- Energy-efficient water pumping
- Reverse osmosis
- Advanced filters and filtration (air or water)
- Emission controls
- Scrubber technology
- Carbon and GHG monitoring and control
- Carbon sequestration
- Carbon capture and storage
- Technology enablers for carbon markets
- Reduction and remediation of VOCs
- Waste cleanup and remediation
- DI water supply
- Agricultural waste treatment
- Recycling
- Microbial water treatment
- Bio-based packaging solutions
- Methane capture and storage
- Soil technology
- Natural pesticides
- Clean coal

Big Data, Communication, and Resource Sharing

Innovation in smart grid 5 years ago was much more concentrated around effective communication with the grid. The wireless was the hottest examples of the "communication network" investment theme. Now that those types of companies are maturing, the new crop of hot companies is trending around the "big data" theme. While "data" was always a focal area for utilities, whether for digitally optimizing grid infrastructure or monitoring "loads" for large customers, a new bucket of businesses are targeting, like never before, the streamlining of large quantities of data. The other area is in resource sharing where many applications are being launched. Examples (CleanTech 100 2014) are:

- Software to help utilities manage complexities in order to provide easily visualized options for decision-making and to address operational challenges
- Software to manage big data in buildings with their behavior and the behavior of their commercial customers through providing them with tailored data to evaluate where real energy savings can be made
- Software for Internet resource sharing of vehicle use and sharing of extra rooms in a home

The scope of Cleantech is extremely broad and involves many scientific and academic disciplines. It is a good field for today's science and engineering students to pursue as a career for the next decade.

Cleantech Technology Trend

This chapter will report the trend by way of detailing **2014 Cleantech 100** – a barometer of the changing face of global Cleantech innovation. In recent years, **CleantechGroup.com** (CleanTech 100 2014) began a process of identifying key 100 Cleantech companies that present the potential of becoming big in the near future.

For **2014 Cleantech 100**, a total of 5,995 companies were nominated with the end result of 100 companies across 17 countries and 17 subsectors. The 84 external panelists active in helping Cleantech Group reach the final list of 100 were drawn from 41 corporations (responsible for Cleantech-related investment) and 43 financial investors (venture capitalist) located in Asia, Europe, and North America. The selection criteria are:

1. Innovation (the problem it solves, uniqueness, sustainability of advantage, etc.)
2. Market (accessibility, size, growth dynamics, barriers to entry, etc.)
3. Ability to execute (finances, team competencies, connections and networks, etc.)

The corporate expert panelists tended to vote more strongly for companies with long-term market potential, whereas financial investors focused more on track record and strength of team. In comparison with previous year, 2014 had a majority of retentions (52 %) compared to new entrants (37 %) on the Global Cleantech 100 list.

Now in its sixth edition, 67 % of the Global Cleantech 100 companies are from the North America region and 28 % from the Europe and Israel region – led by the UK (7), Germany (6), and the Nordics (6). M-KOPA (Kenya) is the first company from the Africa region to make it to the Global Cleantech 100.

There are many B2C models trending among the Global Cleantech 100, testament to the idea that the consumer's mind-set is the most open to disruptive change. Over 15 % of the Global Cleantech 100 companies are providing services to oil and gas companies, representing the mounting case to clean up the industry's operations.

At least 25 % of 2014 Global Cleantech 100 companies are already focusing, or will soon focus, on growing their business into Asia and other emerging and highly populated markets. There were more solar companies in 2014 (9) compared to 2013 (6), suggesting a renaissance of new business models that will continue to help raise deployment figures. A big data service for utilities is a big emergent theme in this year's 100, as companies are continuing to innovate on ways to address ongoing energy challenges.

The 100 Key Stats:

- 37 companies are new entrants represented in blue compared to 51 in 2013.
- Out of the 63 alumni, 52 are retentions from 2013, and 11 are returnees from previous years represented in orange.

Figure 1

The Global Cleantech 100 by Sector

Seventeen sectors are represented, showing a diversity of interests and a continued focus on water and wastewater, advanced materials, and other areas of sustainable innovation that take us well beyond the narrower confines of just energy (Fig. 2).

1. Energy efficiency (24)
2. Water and wastewater (12)
3. Biofuels and biochemicals (10)
4. Solar (9)
5. Smart grid (7)
6. Energy storage (7)
7. Transportation (7)
8. Advanced materials (6)
9. Conventional fuels (4)
10. Air (3)
11. Recycling and Waste (3)
12. Agriculture and Food (2)
13. Fuel cells and hydrogen (2)
14. Biomass generation (1)
15. Nuclear (1)
16. Resource sharing (1)
17. Wind (1)

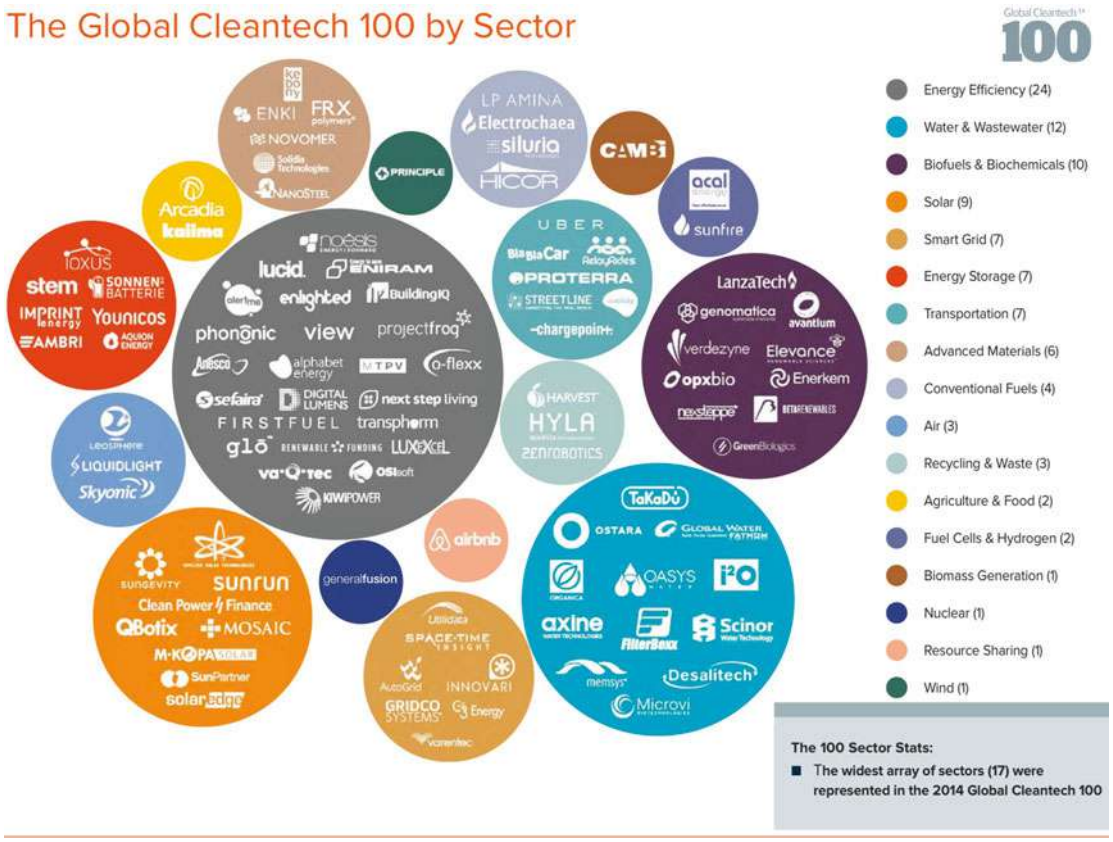
Global Cleantech 100 by Geography

See Fig. 3.

1. Sixty-seven percent from the North America region, with 62 companies from the USA
2. Twenty-eight percent from the Europe and Israel region – led by the UK (7), Germany (6), and the Nordics (6)
3. Four percent from the Asia-Pacific
4. One percent from the Africa region (Kenya) (Fig. 4)

Assessment of Global Cleantech 100 by Expert Panelists

The 2014 Expert Panel was comprised of representatives from 43 financial investors and 41 corporations (or corporate venture units) from all over the world. The most common reasons that all expert panelists gave for positive comments of selected companies are:



The Global Cleantech 100 by Sector

Figure 4

- Companies with an impressive CEO or management team, with the right background and leadership to take the company to the next stage.
- Companies have the longer-term market potential, such as the potential demand size for the product or service.
- Companies have breakthrough technology, evidence of traction, and competitive cost structure importance in the minds of investor and corporate panelists.

At the top of the 2014 List – as measured by companies that received the most peer validations in the expert panel assessments without any negative cases made against them – are the following three companies:

1. **Avantium**, a specialist in advanced catalytic research, has developed a sugar-to-furanics technology that allows for the production of bio-based PEF plastics which has the potential to replace many petrochemical materials (bottles, films, fibers) "if cost and performance goals are met." Avantium is "not only leading the way with renewable chemicals, but the R&D specialization offering they provide is very relevant," said one expert panelist. The company has achieved impressive financing rounds, including a recent $50 million infusion to build its first commercial PEF scale plant. With strategic backers and partners like Coca-Cola, Danone, and ALPLA, Avantium continues to gain traction "with some of the biggest consumers within the plastics industry."
2. **Clean Power Finance** is acting as a key enabler of distributed generation by expanding third-party financing of rooftop solar – a field that is poised to grow tremendously in many countries. The company connects solar professionals with institutional investors through its CPF Market, an online business-to-business marketplace for solar finance products by loans or leases. Although it has several competitors, the company's innovative business model, impressive list of project finance backers, and new channel partners (Kilowatt Financial and North American Power) make revenue growth and traction real.
3. **FRX Polymers** has developed non-migrating, phosphorus-based polymer additives for use in halogen-free flame retardants. The company's patented plastic products – Nofia – have multiple market applications to consumer electronics, building and construction, and transportation markets. This new halogen-free flame retardant will change the plastics industry and is very important for security reasons.

   The company recently received funding from a strong syndicate of investors including the Flemish government and chemical corporations BASF and Evonik – closing a $20 million Series C financing round in May 2014. FRX Polymers is now entering an accelerated growth phase, following the launch of its first commercial plant in Antwerp, Belgium, in 2013.

   The companies in the final 100 that attracted the strongest split of opinions across the expert panel, a mix of positive and negative votes, in significant volumes were:
4. **Ambri**, the liquid metal battery technology company, has a disruptive, high-power energy storage technology and offers a new take on the battery with its

liquid metal technology by using inexpensive, earth-abundant materials. Can it get beyond being a science project and prove itself against Li-ion evolving systems? If it works, it will be disruptive.

5. **General Fusion** has made significant progress in building fusion energy subsystems at scale. Many panelists admire the company for "attempting something so audacious." Will it be commercial in the next 10 years? Is it too dependent on fickle government regulations? The company has the potential to revolutionize power generation if it can succeed with its technical milestones.
6. **Siluria Technologies**, with its proprietary catalysts to convert methane to drop-in fuels and chemicals, could change the way we think about fuels. However, Siluria has to show the cost of capital and the ease of operation.

Top Picks by Corporations with Its Own Venture Unit

Diversified Industrials: Energy efficiency start-ups generally tend to be popular among corporations in the Diversified Industrials vertical, who see a variety of applications for these technologies. This year, building energy management system companies **BuildingIQ** and **Enlighted** are the running favorites. BuildingIQ is a specialist in HVAC for commercial buildings. Enlighted specializes in lighting efficiency along with extended building services such as real estate analytics. Both are entering a phase of accelerated growth in the USA and rapidly expanding into Asia too.

Materials and Chemicals: Avantium and **LanzaTech** appeal particularly strongly to the materials and chemicals corporations. They recently received $50 and $60 million, respectively, from prestigious investors. "Avantium has the potential to replace many petrochemical materials with renewable feedstock," which is why it emerges as a natural winner among materials and chemicals corporations. Similarly, LanzaTech converts carbon-rich wastes and gases into valuable fuel and chemical products. A "fascinating technology" with a "large addressable market," said one of the panelists.

Oil and Gas: Faced with ever-higher operational costs and more stringent environmental standards, oil and gas corporations focused their attention on solutions that may improve the performance and safety of their operations.

Liquid Light, which develops an electro-catalytic technology enabling the conversion of CO_2 into high-value chemicals, was remarked upon for its potential impact on the oil and gas industry, a large emitter of carbon dioxide.

Houston-based **Hicor Technologies** offers a system of trailers that carry natural gas from compression sites to the customer's door at a cost lower than traditional transit infrastructure. Hicor promises to "make it easy for customers to switch to natural gas as a primary energy source."

Environmental Services: Corporations are showing interest in water and wastewater treatment solutions that align with their business operations and help them address a variety of markets. **Cambi** is a supplier of thermal hydrolysis systems for treatment of biowaste prior to anaerobic digestion. The company has "impressive

growth in sludge pretreatment" and "enjoys unrivaled domination of the market for large-scale municipal installations."

Global Water FATHOM provides a geospatial platform that helps water utilities optimize their back operations.

FATHOM's AMS service allows utilities to repair aging water networks and is "the only vehicle available that allows customers to track their own consumption in real time."

Utilities: Utilities remain interested in start-ups that offer solutions to enhance the viability and economics of existing technologies in which they have a vested interest. **Ioxus** has developed ultra-capacitors that prolong the lifespan of batteries used for various alternative energy applications, including micro-hybrid for electric vehicles. "Wait til Elon Musk figures that out to improve his Teslas!" said one panelist. **QBotix** creates rugged and intelligent solar tracking robots that deliver significant project cost savings and high-system-level reliability and flexibility of installation in the commercial- and utility-scale solar power plant sectors.

The Consumer-Centric Business Models

With the endless number of energy-saving tools on the market, a number of companies are seeking to make it simpler and easier for the everyday consumer to make energy efficiency changes in their home.

1. Smart Homes: Users of **AlertMe's** smart home monitoring system can connect to their home's broadband and remotely control household appliances, thereby cutting domestic energy consumption and costs. UK-based AlertMe is "leading the trend towards an ever more connected world on the consumer level – it is a company to watch," said one panelist.

   Anesco provides comprehensive energy efficiency solutions to homeowners (from audits to recommendations, installations, maintenance, and capital funding plans). Anesco's success has impressed panelists, who praised its "strong growth," its "impressive financial performance," and "excellent execution of strategy."
2. **Mobile Devices**: HYLA Mobile collects used mobile devices and refurbishes them to meet certification standards – and subsequently sells them to consumers in developing countries at an affordable price. This consumer-centric recycling solution improves resource efficiency rates in the USA while enlarging access to affordable technology in the developing world.
3. **Consumer Products –** A New Level of Energy Saving: **Phononic** commercializes solid-state heat pumps that displace compressors for home refrigeration, cooling, and heating, thus making home appliances quieter and more efficient. According to Phononic's CEO Anthony Atti, the company aspires to become the "Intel Inside" of refrigerators and air conditioners. "This area of materials has the best chance to impact energy efficiency in the future," commented an expert panel member.

   Germany's **Sonnenbatterie** manufactures battery systems that allow homeowners to store energy generated from residential solar installations.

Sonnenbatterie's customers can avoid peak demand prices and optimize their energy consumption.

4. **Car Sharing – The New Norm in Transportation:** In the age of the "sharing economy," consumers are more interested in gaining access to various modes of transportation, without the burden of owning a car. Next-generation mobility solutions are reducing both congestion and pollution while providing tremendous consumer convenience and operational efficiencies.

   BlaBlaCar has established itself as the leading carpooling platform in Europe, with more than 2.9 million members and 500,000 monthly ride shares to its credit. Building on this success, the company is starting to noticeably reduce congestion and decrease CO_2 emissions. **RelayRides** allows car owners to rent out their vehicles via an online interface. A market leader in peer-to-peer car sharing in the North America, RelayRides has aggressively grown its customer base and has expanded its reach into airport parking. RelayRides' service results in "increased resource efficiency rates."

   Through its mobile app, Uber allows users to book and pay for on-demand private car service and also enables passengers to share rides. The company's success and high valuation "signal the market's acceptance of the changing nature of mobility."

Emerging Market Demand

1. **Feeding the Developing World with Agronomics: Arcadia Biosciences**, a California-based developer of enhanced agronomic products, works with agricultural organizations across the emerging world. Alongside Argentina-based agricultural cooperative Bioceres, it formed Verdeca, a JV specializing in biotech-enhanced soybean varieties. It works with Indian agronomic research companies Advanta and Bioseed Research to develop next-generation products such as salt-tolerant and nitrogen-use-efficient sorghum. Arcadia also has partnerships with research center CIMMYT (Mexico) and the African Agricultural Technology Foundation (Kenya).

   In just 7 years, Israeli seed technology start-up Kaiima has expanded its activities well into emerging markets, with customers in China, Niger, Madagascar, Brazil, Peru, or Mongolia – to name a few. It is working with Philippine-based International Rice Research Institute (IRRI) to bring to the developing world new-generation high-yielding crops. Kaiima's solutions are "critical for water-constrained agricultural regions – there is a huge market opportunity" said a panelist.
2. **Modernizing Wastewater Treatment Systems:** UK-based **i2O** is supplying its water pressure management technology to leading utilities across the emerging world. It boasts Malaysia-based Syabas and Philippine-based Manila Water, two of Southeast Asia's largest water utilities, as customers. i2O works with JOAT Group, one of South Africa's leading water management organizations, to implement its solutions in some of the country's major metropolitan areas. i2O is also active in South and Central America, where it has partnerships with Chile's

Glemans and Aguas de Antofagasta, Peru's Esboña Corporation, and Mexico's Grupo SCR Mexico.

Organica Water, a Hungary-based developer of biological wastewater treatment plants, has gained multiple customers across China, India, and Indonesia. Organica boasts partnerships with India's engineering conglomerate Larsen & Toubro and China's famous Foxconn Group. It delivered a commercial wastewater treatment plant for the latter's industrial park in Shenzhen, China. "The company is thriving in rapidly urbanizing Asian countries, where the sewage networks are not keeping pace with new-build," said one panelist.

3. **Sustainably Fueling Growth in the Emerging World:** Italy's **Beta Renewables** transforms nonfood, cellulosic biomass into biofuels through a conversion technology marketed as Proesa. Beta Renewables has established development partnerships with Malaysia-based chemical companies MyBiomass and Hock Lee Group. It is also active in Brazil and will license its Proesa technology to the world's next largest cellulosic ethanol biorefinery, located in Fuyang, China, and partially owned by one of Beta Renewables' shareholders, the chemical company Gruppo Mossi and Ghisolfi.

   LanzaTech has gained remarkable traction across Asia, establishing partnerships with big players such as steel companies Baosteel, Jindal Steel, and POSCO, with oil giants Petronas and Indian Oil, and in the near term with global industrial multinational Mitsui. LanzaTech has established itself as an industry leader in China, where it has forged solid relationships with the government, steel mills, and other state-owned companies.

4. **Reducing the Cost of Electricity Consumption: Innovari**, a provider of a load duration management platform, is connecting utilities with commercial energy partners to incorporate demand-side management into the grid. The Texas-based start-up is now exporting its solution in the emerging world, for example, by helping Colombian utility EMCALI to implement a demand-side management platform for its local distribution system. And it announced it would deploy its Interactive Energy Solution to the customers of Reliance Infrastructure, India's largest power utility, in Mumbai.

   Utilidata, a Rhode Island-based supplier of voltage optimization products, already caters to multiple utilities across North America, but it is now going global with partnerships in Saudi Arabia, Russia, South Korea, and China. Utilidata's main partner is Saudi Aramco, the largest oil and natural gas company in the world. "We see a big opportunity to scale in Asia, where the benefits of increased efficiency and intelligent control could significantly reduce the cost of electricity, enabling sustainable growth," said one of Utilidata's recent investors.

Cleantech Goes Inside the Oil and Gas Industry

Many promising Cleantech start-ups are working with oil and gas corporations to help them address the growing technical, financial, and environmental challenges

facing both upstream and downstream operations. Here are four ways in which Cleantech start-ups in this year's list are potentially shaping changes in the oil and gas industry.

1. **Converting oil and gas by-products and waste heat into resources**: **Alphabet Energy** manufactures easy-to-install thermoelectric products that transform waste heat in exhaust gas into electricity.

   MTPV Power Corporation develops thermo-photovoltaic technologies for converting waste heat to electricity. It enables oil and gas companies to reduce their operating costs by reusing the exhaust heat.

   Skyonic uses a thermolytic process to capture carbon dioxide at the source of emission and transform it into valuable chemicals. Oil and gas companies, one of the largest industrial emitters of GHGs, could use this technology to curb carbon dioxide emissions generated during the production process.
2. **Facilitating the treatment of oil and gas process water: Axine Water's** chemical-free, scalable system treats high concentrations of recalcitrant toxic materials in oil and gas process water. Axine's solution has huge potential in water treatment of offshore production. FilterBoxx's wide experience in treating process water from enhanced oil recovery operations and unconventional drilling methods makes it a natural partner of the oil and gas industry.

   Memsys develops thermal separation processes based on membrane distillation. The technology is geared toward the unconventional gas marketplace, which faces complex wastewater treatment challenges. **Oasys Water** works with oilfield engineering firms to deliver forward osmosis water reuse solutions into the global oil and gas produced water market. As heavy industries like oil and gas and mining seek to be more sustainable, important treatment components like dewater technology will be increasingly relevant in these markets.

   The **NanoSteel Company** delivers nanostructured steel alloys with a unique combination of high strength, ductility, and wear resistance. With these properties, NanoSteel's metallic coatings meet demand for next-generation material technologies that hold up to the challenge of drilling in high-pressure, high-temperature environments.
3. **Improving the overall performance of oil and gas through software and data analytics**: **OSIsoft's** real-time data analytics help oil and gas companies maximize asset performance, optimize production flows, and centralize enterprise expertise. **Space-Time Insight's** solutions for oil and gas leverage geospatial and visual analytics software to enable pipeline integrity monitoring, crisis mitigation, hydrocarbon supply chain management, risk monitoring, situational awareness, and condition-based maintenance.
4. **Disrupting the downstream segment: Electrochaea** is the developer of a power-to-gas energy storage technology that converts excess electricity from wind and solar into renewable gas. This gas can then be injected into the existing natural gas infrastructure.

Hicor Technologies' compressed natural gas solution allows energy corporations to deliver natural gas to any customer who doesn't have access to a physical pipeline. **Siluria Technologies** develops a methane conversion technology for creating fuels and chemicals from natural gas.

Toward Downstream Solar and Decentralized Energy Services

In the past, most companies were innovating on the "hardware" side of solar (i.e., photovoltaic equipment suppliers, or solar module builders). In 2014, they demonstrate a 180° shift in investor appetite away from such semiconductor-style businesses, and a resulting slowdown in new innovation aimed at higher efficiency upgrades of solar equipment and components. The second trend includes business models that favor decentralization over centralization of solar provision. Consumers are no longer going to their local utility as a one-stop shop to obtain their energy plan. Instead, they are decentralizing decisions and processes by using smaller players with advantageous services.

Clean Power Finance operates an online platform that connects the distributed generation (DG) solar industry with institutional investors who want to own residential solar assets. CPF is a good example of "transactional innovation effectively lowering the cost and accelerating the adoption of rooftop solar."

Mosaic, the organizer of community solar financing projects, has democratized solar investment by allowing the public to elect centers, schools, libraries, etc. to go solar. The company is also making smart alliances with equipment manufacturers to accelerate the pace of deployment.

M-KOPA, the provider of pay-per-use solar charging systems in Kenya, will "revolutionize asset financing in emerging markets," according to one panelist. The company has developed a technology platform that combines embedded GSM and mobile payments to make it affordable for Kenyans to purchase solar energy solutions.

Renewable Funding helps residential and commercial property owners to finance renewable energy and energy efficiency projects. The company provides low-cost financing for home improvements via a secondary market for clean energy loans.

Sungevity, the solar system integrator, has a "strong IT platform" targeting the residential rooftop market and provides its customers with services to secure financing and rebates. The company is "scaling well and has teamed up with E.ON Benelux, to expand solar into the European market."

Sunrun engages customers through PPAs, by owning, insuring, and monitoring the solar panels on a homeowner's roof, while families pay a low rate for clean energy and fix their electric costs for 20 years. "With a good market trend and growing size," the company is bound to lower the cost barrier to residential solar and increase adoption rates.

"From Waste to Wealth": Recovery of a Trillion-Dollar Market

Key innovators today are designing new business models that allow for the recovery of usable materials, chemicals, or gas out of disposed goods, products, and waste. The companies below are pioneering the way forward to bring solutions to the questions: How can we reuse and remanufacture waste in current industrial processes to create economic value and less resource dependence? How can we develop a restorative society, which thrives even when the price of commodities surges? How can we use emerging technologies to help emerging markets to resolve their health and environmental challenges?

1. **Energy Efficiency – Alphabet Energy**, Hayward, CA, USA: More than 60 % of the chemical energy from fossil or renewable fuels today is lost during combustion processes, primarily as waste heat. **Alphabet Energy** solves this problem by developing a thermoelectric technology which can convert heat to electricity with target markets including energy generators and automobiles, and the company is working on military applications for the US Army and US Air Force.
2. **Recycling and Waste – Harvest Power**, Waltham, MA, USA: **Harvest Power** converts organic food waste into renewable energy and soil enhancement products (i.e., mulch and fertilizer). The company's technology "enables value add to organic waste stream" and the "fertilizer angle is an attractive side of the recycling market," according to several panelists. Its largest anaerobic digester site in Vancouver supplies power to over 900 homes.
3. **Biofuels and Biochemicals** – **LanzaTech**, Skokie, IL, USA: LanzaTech is a "pioneer in (syn)gas fermentations." The company's thermochemical technology is based on proprietary microbes that are able to transform industrial waste gases into usable chemicals. The company has established strong global partnerships with multinational corporations (e.g., Baosteel, Shougang Group, POSCO, Boeing, Virgin Atlantic).
4. **Air – Liquid Light**, Monmouth Junction, NJ, USA: Liquid Light develops a waste-to-resource technology that captures carbon dioxide gases directly at the point of emission and uses electrocatalysts to convert them into useful industrial chemicals. The company has generated enthusiasm among the corporate panelists who believe it is "strongly positioned to become the first CO_2-to-chemical technology" and "is very likely to be a long-term winner."
5. **Water and Wastewater – Ostara**, Vancouver, BC, Canada: Expert panelists praised Ostara Nutrient Recovery Technologies for "cleverly combining wastewater treatment with the production of a revenue-generating, green fertilizer." Ostara's proprietary technology recovers otherwise polluting chemicals, such as phosphorus and nitrogen, from municipal and industrial water streams and transforms them into an ecofriendly fertilizer that can increase food production.
6. **Recycling and Waste – ZenRobotics**, Helsinki, Finland: ZenRobotics provides a waste processing recycling system which is able to identify and extract valuable

materials and improves the efficiency of excavator sorting. The company is "linking the worlds of robotics, artificial intelligence, and sorting waste" and claims to be "the most promising cure to the waste and raw material crisis."

The Big Data Solution Providers for Utilities

New businesses are targeting the streamlining of large quantities of data. These companies are seeking to help utilities manage complexities in order to provide easily visualized options for decision making and to address operational challenges. Other companies are helping utilities manage big data in buildings, with the focus on serving their clients' needs for greater energy efficiency and better insights into energy management systems.

1. **Forecast and Management Tools for Distributed Generation: AutoGrid**'s software system runs complex optimization algorithms that enables electricity providers to forecast generation. **C3 Energy**'s software applies big data, smart grid analytics, social networking, and cloud computing to all aspects of power delivery. **Gridco Systems'** products enable utilities to actively manage voltage and other key parameters of the distribution system with precision in real time. Space-Time Insight gives utilities access to data about the power grid to help them to solve challenges around distributed generation, reliability, and security.
2. **Platforms for Better Energy and Building Analytics: FirstFuel Software** has developed a platform that uses advanced meter data analytics to track energy efficiency savings behind the meter in commercial buildings. **KiWi Power** is the developer of demand response software which can track customers' activities and generate automated performance reports.

   OSIsoft has developed a data infrastructure and event management software platform with applications to utilities' operations optimization and real-time situational awareness. **Stem** offers customer-sited, battery energy storage-enabled energy management systems to reduce electricity costs.

The Global Cleantech 100 Mini-Profiles

Advanced Materials
Enki Technology (United States)
Developer and marketer of functionalized coatings for the solar photovoltaic industry, optimizing the way solar modules interface with their environments
FRX Polymers (United States)
Developer of a patent protected, non-halogen, non-burning family of transparent high-flow thermoplastics in the global flame retardant plastics market
Kebony (Norway)
Manufacturer of sustainable hard wood created by modifying sustainably sourced soft wood

(*continued*)

Novomer (United States)
Producer of sustainable polymers and chemicals that use CO_2 as feedstocks via proprietary catalysts
Solidia Technologies (United States)
Developer of proprietary technology used in building and construction materials that can reduce CO_2 emissions up to 70 % while needing less water and lower temperatures
The NanoSteel Company (United States)
Developer of advanced nanostructured material solutions for the oil and gas, mining, power, and automotive industries
Agriculture and Food
Arcadia Biosciences (United States)
Developer of agricultural technologies such as low-water and nitrogen-consuming plants, salt-tolerant plants, and extended shelf-life produce
Kaiima (Israel)
Pioneer of a non-GMO technology platform and advanced breeding program that boosts the inherent productivity and resource usage efficiency of high-impact food and energy crops
Air
Leosphere (France)
Developer of ground-based and nacelle-mounted LIDAR (Light Detection and Ranging) for remote-sensing instruments and atmospheric observation
Liquid Light (United States)
Developer and licensor of process technologies to convert carbon dioxide into high-value major chemicals
Skyonic (United States)
Developer of a carbon dioxide mineralization technology for industrial use in capturing, converting, and sequestering carbon emissions as valuable by-products
Biofuels and Biochemicals
Avantium (Netherlands)
Developer of a process to convert biomass into bio-based materials and fuels
Beta Renewables (Italy)
Developer of cost-effective nonfood cellulosic biomass for biofuel production
Elevance Renewable Sciences (United States)
Creator of specialty chemicals derived from natural oils for use in personal care products, detergents, additives, engineered polymers, and specialty chemicals
Enerkem (Canada)
Producer of biofuels and chemicals from waste with proprietary thermochemical technology
Genomatica (United States)
Developer of green chemicals from renewable feedstocks such as sugar and garbage
Green Biologics (United Kingdom)
Developer of microbial, fermentation, and process technology to turn readily available waste and agricultural byproducts into high-value chemicals and fuels
Energy Efficiency
LanzaTech (United States)
Developer of a carbon capture and reuse technology that transforms abundant waste and low-cost resources into low-carbon fuels and chemicals

(*continued*)

NexSteppe (United States)
Developer of sustainable feedstock solutions for the biofuels, biopower, and bio-based products' industries
OPXBIO (United States)
Manufacturer of renewable bio-based chemicals and fuels including BioAcrylic from sugar feedstocks
Verdezyne (United States)
Producer of bio-based chemicals from renewable, nonfood sources
Biomass Generation
Cambi (Norway)
Provider of a technology to convert biodegradable material to renewable energy
Conventional Fuels
Electrochaea (Denmark)
Developer of a power-to-gas energy storage technology that converts excess electricity from wind and solar into renewable gas for direct injection into the existing natural gas infrastructure
Hicor Technologies (United States)
Developer of compression technology that decreases the energy required to compress and transport natural gas
LP Amina (China)
Provider of products and services that improve the efficiency and reduce emissions of power plants
Siluria Technologies (United States)
Developer of methane conversion technology for creating fuels and chemicals from natural gas
Energy Efficiency
AlertMe (United Kingdom)
Developer of a smart energy and home monitoring system that allows users to control energy usage in all appliances
Alphabet Energy (United States)
Developer of low-cost thermoelectric technology for waste heat recovery
Anesco (United Kingdom)
Provider of energy efficiency and carbon reduction solutions for homeowners, local authorities, and businesses
BuildingIQ (United States)
Provider of a Software as a Service (SaaS) solution to optimize energy use in commercial buildings that can reduce HVAC energy costs by as much as 25 %
Digital Lumens (United States)
Developer of intelligent LED-based lighting systems for industrial facilities that reduce lighting energy use and provide fully integrated controls and reporting capabilities
Eniram (Finland)
Developer of maritime energy management technologies that reduce fuel consumption and emissions in the shipping sector
Enlighted (United States)
Provider of lighting control systems for energy management applications

(*continued*)

FirstFuel Software (United States)
Provider of commercial energy analytics platform to help utilities and government agencies achieve efficiency targets
Glo (Sweden)
Developer of nanowire light-emitting diodes (nLED)
KiWi Power (United Kingdom)
Developer of demand response hardware and software used by large industrial and commercial consumers of electricity as well as government regulators
Lucid (United States)
Provider of cloud-based, real-time performance monitoring software for commercial buildings
LUXeXceL (Netherlands)
Manufacturer of optical solutions for the global LED lighting industry with digital printing, optical and lighting technology
MTPV Power Corporation (United States)
Developer of Micron-Gap Thermal Photovoltaic (MTPV) semiconductors that convert heat to energy with high efficiency
Next Step Living (United States)
Provider of full-service home energy efficiency and environmental impact assessments
Noesis Energy (United States)
Provider of analytical tools and data to help end users make more informed energy management decisions; formerly known as Brazos Software
O-Flexx Technologies (Germany)
Developer of thermoelectric products that convert heat into electricity
OSIsoft (United States)
Provider of enterprise software infrastructure for real-time data
Phononic (United States)
Producer of solid-state heat pumps and fully integrated systems that displace compressors for residential and commercial refrigeration, room air conditioning, and heating
Project Frog (United States)
Designer and manufacturer of resource-efficient and zero-net-energy modular buildings
Renewable Funding (United States)
Developer of innovative solutions for renewable energy and energy efficiency financing
Sefaira (United Kingdom)
Developer of cloud software for high-performance building design
Transphorm (United States)
Developer of technology to eliminate electric conversion losses when converting power from one form to another: AC/DC, AC/AC, DC/AC, and DC/DC
va-Q-tec (Germany)
Provider of customized vacuum insulation panels (VIPs) and heat and cool storage elements containing phase-change materials (PCMs)
View (United States)
Developer of energy-efficient glass technologies for use in buildings

(*continued*)

Energy Storage
Ambri (United States)
Developer of an all-liquid metal battery technology for grid-scale energy storage
Aquion Energy (United States)
Developer of batteries based on ambient-temperature sodium-ion technology; formerly known as 44 Tech
Imprint Energy (United States)
Developer of thin, flexible, print-based, non-lithium rechargeable batteries that use high-conductivity polymer electrolytes
Ioxus (United States)
Developer of ultra-capacitors and hybrid capacitors that can be made into individual cells, prepackaged modules, or complete systems
Sonnenbatterie (Germany)
Provider of battery systems specifically designed to support distributed solar photovoltaic arrays
Stem (United States)
Provider of energy optimization services that combines big data, predictive analytics, and energy storage to reduce electricity costs for businesses
Younicos (Germany)
Younicos is a leading global provider of intelligent energy storage solutions that make grids smarter, more flexible, and more resilient and thus able to accommodate greater amounts of renewable energy
Fuel Cells and Hydrogen
ACAL Energy (United Kingdom)
Developer of chemicals and systems used to power fuel cells both for automotive power trains and stationary power source
Sunfire (Germany)
Provider of energy conversion technologies including solid oxide fuel cells as well as solutions that produce renewable synthetic fuels based on solid oxide electrolyzers
Nuclear
General Fusion (Canada)
Developer of magnetized target fusion energy generation with a new compression system to collapse the plasma
Recycling and Waste
Harvest Power (United States)
Developer of systems that maximize the value of organic materials through the production of renewable energy and soils, mulches, and natural fertilizers
HYLA Mobile (United States)
Provider of mobile phone recycling services (formally known as eRecyclingCorps)
ZenRobotics (Finland)
Developer of robotic recycling systems that use artificial intelligence-enabled waste sorting for construction and demolition waste
Resource Sharing
Airbnb (United States)
Developer of online marketplace that allows people to list and book private accommodations, improving resource utilization and decreasing idle capacity and urban sprawl

(*continued*)

Smart Grid
AutoGrid Systems (United States)
Provider of software and cloud-based services for utilities, grid operators, and end users
C3 Energy (United States)
Developer of smart grid analytics software with applications such as transmission, distribution, and advanced metering
Gridco Systems (United States)
Leader in active grid infrastructure solutions, enabling utilities to more effectively integrate renewable and distributed generation, increase energy efficiency, manage peak capacity, and improve system reliability
Innovari (United States)
Platform provider connecting utility companies with commercial energy partners to incorporate demand-side technology into the grid
Space-Time Insight (United States)
Developer of situational intelligence solutions that transform disparate information into intuitive visual displays that businesses can use to analyze their resources across location and time
Utilidata (United States)
Supplier of voltage optimization products for the electric utilities
Varentec (United States)
Developer of next-generation digital power electronics
Solar
Applied Solar Technologies India (India)
Developer of solar PV off-grid power solutions for telecom towers
Clean Power Finance (United States)
Developer of an online business-to-business marketplace to connect the solar industry with capital markets
M-KOPA Solar (Kenya)
Provider of pay-per-use solar charging systems
Mosaic (United States)
Organizer of community solar financing projects
QBotix (United States)
Developer of robotic technology to improve the operation and management of solar plants
SolarEdge (United States)
Provider of distributed DC systems that maximize power generation of residential and large-scale photovoltaic solar sites
Sungevity (United States)
Solar system integrator targeting the residential rooftop market
Sunpartner Technologies (France)
Developer of thin photovoltaic surface materials
Sunrun (United States)
Developer of solar systems that engage customers through PPAs to eliminate the cost barrier to residential solar adoption
Transportation
BlaBlaCar (France)
Provider of a carpooling online marketplace

(*continued*)

ChargePoint (United States)
Provider of electric vehicle (EV) charging solutions
Proterra (United States)
Developer of battery-powered buses and other clean commercial transit solutions
RelayRides (United States)
Developer of a peer-to-peer car sharing platform that connects car owners willing to rent their cars that are not in use, with drivers who need short-term vehicle access
Streetline (United States)
Provider of smart parking solutions through wireless sensors located in parking spots and managed through a wireless mesh network
Uber (United States)
Provider of an integrated, mobile-based car booking and payment system
Ubitricity (Germany)
Developer and provider of a mobile metering technology and billing platform for EV smart charging infrastructure
Water and Wastewater
Axine Water Technologies (Canada)
Developer of a low-cost, chemical-free solution for treating toxic organic pollutants in industrial wastewater
Desalitech (United States)
Developer of reverse osmosis water desalination projects
FilterBoxx (Canada)
Supplier of containerized water treatment systems to industrial, municipal, resort, and aboriginal clients
Global Water FATHOM (United States)
Provider of cloud-based utility-to-utility solutions for municipalities to manage water systems
i2O Water (United Kingdom)
Developing the world's leading technology solutions for optimizing the performance of water distribution networks
Memsys (Singapore)
Developer of thermal process modules for various water and wastewater applications
Microvi Biotechnologies (United States)
Developer and manufacturer of innovative biocatalytic technologies in water, wastewater, and chemical sectors
Oasys Water (United States)
Developer of a forward osmosis platform for desalination, water treatment, and waste heat recovery
Organica Water (Hungary)
Provider of Fixed-Bed Biofilm Activated Sludge (FBAS) wastewater treatment plants in urban and residential population centers
Ostara Nutrient Recovery Technologies (Canada)
Provider of solutions recovering phosphorus and nitrogen from used water streams and transforming them into environmentally responsible, slow-release fertilizer

(*continued*)

Scinor Technology (China)
Provider of membrane-based water treatment technology
TaKaDu (Israel)
Provider of a Web-based platform that monitors water distribution networks and alerts in real time on inefficiencies, water loss, faults, and other network problems
Wind
Principle Power (United States)
Supplier of WindFloat foundations and design services to offshore wind project developers and utilities

Cleantech in Silicon Valley

USA has been a leader in venture capital financing for Cleantech, which has been particularly vibrant in California where strong Cleantech investment continues. Silicon Valley earned its name and first great fortune as the cradle of the computer age. Then it built a launching pad for the Internet age. Now the valley has assumed a leading role in the global competition to develop renewable energy and other clean, green technologies. Cleantech is poised to be the valley's third great wave of innovation (Harris 2010) – not just the next big thing, but perhaps the biggest thing ever. Confronting the peril of greenhouse gases and climate change happens to be a multi-trillion-dollar business opportunity.

Silicon Valley Could Be Called Solar Valley

Leading venture capitalist suggests that Silicon Valley may someday be called Solar Valley, given that dozens of solar companies have sprung up in recent years. But solar represents just one aspect of the Cleantech revolution. Around the valley, technologists are now busy trying to electrify the automobile industry, driverless cars, while other technologists are developing energy-efficient glass, drywall, and cement. Still others are introducing cutting-edge information technology to the twentieth-century electricity grid, working on biofuels and fuel cells, and pioneering new methods to recycle waste, protect air and water quality, and enhance agriculture and aquaculture.

Cleantech may seem like a radical departure from Silicon Valley's semiconductor roots. But solar photovoltaic cells are a simple form of semiconductor, and smart grid innovators are essentially integrating twenty-first-century software efficiencies into a wasteful twentieth-century electrical infrastructure. The valley's expertise in biotechnology is vital to biofuels, and its work in nanotechnology is critical to new materials that might find their way into nuclear reactors or a suburban home.

However, Silicon Valley does not have a natural advantage in talent – like chemical engineers, fermentation experts, engine designers, and physicists. But Silicon Valley does have a support culture for entrepreneurship and a culture of risk-taking and risk-funding.

Goldman Sachs' Investment in Silicon Valley

Investment banking giant Goldman Sachs (Parkinson 2014) has declared the renewable energy sector to be one of the most compelling and attractive markets and is backing up its talk with $US40 billion of made and planned investments.

Goldman Sachs is not the first big bank to talk up the renewable energy sector, or even "sustainable" investment. But it is one of the first to put real money behind it. In 2012, the bank made a commitment to invest $US40 billion in renewable energy, and it has made a number of large equity investments, over and above the normal advisory and fundraising work that is the usual bread-and-butter revenue for investment banks such as Goldman Sachs.

Among Goldman Sachs' key investments are the recently approved $1.5 billion investments for a near 20 % stake in Danish offshore wind energy developer Dong Energy. It has also a substantial investment in BrightSource Energy, which is about to bring its huge Ivanpah solar power project (pictured) into full production; it will be the largest in the world.

Goldman Sachs also provided $500 million of finance to SolarCity, to allow the biggest solar installer in the USA to expand its solar leasing business. Goldman is one of a number of banks to do that; the latest was Bank of America/Merrill Lynch.

0.01w?>It has also been an early investor in First Solar, the largest solar PV manufacturer in the USA, and SunEdison and made big money from the sale of Horizon Wind Energy to Portugal's EDP for $2.15 billion in 2007. Goldman's commitment of $40 billion is based around a number of assumptions: that costs will continue to decline as efficiency improves, that solar and wind will reach grid parity without subsidies in the nottoodistant future, and that energy storage issues will also be solved.

Google Makes Huge Investment in Clean Energy

When we conduct a search on Google, our query goes across the Internet, hits a server, gets processed, and is sent back to us in microseconds. One would be surprised how much energy is consumed in that process.

In the fourth quarter of 2013, Google (Berniker 2014) spent $2.25 billion on data centers and infrastructure spending, a huge area of costs for the company. That's one of the reasons the company is aggressively moving to solar, wind, and other alternative energies to power its data centers and banks of servers scattered around the world (Fig. 5).

If you ask the executives of Google, Apple, Facebook, or Microsoft, they will all tell you they are gigantic consumers of energy. And it's for this reason that top companies in Silicon Valley are in a race to be the leader of clean and renewable energies. But more than any other, Google is the most aggressive in advancing a clean energy agenda. Google has made 15 wind and solar investments totaling more than $1 billion in 15 projects that have the capacity to produce two gigawatts of

Figure 5 The Google campus has numerous green buildings designed for minimum power usage that helps reduce the company's carbon footprint. (Source: Nickelsberg, Getty Images)

power around the world, mostly in the USA, but that's the equivalent of Hoover Dam's worth of power generation.

In Feb 2014, one of the Google's solar investments kicked into operation. Google and several partners flipped the switch on the world's largest solar thermal project in Ivanpah, near the California-Nevada line. The project uses 347,000 sun-facing mirrors to produce 392 MW of electricity. Ivanpah's clear energy will power electricity for more than 140,000 California homes.

And while Google isn't alone among Silicon Valley's top tech companies to embrace alternative energy usage, no other company is looking at solar and wind as integrated in fueling its internal operations and also making sizable external investments.

Cleantech in Emerging Markets

The Pew Environment Group has released a report which shows that China's investments in clean energy have overcome the US figures. According to Pew, China now leads the way with $34.6 billion invested in 2009 across all investment types – nearly double the US figure of $18.6 billion (Berger 2010).

Top 10 Developing Nations Investing in Clean Energy

The history of clean energy in leading countries like Denmark, Spain, or Germany is well known: big investments, subsidies, and an energy matrix that is much greener than that of other developed nations like the USA or Japan. However, developing nations represent a large and rapidly growing share of the world's clean energy investment, according to Climatescope 2014 (Climatescope 2014), a

country-by-country assessment, interactive report, and index that offers the clearest picture yet of clean energy in 55 emerging markets in Africa, Asia, and Latin America and the Caribbean.

The results of this study suggest that renewable technologies can be just as cost-competitive in emerging parts of the world as they are in richer nations and show how clean energy capacity added in these nations grew at a faster pace than in developed countries, more than doubling in the past 5 years and totaling 142 GW, more than France's current capacity. According to Climatescope, these are the top 10 developing countries in clean energy investments:

1. China
2. Brazil
3. South Africa
4. India
5. Chile
6. Uruguay
7. Kenya
8. Mexico
9. Indonesia
10. Uganda

China's Cleantech has primarily been a project of government initiative and funding and ranks #1 and received the highest ranking as the largest manufacturer of wind and solar equipment in the world and the largest demand market for said equipment, followed closely by Brazil, Latin America's biggest economy. While Brazil still dominates, Latin America and the Caribbean as a whole are emerging as a destination for clean energy investment with Chile, Uruguay, and Mexico making it to the top 10.

Demand for clean energy is growing faster in these countries than in more developed nations. From 2008 to 2013, Climatescope nations added 142 GW of new, non-large hydro-renewable capacity. That represented a 143 % growth rate. By comparison, wealthier OECD nations added 213 GW, posting a clean energy capacity growth rate of 84 %. At a regional level, clean energy provided more than 92 TWh in 2013 to the Latin American and Caribbean's 600 m population, representing 6.4 % of total energy generation. Adding large hydro-generation, which is not included in the Climatescope survey, the region met more than half of its power demand through zero-CO_2 emitting power sources.

Goldman Sachs' Investments in Emerging Markets

In the past two years, Goldman Sachs' investments are focus on the emerging economies of Brazil, China, India, and Mexico – along with developed economies such as Japan and South Korea that have also made a large commitment to renewables and are reliant on expensive fossil fuel imports.

In Japan, Goldman Sachs has established a new independent power producer called Japan Renewable Energy (JRE) – to develop, build, and operate solar, wind, and other renewable projects. It is backed by the bank's $3.1 billion GS Infrastructure Partners II fund (GSIP). It has already committed to a 250 MW solar project in Okayama and a 40 MW PV plant near Tokyo.

Goldman has paid more than $3400 million for a majority stake in an Indian wind energy business called Renew Wind Power, which plans to build 1 GW of facilities within 2 years, and it is looking to build solar energy plants to supply mining operations in Chile, where even companies such as BHP Billiton are looking at alternatives. Other investments include the FloDesign Wind Turbine, a startup that was developing an experimental high-efficiency shrouded wind turbine, and South Korean wind turbine manufacturer CS Wind, which plans an IPO this year.

Hong Kong as a Launchpad for Overseas Green Tech Start-ups

The limelight has long been shed on Hong Kong as a start-up-friendly destination (2015). Besides efficient business setup, a robust legal system, easygoing regulatory environment, and a simple tax system, one of the Hong Kong's greatest advantages is its proximity to the largest economy in the world.

China, a massive but notoriously challenging market to navigate, is the ultimate expansion destination for many foreign start-ups – especially those in the green energy space. Besides overtaking Germany as the world's biggest market for solar power in 2013, China has also exceeded the USA in energy-efficient investments – spending $4.3 billion on smart grids in the same year. According to the Global Status report 2014, China has also dropped a whopping $56.3 billion on projects within the wind, solar, and renewable arena. The following is an example of a start-up story reported by Asia on 04 Jan 2015.

A Canadian hardware start-up Nanoleaf, which makes the world's most efficient LED lightbulb **(photo on the right)**, used Hong Kong to grow the Asia side of their

business. Cofounder and COO Christian Yan said: "Electronics-wise, Shenzhen, Guangzhou and the Dongguan area is your epicenter for everything that is made, and Hong Kong being so close to Taiwan as well – that makes it the perfect place to be. Plus the English transparency, almost zero corruption, fast company registration, small accounting firms, co-working spaces and trademark registration."

On their road to IP protection, Nanoleaf needed to register a trademark in China, Hong Kong, Europe, and the USA, and Yan noted the vast differences in efficiency. He revealed that while the registration process in Hong Kong was completed within 6 months, with the USA and Europe finishing soon after, Nanoleaf is still waiting on China's approval. As for entrepreneurs looking to apply for a design or utility patent in China, Yan said they should expect more than 3 year's wait.

Staying close has contributed to Nanoleaf's success. Besides piquing the interest of Li Ka-shing – one of the richest men in Asian, who has invested an undisclosed sum via his VC firm Horizons Ventures – Nanoleaf raised almost $500,000 through two Kickstarter campaigns and has also launched into Hong Kong retail stores. With distribution partners in the USA, Canada, Germany, Scandinavia, and Dubai, Yan said that Nanoleaf has 50,000 units in the pipeline ready to be sold globally and will be moving into Australia and China by 2015.

For other start-ups in the green tech space seeking a launchpad for Asia-Pacific, they should look no further than Hong Kong.

Why Greentech Will Be Huge in India

Compared to the difficult market that technologies like clean power and water desalination face in many states in the USA, because of India's rapidly growing GDP, the country is quickly building out its infrastructure – including power generation and water systems (2011). That means green technologies have the potential for a vibrant and growing market within the country. The Indian government has also taken a large role in setting mandates to push clean power from the top down.

Because of the desire for more energy, Indian plans to add 100 GW of power generation over the next 5 years, and that will be made up by mostly coal and clean power. The rapidly growing Indian middle class will soon want to consume similar amounts of power to the USA and Europe, and that will require these massive power infrastructure projects.

GE is focusing to develop technology and people in renewable energy and smart grid. Wind is currently cheaper than solar on a per kWh basis and is an even bigger market than solar in India right now. GE, which is one of the world's largest wind blade makers, is also working on how to use energy storage to make the grid more reliable, as well as smart grid technology in the country.

Clean power growth – Indian is installing 3 GW of solar by 2016, compared with the 54 MW of solar installed in 2010. The government has a top-down plan to hit

20 GW of solar by 2020, and big power companies and start-ups alike are developing solar project development businesses.

Smart grid and clean water – The power grid is a major bottleneck for adding on 100 GW to India's power grid, and the power companies will need to invest in making the grid much more efficient than it currently is. GE has been researching and testing smart grid technologies for the domestic market in its labs, and other companies like IBM have a strong presence in India.

India's utilities are also looking to build out clean water infrastructure, as clean running water has been notoriously poor to date. Desalination projects that can't get funding in markets like the USA – where clean water pipelines reach almost 100 % of the population – are far more economic in India. And there is a lot of money to be made in clean water. A desalination company VA Tech Wabag, based in Chennai, India, went public in 2010.

Israel Crowned World's Top Innovator in Cleantech Field

Israel is the country with the most potential to produce and commercialize entrepreneurial Cleantech start-up companies according to the 2014 Global Cleantech Innovation Index (2014). "Israel topped the 2014 index, with its relative outperformance on the measure of start-up companies per capita being a key reason that it did so," the report, released Tuesday, said. "The country generates the culture, education and 'chutzpah' necessary to breed innovation, plus it has the survival instincts."

The annual report, compiled by the Cleantech Group and World Wildlife Foundation, compiled data on 40 countries reflecting their level of innovation, government support, infrastructure, and existing Cleantech companies in fields such as alternative or renewable energy, water technology, and other environmental technology.

Israel scored a 4.34 on the index, followed by Finland with 4.04, the USA with 3.67, Sweden with 3.55, and Denmark with 3.45. In the past 3 years, Israel had 19 Cleantech companies voted onto the shortlist of the Global Cleantech 100 index.

Yet while Israel's overall score put it on top, other countries bested it in the individual categories. Israel pulled ahead with a particularly strong score on its Emerging Cleantech Innovation score: 8.92. Only three other countries scored above a five on the measure, which included data on early-stage investment, high-impact companies, and environmental patents. Most scored between zero and two.

"No one country excelled in all four indicators," the report stated. "Israel, for example, far exceeded others in the emerging cleantech innovation factor, however dropped to eighth place in the 'evidence of commercialized innovation' factor – confirming that there is room for improvement in even the most inspiring countries."

Avi Feldman, who leads the Cleantech forum at the umbrella group Israel Advanced Technology Industries, says that while the government is generally

helpful, it could play a stronger role in helping Cleantech companies develop beyond their early stages. Like biotechnology, he says, Cleantech companies take longer than others to get from early development to marketing their products and producing revenues. “The support has to be divided into the different stages of company growth. I think that most of the government support is directed at the very early stages, leaving the companies to die later on,” he said.

Even though most Cleantech companies look toward a global market, he believes that Israel could do more to encourage companies by adopting more renewable technology into its energy plans. While German energy is about 27 % renewable and American energy about 13 %, Israel lags far behind. Israel has the best conditions for solar [energy production] but gets only 1 % of its energy resources from it.

Concluding Remark: Integration and Deployment of Cleantech

The following four phases are essential to implement a Cleantech innovation:

(a) A concept development through academic approach from multidiscipline field
(b) A prototype development
(c) A small-scale infrastructural project
(d) A larger-scale infrastructural implementation

This sequence involved multidiscipline, integration of Cleantech individual partners, venture capital investment, and multinational corporations.

Deployment of Cleantech – Modern society is counting on Cleantech to meet growing energy and other resource demands while reducing environmental impacts and generating new opportunities for the economy. However, it is important to remember that ultimate success will depend on the coordination of technology development and technology deployment, two separate endeavors, each with requisite incubation characteristics and catalysts.

Deployment often depends on the scalability and price parity of new technologies, which often takes years beyond the time of the initial innovation for it to reach the mainstream. New technologies have the potential to continue to improve the world but also require planning and long-term commitment to its application – indeed, a different skill set than the work of innovation itself.

Therefore, it is important that individuals, engineering and science graduates, participating in Cleantech maintain a balanced perspective, based on creativity on the one hand and pragmatism on the other hand, while focusing on the goal of advancement. Through this chapter, readers should gain an overview of the trends in venture capital-funded innovation in Cleantech, the broad scope of the basic science and technology, and Cleantech implications that affect world climate change.

Appendix

Venture Capital Firms in the USA

USA has more than 2000 VC firms. The best way for an entrepreneur to seek VC funding is first look at the local or regional VC firms to begin with. The following is the list of 100 of the most active venture capital firms funding US start-ups in 2014. It is critical to find a firm that fits your journey. A true venture partner provides more than money but mentorship and strategic advice that can elevate your business to new heights (100 of the most active venture capital firms).

Ranking	Firm names	US $million invested	No. of deals
1.	Andreessen Horowitz	1,020.23	50
2.	Khosla Ventures	808.63	45
3.	SV Angel	736.74	47

Venture Capital Firms in Europe

Europe historically did not have many VC firms. In recent years, the VC industry has flourished. Here is a directory as provided by Directory (2010):

3i	Investment focus: European and South-East Asian start-ups
Add Partners Limited	Focus: early- to late-stage European start-ups in information technology
AltAssets	Focus: news service for global venture capital and private equity professionals

Ariadne Capital	Focus: part of a new European model, helping manage investor exits, drive consolidation, and leverage entrepreneurialism
Athena	Focus: international, for-profit, high-technology, business incubator
Baring Communications Equity	Focus: media and communications focused fund for Central and Eastern Europe and the CIS
Business Angels Connect	Focus: global services package to young entrepreneurs
CGS Management	Focus: medium-sized technology-based European companies with an emphasis on Switzerland
Cobblestone Private Equity	Focus: venture-oriented direct investments in emerging European technology companies seeking expansion and US market penetration
Copan	Focus: leading European technology executives and investors
Delta Partners	Focus: venture capital and private equity early-stage funding to high-technology companies in Europe and Ireland
DeMinds	A pan-European investment group focused on the global Internet market
European Equity Partners	Investment focus: Euro one-half to three million initially and up to Euro five to eight million based on meeting key milestones and criteria
Financier Natexis Banques Populaires	Focus: private equity investment holding company active in all segments of the business including venture capital
Hunter Lovec	Focus: consultants helping Central European companies solve their financial problems and achieve their financial goals
IDEA Network	Focus: network of international experts and consultants working under donor-funded projects
Innova Capital	Focus: advises private equity funds with more than Euro 300 million for investments into profitable companies in the EU accession countries of Central Europe
Internet Ventures Scandinavia	Focus: adds capital and partner experience to unique Internet ventures

Invest Mezzanin	Investment focus: later-stage private equity investing in companies in Austria, Switzerland, and Germany
Investindustrial Holdings Limited	Specializes in medium-sized companies, principally in Italy and Spain
Kildare European Leader Teoranta	Focus: rural development company for County Kildare, Ireland, with funding to distribute to innovative rural projects
Mericom	Focus: venture capital financing and investment services for telecommunication projects, start-up companies, and new businesses in the telecom industry
Michelsen-Partners	Focus: European cross-border mergers and acquisitions advisory services, structured finance advice, and international fund management
Net Partners	Investment focus: European start-up and early-stage initiatives related to the Internet
Northzone Ventures	Offers early-stage venture capital investments and focusing on technology companies
ORAH Investments	Swiss-based venture capital holding financing businesses in Southeast Europe
Permira	Investment focus: formerly known as Schroder Ventures Europe, a leading private equity group and advising funds
Pino Venture Partners	Investment focus: Italian company for operations in information technology, communications, and media
PrivateEquityOnline.com	Focus: tracks private equity activity across Europe, delivering daily news on funds, deals, and exits
PROPHETES	Focus: providing and investing venture capital into innovative companies and projects and providing support to investors who invest capital in the countries of Southeastern Europe
Seven Summits Capital	Focus: active in the international private equity market participating in buyouts as an investor, initiator, or catalyst
Start-up Avenue	Paris-based B2B incubator funding Internet start-ups that focus on Europe

Stratos Ventures	Investment focus: wireless information and communications technology companies with substantial global growth potential
Triago	Focus: private equity fund-raising, limited partnerships, and joint ventures
Trust Capital Partners	Focus: Belgian venture capital investment fund
VCG.dk	Focus: lists all Danish venture companies and a profile on them
Venture Capital in Europe	Discussion of the state of venture capital in Europe and its trends
Venture Consulting	Focus: professional business consultancy and services based on extensive international experience
ViewPoint Capital Partners	Specializes in software technology companies in early-, expansion-, and late-stage situations. Offices in Frankfurt, Amsterdam, and Zurich
West Private Equity	Focus: provides capital for management buyouts and buy-ins and the expansion or refinancing of companies headquartered in Western Europe

Venture Capital Firms in India, China, Japan, and Israel

India's venture capital industry has about 25 VC films. Wekpedia.com has a listing.

China's venture capital industry has more than 150 VC firms, which altogether manage over US$100 billion in venture capital and private equity funds. China Venture Capital Association (CVCA) provides details of its VC services at www.cvca.com.cn (China Venture Capital 2010).

Japan's venture capital industry has about 100 active funds. A list could be found at www.irasia.com/venture/jp (2010).

Israel's venture capital industry has about 70 active venture capital funds, of which 14 international VCs with Israeli offices. For more information, refer www.investinisrael.gov.il (2010).

Australia's venture capital industry has very limited VC films. It is mainly supported by the government. For detail, see www.avcal.com.au (2010).

How to Secure Venture Capital Money?

Venture capitalists invest money in start-ups in exchange for an equity ownership in the company. VCs receive hundreds of business plan from entrepreneurs each year. There are more than 1,000 venture capital funds around the world. Here are few tips to gain the attention of VC:

Step 1: Prepare a comprehensive **business plan**. VCs will expect you to clearly define the purpose of your business, disclose pertinent financial information (including revenue streams and projections), and provide information on your executive management team.

Step 2: Do research on venture funds to find the appropriate fit for your company. Look in Pratt's Guide to Venture Capital Sources, available in many bookstores and libraries, to see what fields each firm is likely to fund. Some focus on retail and service companies, while others look specifically for technology start-ups.

Step 3: Get an introduction to the venture capital firm. You'll have a much better chance if you've been personally introduced to the VC rather than blindly sending your business plan. These introductions can be made by executives of companies already being funded by the VC or by lawyers and accountants who work with the firm. Try to contact four to five VCs.

Step 4: Arrange a meeting with the VC. Consider bringing key members of the management team to the meeting.

Step 5: Follow up your visit with a thank-you note and additional information.

Step 6: Be persistent and polite; wait for VC evaluations.

How a Business Plan Is Evaluated?

When a business plan (BP) arrived at VC office, venture capitalists tend to give a quick review. If they decide a BP deserves a further study, the entrepreneur is invited to VC office for a power point presentation. In the process, one venture capitalist categorized BP into four types (2010): *a Home-run*, *a Struggle*, *a Joy-ride*, *or a Time-waster*. A Joy-ride project will get many media publicity, but investors would not make much return. The objective of VC is to sponsor a real winner – a Home-run. A project that is not too obvious or too easy to implement; otherwise, others will launch the identical or similar one. When great minds think alike, most of them don't make much money. So a good BP needs:

- High market potential – customers will buy it.
- Technology novelty – nonobvious innovation.
- An entrance barrier – a valid patent protection.
- A cohesive and complementary team – technology skill plus management professional.
- A complementary business alliance.
- Reasonable funding requirement.
- Reasonable timing to realize a high return.

Cleantech Expert Panel for Global Cleantech 100

Analysis of the Co-benefits of Climate Change Mitigation

Douglas Crawford-Brown

Contents

Abstract

Economic development of the poorer nations brings competing influences on public health. On the one hand, the increase in per capita wealth reduces susceptibility to environmental pollutants. On the other hand, industrialization may increase the emissions of those same pollutants. Global climate policy negotiations have recognized this conflict, striving to identify a pathway to decarbonize the global economy while allowing growth in world regions at the bottom of the economic pyramid. This chapter explores the conflict by developing a quantitative methodology for calculating the economic growth's net impact on public health and the co-benefits of greenhouse gas reductions associated with exposure to particulate matter. The chapter shows that co-benefits of decarbonization are significant; GDP growth in non-Annex I nations carries its own health benefit; the co-benefits are in part reduced through the increase in GDP by between 12 % and 17 %; and failure to include economic growth projections into co-benefit calculations produces greater errors in co-benefit estimates as the stringency of climate policies is increased.

W.-Y. Chen et al. (eds.), *Handbook of Climate Change Mitigation and Adaptation*,
DOI 10.1007/978-3-319-14409-2_59

Introduction

Justifications for decarbonizing the global economy usually focus on the reduction in greenhouse gas (GHG) emissions and the resulting change in climate risks (Markandya and Chiabai 2009). The political will to carry out ambitious mitigation policies then rests on a belief in the reliability of the science of climate change, the effectiveness of policies at reducing GHG emissions, and the economic costs of the policy actions. Since impacts from climate change can be in areas of the world and for periods of time outside the time and geographic scope of a single nation, political will to act is often reduced.

There are, however, many other reasons why a nation might move along a trajectory of decarbonization. There might be concern for reducing risks of damage to human health from co-pollutants of GHG emissions. There might be concern for energy security. There might be a desire for lower energy bills through reduced energy consumption, reducing energy poverty. There might be a government target for economic development, with investment in low-carbon buildings or infrastructure providing a stimulus for this development. Experience shows that moving a policy such as decarbonization forward is most viable when there are multiple reasons for doing so and where the impacts are local and immediate, ensuring the widest range of participating actors and protection against deep regrets should any one policy justification prove in hindsight to be unwarranted.

It is therefore natural to ask whether decarbonization might bring with it impacts that affect the ability of a nation to reach other economic, energy, and/or environmental aims. These impacts might be beneficial, helping to reach these other policy goals, or they might present new problems that impede reaching climate change goals (a process of maladaptation). Consideration of these co-impacts is important for several reasons:

- If they are co-benefits, they can be used to marshal additional political support for policies of decarbonization.
- Inclusion of co-impacts provides a more complete understanding of the multiple effects of a policy, improving the ability to inform multi-attribute decisions.
- Assessment of co-impacts potentially provides a more balanced perspective on the net costs and benefits of a policy to and within society.
- Co-impacts may reveal a multiplier effect of policies in the economy, better characterizing the beneficiaries of those policies.
- Identification of co-impacts provides insights into where hurdles might be encountered in implementing policies of decarbonization and how they might be overcome.
- Early recognition of adverse co-impacts can avoid situations of backlash if the impacts become evident in the future.

This chapter assesses co-impacts in regard to climate change and decarbonization policies using the example of global public health.

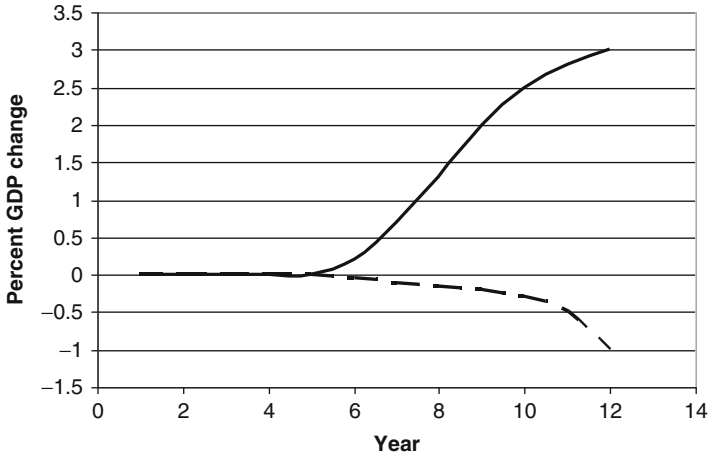

Fig. 1 Predicted impact of a carbon tax on the economy of Bangkok, Thailand, without considering co-benefits of PM reduction (*dashed line*) and with co-benefits (*solid line*). The *y*-axis is a cumulative percent change in GDP relative to the baseline projection with no carbon tax

Since the assessment of co-impacts can add appreciably to the effort involved in policy assessment, it is natural to ask whether the additional information brings significant new insights to the overall societal effect of a policy. As a partial answer to that, consider the case of a study of the impact of carbon taxes on the economy of Bangkok, Thailand (Li 2002). In that study, the impact of a carbon tax on GHG emissions and national GDP was first assessed using an economic model without co-benefits associated with public health. The policy was reassessed taking into account the co-reduction of emissions of particulate matter (PM) when strategies that reduce GHGs through reduced energy consumption driven by a carbon tax are introduced.

The results are shown in Fig. 1, indicating that consideration of co-benefits of reduced PM emissions not only changed the magnitude of predicted GDP impacts but reversed the sign of those impacts. What appeared to be a climate change policy creating a loss of GDP without considering the co-benefits of PM reduction became an impact that was positive on GDP growth when these co-benefits were considered.

Figure 1 concerns only the influence of PM reductions. There are, however, many more co-benefits than from PM reduction, including a variety of environmental and ecological indicators of sustainability. A good review of the literature on these has been provided by Bollen et al. (2009). Their review draws several key conclusions:

- Mitigation policies yield long-term benefits, but effects from co-benefits often are much more immediate and reliable. In the short-to-medium term, it will be largely the co-benefits that will be realized by a nation rather than the direct impacts related to climate change.

- Co-benefits could be achieved by other, more direct policies than climate change mitigation. A key issue is the cost-effectiveness of producing the same improvements in the environment and/or health through GHG reduction policies or through policies targeting benefits directly.
- Climate change and local air pollution policies can at times be in conflict. It is crucial that these interactions be taken into account to ensure the net effect of a co-impact is truly beneficial.
- The health-care cost savings of these co-benefits range between $10 and $60 per ton of carbon dioxide abated. As shown in a study by the OECD (Bollen et al. 2009), the cost savings from the health co-benefits alone will be higher than the cost of abatement for a ton of carbon dioxide equivalent for five of the 15 regions they studied in the global economy.
- The same OECD study (Bollen et al. 2009) estimated that the percentage reduction in premature mortality of all air pollutants combined was slightly below the percentage reduction in GHG emissions; an 80 % reduction in GHG emissions produced approximately a 50 % reduction in annual premature mortality (attributable to air pollution) as of 2050.
- Depending on existing concentrations of pollutants in ambient air, the co-reduction of non-GHG pollutants can bring about savings in air pollution control costs, since a reduction in PM and other pollutants by GHG mitigation equates with a savings in reduction by other methods such as investments in scrubbers, baghouses, etc.

The most significant co-pollutants are black carbon, PM, SOx, NOx and N_2O, CH, O_3, and NH_3. As just one example, a study by International Institute for Applied Systems Analysis (IIASA) and the EC Joint Research Centre (IIASA 2004) indicates that a pathway to decarbonization would produce a reduction of 10–25 % for ozone, which is significant given the estimated cumulative loss globally of $580B (2,000 USD) as a result of increased mortality and morbidity associated with tropospheric ozone (Selin et al. 2009).

Co-benefits to Human Health

The human health co-benefits considered here are those of the air toxic that is of primary concern globally in regard to human health as this relates to a co-benefit of GHG reduction: particulate matter (PM). These co-benefits are a function not only of decarbonization policies but also of economic change. Various studies have established a relationship between a country's health variables and economic growth (Barro 1996; Bloom and Canning 2003; Bloom et al. 2004; Weil 2005). Both the susceptibility and sensitivity of populations to environmental change such as ambient PM are functions of socioeconomic status. Significant links between income and general health conditions have been demonstrated in sociology and epidemiology literatures. The change in GDP in many of the poorer nations in the recent past, as those nations simultaneously improve their economic condition and increase GHG

emissions, will therefore change the susceptibility and sensitivity of the populations to PM exposures, in turn changing the co-benefits of decarbonization. It is necessary to include within co-benefit calculations, therefore, the impact of GDP change under decarbonization scenarios on the susceptibility and sensitivity of populations.

The methodology used in this chapter is similar to that used in regulatory assessments of policies aimed at other reductions in air or water toxics. Calculations of the relationship between health and emissions of an air toxic such as PM are often executed at refined levels of spatial and temporal resolution for regulatory assessments (Li and Crawford-Brown 2011). This involves (i) creating the emission inventory for each pollutant for each source category (e.g., mobile, stationary, nonpoint); (ii) gridding the geographic area, often into census blocks or census tracts of several thousand people each; (iii) assigning each source a pollutant emission rate into the relevant geographic gridblock; (iv) using atmospheric dispersion and chemistry models to calculate ambient air concentration; (v) applying "microenvironment" factors to account for differences between ambient air concentration and the concentration indoors, near roadways, etc.; (vi) assigning individuals to specific gridblocks; (vii) developing activity patterns that move people between grid blocks (e.g., through travel) and that determine metabolic rates due to physical activities (e.g., breathing rates); (viii) calculating exposures in each gridblock based on air concentration and activity; (ix) applying age-specific risk coefficients in each grid block to convert exposures to probability, frequency, and/or severity of effect; (x) multiplying per capita incidence by population size to obtain estimates of annual or lifetime disease incidence; and (xi) applying cost of illness (COI) values to convert incidence of morbidity and mortality into annual costs of health impacts.

This level of spatial and temporal detail is not feasible for the global models of coupled energy-economy-environment policies because the computational resources required are quite high and because the data required are insufficient for the majority of nations and regions. As a result, the present analysis uses an approximation employed elsewhere in the literature (Li 2002; Li and Crawford-Brown 2011) in which:

1. An economic model is used to estimate economic activity, energy demand, and energy provision due to a policy scenario. This is repeated for all regions of the global economy. The same is done for the baseline (no policy) scenario.
2. The material and energy use from Step 1 is utilized to estimate emissions of air toxics such as PM. By running these first two steps both with and without a climate change policy, the difference in emissions resulting from the policy can be calculated.
3. Empirical factors are developed to convert fractional changes in emissions (Step 2) into fractional changes in ambient air concentration. For PM, the empirical factor is approximately 0.5 (a 50 % change in ambient air concentration associated with a 100 % change in emissions) based on available global data. This empirical factor varies between regions depending on degree of industrialization, density of vehicular traffic, mix of petrol and diesel use in vehicles, and existing air pollution control measures. For example, in Hyderabad, India, it is estimated

to be 0.5 (Guttikunda and Aggarwal 2009). The values are approximately 0.53 in several regions of China (Zhang et al. 2004) and 0.4 in Korea (Heo et al. 2009). Roughly similar results have been obtained in the Southeastern US (Lee et al. 2007). This chapter uses a central tendency value of 0.5.

4. The result of Step 3 is multiplied by region-specific estimates of ambient air concentration to calculate the change in ambient air concentration resulting from a policy, in units of $\mu g/m^3$. For PM, the assumption used here is that the contribution of a given source to ambient air concentration in a particular region is proportional to the contribution of that source to the total rate of PM emissions in that region, following a process of Source Apportionment (Lee et al. 2007). This is repeated for all regions in the global economy.
5. Changes in ambient air concentration (Step 4) are converted to estimates of change in incidence of disease (number of cases annually or over a lifetime of a policy) through application of risk coefficients taken from meta-analyses performed on the global literature concerning population sensitivities. This is repeated for all regions in the global economy.
6. Finally, changes in cost of illness are determined through application of cost of illness (COI) factors for each illness, multiplying these by the results of Step 5 on the number of cases avoided by the policy. For mortality, cost of illness is not applied.

The illnesses considered here are respiratory and cardiovascular, as the majority of epidemiological studies conducted worldwide have focused on these effects for exposures to air toxics (USEPA 2010).

The analysis in this chapter uses a multivariate regression equation estimated by Philip Chen of the Cambridge Centre for Climate Change Mitigation Research (4CMR) using ordinary least squares regression to explicitly account for country-specific socioeconomic status (SES) characteristics using the Global Burden of Disease study (Lim et al. 2013; Murray et al. 2013). The specific illness categories measured are "lower respiratory infections"; "trachea, bronchus, and lung cancers"; "ischemic heart disease"; "cerebrovascular disease"; and "chronic obstructive pulmonary disease (COPD)."

Considering first mortality, the estimated regression equation using an excess relative risk (ERR) model is

$$Ln(\mathrm{ERR}) = -0.3916 + 0.0139^{*}\mathrm{PM2.5} - 0.0000232^{*}\mathrm{GDP\ perCap} + 0.889^{*}\mathrm{UrbRate} - 6.617^{*}\mathrm{Gini}$$

And so the incidence, y (deaths per year), as a function of PM exposure (E), per capita GDP (GDPperCap), urbanization rate (UrbRate), and measure of economic inequality (Gini coefficient, which is a method for calculating the degree of variance – between individuals – in access to wealth within a nation) is

$$y(\mathrm{E}) = \mathrm{BM}^{*}\exp(-0.3916 + 0.0139^{*}\mathrm{PM2.5} - 0.0000232^{*}\mathrm{GDP\ perCap} + 0.889^{*}\mathrm{UrbRate} - 6.617^{*}\mathrm{Gini})$$

The coefficient in the term associated with PM2.5 is similar to that found in meta-analyses of epidemiological studies, which report an increase of 0.5–1 % in daily respiratory and cardiovascular mortality per 10 μg/m^3 increase in daily average PM10 (divide approximately by 2 for PM2.5) among exposed adults (USEPA 1996, 2008).

Studies on the association of morbidity and air pollution exposure are less comprehensive (Wang and Mauzerall 2006), but indicate a relative risk ratio for chronic obstructive pulmonary disease and pneumonia of between 1.06 and 1.25 for a 50 μg/m^3 increase in daily PM10. This translates into a relative risk coefficient for acute morbidity effects of approximately 1–5 % per 10 μg/m^3 increase in daily PM10 or 2–10 % per 10 μg/m^3 increase in daily PM2.5. Studies in developing countries produce approximately the same range of values (Chen et al. 2002; Hagler Bailly 1998; Xu et al. 1995; Ostro 1987).

For morbidity, the economic value associated with a change in health outcome (V_i), is given by:

$$V_i = A_i \times COI_i \times SF$$

where, A_i is the change in the incidence (annual number of cases) of a specific health endpoint i, COI_i is the cost of illness per case of effect i (for morbidity), and SF is the scaling factor equal to the ratio of per capita GDP in the region divided by per capita GDP in the reference developed nation (here, the US), with a minimum ratio of 0.2.

The specific values for COI are taken from the USEPA Benefits Assessment (USEPA 2008), using the 2020 values provided in that report. All are given as 2020 USD per statistical case of the effect. They are equal to: $90,000 for nonfatal heart attack, $16,600 for hospital admissions for chronic obstructive pulmonary disease, $8,900 for hospital admissions for asthma, $24,700 for hospital admissions for all cardiovascular effects combined, $24,600 for hospital admissions for all respiratory effects combined, and $130 for work loss days.

The risk coefficients for morbidity effects specify only the increase in PM-related effects overall and are not tied directly to these specific categories of health care expenditure. In Deck et al. (2001), the summary of studies examined produces a ratio of all respiratory effects over hospital admissions and extended health-care (including cardiovascular and respiratory admissions) – as a result of PM exposures – equal to 0.018/0.0016 or approximately 10:1. From the cost information above, the average cost per case of hospital admission and/or significant health-care is $27,000. Since only 10 % of effects are assumed to result in such health care costs, the average cost per effect used here is $2,700 (alternatively, the COI value is left at $27,000 and the number of effects multiplied by 0.1).

Co-benefit Calculations for Decarbonization Policies

This chapter considers policies that focus solely on reducing energy consumption from fossil fuels, in which a percentage change in GHG emissions is accompanied by the same percentage change in PM emissions. This is equivalent to assuming that

the climate policy changes the total consumption of fuels by changing demand, but not the mix of fuels or the technologies in which they are used.

The first calculations consider percentage change in GHG emissions that vary between 0 % and 100 %, with no associated change in GDP within nations. Fractional reductions in GHG and hence PM emissions are assumed uniform in all nations globally (which differs from many of the results reported elsewhere in this book). Published values of the ratio of percentage PM reduction to percentage carbon dioxide reduction vary from 0.77 (Cifuentes et al. 2001) to 1.0 in transport resulting from fuel efficiency improvements (Caton and Constable 2000) and as high as 140 % (Changhong et al. 2004). Policies that cause a switch to biomass fuel, carrying carbon dioxide emission reductions (by up to 80 %), result in reductions of up to 75 % when the switch is from coal-fired plants, but can increase PM emissions when the switch is from fuel oil, gas oil or natural gas (AEA 2008). Hence the assumption in the current study that a percentage reduction in PM emissions equals that of the carbon dioxide emissions reduction appears valid.

Figures 2, 3, and 4 show the reduced annual costs and number of cases of morbidity (all PM-related causes combined) and mortality (number of cases only) globally as a function of the fractional reduction in GHG emissions.

When socioeconomic change (per capita GDP) is included in the calculations, the results change, although not dramatically. For this analysis with socioeconomic change (i.e., economic growth both increases GHG emissions and decreases sensitivity to co-pollutants), results for mortality only are considered to determine whether inclusion of economic growth significantly alters conclusions from above.

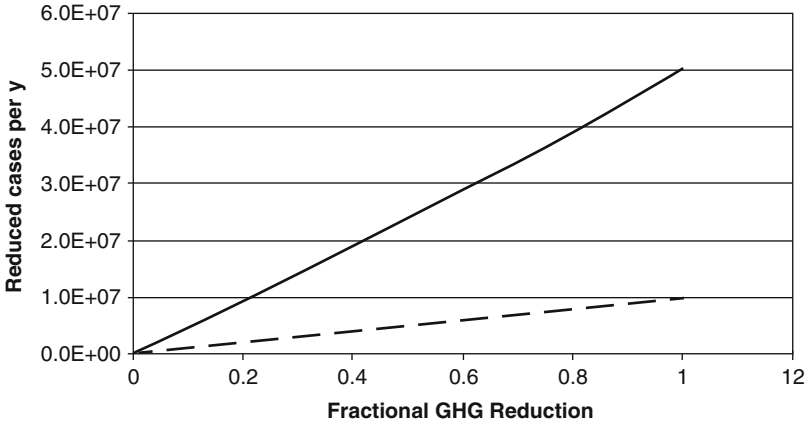

Fig. 2 Reduction in annual PM-induced morbidity (respiratory and cardiovascular combined) globally for different levels of GHG emission reductions shown on the *x*-axis. The results shown as *solid lines* assume that climate policies cause emission reductions uniformly across all nations, with no distinction between Annex I and non-Annex I nations (and hence no distinction between developed and developing economies). The results shown as *dashed lines* assume that reduction policies are in place only in the Annex I, developed, nations

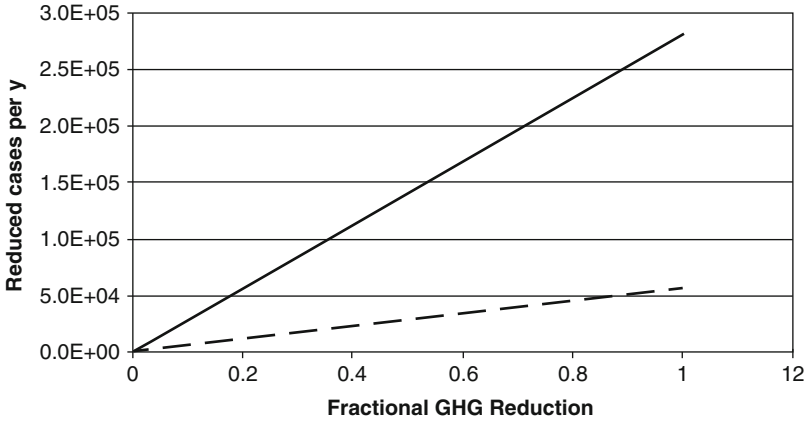

Fig. 3 Reduction in annual PM-induced mortality (respiratory and cardiovascular combined) globally for different levels of GHG emission reductions shown on the *x*-axis. The results shown as *solid lines* assume that climate policies cause emission reductions uniformly across all nations, with no distinction between Annex I and non-Annex I nations (and hence no distinction between developed and developing economies). The results shown as *dashed lines* assume that reduction policies are in place only in the Annex I, developed, nations

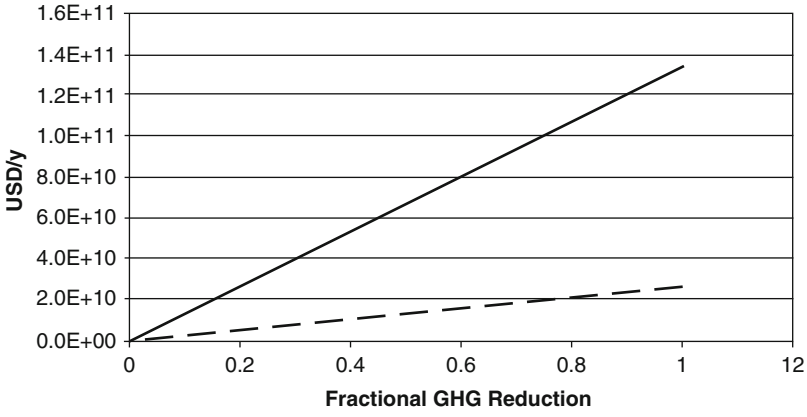

Fig. 4 Reduction in annual cost of PM-induced illness from morbidity (respiratory and cardiovascular combined) globally for different levels of GHG emission reductions shown on the *x*-axis. The results shown as *solid lines* assume that climate policies cause emission reductions uniformly across all nations, with no distinction between Annex I and non-Annex I nations (and hence no distinction between developed and developing economies). The results shown as *dashed lines* assume that reduction policies are in place only in the Annex I, developed, nations

In this analysis, a baseline scenario of very little decarbonization prior to 2050 is used as a baseline and compared against the results from three scenarios where decarbonization is more significant. Scenario 1 is a moderate level of decarbonization needed to remain below approximately 600 ppm CO_2; Scenario

2 is a weakly decarbonizing scenario equivalent to only current, pledged mitigation policies being implemented; and Scenario 3 is a more ambitious decarbonization trajectory needed to remain below a target of 550 ppm.

Future Directions

The co-benefit estimates in section "Co-benefits Calculations for Decarbonisation Polices" support the contention that co-impacts of climate change mitigation strategies can be a significant adjunct to policies focused solely on climate change itself and will provide the basis for justifying transitions of the energy system in both the near and long-term future. The reduction in lives lost (mortality) associated with an 80 % reduction in carbon dioxide emissions globally is approximately 220,000 per year across these nations. With a global population of seven billion, this corresponds to a reduction in mean annual probability of death equal to 3.1×10^{-5}, or about three chances per year per 100,000 people. Over the course of a lifetime of 70 years, the reduction in mean lifetime probability of death is 2.2×10^{-3}, above the "fuzzy bright line" level of excess mortality (10^{-4}) usually considered a level requiring corrective action.

Short-term action on climate change is restricted to the Annex I nations under the UN Framework Convention on Climate Change (UNFCCC). If attention is focused solely on these nations, arguing that they are the ones that must marshal the will to political action first, the results are not dissimilar to the global results above. The reduction in lives lost (mortality) associated with an 80 % reduction in carbon dioxide emissions in only the Annex I nations is approximately 50,000 per year across these nations. With a population of 1.3 billion in the Annex I nations, this corresponds to a reduction in mean annual probability of death equal to 3.9×10^{-5}, or about four chances per year per 100,000 people. Over the course of a lifetime of 70 years, the reduction in mean lifetime probability of death is 2.7×10^{-3}. Again, these co-benefits would usually be considered adequate justification for regulation under risk-based approaches in the Annex I nations.

Note also that inclusion of economic growth in co-benefit calculations makes a significant but not dramatic difference in the results of those calculations. Under all four scenarios, there is a decrease in both the cumulative and average annual mortalities induced by PM2.5 exposures as a result of increasing per capita GDP over the simulation period (2010–2050), as seen in the first four rows of Table 1. This decrease is approximately 13 %, 12 %, 13 %, and 11 % for scenarios 0 (baseline), 1, 2, and 3, respectively. Similar percentage reductions are noted for annual average mortality rate (excess deaths per year due to PM2.5 exposures). These changes indicate that allowing for continuing increases in per capita GDP while designing global climate policies can have a health benefit by itself, not necessarily in relative terms but in absolute terms.

Given these findings, it is likely that decarbonization of the global energy system will be increasingly allied with issues of improvement in public health. Both national

Table 1 Summary of findings on PM-related mortality co-benefits with and without consideration of GDP change, given for the baseline of no policy (0), policy Scenario 1, policy Scenario 2, and policy Scenario 3. The differences between Scenarios 1, 2, and 3 and the baseline are shown as (0-1), (0-2), and (0-3), respectively

	No GDP change		With GDP change		Fractional difference

and international environmental laws have demonstrated the role of public health in creating binding legislation, even when reference to climate change alone has proven ineffective.

The Role of Aviation in Climate Change Mitigation

Katsuya Hihara

Contents

Abstract

This chapter summarizes the recent policy and research development of the aviation emission reduction and its mechanism. First we trace the policy process surrounding UNFCCC, Kyoto Protocol, and Post-Kyoto Protocol negotiations, mostly focusing on the activities in the ICAO. Key factors in the policy process are (1) the disparities in the field of international aviation among the nations, such as income level and preferences between environment and growth. Such disparities could be interpreted as the notion of "common but differentiated responsibilities and capabilities (CBDR)" in the Kyoto Protocol. The second key factor is (2) uncertainties surrounding the impact of GHG emission on utilities of nations. Then we look into the theoretical developments in the field of

international aviation from the economics viewpoint. Main objectives are to illustrate the impact of market-based mechanism (MBM), such as the emission allowance trading, and the inherent difficulties to reach social optimal allocations through the bargaining among nations in the presence of nations' disparities and uncertainties of GHG emission's impact on nations' utilities.

Policy Developments

Introduction

The scientific researches about the impact of aviation on climate change are still underway. The aviation is the total complex system comprising various subsystems such as the process of fuel burning in an engine of an aircraft to the accumulation of thousands of flights of many aircrafts. The scientific impact on the climate of simple phenomenon, such as contrail entailing aircraft in the sky for a while, is still very much the main research topic from the pioneering work of the IPCC special report (1999) and ICAO (2010). The schematic illustration of aviation and its climate impact are shown in Fig. 1.

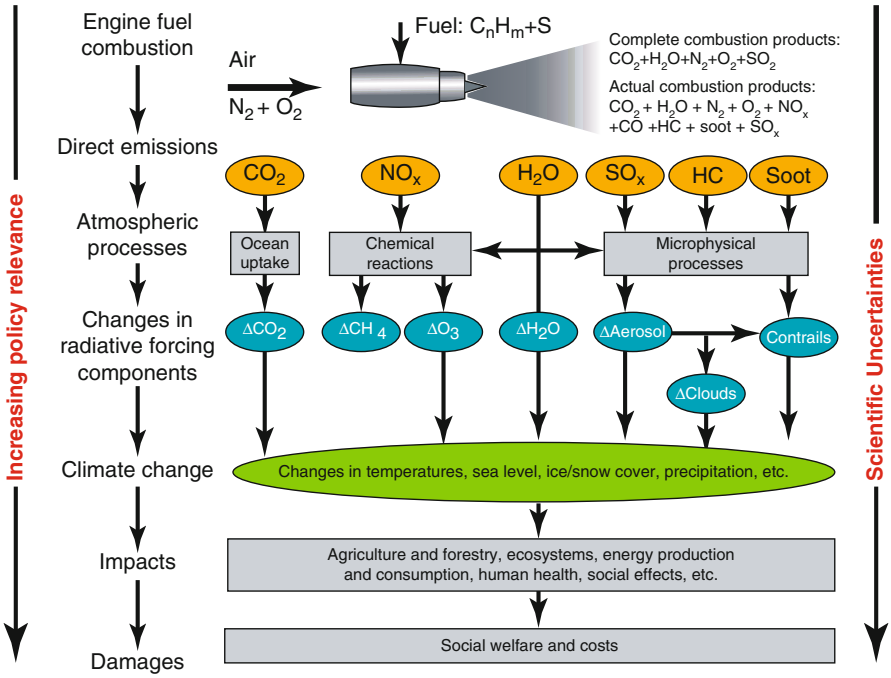

Fig. 1 Schematic representation of aircraft emissions and their causal linkage with potential climate and social welfare impacts (ICAO 2010)

Out of many greenhouse gases (GHGs), CO_2 have politically special importance, since it is not toxic in itself, and its effects probably is larger than other GHGs. UNFCCC sets aside the international aviation and maritime sector, and the GHG reductions' matters of both sectors are to be tackled by the ICAO (International Civil Aviation Organization) of the UN[1].

According to the ICAO, the share of aviation in total emission is about 2 % of the total anthropogenic CO_2 emission. Out of the emission, the international aviation emission accounts for about 60 % of the total emission of the aviation. But the growth rate is rather large, and emission level is expected to be double around the next two decades or so. Especially around Asia-Pacific region is the high growth area.

Aviation Sector Growth

According to the ICAO forecast (ICAO (2013)), the world passenger traffic, expressed in terms of revenue passenger kilometers (RPKs), is expected to grow from 5 billion to more than 13 billion RTKs over the 2010–2030 periods, at an average annual growth rate of 4.9 %. The international traffic section would grow at 5.1 % per year, and the domestic traffic section would grow at a slower rate of 4.4 % per year.

During the next 10 years, 2030–2040, growth is estimated to moderate to an average of 4.0 % per year with international and domestic air traffic growing at the rate of 4.1 % and 3.8 % per annum, respectively.

Geographical distribution of the passenger traffic and its growth from 2010 to 2040 is shown in Fig. 2. The Domestic North America is the highest traffic volume in 2010. Intra Europe and North Atlantic are the second and the third. The Intra Asia and Pacific routes are the most expected to grow, while Domestic China/Mongolia and Domestic North America are following. So in 2040, Intra Asia is the highest traffic volume, and Domestic China/Mongolia and Domestic North America are the second and the third, respectively.

Under such demand forecast, Fig. 3 shows the fuel burn from the international aviation from 2005 to 2050. Some of the emission mitigation technologies are taken into account, but the global aspirational goal of 2 % annual fuel efficiency improvement, which will be discussed later in this section, is very hard to achieve as the graphs show.

Uncertainties: Large Impacts

A lot of uncertainties are involved in the environmental issues. The aviation is the total system of a lot of human activities and mechanical functions in addition to natural/climatological/meteorological phenomena. The aircraft movements,

[1]Kyoto Protocol Article 2.2. "The parties shall pursue limitation or reduction of emissions of greenhouse gases… from aviation …, working through the International Civil Aviation Organization…."

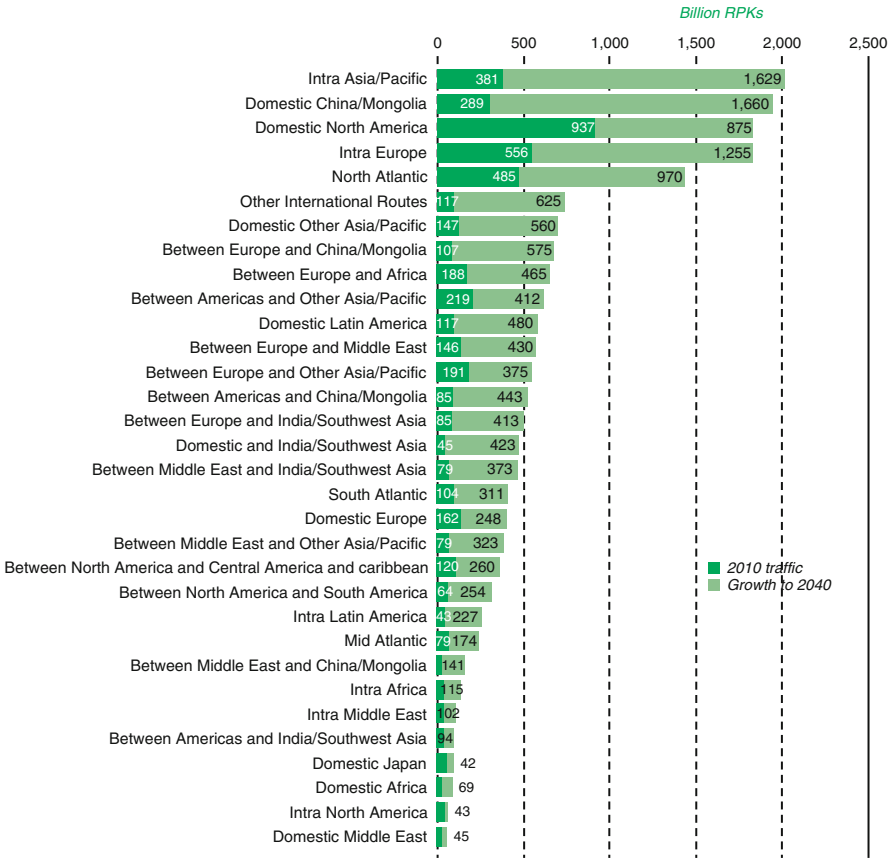

Fig. 2 ICAO/CAEP passenger traffic forecast (*central*) by Route Group (ICAO (2013))

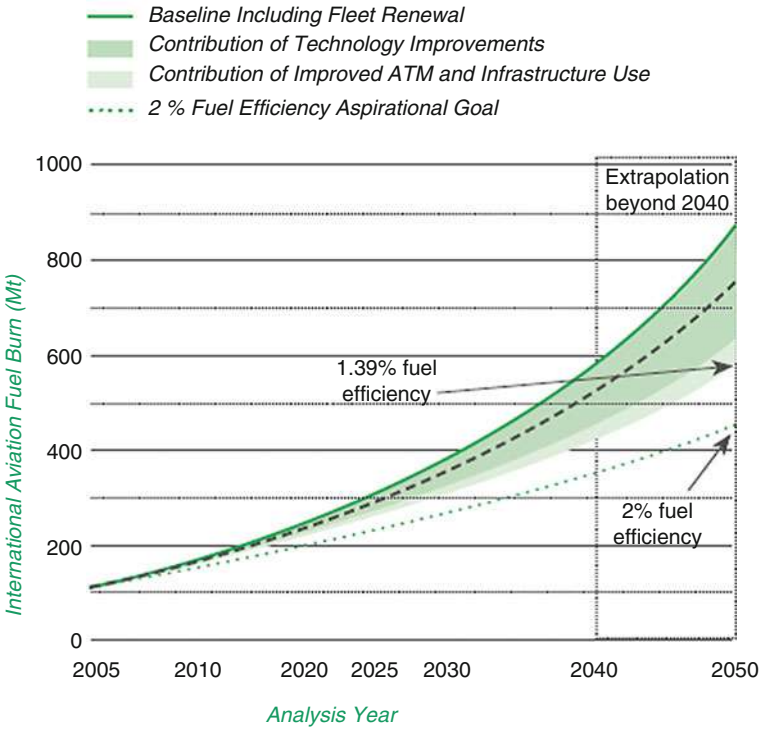
including maintenance/repair, are both human and mechanical, so is air traffic control service with human judgment and ICT system combined. Fuel composition and selection are also very important in the impact alleviation front.

The impact of aviation on climate change through the natural system is far more complicated and yet to assess accurately than that of human activities. Contrails that aircraft entail in sky, for example, stay for a while and seem to have certain level of impacts on climate system, but the accurate assessment is still in the early stage of research according to the UNFCCC report.

So uncertainties in the field of international aviation and their impact on climate change come from all fronts, either from human activities or from natural/ecosystem. From human fronts comes all the uncertainty involving human activities like demand uncertainty, as well as more trivial problem such as measurements inconsistencies, counting errors, and reporting inaccuracies. But the uncertainties involving the global ecosystem through which CO_2 emission has impacts on the climate are at least as complicated and hard to analyze as those involving human activities.



*Dashed line in technology contribution range represents the "Low Aircraft Technology Scenario".

Note: Results were modelled for 2005, 2006, 2010, 2020, 2025, 2030, and 2040 then extrapolated to 2050.

Fig. 3 ICAO/CAEP fuel burn trends from international aviation, 2005–2050 (ICAO (2013))

As we can see in Fig. 4, the uncertainty involving mainly human factors, about the demand forecast for future aviation passengers roughly based on population and income level forecasts, has a very wide range, as much as 50 % of central forecast in 45 years of forecast time.

Under the fuel burn estimations, the ICAO calculated the CO_2 emission from international aviation. Figure 5 is the projection of CO_2 emission by the ICAO from the international aviation from 2005 to 2050.

The Total Approach

As we discussed, the aviation is the complex system of many airplanes/airlines, airports, air traffic controlling service providers, various ground service providers, and local and central government authorities, which are in charge of many matters

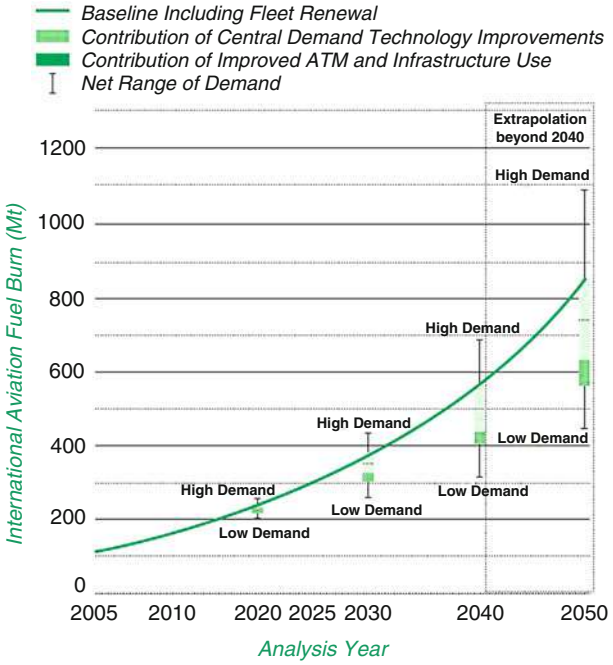


Fig. 4 Range of uncertainties associated with demand forecast, 2005–2050 (ICAO (2013))

including local air quality control and global environmental constraints as well as the safety and human or mechanical issues.

Fuel selection is a major front in the reduction technological challenge in the international aviation. Fuel burn reduction directly contributes to the CO_2 emission reduction. Fuel burn efficiency has improved about 70 % since 1950s, mainly thanks to the improvement of the engine and aircraft body[2].

On the technical fronts of emission reduction, here we introduce briefly the two major environmental technological projects in the EU and USA. In the EU front, the Advisory Council for Aeronautics Research in Europe (ACARE) published a report, "ACARE 2020," in which they set goals for 2020, such as 50 % noise reduction, 80 % NOx emission reduction, and 50 % CO_2 emission reduction from the levels of 2000. They are projected based on active wing design project to actively control streamline flow and its connected projects. Also more recent and long-term vision after 2020 is announced.

1 **Potential Alternative Fuels Contribution in 2050**[2]
State targets could close up to 25% of gap
Maximum potential contribution could close in excess of 100% of gap

2 if all alternative fuels in 2050 were zero net carbon

*Actual carbon neutral line is within this range. Dashed line in technology contribution range represents the "Low Aircraft Technlogy Scenario."
Note: Results were modelled for 2005, 2006, 2010, 2020, 2025, 2030, and 2040 then extrapoled to 2050.

Fig. 5 Net life cycle CO_2 emission trends from international aviation, 2005–2050 (ICAO (2013))

In the US front, the National Aeronautics Research and Development Plan was announced in 2007. Based on the plan, the goals were set to 50 % reduction of CO_2 from 2005 level and 75 % reduction of NOx from CAEP 6 level, for example, through the development of subsonic transportation system. For that goal, ERA (Environmentally Responsible Action) project was also deployed to develop the necessary technologies for the plan, such as wing-body integrated design and laminarization technology.

In addition to these projects, we still have several fronts for the reduction of gas emissions. First is the reduction of body weight of aircrafts. Now, more and more part of aircrafts is made of CFRP (carbon-fiber-reinforced plastics) instead of aluminum alloy. 50 % of the weight of the recent B-787 is made of CFRP, while in the case of B-777, just 11 % of its weight is made of CFRP.

The second is the research of BWB (blended wing body) to decrease airflow resistance. In a proposed concept of BWB, wings are integrated with the main body, which results in increased aerodynamic characteristics.

Third is the increase of fuel efficiency of jet engines. We still have quite a few challenges in this front. Improving thrust efficiency and heat efficiency is the main way of increasing fuel efficiency. Open-rotor engines are still under research, for example, for improving thrust efficiency. Also ceramic-composite materials are under development for improving heat efficiency.

Aviation is one big system, which combines human activities and natural/ecosystems. So the system optimization is another source of emission reduction. One is the flight path optimization. The dynamic flight path adjustment based on the most up-to-the-minute meteorological conditions and measures is the example. Also the smooth descent approach, called CDA (continuous descent approach), is being tested for real implementations.

As we can see so far, the approaches taken to curve the emission from aviation are the total strategies that involve all of the major players mentioned above.[3] According to their document_1, the industries' reduction strategies into the future include various approaches from fleet renewal/mechanical technology developments and better air traffic managements to low carbon fuel usage.

UNFCCC and Aviation: Disparities Among Nations

Under the UNFCCC (UN Framework Convention on Climate Change), contracting parties of the convention agreed to the Kyoto Protocol in 1997. One of the key elements of the Kyoto Protocol is the principle of CBDR (common but differentiated responsibilities and respective capabilities). The principle basically means that the industrialized countries which have mainly provided emissions so far should bear more responsibilities of future reductions than developing countries that provided emissions less thus far.

Annex I of the Kyoto Protocol lists up mainly the developed countries, and such countries are to bear the responsibility of GHG reduction target during the commitment period (2008–2012) for each county, based on CBDR. So the Kyoto Protocol clearly distinguishes the role of developed countries from that of developing ones.

In the aviation, the Kyoto Protocol allocated the responsibilities of emission reduction from aviation in two ways. First, reduction of the domestic aviation emission is under the national reduction target stipulated in Annex I. Second, the reduction of international aviation emission is stipulated to be worked through international organization, namely, the ICAO, since the international nature of international aviation is very hard to allocate among relevant countries.

[3]Material presented to ICAO GIACC/3 February 2009 by Paul Steele on behalf of ACI, CANSO, IATA, and ICCAIA.

In 2012, COP (congress of parties) 18 of UNFCCC decided the extension of the Kyoto Protocol and made another commitment period (the second commitment period, 2013–2020) beyond the previous period (the first commitment period, 2008–2012). In addition to the USA, which never ratified the Kyoto Protocol, industrialized countries, such as Japan, Canada, New Zealand, and Russia, had announced that they would not take on reduction target for the second period. The contracting parties are discussing the framework beyond 2020, and they are scheduled to agree on the new framework by the end of COP 21 in 2015.

Works at the ICAO

Entrusted with the reduction of international aviation emission by the Kyoto Protocol, the ICAO convened GIACC (Group on International Aviation and Climate Change) in 2008. The main cause of difficulties comes from the ICAO principle set by the Chicago Convention of nondiscrimination and equal and fair opportunities to develop international aviation, which is in conflict with CBDR of the Kyoto Protocol.

European countries pursue the nondiscrimination principle, and developing countries, including China and India, support CBDR over nondiscrimination principle. To overcome this conflict, GIACC came up with the target index based on the fuel burn efficiency[4]. The index is fuel liter/RTK (revenue ton kilometer). Both developed countries and developing countries have almost the same level of index of fuel burn efficiency, since the efficiency mainly depends on the manufacturing date of each airplane irrespective of the country of airline that owns the airplane.

In 2009, the ICAO decided the world global aspirational goal for the international aviation sector, namely, improving fuel efficiency (fuel liter/RTK) by 2 % per year. This global aspirational goal is, unlike the Kyoto Protocol, shared by all of the main aviation countries, such as the USA and China in addition to the EU and other industrialized countries.

Also the ICAO agreed on the carbon-neutral growth from 2020, which means keeping net CO_2 emissions from international aviation at the same levels from 2020 onward.

In addition, the ICAO is taking the total approach for the international aviation GHG emission reduction. This means that the aviation authorities and industries will seek to establish the measurement/methodology of GHG emission level from individual aircrafts, industries will seek to diffuse the use of biofuel, air service provider bodies will seek to efficiently use air traffic management, and the ICAO and other public authorities will seek to establish the scheme of global market-based mechanism (MBM).

[4]The negotiations process among major member states and relevant papers in the process can be found in GIACC (2008), GIACC (2009), and ICAO (2009).

The Resolution A38-18 in 2013 builds upon the series of the ICAO's recent achievements and incorporates a number of important key elements. The following is the main points of the resolution.

The ICAO General Assembly Resolution A38-18 in 2013

1. Reaffirmation of collective global aspirational goals for the international aviation sector, namely, improving fuel efficiency by 2 % per year and keeping net CO_2 emissions at the same levels from 2020 onward
2. Further work to explore the feasibility of a long-term global aspirational goal for international aviation
3. Maintenance and enhancement of appropriate standard, methodologies, and a mechanism to measure/estimate, monitor, and verify global greenhouse gas (GHG) emissions from international aviation
4. Development of a global CO_2 Emissions Standard for aircraft, aiming for adoption by the ICAO Council in 2016
5. Maintenance and update of guidance on air traffic management (ATM) improvements and other operational measures to reduce international aviation emissions and continue development of tools to assess their benefit
6. Development of coordinated national policy actions to accelerate the appropriate development, deployment, and use of sustainable alternative fuels for aviation with measures to ensure the sustainability of alternative fuels for aviation
7. Development of a global market-based mechanism (MBM) scheme for international aviation, which addresses key design elements, including means to take into account the special circumstances and respective capabilities of states, in particular developing states, as well as the implementation mechanisms from 2020, for decision by the 39th Assembly in 2016
8. Voluntary preparation and update of states' action plans on CO_2 emissions reduction activities, for submission to the ICAO by June 2015, and to be made publically available
9. Enhancement of the ICAO's strategy for capacity building and assistance, including support for the development and update of states' action plans, as the mechanisms to facilitate access to financial resources[1]

The interesting point is the market-based mechanism (MBM) from the economical point of view. To tackle the emission reduction, there are mainly two ways. The first is the reduction by regulation, such as the forced emission reduction by law. The second is using the market and pricing mechanism, such as cap and trade.

By cap-and-trade approach, first the total emission amount is set, and emission allowance is allocated for each emitter. The emission allowance can be tradable for cash or other remunerations. If the emitter exceeds its allocated allowances, then the one can buy the necessary amount of allowances for the difference of actual emission levels and the allocated emission level, which allocated allowance indicates.

The ICAO's MBM could be the example of the second approach. For cap-and-trade approach, we have some examples already implemented, for example, the EU-wide emission trading mechanism, called EU-ETS, which is cap-and-trade system.

Originally, the EU unilaterally proposed its own emission allowance trading mechanism for international aviation in/out of the EU region using EU-ETS. In the EU's application to international aviation[5], total amount of CO_2 emission is set for each airline of each county, whether they are EU member state or not, and if an airline emit more than the allocated free allowance, it should buy the allowance for the extra emission allowance from EU-ETS.

This proposal was vehemently opposed by the USA, China, and other industrialized/newly developing countries. Despite these oppositions, in 2008, the EU again unilaterally announced to begin its scheme in 2012. Because of the strong opposition from the USA, China, India, and other countries, the EU finally decided to "stop the clock," meaning that the EU suspends the procedure to introduce international aviation into EU-ETS until the end of 2016. Meanwhile, the ICAO has time to contemplate the framework of global MBM to curve the GHG emission reduction and to consult it with the member nations. If the ICAO delivers the MBM, the inclusion of aviation to EU-ETS will never happen. If the ICAO fails to deliver it, however, the inclusion enforcement will "automatically" revive.

The main difficulty lies with the structural disparities. The Kyoto Protocol, with the legal obligation, sets only on the industrial nations but not on developing nations. The concept of CBDR (common but differentiated responsibilities and capabilities) in the Kyoto Protocol clearly reflects this uneven burden sharing of the Kyoto Protocol. As it is often pointed out, the environmental issues are very difficult, since they entail long-term effects, generationally unequal impacts, and various uncertainties from scientific mechanism of cause and effects to economic and social impacts, for which accurate, objective, or plausible assessments are usually very difficult.

It is a challenge to cope with the conflicting contents of CBRD, based on the disparities among nations, and ICAO's equal and fair treatment among them, in the field of GHG issues of international aviation in a constructive way. Some level of ingenuity in the policy process, such as coming up with the inclusive target of fuel efficiency in the global aspirational goal in ICAO, instead of zero-sum-type emission allowance allocation, is very important in order to attain meaningful policy progress.

Theoretical Illustrations

Introduction

Understanding the basic interaction mechanism among nations surrounding CO_2 emissions is critically important for the policy formulation analysis in aviation sector at present, especially for market-based measures such as emission allowance

[5]The EU's inclusion of international aviation into the EU-ETS is documented in EU (2009).

trading. Also we would like to incorporate the large impacts uncertainties entail into our analysis.

Here, we show, based on Hihara (2012), some emission trading simulations and two theoretic analyses of the global welfare in the field of international aviation emission reduction.

First, this study performed simulation analyses on the hypothetical emission allowance trading if China and the USA joined the Kyoto Protocol and participated in the global trading at the time in 1990 and showed the numerical effects based on the conditions.

Second, the study analyzed the socially efficient allocation condition with the presence of negative public goods, namely, CO_2, and the uncertainty of such impact that CO_2 emission has on our utility levels through the ecosystem.

Third, the study constructed the theoretical model and illustrated the effects of asymmetric structures of difference of initial conditions and risk aversion among countries and uncertainty level increase.

With all the analyses, the study showed under the asymmetric structures, including the difference of the initial conditions (income level, consumption, and production level) and the preference (pro-environment or pro-development) of player countries, that the bargaining among the countries on the emission allowances is inherently difficult to reach social optimum. The study's main points are as follows.

So it is necessary and relevant to study the effects of these typical uncertainties on the welfare level with or without emission allowance trading in order to understand deeper into the negotiation dynamics and to possibly reach long-run agreement.

The first key question for the policy formulation on emission allowance trading is, "how will the trading market work, and how will prices result after trading?" The second key question is, "what is the impact of uncertainties, other than uncertainties of CO_2 production or bunker fuel consumption in the international aviation sector, on the global social welfare level with emission allowance trading or without such trading (e.g., game-theoretic emission allowance allocation without trading)?"

In this study, we first illustrate how emission allowance trading works in the hypothetical global trading market based on the past game-theoretic study with other relevant research results for the first key question. Secondly, we look into more general and theoretic framework as to how the uncertainties affect the global welfare level with or without emission allowance trading for the second key question.

Emission Allowance Allocation Process Simulations

Past Literature

A lot of analyses were performed about the emission allowance allocation process, like that of the Kyoto Protocol Negotiation process. Okada (2004), for example, analyzed the bargaining mechanism for the initial allowance and reduction costs by the method of noncooperative game theory based on the empirical work done by Nordhaus (1991) and Bohm and Larsen (1994).

Also a lot of cooperative game-theoretic analyses were done about the allowance distribution bargaining. The work done by Tadenuma in Imai and Okada (2005) shows there is a stable coalition set (von Neumann-Morgenstern solution) even though, according to Okada (2003), the core of the voting game on distributions of a fixed total amount of emission allowances is empty.

Here, we focus on noncooperative game framework and make some simulation of including new members into the bargaining.

Base Model

According to the work by Nordhaus (1991), Bohm and Larsen (1994), and Okada (2004), we have the formulae for the competitive price of carbon emission allowances under the framework of noncooperative game approach, indicated below. The following equations and notations are from Okada (2004).[6] Okada (2004) assumes marginal cost pricing of emission allowance in the trading market after the reduction level or emission allowance allocation is attained by asymmetric Nash bargaining solution among nations.[7] Data for the estimated parameters of the following equations are from Nordhaus (1991) and Bohm and Larsen (1994).

Let $N = 1,\ldots, n$ be the set of counties. For every $i \in N$, we denote by E_i country i's current level of carbon emission. The total level of carbon emitted by n countries is given by $E = \sum_{i \in N} E_i$. x_i denotes the country i's reduction of carbon emission. ω_i is the emission allowance allocation for country i $\overline{\omega} = \sum_{i \in N} \omega_i$.

$$p^* = -185.2 \ln\left(1 - \frac{E - \overline{\omega}}{\sum_{i \in N} E_i (1 - r_i)}\right) \tag{1}$$

$$x^* = \frac{E(1 - r_i)}{\sum_{i \in N} E_i (1 - r_i)} (E - \overline{\omega}) \tag{2}$$

$$c_i^e = 185.2 x_i^* + p^* (E_i r_i - \omega_i) \tag{3}$$

$$r_i = \begin{cases} 1 - \dfrac{e_i}{e_{USA}} (e_i \leq e_{USA}) \\ \dfrac{e_{USA}}{e_i} - 1 (e_{USA} \leq e_i) \end{cases} \tag{4}$$

$$e_i = \frac{E_i}{GDP_i} \tag{5}$$

e_i is the carbon intensity of country i, which is emission level E_i over GDP. p^* is the competitive equilibrium price of this negotiation.

[6] They are specifically from proposition 3 in Sect. 4, "Numerical Results" of Okada (2004).

[7] They are specifically from line 14 of page 9 and Theorem in page 19 in Sect. 3, "Noncooperative Bargaining Process of Emission Reduction" of Okada (2004).

x_i^* is the equilibrium reduction of CO_2 emissions for country i.
c_i^e is the cost of country i with the initial allocation ω_i, competitive equilibrium price p^*, and reduction amount x_i^*.
r_i is the marginal cost index of country i in relation with that of the USA.

This model is about the mechanism of global emission allowance trading across countries based on the relative reduction cost of each nation compared with that of the USA.

By Eqs. 1–5, we can simulate any number of countries with any type of initial allowances or any type of emission intensity.

These equilibrium equations loosely states that if the countries anticipate competitive equilibrium market for emission allowance trading in the second stage, they can attain a bargaining solution on emission reduction level or emission allowance allocation in the first stage. Although the emission allowance trading market could be oligopolistic, here we use these setting of competitive market, as a start, to illustrate the price effect of new entrants into the hypothetical global trading market.

However, since these numbers are available, based on empirical works, only for 1990, we can only perform the simulation about 1990 and cannot do about other years like 2005, for example.

Simulation

What would have happened if major players such as China and India were included in the Kyoto Protocol and the hypothetical global emission trading in 1990?

Table 1 below is the basic real data for the carbon emission level (million ton carbon, GDP in US dollars, carbon intensity for the15 EU nations (EU15), Former Soviet Union nations, Japan, the USA, China (including Hong Kong and Macau), Korea (not including DPRK), and India from the UN and IPCC database.

If the hypothetical emission trading had been done in 1990 among the original contracting developed countries of 15 EU nations, Former Soviet Union nations, Japan, and the USA, what would have happened? The simulation result is indicated in Table 2. The reduction rate are based on the Kyoto Protocol, and initial permits are calculated by subtracting a reduction ton based on reduction rate from carbon emission level of 1990 for each country.

The equilibrium price and equilibrium cost are derived from 1 to 5 by inputting the relevant numbers for each country and summations of those for all countries into variables of these equations. The resulting equilibrium price is about 9.65 US dollars per ton carbon.[8]

[8]Notice that the price here is US$ per ton carbon, not US$ per ton CO_2. External cost from car gasoline consumption is about 5,000–50,000 yen per ton carbon, and 30,000 yen per ton carbon is the medium estimate according to Kanemoto et al. (2006). According to IPCC (2007a), the average social cost of CO_2 based on 100 estimates is about 12 US$ per ton of CO_2 for 2005, although the estimation range is from −3 to 95 US$. The external cost of aviation is from 0.16 to1.09 euro per aircraft-km for CO_2 and H_2O for average technology if price of CO_2 ton is 30 euro according to Ding et al. (2003).

Table 1 Basic real numbers of the players

Country or area	Carbon emission in 90 (mil. ton)	GDP in 90 (Bil. US$)	Carbon intensity[c]
EU 15	915	6,961	0.13
FSU 22	989	1,535	0.64
Japan	292	2,970	0.10
USA	1,315	5,794	0.23
China[a]	662	484	1.37
Korea[b]	66	264	0.25
India	186	327	0.57

Source: UN and IPCC web data base
[a]China includes Hong Kong and Macau
[b]Korea excludes DPRK
[c]Carbon intensity is the carbon emission level per GDP (ei = Ei/GDPi)

Table 2 Results of hypothetical emission trade among four players

Country	Reduction rate	Reduction (mil. ton)	Initial permits (mil. ton)	P* (US$)[a]	Equilibrium cost (mil. US$)
EU 15	0.08	73	841	9.65	575
FSU 22	0	0	989	9.65	−402
Japan	0.06	18	275	9.65	138
USA	0.07	92	1223	9.65	563

[a]P^* is the equilibrium price of carbon emission allowance

Table 3 Results of hypothetical emission trade among seven players

Countries	Reduction rate	Reduction (mil. ton)	Initial permits (mil. ton)	P* (US$)	Equilibrium cost (Mil. US$)
EU 15	0.08	73	841	6.65	424
FSU 22	0	0	989	6.65	−192
Japan	0.06	18	275	6.65	102
USA	0.07	92	1223	6.65	457
China[a]	0	0	662	6.65	−143
Korea[b]	0	0	66	6.65	−8
India	0	0	186	6.65	−35

[a]China includes Hong Kong and Macau
[b]Korea excludes DPRK

If the major emission countries such as China, Korea, and India also had participated in the hypothetical emission trading with the obligation of zero reduction like Former Soviet Union nations, the results would have been those in Table 3.

The equilibrium price is about 6.65 US dollars, since the new entrants are not obliged to reduce the emission level and they can sell emission allowances to the USA, EU15, and Japan.

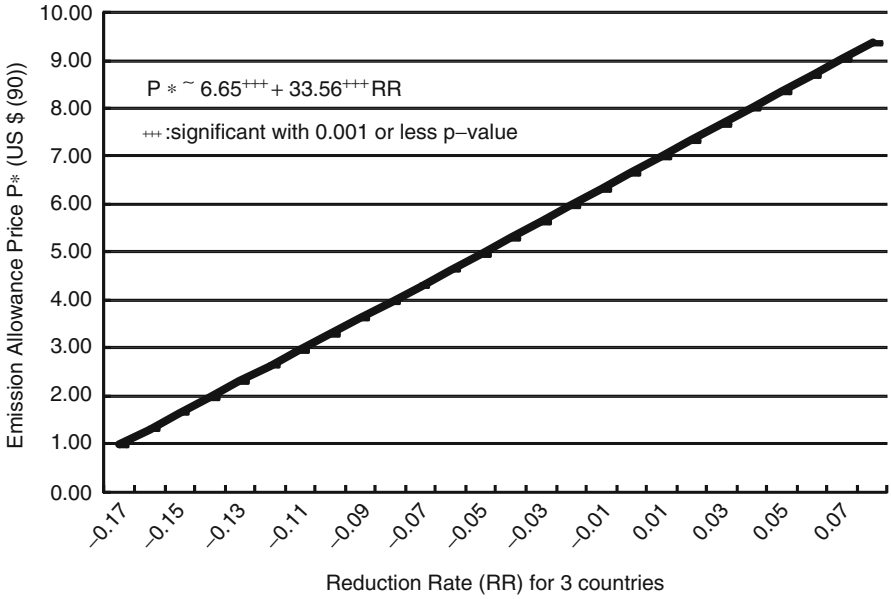

Fig. 6 Sensitivity of reduction rate for three countries

What happens if the reduction obligation increases commonly for all the three countries from zero percent to higher percentages is in Fig. 6.

According to our basic model, 1 % increase (+0.01) of reduction obligation among these three nations lead to about 33 cents increase of the emission allowance price, which is indicated by the slope 33.56 of our estimated line in Fig. 6. 0.33 is the effect of 0.01 increase of reduction obligation.

The price and its slope are common to all countries participating in the emission allowance trading, since the equilibrium price is determined uniquely by Eq. 1 in the market. Therefore, the slope of estimated price change is also common to all countries. If reduction obligation increases for these countries, the needs for emission allowance go up and so does the price of emission allowance.

If carbon intensity (= emission level over GDP) of these three countries commonly improves by 1 % (−0.01), the emission allowance price would go up by about 2 cent. This relationship is depicted in Fig. 7. The slope of the estimated line is about –2.40, and 0.024 is the effect for −0.01 change in carbon intensity variation.

With these simulations, more players' participation can reduce the price of emission allowance, but the situation depends on the factors such as the reduction obligation of the new players and carbon intensity variations.

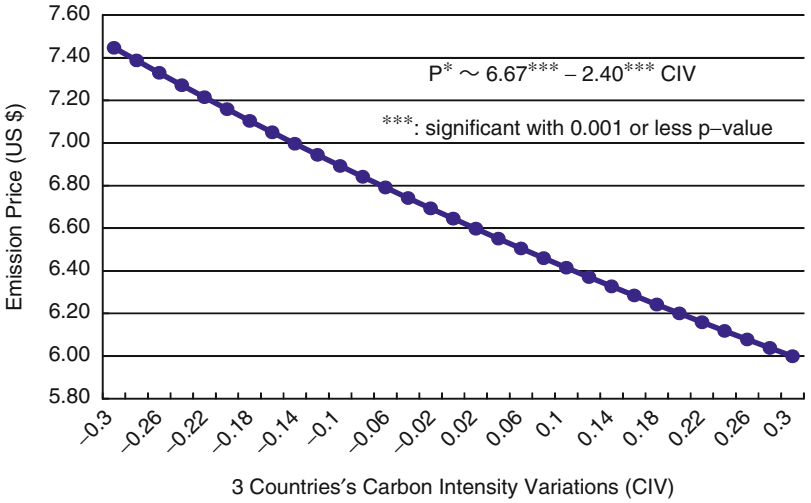

Fig. 7 Sensitivity of three countries' carbon intensity variation to emission price

Welfare Analysis with a Negative Public Good

Past Literature

Emission charge on airlines is studied by several authors on the effect on airfares, service quality, and aircraft design as shown by Brueckner and Zhang (2009).

In more general context, including other sectors in addition to international transportation, a lot of literature on the climate change policy is published. The standard book on environmental economics is by Kolstad (2000), for example. Roger Guesnerie (2008) and Yang (2008) are among the most recent publications.

But a limited number of literatures are on the welfare impact analysis using the characteristics of CO_2 as negative public goods and further limited number of literatures are based on the game theory or bargaining theory analysis in addition to the characteristic as negative public goods. This study explores the welfare implication analysis, using the characteristic of negative public goods, by game theory and bargaining theory in order to depict more general situation than competitive market of emission allowance trading in addition to reduction level or emission allowance allocation stage.

Lindahl-Bowen-Samuelson Condition

Lindahl-Bowen-Samuelson Condition

The condition for the allocation in the economy with a public good to be Pareto efficient is that the sum of all members' marginal rate of substitution of private

goods for the public good is equal to the marginal rate of transformation of private goods for the public good.

$$\sum_{i=1}^{n} \frac{u_{s+j}^{i}}{u_{r}^{i}} = \frac{F_{s+j}}{F_{r}} (i = 1, 2, \ldots, n; r = 1, 2, \ldots, s; j = 1, 2, \ldots m) \tag{6}$$

n is the number of the players. s is the number of private goods and r is their index. m is the number of public goods and j is their index. u is the utility function. F is the production function.

This is the condition of Lindahl-Bowen-Samuelson (=LBS condition) based on Samuelson (1954). The CO_2 emission quantity is the negative public good. So in the case of the CO_2 emission, we could directly use the LBS condition for the Pareto efficient allocation of the CO_2 emission.

Extension of LBS Condition to Consumption Externalities

In the presence of external effect from the consumption as well as that from production, we can use the extension of the Lindahl-Bowen-Samuelson according to the work of Tadenuma (2003, 2005), which extended the LBS condition to the cases where consumption activities also generate greenhouse gases. The following derivation of the extension of LBS condition to consumption externalities is in Tadenuma (2003, 2005). Here, we introduce them so that we can later extend them further to include uncertainty.

There are n countries, $N = 1, \ldots, n$. Let $y_i \in R_+$ denote the gross domestic product (GDP) of country $i \in N$, $c_i \in R_+$ the consumption of country i. Both production and consumption are accompanied by emissions of greenhouse gases. Let $x_i^p \in R_+$ denote the emission of greenhouse gases from production.

The relation of x_i^p and y_i is represented by the function $x_i^p = f_i(y_i)$, where $f_i' > 0$, $f_i'' > 0$.

Let $x_i^c \in R_+$ denote the emission of greenhouse gases from consumption. The relation of x_i^c and c_i is represented by the function $x_i^c = g_i(c_i)$, where $g_i' > 0$, $g_i'' \geq 0$.

Here, we assume, just as in Tadenuma (2003, 2005), $f_i'' > 0$and $g_i'' \geq 0$ so that the values of the CO_2 emission functions from production and consumption are increasing or nondecreasing to the right similar to the standard assumption of production cost function.

Let $x_i \equiv x_i^p + x_i^c$ be the total emission of greenhouse gases of country i, and let $X \equiv \sum_{i \in N} x_i$ be the global emission of greenhouse gases.

We assume that there is an amount $\widehat{X}$ of global emission of greenhouse gases such that the human beings cannot survive if the emission exceeds $\widehat{X}$. Each country i has the preferences over pairs $(c_i, X) \in R_+ \times \left[0\widehat{X}\right]$ of its own consumption and a global amount of emissions of greenhouse gases. The preferences are represented

by a continuously differentiable and strictly quasi-concave function $V_i : R_+ \times \left[0\widehat{X}\right] \to R$. We call the function V_i the welfare function of country i.

Problem A

$$\max_{(\mathrm{y},\mathrm{c},x)\in R_+^{3n}} V_i\left(c_i, \sum_{h\in N} x_h\right) \tag{7}$$

subject to

$$x_j = f\left(y_j\right) + g\left(c_j\right)(\forall j \in N) \tag{8}$$

$$\sum_{h\in N} y_h = \sum_{h\in N} c_h \tag{9}$$

$$V_j\left(c_j, \sum_{h\in N} x_h\right) = \breve{V}_j(\forall j \in N, j \neq i) \tag{10}$$

The condition (10) means that other players are at the optimal level of utility at $\breve{V}_j \equiv V_j\left(c_j^*, \sum_{h\in N} x_j^*\right) \in R$.

Solving this problem, we can get the extended condition of LBS to include the external effect from consumption. The Lagrangian for the problem A is as follows;

$$\begin{aligned} &L\left(\left(c_h\right)_{h\in N}, \left(x_h\right)_{h\in N}, \left(y_h\right)_{h\in N}, \left(\lambda_h\right)_{h\in N}, \left(\gamma_h\right)_{h\in N}, \delta\right) \\ &\equiv V_i\left(c_i, \sum_{i\in N} x_h\right) - \sum_{j\neq i} \lambda_j \left(V_j\left(c_j, \sum_{h\in N} x_h\right) - \breve{V}_j\right) \\ &\quad - \sum_{j\in N} \gamma_j \left(x_j - f_j(y_i) - g_j\left(c_j\right)\right) - \delta\left(\sum_{h\in N} y_h - \sum_{h\in N} c_h\right) \end{aligned} \tag{11}$$

From the first-order condition,

$$\frac{\partial V_i\left(c_i^*, \sum_{h\in N} x_h^*\right)}{\partial c_i} + \gamma_i g_i{}'\left(c_i^*\right) + \delta = 0 \tag{12}$$

$$\frac{\partial V_i\left(c_i^*, \sum_{h\in N} x_h^*\right)}{\partial X} - \sum_{j\neq i} \lambda_j \frac{\partial V_j\left(c_j^*, \sum_{h\in N} x_h^*\right)}{\partial X} - \gamma_i = 0 \tag{13}$$

$$\gamma_i f_i'\left(y_i^*\right) - \delta = 0 \tag{14}$$

and for each $j \neq i$,

$$-\lambda_j \frac{\partial V_i\left(c_i^*, \sum_{h \in N} x_h^*\right)}{\partial c_j} + \gamma_j g_j'\left(c_j^*\right) + \delta = 0 \tag{15}$$

$$\frac{\partial V_i\left(c_i^*, \sum_{h \in N} x_h^*\right)}{\partial X} - \sum_{j \neq i} \lambda_j \frac{\partial V_j\left(c_j^*, \sum_{h \in N} x_h^*\right)}{\partial X} - \gamma_j = 0 \tag{16}$$

$$\gamma_j f_j'\left(y_j^*\right) - \delta = 0 \tag{17}$$

Solving these equations, we get the following extended condition of LBS including the consumption externality, which is exactly the same as in Tadenuma (2003, 2005).

Extended Condition of LBS for Consumption Externalities
The allocation (y^*, c^*, x^*) is Pareto efficient, if the following is satisfied.

$$\sum_{i \in N} \nu_i \left(c_i^*, \sum_{h \in N} x_h^* \right) \left(f_i'\left(y_i^*\right) + g_i'\left(c_i^*\right) \right) = 1 \tag{18}$$

$$\nu_i\left(c_i^*, X\right) \equiv \left| \frac{\dfrac{\partial V_i\left(c_i^*, X\right)}{\partial X}}{\dfrac{\partial V_i\left(c_i^*, X\right)}{\partial c_i}} \right|$$

This is the extension of Lindahl-Bowen-Samuelson condition in a sense that the impacts of CO_2 emission from consumption as well as that of production are considered. Specifically, at Pareto optimal allocation, the weighted sum of the marginal rate of substitution of consumption for global emission of GHGs over all the countries is equal to one, where each weight is the sum of the marginal emission from production and the marginal emission from consumption in each country.

Extension of LBS Condition to Utility with Uncertainty
So far, we deal with the Pareto optimal condition with a negative public good. This setting has no uncertainty. In other words, the setting is based on perfect information.

Now we try to extend the LBS condition further to uncertain world. If we add the uncertainty to utility function, then **Problem** A becomes the new maximization problem with the uncertainty. But in order to track the utility function and

constraints, we need to set the structure of the relationship between the uncertainty and the other factors in utility function, namely, consumption c_i, production y_i, and their emission levels $f_i(y_i)$ and $g_i(c_i)$.

In order to set the structure, we introduce the following assumption.

Assumption 1

The uncertainty is linearly separable from production, consumption, and their emission functions. In other words, the uncertainty does not exist in production y_i, consumption c_i, their emission function $f_i(y_i)$ or $g_i(c_i)$, or their relationship in the utility function.

This means that the uncertainty is not about observation accuracy or accounting consistency, but is purely the remaining category other than human activities, i.e., consumption expenditures, or the emission amount of CO_2 from each country's human activities.

So this uncertainty could be the other type of uncertainty after we know the exact amount of CO_2 emission. This could be, for example, such uncertainty about the net ultimate effect of CO_2 emission through the earth ecology system on our utility level even if we know the exact level of consumption expenditures and the entailing exact emission level of CO_2 in each country.

In the aviation sector, the best estimate still have ± 30 % uncertainties about the effect of CO_2 even if we know the exact amount of fuel burn or CO_2 concentration in the atmosphere.[9] These scientific uncertainties are typical and persistent in the discussion of policy formulation about global climate change. What kinds of effect these uncertainties have on the negotiation by countries and organizations are very much central to the analysis of the study of bargaining mechanism of climate change policy. These uncertainties can be separable from fuel burn activity itself and CO_2 concentration in the atmosphere from the international aviation sector, since they are the uncertainties that remain even if we know the exact amount of emission level.

(continued)

[9]According to"6 Potential Climate Change from Aviation" in IPCC (1999), CO_2 is, unlike ozone and water vapor perturbations, one of well-mixed gases, and there is small uncertainty in calculating radiative forcing (RF, a single measure of climate change defined by IPCC, which calculates the global annual average of radiative imbalance ($W/m2$) to the atmosphere-land-ocean system caused by anthropogenic perturbations and sets the RF of preindustrial atmosphere to be zero). Still the RF for aviation CO_2 in 1992 based on NASA-1992 aviation scenario, for example, is estimated to be +0.018($W/m2$) with a likely range of ± 30 % that includes uncertainties in the carbon cycle and in radiative calculations for a fixed amount of fuel burn (160.3(*million tons/year*)) and a fixed CO_2 concentration level (1.0 ppmv). Also, while the persistent linear contrails have relatively small impact on the environment, other spreading types of contrail from global aviation have no best estimates of their effects on cirrus cloudiness. Global effect of aviation aerosol on background cloudiness remains unknown according to IPCC report (IPCC 2007b).

As we already mentioned earlier, the ICAO agreed to collect CO_2 emission data from its member countries. This measure will significantly reduce the uncertainties about level of CO_2 emission from production or consumption in the international aviation sector. Also that measure makes the typical scientific uncertainties relatively more relevant in the welfare analysis on climate change from the international aviation sector. So it is necessary and relevant, in our view, to include such scientific uncertainties in welfare analysis. Here, we are capturing these kinds of uncertainties.

Based on **Assumption 1**, the uncertainty is a rather limited structure in the welfare function. To include uncertainties around production, consumption, or their emission functions and to combine them with the typical scientific uncertainties are very much desirable for the deeper analysis. This, however, could drastically enhance the requirement of mathematical treatment, resulting in the complexity.

Here, we start with the very simple structure but with relevant kind of uncertainties in utility function as the beginning to be able to capture the situation in the real world where the information is not always perfect and there remain uncertainties.

By **Assumption 1**, our uncertainty is linearly separated from production y_i, consumption c_i, or their emission function $f_i'(y_i)$ and $g_i(c_i)$.

With this assumption of the linear separability of uncertainty, **Problem** A now becomes **Problem** B below. By solving **Problem** B, Lindahl-Bowen-Samuelson condition can be extended further to the situation where uncertainty exists.

Problem B

$$\max_{(y,c,x)\in R_+^{3n}} E\left[V_i\left(c_i, \sum_{h\in N} x_h, \varepsilon\right)\right] \tag{19}$$

subject to

$$x_j = f\left(y_j\right) + g\left(c_j\right)(\forall j \in N) \tag{20}$$

$$\sum_{h\in N} y_h = \sum_{h\in N} c_h \tag{21}$$

$$E\left[V_j\left(c_j, \sum_{h\in N} x_h, \varepsilon\right)\right] = \breve{V}(\forall j \in N, j \neq i) \tag{22}$$

ε could be a random variable according to any probability distribution. In this sense, since we do not know the probability distribution of ε yet, what ε represents is not "risk" but "uncertainty" in the meaning of Frank Knight's terminology.

Also notice that ε is introduced to all the countries, is common to all, and is not varying from one county to another. In this sense, all the countries share the common uncertainty, which is very much the characteristic of typical scientific uncertainties surrounding climate change.

Because of **Assumption 1**, we can describe the equality constrains without quoting ε.[10]

But solving **Problem** B is not simple. Here, we introduce additional assumption.

First, we define $\overline{V}_i$ as the expected value of $V_i\left(c_i, \sum_{h\in N} x_h, \varepsilon\right)$;

$$\overline{V}_i\left(c_i, \sum_{h\in N} x_h\right) \equiv E\left[V_i\left(c_i, \sum_{h\in N} x_h, \varepsilon\right)\right] \tag{23}$$

Assumption 2
ε is from normal distribution, $N(\mu, \sigma^2)$ and utility function is CARA (constant absolute risk aversion) utility function.[11]

Under **Assumption 1** and **Assumption 2**, Eq. 23 becomes

$$\begin{aligned}\overline{V}_i\left(c_i, \sum_{h\in N} x_h\right) &= E\left[V_i\left(c_i, \sum_{h\in N} x_h, \varepsilon\right)\right] \\ &= E\left[-\exp\left\{-\eta_i\left(H_i\left(c_i, \sum_{h\in N} x_h\right) + \varepsilon\right)\right\}\right]\end{aligned} \tag{24}$$

where $H_i\left(c_i, \sum_{h\in N} x_h\right)$ is the relationship function between c_i and $\sum_{h\in N} x_h$

[10]The uncertainty here is only one dimension. The structure, however, can be extended to multidimension uncertainties without loss of generality.

[11]CARA utility function has the general form $V = A1 + A2\exp\{-\eta c\}$, with η indicating coefficient of absolute risk aversion, i.e., degree of risk aversion. We can arbitrarily set the value $A1$ and $A2$. In the following case, we use $A1 = 0$ and $A2 = -1$ for simplicity.

Although, in this case, the welfare function returns a negative value, we can interpret this negative welfare value as the difference from the highest welfare value, for example.

$A1$ and $A2$ could be considered as the location adjusting parameter and scale parameter, respectively, for the CARA utility function.

without any uncertainty. This can be possible because of the linear separability of uncertainty from other economic activities under **Assumption 1** and the CARA utility function's characteristics form **Assumption 2**.

So we get,

$$\begin{aligned}\overline{V}_i\left(c_i, \sum_{h\in N} x_h\right) &= -\exp\left\{-\eta_i\left(H_i\left(c_i, \sum_{h\in N} x_h\right)\right)\right\} E[\exp\{\eta_i(\varepsilon)\}] \\ &= -\exp\left\{-\eta_i\left(H_i\left(c_i, \sum_{h\in N} x_h\right)\right) - \mu\eta_i + \frac{\eta_i^2\sigma^2}{2}\right\}\end{aligned} \tag{25}$$

Notice that under **Assumption 2**, $\varepsilon \sim N(\mu, \sigma^2)$;

$$\begin{aligned}&E[\exp\{-\eta(\varepsilon)\}] \\ &= \int_{-\infty}^{\infty} e^{-\eta\varepsilon} \frac{1}{\sqrt{2\pi}\sigma} e^{\frac{-(\varepsilon-\mu)^2}{2\sigma^2}} d\varepsilon \\ &= e^{-\eta\mu+\frac{\eta^2\sigma^2}{2}} \frac{1}{\sqrt{2\pi}\sigma} \int_{-\infty}^{\infty} e^{\frac{-\left(\varepsilon-\left(\mu-\sigma^2\eta\right)\right)^2}{2\sigma^2}} d\varepsilon \\ &= e^{-\eta\mu+\frac{\eta^2\sigma^2}{2}} \cdot 1.\end{aligned}$$

Now we can derive the extension of LBS condition to include the uncertainty described above. Equations 19–22 become as follows.

Problem B ⋆

$$\max_{(y,c,x)\in R_+^{3n}} \overline{V}_i\left(c_i, \sum_{h\in N} x_h\right) \tag{26}$$

subject to

$$x_j = f\left(y_j\right) + g\left(c_j\right) (\forall j \in N) \tag{27}$$

$$\sum_{h\in N} y_h = \sum_{h\in N} c_h \tag{28}$$

$$\overline{V}_j\left(c_j, \sum_{h\in N} x_h\right) = \breve{V}\,(\forall j \in N, j \neq i) \tag{29}$$

By Eq. 25, we can treat Eqs. 26–29 without any random variables. These equations in **Problem B** ⋆ can be solved by the usual maximization problem just as in **Problem** A.

Define the Lagrangian as follows:

$$\begin{aligned} &L\left((c_h)_{h\in N},(x_h)_{h\in N},(y_h)_{h\in N},(\lambda_h)_{h\in N},(\gamma_h)_{h\in N},\delta\right) \\ &\equiv \overline{V}_i\left(c_i,\sum_{i\in N}x_h\right)-\sum_{j\neq i}\lambda_j\left(\overline{V}_j\left(c_j,\sum_{h\in N}x_h\right)-\breve{V}_j\right) \\ &-\sum_{j\in N}\gamma_j\left(x_j-f_j(y_i)-g_j(c_j)\right)-\delta\left(\sum_{h\in N}y_h-\sum_{h\in N}c_h\right). \end{aligned} \tag{30}$$

Notice that the term $V_i\left(c_i,\sum_{h\in N}x_h\right)$ in the Lagrangian (11) in **Problem** A now becomes $\overline{V}_i\left(c_i,\sum_{h\in N}x_h\right)$ in the Lagrangian (30) in **Problem B** $\star$.

Other than this, the Lagrangian is the same as in solving **Problem** A.

Thus, we can get the following familiar condition.

As the first-order condition,

$$\frac{\partial\overline{V}_i\left(c_i^*,\sum_{h\in N}x_h^*\right)}{\partial c_i}+\gamma_i g_i{}'\left(c_i^*\right)+\delta=0 \tag{31}$$

$$\frac{\partial\overline{V}_i\left(c_i^*,\sum_{h\in N}x_h^*\right)}{\partial X}-\sum_{j\neq i}\lambda_j\frac{\partial\overline{V}_j\left(c_j^*,\sum_{h\in N}x_h^*\right)}{\partial X}-\gamma_i=0 \tag{32}$$

$$\gamma_i f_i{}'\left(y_i^*\right)-\delta=0 \tag{33}$$

and for each $j\neq i$,

$$-\lambda_j\frac{\partial\overline{V}_i\left(c_i^*,\sum_{h\in N}x_h^*\right)}{\partial c_j}+\gamma_j g_j{}'\left(c_j^*\right)+\delta=0 \tag{34}$$

$$\frac{\partial\overline{V}_i\left(c_i^*,\sum_{h\in N}x_h^*\right)}{\partial X}-\sum_{j\neq i}\lambda_j\frac{\partial\overline{V}_j\left(c_j^*,\sum_{h\in N}x_h^*\right)}{\partial X}-\gamma_j=0 \tag{35}$$

$$\gamma_j f_j{}'\left(y_j^*\right)-\delta=0 \tag{36}$$

Notice also that

$$\frac{\partial\overline{V}_i}{\partial X}=\overline{V}_i(-\eta_i)\frac{\partial H_i}{\partial X},\ \frac{\partial\overline{V}_i}{\partial c_i}=\overline{V}_i(-\eta_i)\frac{\partial H_i}{\partial c_i}$$

We get the following result:

$$\nu_i(c_i, X) \equiv \left| \frac{\dfrac{\partial \overline{V}_i(c_i, X)}{\partial X}}{\dfrac{\partial \overline{V}_i(c_i, X)}{\partial c_i}} \right| = \left| \frac{\overline{V}_i(\eta_i) \dfrac{\partial H_i}{\partial X}}{\overline{V}_i(\eta_i) \dfrac{\partial H_i}{\partial c_i}} \right| = \left| \frac{\dfrac{\partial H_i(c_i, X)}{\partial X}}{\dfrac{\partial H_i(c_i, X)}{\partial c_i}} \right| \tag{37}$$

By solving Eqs. 31–36 and Eq. 37, we can describe the extended condition of LBS for uncertainty.

Proposition 1: Extended Condition of LBS for Uncertainty
Under **Assumption 1** and **Assumption2**, at Pareto optimal allocation, the weighted sum, over all the countries, of the marginal rate of substitution of consumption for global emission of GHGs, which is composed only of the certain part of the utility function with uncertainty, is equal to one, where each weight is the sum of the marginal emission from production and the marginal emission from consumption in each country.

$$\sum_{i \in N} \nu_i \left(c_i^*, \sum_{h \in N} x_h^* \right) \left(f_i'(y_i^*) + g_i'(c_i^*) \right) = 1 \tag{38}$$

$$\nu_i(c_i^*, X) \equiv \left| \frac{\dfrac{\partial H_i(c_i^*, X)}{\partial X}}{\dfrac{\partial H_i(c_i^*, X)}{\partial c_i}} \right|$$

This is the extended condition of LBS to include the uncertainty under **Assumption 1** and **Assumption 2**. Notice that in $\nu_i(c_i^*, X)$, we have $H_i(c_i^*, X)$, instead of $V_i(c_i^*, X)$. $H_i(c_i^*, X)$ is the certain (= without any uncertainty) part of the utility function V_i $\left(c_i^*, \sum_{h \in N} x_h, \varepsilon \right)$ with uncertainty ε under **Assumption 1** and **Assumption 2**.

Welfare Implication with Numerical Examples

Basic Model

Let $N = 1, 2$. The emission functions are defined as follows: for every $i \in N$,

$$f_i(y_i) = y_i^2 \tag{39}$$

$$g_i(c_i) = c_i \tag{40}$$

For each $i \in N$, the welfare function $V_i : \in {R_+}^3 \rightarrow R$ is expressed with the assumption of CARA utility function as follows:

$$E[V_i(c_i, X, \varepsilon)] = E[-\exp\{-\eta_i(H_i + \varepsilon)\}] \tag{41}$$

$$H_i = c_i^{a_i}(10 - X)^{1-a_i} (0 \le a_i \le 1) \tag{42}$$

Under the assumption of the normal distribution for ε, we can get the following:

$$\overline{V}_i(c_i, X) = -\exp\left\{-\eta_i\left(c_i^{a_i}(10 - X)^{1-a_i}\right) - \mu\eta_i + \frac{\eta_i^2\sigma^2}{2}\right\} \tag{43}$$

If we pick the specific numbers for parameters $a_1 = 0.8$, $a_2 = 0.2$, then we have the following equations:

$$\overline{V}_1(c_1, X) = -\exp\left\{-\eta_1\left(c_1^{0.8}(10 - X)^{0.2}\right) - \mu\eta_1 + \frac{\eta_1^2\sigma^2}{2}\right\} \tag{44}$$

$$\overline{V}_2(c_2, X) = -\exp\left\{-\eta_2\left(c_2^{0.2}(10 - X)^{0.8}\right) - \mu\eta_2 + \frac{\eta_2^2\sigma^2}{2}\right\} \tag{45}$$

Notice that parameters $a1$ and $a2$ represent the weights on consumption and on climate change effect in their utility functions. If $a_1 > a_2$, country 1 puts more weight on consumption than country 2, and country 1 puts less weight on climate change effect than country 2.[12]

With Eqs. 44 and 45 as well as the extended condition of LBS for uncertainty, we can derive the Pareto frontier, bargaining frontier, disagreement point, and Nash product[13] based on Tadenuma (2003, 2005), which is the model for no uncertainty.

Here, we do not go into the details for these frontiers and points, which are explained in Tadenuma (2003, 2005). But the gist of them is as follows.

Pareto frontier is the locus of the welfare vectors of the two countries under our study that can be attained by satisfying the extended condition of LBS depicted in Eqs. 18 and 38. Namely, the vectors(V_1, V_2) must satisfy the following relationships in our numerical example:

$$V_1 = \overline{V}_1(c_1(c_2), X(c_2))$$

$$V_2 = \overline{V}_2(c_2, X(c_2))$$

$$(c_1 + c_2 + 1)\left(\frac{c_1}{4} + 4c_2\right) - 10 + \frac{(c_1 + c_2)^2}{2} + c_1 + c_2 = 0$$

[12]According to sensitivity analysis, the more a_1 and a_2 are different, the more bargaining frontier spread. This means more room for the two countries to bargain. If these parameters are closer, the bargaining frontier is getting tighter. This means less room for the two countries to bargain.

[13]The bargaining model is theoretically founded in Nash (1950).

$$X(c_2) = \frac{(c_1 + c_2)^2}{2} + c_1(c_2) + c_2$$

The last two equations can be derived from the extended condition of LBS in (18) or (38). The locus welfare vectors (V_1, V_2) are drawn for the relevant value for c_2.

Bargaining frontier is the locus of the welfare vectors that are attained at various levels of the total emission X with a given proportional rule, i.e., the share of initial emission allowances, (θ_1, θ_2) in our case, and emission allowance trading, entailing the trade price $q(X)$. Namely, the vectors (V_1, V_2) in the locus are those that satisfy the following relationships:

$$V_i = \overline{V}_i(c_i(X), X)$$

$$c_i = \frac{1}{4q(X)(1 + q(X))} + \frac{q(X)\theta_i X}{1 + q(X)}$$

$$X = \frac{1}{4q^2} + \frac{1}{4q^2} + \frac{1}{q}$$

In these settings, $q(X)$ is the inverse function of the last equation. Over the relevant range of X, we have the locus of (V_1, V_2), which is the bargaining frontier. Notice that the bargaining frontier depends on the initial allocation, (θ_1, θ_2). The bargaining frontier changes its shape according to the value of the initial allocation.

Disagreement point of the Nash bargaining theory is the Nash equilibrium welfare levels of the two countries in the emission game without any regulation. Specifically, we have the two players who do not bargain with each other and take the other's emission level as given. Their utility function is as follows:

$$V_1 = \overline{V}_1 = -\exp\left\{-\eta_1\left(c_1^{0.8}\left(10 - x_2 - c_1^2 - c_1\right)^{0.2}\right) - \eta_1\mu + \frac{\eta_1^2\sigma^2}{2}\right\}$$

$$V_2 = \overline{V}_2 = -\exp\left\{-\eta_2\left(c_2^{0.2}\left(10 - x_1 - c_2^2 - c_2\right)^{0.8}\right) - \eta_2\mu + \frac{\eta_2^2\sigma^2}{2}\right\}$$

The best response functions are obtained by differentiating the functions with respect to c_i and setting the value to zero. Then, by solving these response function equations, the Nash equilibrium consumption, emissions, and welfare levels are derived. This vector of the derived welfare, which could be thought as what you get if you fail to bargain, is the disagreement point (d_1, d_2).

Nash product is defined by

$$(V_1 - d_1)(V_2 - d_2)$$

Before we go further, we first set the parameters as follows:

$$\mu = 0$$

$$\sigma = 1$$

$$\eta_1 = \eta_2 = 0.2$$

Also the initial allocations for the emission allowances for player 1 and player 2 are θ_1 and θ_2, respectively. We set these as follows:

$$\theta_1 = 0.925$$

$$\theta_2 = 0.075$$

Fig. 8 is the result loci for these frontiers and points.

Since our CARA utility function is the monotone transformation of the utility function in Tadenuma (2003, 2005), the shape of the frontiers are quite similar except for their location and scale. The same comparison can be derived about the disagreement points. As in Tadenuma (2003, 2005), Pareto frontier and bargaining frontier touch at one point, where each player's emission levels are equal, i.e., $x_1^* = x_2^*$. In these settings, disagreement point is within the bargaining frontier. So it could be possible that starting from disagreement point both players can reach higher utility level by bargaining. But as Fig. 8 shows, limit of bargaining is not as

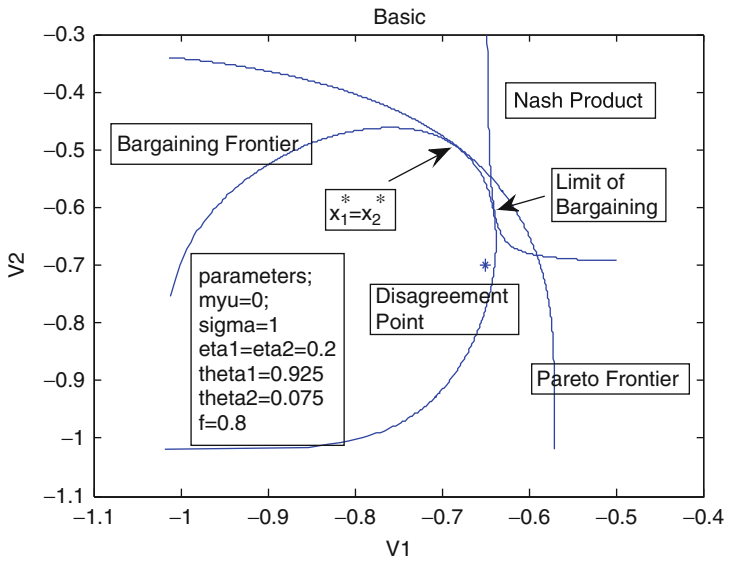

Fig. 8 Frontiers and limits of asymmetric world

high as the Pareto frontier, of which is the point where each player's emission is the same, namely, $x_1^* = x_2^*$.

Symmetric Structure World

If both players' H_i function is the same function (their degree of risk averse was already set to be the same, i.e., $\eta_1 = \eta_2 = 0.2$), then both players' Vi functions are as follows:

$$\overline{V}_1(c_1, X) = -\exp\left\{-\eta(c_1(10 - X)) - \mu\eta + \frac{\eta^2\sigma^2}{2}\right\} \tag{46}$$

$$\overline{V}_2(c_2, X) = -\exp\left\{-\eta(c_2(10 - X)) - \mu\eta + \frac{\eta^2\sigma^2}{2}\right\} \tag{47}$$

Furthermore, the initial allocation is even, namely,

$$\theta_1 = 0.5$$

$$\theta_2 = 0.5$$

Under the setting, the bargaining frontier collapses as in Fig. 9. In this world, everything is symmetric. So both players can start with the disagreement point

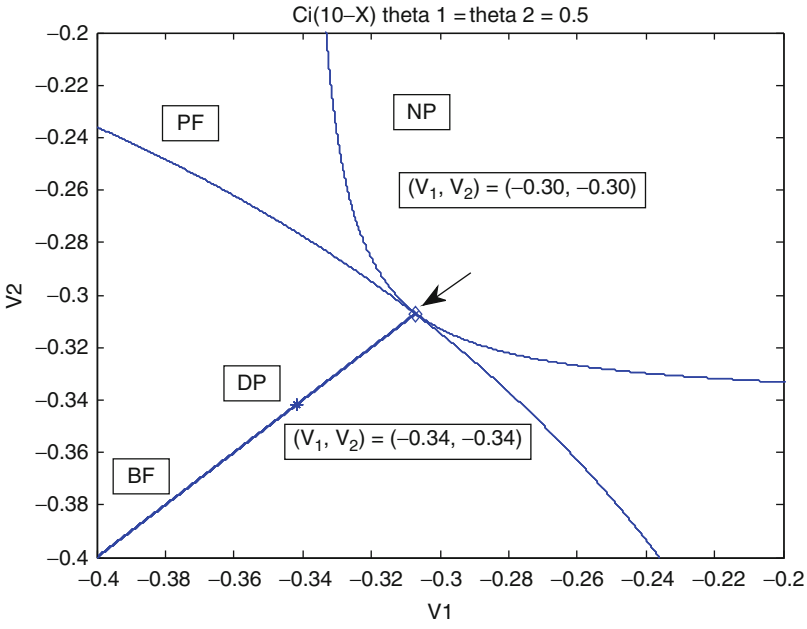

Fig. 9 Frontiers and limits of symmetric world

(DP), moving along the bargaining frontier, now a line, and the two can reach the Pareto frontier and realize the social efficiency.

If the real world is symmetric as in Fig. 9, then the bargaining could lead to social efficiency.

Impact of Uncertainty Increase

Back in the basic case, which is in Fig. 8, if the uncertainty increases, the σ would increase. In Fig. 10, we depict the world as σ increases, namely, $\sigma = 1, 2, 3, 4, 5, 6$. As the uncertainty, namely, σ, increases, the world shrinks to the lower left corner.

This means you have to settle for smaller level of utility. Under uncertainty increase settings, bargaining is almost surely more difficult than otherwise.

Asymmetric Risk Aversion

If player 1's risk aversion level is more than that of player 2, player 1's utility function changes like in Fig. 11.

The utility function is getting more skewed into the upper left as the risk aversion parameter η increases, namely, $\eta = 0.2, 0.4, \ldots, 1.8, 2.0$.

Under these settings, player 1 evaluates more in the upper side of income, namely, higher x in Fig. 11, to compensate the lower evaluation for lower side of income. This is the content of risk aversion. As a result, under our parameter setting, player 1 needs more than player 2. So the world in Fig. 8 is skewed to the right to allocate more to player 1 just as in Fig. 12.

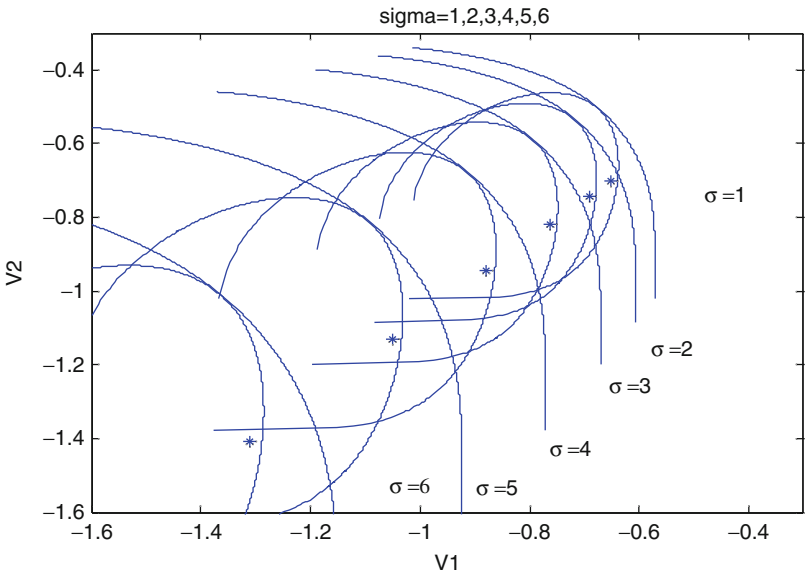

Fig. 10 As uncertainty increases, world shrinks

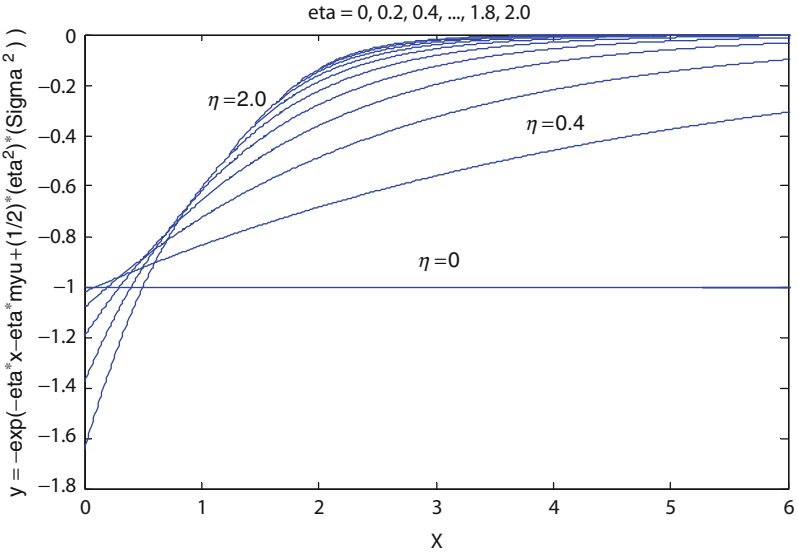

Fig. 11 CARA utility function skews as risk aversion increases

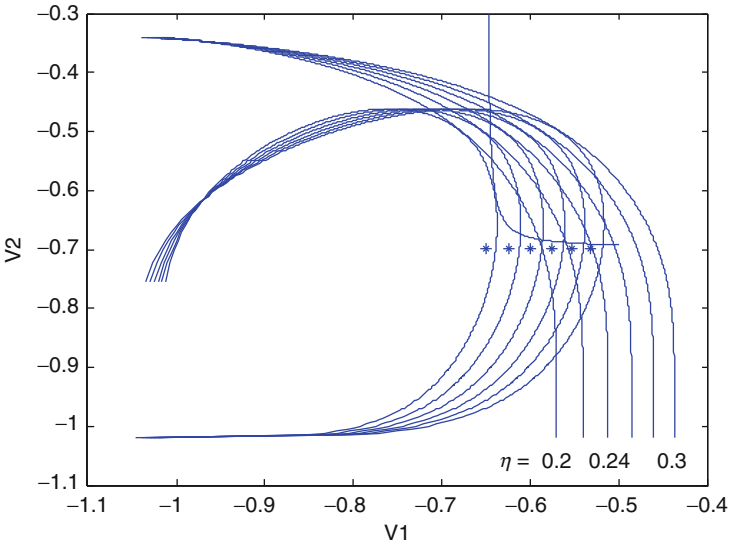

Fig. 12 Player 1 is getting more risk averse than player 2

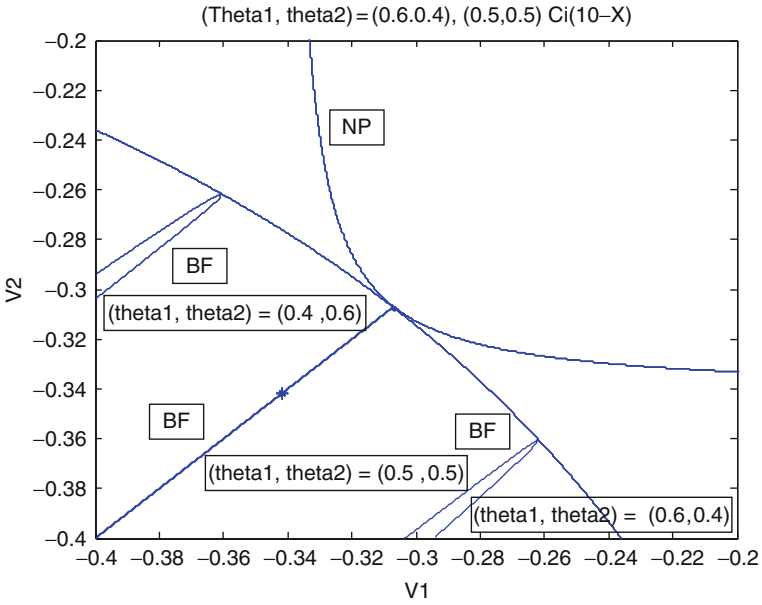

Fig. 13 Initial allocation perturbation in symmetric world

All things equal, if the risk aversion of one of the players is more than the other, the player could ask for more in bargaining, and this could lead to more difficult bargaining process since in the real bargaining process, you cannot see the other players' risk aversion parameter.

Initial Allocation Perturbation

To make the comparison easier, we go back to the even world in Fig. 9.

The initial allocation for each player is even in Fig. 9, namely,

$$\theta_1 = 0.5$$

$$\theta_2 = 0.5.$$

The disagreement point is on the bargaining frontier.

If the allocation is off from the even about 0.1 in our setting in Fig. 9, the bargaining frontier dislocates from the original collapsed bargaining frontier (line) to the upper side or lower side depending on the plus or minus of the deviation from the original allocation as in Fig. 13.

In these cases, the disagreement point, which does not move, is out of the bargaining frontier in either upper or lower case. Getting to the higher welfare level through bargaining starting from the disagreement point is not feasible, let alone attaining the social efficiency frontier.

Conclusion of the Theoretical Study

We performed simulation analysis on the international CO_2 emission allowances trading, especially on the effects on pricing of CO_2 emission allowances by including major players such as China, India, and Korea into the hypothetical global trading scheme according to noncooperative game-theoretic framework. As the three countries enter into the trading and their reduction obligation increases by 1 %, the emission allowance price goes up by about 33 cents. Also if the three countries improve their carbon intensity variation by 1 % (−1 %), then the emission allowance price goes up by 2 cents.

In the presence of negative public goods, i.e., CO_2 emission into the earth atmosphere, we extended the Lindahl-Bowen-Samuelson condition so as to include at least some class of the uncertainty into the utility. That is, under **Assumption 1** and **Assumption 2**, we introduce the CARA utility function and linearly separable uncertainty from consumption, production, and their emission functions. This kind of scientific uncertainty is typical in climate change policy.

If such uncertainty increases, then both Pareto frontier and bargaining frontier shrink and make the negotiation harder, since the players have to settle for less than before. If the risk preferences are different between the players, then the Pareto frontier and bargaining frontier skew. So the simple allocation rule, like the same percentage reduction for different countries, could be difficult to be agreed upon. Moreover, under the condition of asymmetric risk aversion levels and asymmetric utility structure, with uneven initial allocations of CO_2 allowances, it is shown that reaching the bargaining frontier, let alone Pareto frontier, by bargaining could be extremely difficult.

The policy implications from these results could be that if typical scientific uncertainties become large due to, for example, discovery of contradicting observations or people's losing confidence in the scientific researches by noticing some mistakes in the researches, then the negotiation process becomes very difficult. IPCC scientific research effort and keeping its research integrity are very important in the highly complex problems with large uncertainties like global climate change.

Also if the negotiating countries' preferences are very different (due to the difference of how much to put weight on climate change in their utility structure, for example), the adjusting efforts to decrease the differences (by transferring fund or technology so that the countries seeking development more than environment can get development cheaply or environmentally friendly) are more important.

Impact of Climate Change and Adaptation

Carbon Liability

Yoshihiro Fujii

Contents

Abstract

By the term "carbon liability," we mean a calculation of values approximating to the economic externalities of carbon emissions in the global economy, in relation to the totality of global economic activity. As a consequence of over two centuries of industrialization, the global carbon budget and its associated global carbon balance sheet have clearly diverged from a state of natural equilibrium. Deterioration of carbon budget has affected on asset value of energy intensive companies which have huge fossil fuel reserves, called as stranded assets. Three material identifiable, types of carbon risks, "cap-and-trade" schemes are important economic mechanism aiding both the rectification of these imbalances and restoration of natural carbon cycle disrupted by emissions of anthropogenic greenhouse gas (GHG) in both developed and emerging countries. Such schemes establish an economic value to carbon through open market trading. They serve to quantify and to reduce carbon risk, in accordance with appropriate and efficient economic regulation. Monetizing carbon liabilities through these market mechanisms is a

means to place boundaries on, and thus to mitigate, the uncertainties of carbon liability. This process of monetization may also transform market risk into an opportunity for economic exploitation.

Introduction

The Fifth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC 2014, AR5 (The Fifth Assessment Report of the Intergovernmental Panel on Climate Change 2014)) concluded that "human influence on the climate system is clear, and recent anthropogenic emissions of greenhouse gases are highest in history" and that "warming of the climate system is unequivocal, and since the 1950s." The certainty of the relation between increase in global average temperatures since the mid-twentieth century and increase in anthropogenic greenhouse gas(GHG) concentrations is defined as "extremely likely" rather than "very likely" in previous report (AR4, 2007) which means probability of causality increase 95 ~ 100 % in AR4 to 95 ~ 100 % in AR5. The report said "Climate change will amplify existing risks and create new risks for natural and human systems. Risks are unevenly distributed and are generally greater for disadvantaged people and communities in countries at all level of development." This means managing carbon balance sheets both in global economy and individual economic entities would be emerged critical issues.

Carbon Liability as a Concept in Accounting and in Ecology

Carbon Liability

This chapter focuses on the importance of these findings, in relation to the concept of "carbon liability" and its implications. By this term, it means a calculation of values related to the economic externalities of carbon emissions in the global economy and the process of apportioning those values, both in macroeconomic terms within the global economy and microeconomically, to achieve a more true economic value for each individual emitting entity. It can be referred to these processes as "carbon management."

What is a "carbon liability"? Liability is a concept which arises in accounting and in law. It means a legally enforceable obligation, whether imposed contractually or unilaterally or by civil society. The obligation on a citizen to pay tax is an example of a unilateral liability imposed by a government. From an accounting point of view, liability means a present obligation arising from past events. Its settlement is expected to result in an outflow of resources. The International Accounting Standards Board (IASB) sets out the accounting and disclosure requirements for provisions, contingent liabilities, and contingent assets as International Accounting Standards (IAS) 37. This chapter discusses the current definition.

Carbon liability has its roots in this environment of civil obligation. In recent years, governments have introduced regulations to restrict quantified volumes of

GHG (greenhouse gas) emissions by incorporated entities, a measure directed toward the public goods of controlling the unequivocal danger – an economic "bads" – of which is global warming. Thus "carbon liability" arises from an established tradition of state-initiated regulation.

Entities addressed by governments are required to meet the costs of their obligations using their own resources in order to comply with the demands of regulation. Liability in relation to carbon emissions differs in kind, however, from other forms of liability, in that it includes a lot of messy uncertainties about its causality and its composition. The IASB's International Financial Reporting Standards (IFRS) categorizes such instances as a "contingent liability," in the IFRS' words, "a possible obligation depending on whether some uncertain future event occurs" and "a present obligation but payment is not probable or the amount cannot be measured reliably." These characteristics correspond to the nature of carbon liability, which encompass the past, present, and future responsibilities for GHG emissions.

Carbon liability belongs in addition to a broader definition of environmental liability. This field has already been defined legally and in accounting terms in both the USA and the European Union. The US Environmental Protection Agency (EPA) has defined "environmental liability" as an obligation in environmental law to make a future expenditure to remedy the past or ongoing manufacture, use, release, or threatened release of a particular substance, or other activities that adversely affect the environment (Environmental Protection Agency 1996). This regulatory stance arose from a succession of environmental disasters in the USA during the 1970s and 1980s, which resulted in asbestos exposure and soil contamination and damage to people, property, and the natural environment. To prevent and remedy such damages, US legislators enacted the Comprehensive Environmental Responses, Compensation, and Liability Act (CERCLA), otherwise known as the "Superfund Act." It was enacted in 1980 then was amended as Superfund Amendment and Reauthorization Act (SARA) in 1986. Small Business Liability Relief and Brownfields Revitalization Act in 2002, respectively.

Drawing on this American legislation, the European Union constructed its own legal framework for the prevention and remediation of damages to the human and natural environment. In 2004, the EU Commission published its Directive on Environmental Liability (ELD), and it came into effect in all EU states in 2008. These legal frameworks on either sides of the Atlantic share common characteristics.

Drawing on these models, the US Federal Accounting Standards Board (FASB) and the IASB have developed an accounting framework on environmental liability. The FASB issued EITF 93-5, "Accounting for Environmental Liabilities," in 1993; in 1996, it was included in the Statement of Position (SOP 96-1, Environmental Remediation Liabilities) in the American Institute of Certified Public Accountants (AICPA). As noted earlier, the IASB has referred to environmental liabilities in its IAS 37 standard.

What definitions of "the environment" are used in these legal and accounting frameworks? The concept in those frameworks is very broad. For example, the Lugano Convention (Convention on Civil Liability for Damage Resulting from Activities Dangerous to the Environment, June 1993) which laid down fundamental

concepts of strict liability for environmental damages caused in EU territories considers environment to be the realm of all natural resources, both abiotic and biotic, such as air, water, soil, fauna and flora, and the interaction between the same factors, property which forms part of the cultural heritage and the characteristic aspects of the landscape.

Similarities and Differences Between the Concepts of Carbon Liability and Environmental Liability

It is clear that any concept of "carbon liability" should be considered in the context of an established corpus of environmental liabilities. Carbon emitted by corporations shares characteristics with other forms of environmental damage including, as already noted, cost of damages attributable to past or present commercial activities, including production of GHGs and/or their release into the atmosphere. To discharge these obligations, entities must pay the expenses of remediation or reparation from their own resources. In other words, this discharge of legal responsibilities under regulation entails for corporate entities an internalization of a type of cost control of carbon emissions – which was previously considered as an economic externality. What these similarities in definitions demonstrate is that they can be constructed the same kind of legal and accounting framework for carbon liabilities in order to manage resulting marginal costs to the environment and to society as a whole.

Similarities notwithstanding, the concept of carbon liability also has several differences from general environmental liability. Most importantly, GHGs are not in themselves toxic. This contrasts directly with the toxic or noxious characteristics of most general pollutants specified or implicated in legislation on environmental liability, such as asbestos, sulfur dioxide, heavy metals, etc. Directly and indirectly, the latter harm human health and the ecosystem. Carbon dioxide, the most common GHG and a primary factor in most cases of carbon liability, is not toxic in itself. It is merely one component in the atmosphere, a natural chemical by-product of all plant and animal life. Of course carbon monoxide (CO), which is chemically related to CO_2, is clearly toxic. In theory, CO_2 itself can be poisonous in high volumes; such a danger is however never likely in naturally occurring concentrations.

In this context, concentrations of CO_2, even in the most dangerous scenario simulated in the IPCC's AR5 toward the end of this century, will cause only *indirect* loss and damages, as part of the indirect consequences resulting from climate change. This indirect attenuated chain of causality presents serious difficulties in the calculation of carbon liability in society.

Cows' Belch Can Be Tradable Commodities

The planet is populated with very many agents of GHG emissions, whether animal, corporate, or human. Corporations contribute GHGs by their activities in resource consumption, in production and distribution, and in demand stimulation. Nature's emission processes include deforestation, volcanic eruptions, swamps, and wetlands. Even ruminant livestock in agriculture add to the emissions of animals: the human population, now on the cusp of 7.0 billion, is of course the most highly polluting species of fauna. A belch from a cow or other ruminant emits methane, a GHG with

28 times the warming power of CO_2. Estimates of global warming potential by methane have increased from 21 in AR4 to 28 in AR5.

The Worldwatch Institution, an independent research organization, has estimated that GHG emissions from ruminants contribute between 10 % and 15 % of the planet's annual GHG total from all sources (Goodland and Anhang 2009). The legal implication is clear: the belch of a cow might be regarded as a carbon liability for its owner. A rancher might compensate by participating in carbon trading, offsetting the wider economic cost of methane from his livestock. If he can find a way of reducing methane from his cows, he trade a carbon credit on the free market linked to his animals thereby earning additional income besides selling milk or meat. Actually, Idemitsu Kosan, a Japanese petroleum company, with Hokkaido University has developed a new food for cattle to reduce output of methane gas bovine eructation in 2007.

Besides biology, GHGs are emitted through innumerable economic and industrial processes in manufacturing, power generation, farming, logging, transportation, and so on. These are in addition to the emissions of individual humans, of course. Consequently, it is very difficult to restrict GHG emissions from all sources. This near-universal emission by billions of agents and processes, of gases which are very often essential to life itself, presents a completely different, universally pervasive causality which is more complex than with other recognized pollutants. This difference presents a major obstacle in forming policies to reduce emissions and to manage carbon, both in macroeconomic policy and in the carbon management strategies of individual corporations.

Different Legal Treatments of Carbon Liability

As noted above, the concept of carbon liability can be seen as an obligation like others in environmental law. Its treatment and remedies differ from jurisdiction to jurisdiction, however. Developed countries which ratified the Kyoto Protocol recognized a duty to reduce their GHG emissions from 1990 levels. On the other hand, developing countries including even major emitters such as China, India, and Brazil face only a voluntary, nonbinding commitment to reduce their own emissions. These differences are called "common but differentiated responsibilities."

Some additional differences remained between developed countries. Targets in GHG reductions to be achieved before 2012 under the Kyoto Protocol range from 6 % for Japan, 7 % for the EU, and 8 % for the USA. After promising quantified reductions, the USA failed to ratify the agreement and left for domestic political reasons. As a result, even in developed countries, there have been different types of legal measures for reducing GHG emissions. These have affected the respective impact of carbon liabilities under different jurisdictions, both in terms of global macroeconomic policy and in relation to the responses and obligations of individual corporations.

In consequence, discussions on the post-Kyoto framework focused as much on the differences between the commitment and stances of developing countries as on the importance of emerging economies such as China, India, and Brazil. Through a series of COP (Conference of the Parties of UNFCCC) meetings, developed and

developing countries have agreed to fill up these differences in the climate change negotiations beyond 2020. At COP17 in Durban of South Africa in 2011, they all agreed to play their part to the best of their ability and all will be able to reap the benefits of success together based on "common responsibility" and some kinds of "burden sharing."

Contents of the new framework would be discussed and expected to reach the legal agreement at COP 21 in Paris at the end of 2015, although there will be still many things remained unclear.

Invisible to Visible

Impact of Potential Carbon Cost

What consequences do carbon liabilities carry for carbon-emitting corporations? There are a lot of works for this subjects, and one of them is a renown study by Trucost, which is a UK-based environmental consulting firm published under the auspices of the UN's Principles for Responsible Investment and the United Nations Environment Program (UNEP), which reveals some interesting answers. It calculates that the full cost to the world's biggest companies of GHG emissions, pollution, and other environmental damage was almost $6.6 trillion in 2008. This figure is 20 % larger than the $5.4 trillion decline in the value of pension funds in developed countries caused by the global financial crisis in 2007/2008 and equivalent to 11 % of world's GDP (UNEP FI and PRI 2010).

IPCC also estimates macroeconomic impact by carbon liability in AR5, as the aggregate economic costs of mitigation. It's mitigation scenarios that are likely to limit warming to below 2 °C through the twenty-first century relative to preindustrial levels entail losses in global consumption – not including benefits of reduced climate change as well as co-benefits in global consumption – of 1–4 % (median, 1.7 %) in 2030 and 2–6 % (median, 3.4 %) in 2050 and 3–11 % (median, 4.8 %) in 2100 relative to consumption in baseline scenarios (BAU) that grow anywhere from 300 % to more than 900 % over the century. Monetary value of world's GDP (equivalent to global consumption) in 2012 is $72.7 trillion, which means carbon liability for mitigating cost below 2 °C would be $1.2 trillion in 2030 and $2.5 trillion in 2050 and $3.5 trillion. These figures would be manageable for global economy. On the contrary, carbon liability will expand from $220 trillion to $650 trillion over the century in BAU scenarios. It couldn't be manageable for all of us. This means that carbon liability is quite variable depending on policy selection.

In addition to this huge mitigation cost, we have to count adaptation cost as carbon liability. United Nations Environment Program (UNEP) estimates that the cost of adapting to climate change in developing countries is likely to reach as high as $150 billion by 2025/2030 and $250–500 billion per year by 2050 (UNEP 2014a). These figures are two to three times higher than estimate in AR5 because UNEP uses the latest figures.

In calculating carbon impacts over the entire global economy, it must consider the tasks both of quantifying carbon impacts on the planet's ecosystem and, secondly, of

monetizing these carbon liabilities. The first task, an impact assessment of GHG volumes, can be focused on.

Quantifying Carbon Impacts

The fast developing science of climate change obliges all countries on this planet to cut very quickly the GHG concentrations in the atmosphere back toward sustainable levels. Based on the IPCC's AR5, although it has been already well known in the world, concentrations of CO_2 in the planet's atmosphere were approximately 390 ppm in 2011, an increase of about 100 ppm – or 40 % – from levels before the Industrial Revolution began in Europe in the late eighteenth century. Over the past two centuries, the growth in GHG concentrations has averaged 1.9 ppm per year. The long-term rise in GHGs is calculated to have pushed up average global temperatures by 0.85 °C during 1880–2012 and to have caused sea levels to rise almost 19 cm across all oceans, according to IPCC AR5.

IPCC said anthropogenic greenhouse gas emissions are mainly driven by population size, economic activities, lifestyle energy use, land use patterns, technologies, and climate policy. They have introduced new estimate methods called the "Representative Concentration Pathways (RCP)" divided into four pathways to the end of this century, which are used for making projections based on these various factors. Desirable scenario, RCP2.6 aims to keep global warming likely below 2 °C, above preindustrial temperatures. Two intermediate scenarios (RCP4.5 and RCP6.0) and worst scenario with very high greenhouse gas emissions is RCP8.5. Scenarios without additional efforts to constrain emissions (baseline scenarios) lead to pathways ranging between RCP6.0 and RCP8.5.

Assuming an unchanged global dependence on fossil fuels, the IPCC AR5's worst-case scenario (RCP8.5) predicts a 3.7° rise in average temperatures by 2100 compared to 1986–2005, resulting in an 82 cm rise in sea levels. Such a worst-case scenario is anticipated to result in near-cataclysmic damage, affecting all life on the planet. In order to avoid such cataclysm and to discharge the intergenerational liability to children and to theirs, action is imperative to decrease concentrations of GHGs in the planet's atmosphere.

Global Carbon Budget

The concentrations of GHGs which have built up through human economic activities, due primarily to more than two centuries' use of fossil fuels, have clearly harmed the earth's natural ability to sustain life. In nonscientific terms, "Mother Nature" has for billions of years supported plant, animal, and human life through her generosity and tolerance. But now, emissions of carbon dioxide have combined with other GHGs and sources of man-made pollution, waste, and other detritus of postindustrial economies. The effect is to exceed the planet's inherent capacity to absorb the shocks imposed on it by humanity's weight of life, as much as by its way of life.

UNEPreport (UNEP 2014b) pointed out that IPCC's estimated a total carbon dioxide budget of about 3,670 Gt CO_2 for a likely chance of staying within the 2 °C limit. But since emissions began rapidly growing in the late nineteenth century, the

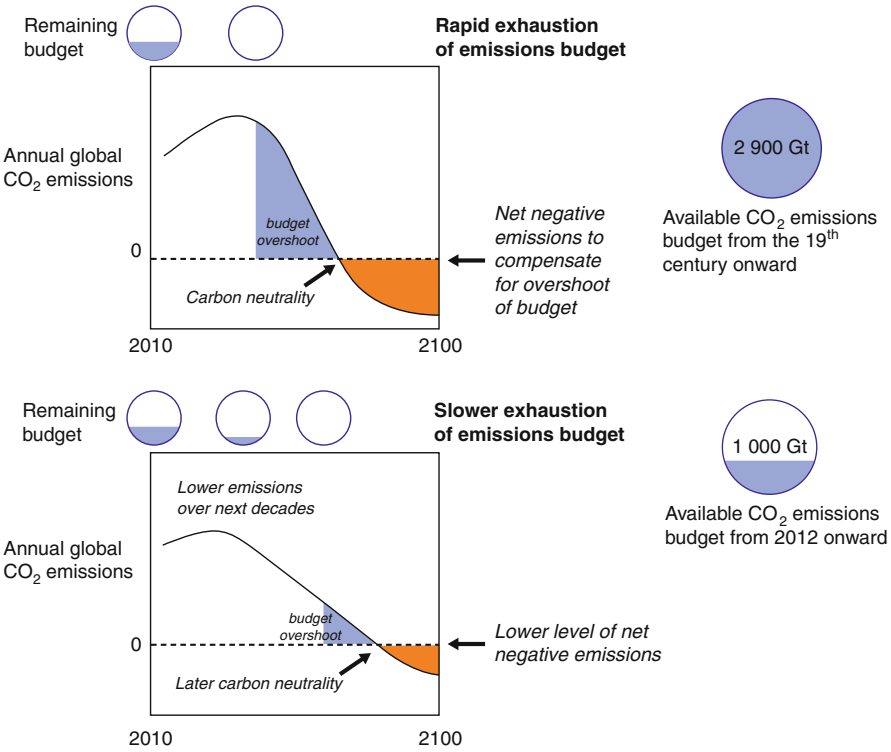

Fig. 1 Carbon neutrality (Notes: The Emissions Gap Report 2014. A UNEP Synthesis Report. November 2014)

world has already emitted around 1,900 Gt CO_2 and so has used up a large part of this budget. Moreover, human activities also result in emissions of a variety of other substances including methane from our cows' belches that have an impact on global warming, and these substances also reduce the total available budget to about 2,900 Gt CO_2. This means there are less than about 1,000 Gt CO_2 to "spend" in the future as Fig. 1 explains. (AR5 mentioned CO_2 budget between 2011 and 2100 of about 630–1,180 Gt CO_2.)

Since 1990, global emissions have grown by more than 45 % and were approximately 54 Gt CO_2-e in 2012. About 40 % of these emissions have remained in the atmosphere and the rests have been removed from the atmosphere and stored on land and in the ocean by the earth. The ocean has absorbed about 30 % of the emitted anthropogenic, causing ocean acidification which means another carbon liability.

According to BAU scenarios like RCP8.5, GHG emissions would rise to about 59 Gt CO_2-e in 2020, 68 Gt CO_2-e in 2030, and 87 Gt CO_2-e in 2050. It is clear that global emissions are not expected to peak unless additional international emission reduction policies are introduced. Based on the CO_2 budget approach, the levels of annual global emissions consistent with the 2 °C limit have been estimated. GHGs in

2050 are around 55 % below 2010 level. This means that by 2030, global emissions have already turned the corner and are more than 10 % below 2010 levels after earlier peaking. It also estimates the global carbon neutrality which means staying within the 2 °C limit, or net zero emissions on the global scale which implies some remaining CO_2 emissions could be compensated by the same amount of CO_2 uptake (negative emissions) so long as the net input of CO_2 to the atmosphere due to human activities is zero. The best estimate by AR5 is that global carbon neutrality is reached between 2055 and 2070 in order to have a likely chance of staying within the 2 °C limit.

If we fail to follow these carbon neutrality scenarios and shift to BAU ones, the resultant rises in global temperatures will not only continue but will speed up, following the well-established principle of positive and exponential feedback in complex natural systems. In other words, the absorptive or "uptake" functions of the Earth have fallen into environmental near bankruptcy in terms of their capability to adjust to the changes humanity has made to the makeup of the atmosphere.

Before the Industrial Revolution, man-made concentrations of GHGs could be contained safely within the earth's natural capacity to absorb them. This historical fact clearly compels human beings to recover as quickly as they can the earlier successful balance of consumption and of nurture in which humans must coexist with the planet. In economic terms, people must respect the planet's natural "uptake capacity." More broadly, they must restore the relationship between the earth and human activities. This means that they have to mitigate and decrease unabsorbed GHG concentrations.

Annual imbalance in emissions toward neutrality might be referred to it as a global "income statement of emissions," as a "profit and loss statement," for anthropogenic GHGs. Any year's excess of GHG adds to a huge GHG accumulation in the atmosphere, built-up over two centuries' use of fossil fuels.

Excess Cost of Carbon Imbalance

How can monetary values be assigned to these quantities of emissions? In the previous section, global CO_2 emissions volume estimated approximately 54 Gt CO_2-e in 2012. Then a monetary value can be derived for these quantities by referring to market prices for carbon in the EU's Emission Trading Scheme (EU-ETS), the world's first mandatory GHG emission trading market. But a value of EUA (European Union Allowances) has been fluctuated by supply and demand since its inception in 2005, roughly nearly €30 to below €5 per tonnes (Fig. 2).

In 2012, it has been traded as many as 40 million allowances per day and 7.9 billion allowances were traded yearly. The total value of carbon under the system in 2012 was €56 billion (European Union 2013). Carbon price traded in RGGI (Regional Greenhouse Gas Initiative) which is an initiative of the Northeast and Mid-Atlantic States of the USA has traded quite steady around $4–6 per tonnes during 2014 (RGGI Inc 2014). Another regional carbon trading scheme in the USA is California's Cap-and-Trade Program that took effect in early 2012. The price of carbon under their quarterly auction of GHG allowances for sale in 2014 was $11.34, almost double of the other side of the continent (California Environmental Protection

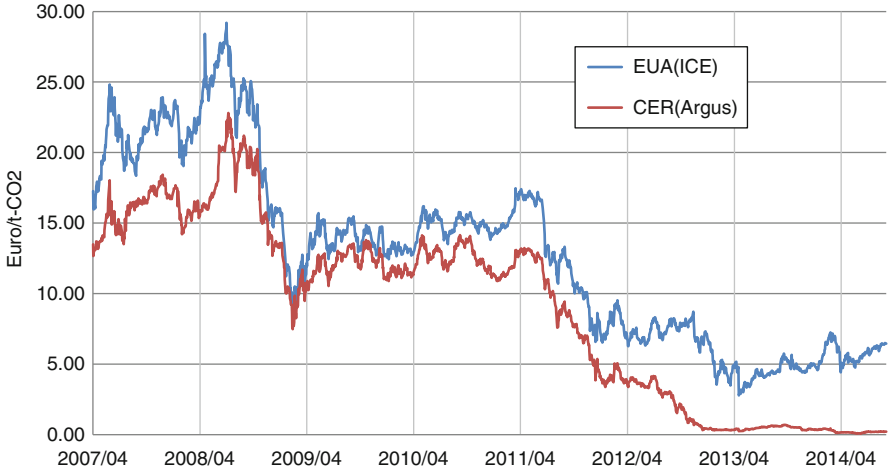

Fig. 2 Price differences between EUA and CER (Note: Argus Media, ICE (2014))

Agency, auction and reserve sale information 2014). If we use €30 per tonnes as historically highest price of EUA to calculate total global carbon deficit, it would monetize to €1.6 trillion and €5 as the lowest price of that would be €270 billion annually.

The annual buildup of CO_2 in the atmosphere represents the net increase of carbon liabilities across the planet – or rather, it represents the liabilities of the human race. Huge though these carbon deficits are, they show only one side of the picture. As already mentioned, these trends in accumulation have continued for almost 200 years, since the start of the Industrial Revolution in the eighteenth century. What are the continuing impacts on the earth of those early and long-lasting carbon burdens? They can be considered not only as yearly increments but also on a fully amortized, "total cost of ownership" basis, as might be used in calculating a "global carbon balance sheet" of the planet. Sadly, these calculations are not easy, due not least to major gaps in the knowledge and in available data sets.

For example, it cannot be reconciled as the total assets and liabilities of the earth in both monetary sense and in a nonmonetary one. It is very difficult to calculate the remaining periods of atmospheric carbon in the earth. Much recent debate in economics has focused on this topic; estimates vary from 15 years to as much as 200 years. Using 15 years as the hypothesis for the remaining period of atmospheric carbon, it must be increased by 15 times AR5's "per year" assessment of excess liability and monetized to €24 trillion as a total price of carbon liabilities.

On any basis of calculation, this number will be huge. In accounting terms, it has to be concluded that, if the earth was an enterprise, she should go bankruptcy, owing to her children's persistent ecological trashing of the family home, sustained over a score of decades.

Recent studies in the economics of climate change have attempted to set fair value (market value) on human centuries of ecological vandalism. Among the varying

estimates produced, the safest conclusion is that the differences between the balance sheets of man-made carbon production of the earth would be huge even in comparison to the previously mentioned annual income statements of carbon. This much is true, not least because account has to be taken of 200 years of anthropogenic CO_2 accumulation. Huge liabilities remain, in the form of excess, unabsorbed carbon. That is the reason why it is not enough merely to stabilize the human beings' consumption of fossil fuels at current levels. People should be aggressively cutting consumption if they are to stand any chance of achieving 80 % cuts in GHG emissions by 2050.

Stranded Assets

To examine on carbon budget of the earth, we should see an asset side of carbon balance sheet as well as the liability one. As Fig. 1 explained, we could spend less than about 1,000 Gt CO_2 toward 2100 in order to achieve 2 °C scenario. What does it mean on asset side of our carbon balance sheet?

According to Carbon Tracker[1], that expected CO_2 emissions from world fossil fuel reserves, total of oil, gas, and coal, are estimated 2,860 Gt CO_2. It means nearly three times larger than 2 °C limits. They calculate that only 20 % of total fuel reserves can be burnt by 2050. In the absence of negative emissions technologies like CCS, the carbon budget for the second half of the century would be only 74 Gt CO_2 to have an 80 % probability of hitting 2 °C target. This is equivalent to just over 2 years of emissions at current levels. Carbon Tracker has named these impacts of the asset side of the balance sheet of the earth as "unburnable carbon" or "stranded assets" (Carbon Tracker).

Stranded assets are assets that have suffered from unanticipated or premature write-downs, devaluations, or conversion to liabilities, and therefore they can be caused by not only carbon risk but also other environment-related risks. Smith School of University of Oxford pointed out these risk factors as follows (Smith School of Enterprise and the Environment 2014):

- Environmental challenges (e.g., climate change, natural capital degradation)
- Changing resource landscape (e.g., shale gas abundance, phosphate scarcity)
- New government regulations (e.g., carbon pricing, air pollution regulation)
- Falling clean technology costs (e.g., solar PV, onshore wind, electric vehicle, carbon capture, and storage)
- Evolving social norms (e.g., fossil fuel divestment campaign) and consumer behavior (e.g., certification scheme)
- Litigation (e.g., carbon liability) and changing statutory interpretations (e.g., fiduciary duty, disclosure requirements)

In their definition, the meaning of the carbon liability is limited narrowly for individual entities which have emitted CO_2 or will emit in the future. Based on their

[1]Carbon Tracker is a team of financial, energy, and legal experts in the UK.

definition, stranded assets mean that 60–80 % of coal, oil, and gas reserves of listed energy companies are unburnable. These carbon budget deficits pose a major risk for investors. Therefore listed energy companies face the litigation risk from investors.

The net lost impact of stranded assets by carbon budget was estimated to amount $3 trillion including governments, producers, and consumers during transition periods (New Climate Economy 2014). But, if innovation could spark during the transition, we could get net profit from lower fuel expenses, new business return related to the innovation, some estimate $7 trillion.

Avoiding Carbon Insolvency

Continuing the "balance sheet" analogy, people must conclude that after two centuries of mass industrialization, they in mankind remain terrible managers of carbon factors of production, of carbon assets, and of carbon liabilities. Judged on such universally accepted principles of accounting as "true and honest valuation" and "prudence," the history of economic activity amounts to a disaster tantamount to "carbon insolvency" or, at the very best, a staggering profligacy with nonrenewable carbon assets.

AR5 presents a simple benchmark for assessing the short- and long-term effects of CO_2 increase. This is the "airborne fraction" – in other words, the increase in CO_2 concentrations in the atmosphere, as a share of all fossil fuel emissions. From 1960 to 2010, with remarkably little variation, the airborne fraction has averaged 0.44 ($\pm$0.06). That means the absorptive capacity of the earth's biosphere has consistently removed the remaining 56 % of fossil-derived CO_2 from the atmosphere (but there is no consensus on the trend). So the recent accelerating rate of increase in atmospheric CO_2 reflects an increased level of emissions from burning fossil fuels.

The Carbon Break-Even Point

Correcting and rewriting the global balance sheet of carbon places us in a series of double binds, in multiple tensions between growth and the ecology, between developing and developed countries, between uncertainty and certainty, and between present and future. Reconciling these oppositions is far from easy, but it has to be done. The labor of finding balancing points on each continuum depends on how resources distribution can be improved. In short, it must be identified by the level of resources people should provide, appropriate both to achieving cuts in carbon emissions and to securing economic growth.

Any honest or prudent management of the planet's carbon balance sheet to keep 2 °C would oblige people to allocate to responsible agents €1.6 trillion (maximum) or €270 billion (minimum) worth of costs of GHG reductions. If we consider future strengthening of regulation to curve GHG emissions, these monetized estimates should be increased more on how would these amounts of money impact on world economic balance sheet? There are famous analyses produced by Sir Nicholas Stern in his 2006 book, *The Economics of Climate Change* (2006). It might be defined as the classical theory of the environmental finance like Adam Smith of conventional economics.

At that time Stern wrote that

> If a wider range of risks and impacts [of climate change] is taken into account, the estimates of damage could rise to 20 % of GDP or more. In contrast, the costs of action can be limited to around 1 % of global GDP each year. (Stern 2007)

The latest estimate of world GDP in 2013 amounted to $87.25 trillion (purchasing power parity) (CIA. The world fact book). Under this analysis in consequence, estimates of the damage due to climate change could vary as high as $17.57 trillion and as low as $0.87 trillion. Comparing Stern's figures to the carbon balance sheet for staying within the 2 °C limit, both of our €1.6 trillion ($1.95 trillion[2]) and €270 billion ($330 billion) estimates are regarded as the cost of action by Stern and almost medium in between his lower figure. But Stern's estimates are approximately 10 years before; after that, lots of works have been done. The latest one by the International Energy Agency (IEA) showed that figure is almost similar to our estimate, $1.9 trillion. So it can be safely concluded that securing this value of resources for measures to cut carbon would represent the break-even point. In other words, such a resource base would constitute a "sweet spot," a point of balance favoring continued economic growth while at the same time preventing further global warming.

Besides monetizing and valuing carbon emissions into carbon liabilities, it also has to be accounted for the effects of feedbacks and positive reinforcement in the climate-carbon cycle. These feedback effects mean that global warming tends to slow down absorption of carbon dioxide by the planet's landmasses and oceans, thus increasing the fraction of emissions remaining in the atmosphere. According to one estimate, the phenomenon of positive feedback will be responsible by itself for a rise in corresponding global average warming of more than 1 °C by 2100.

This assumption suggests that people might reach a sustainable point of equilibrium, merely by establishing break-even points of GHG emissions. But this action would be only one step. They need to move very far and very quickly, if people are to achieve meaningful reductions in emissions and stabilize the climate by the middle of this century.

Measuring the Valuation Materiality of Corporate Carbon

SEC Guidance

The next task is clear. It must be allocated and distributed in calculable amounts of cash toward reducing global GHG emissions. The most cost-effective way of achieving this allocation would be by considering both macroeconomic and microeconomic issues. The issues could affect more closely human beings' own destinies and that of the earth. Nobody can escape and survive from the implications of climate change.

[2] €/$ = 1.22 (as of December 2014).

The microeconomic agenda including compelling corporations has emerged to apportion sufficient resources to cover climate-related carbon liabilities. The US Securities and Exchange Commission (SEC) published a guidance to companies facing responsibilities to disclose to investors the materiality of their carbon-related activities in 2010[3].

The SEC issued its guidance in answer to requests from members of United States Climate Action Partnership (USCAP)[4] and other. An urgent need is being felt for a policy framework on climate change, in order to make coherent disclosures of material relevant to carbon-related liabilities, for the purposes of valuing companies. The SEC guidelines stress the necessity of carbon disclosure to investors, as defined in regulations from the US Environmental Protection Authority (EPA), especially as the rules on GHG data affect reporting by the large emitter entities as well as the disclosure regulations contained in the EU-ETS. Currently, based on EPA rule, as of 2013, over 8,000 facilities in nine industry sectors reported direct GHG emissions to the GHG Reporting Program(GHGRP) totaled 3.18 billion metric tons CO_2, which were about half of the total US GHG. Reporting entities are 965 suppliers, and 92 facilities reported injecting CO_2 underground.

Regulation Risk

The SEC's guidance examines the materiality of carbon-emitting activities under three categories:

1. Regulatory risk
2. Physical risk
3. Market risk

This scheme seems to be recognized generally by businesses as acceptable and workable. The SEC document begins by explaining the impact of regulatory risk on three types of companies. For some, the regulatory, legislative, and other developments could have a significant effect on operating and financial decisions, chiefly decisions involving capital expenditure needed to reduce GHG emissions.

Secondly, for companies subject to "cap-and-trade" legislation (not yet introduced in Japan, in the USA it has been introduced only to several states under RGGI and AB32[5]), the SEC note sets out the expenses permissible to purchase emissions allowances, where reduction targets cannot be met. Thirdly, the notes describe how firms not directly affected by emissions regulation could still be affected indirectly, through higher prices, charged by directly affected companies who need to pass on their own increased costs of compliance. One consequence is that even in jurisdictions still without a mandatory "cap-and-trade" regime, companies may yet face

[3]SEC, Commission Guidance Regarding Disclosure Related to Climate Change, February 2010.

[4]http://www.us-cap.org/

[5]The State of California introduced their own cap-and-trade system from November 2012 under the California Global Warming Solutions Act called as Assembly Bill No.32, AB32).

some regulatory risk, as a consequence of international trade or cross-border procurement and supply chains.

These new regulations on emissions reduction may also present new opportunities for investment. This has been the lesson from the EU-ETS and its associated carbon markets, although carbon prices have been volatile in the markets. Companies with more allowances than they need, or who are eager to earn offset credits, can raise capital by selling these instruments on the markets. Companies must thus manage both sides of their own carbon balance sheets to balance their carbon assets and liabilities.

Just as important in assessing regulatory risk associated with carbon liabilities is the necessity for companies to understand cycles of trading and regulation. Even in the EU-ETS, which was initially based on the Kyoto Protocol, trading was limited to a defined period. But then EU decided to extend the trading period to the end of 2020 under the third phase of the ETS. Also beyond 2020, EU has showed further extension of the trading period toward 2030. These practical reform concerning trading period have been welcomed in the markets, but what the trading periods are decided by the political will mean there are always regulatory risks potentially; as a result, companies face uncertainty and unclarity. The SEC's guidelines are equally unclear on this point.

Physical and Market Risk

Climate change presents corporations with increased physical risk. Extreme weather events such as fiercer storms, hurricanes, more frequent flooding, deeper erosion of coastlines, melting of permafrost, and higher temperatures will all affect enterprises' facilities and operations. Changes in the availability or quality of water and other factors of production are among innumerable physical challenges about to confront to businesses.

Physical changes associated with climate change may depress consumer demand for products or services. Warmer winters may cut demand for heating fuels, servicing, and equipment. These effects could affect companies' operations and the value of their assets.

Market risk due to climate change may be defined as companies confronting the risk of reductions or eliminations in business opportunities, consequent upon changes in consumer demands and in society's needs. If companies have not reacted astutely in response to regulatory and physical risks, they could lose consumers' or investor's confidence. This risk is reputational and can be considered a type of market risk.

The SEC's guidance advises that, depending on a registrant company's business and its reputation with the public, it may need to consider whether public perception of its published data on GHG emissions could expose it to potential adverse consequences to its business operations or financial condition.

The SEC emphasizes the importance of disclosing risk factors linked to climate change in companies' financial reports, even where the data's materiality may be hard to assess. The SEC notes fail to give methods for evaluating such data, neither do they provide any criteria to measure the materiality of nonfinancial factors.

The sole quantified threshold shown is the SEC's explanation on Instruction 5 to Item 103 of Regulation S-K. This recommends citing any current or outstanding environmental litigation related to governmental regulation.

Notwithstanding the SEC's guidance on climate change, familiar questions remain. How can corporations and other carbon-emitting organizations calculate the materiality of their own carbon liability? How should this be measured? There are several efforts and trials to solve these questions. Let's explain and describe them one by one.

Quantitative Carbon Disclosure

Companies are left to their own devices in deciding how to measure the materiality of their carbon exposure and to disclose this in financial reports. With this realization the next problem, namely, measuring a corporation's carbon liability, must be focused.

Research in corporate reporting reveals several different approaches to climate-related risk. Examples include the disclosure of a company's carbon budget, as described above, and its philosophy for carbon management. Firms in such carbon-intensive sectors such as oil exploration, electricity, chemicals, steel, and cement have been quick to adopt such approaches. This is because they have hitherto faced the three types of carbon risks already mentioned.

Firms can no longer tuck such data away in financial reports. In its latest corporate citizenship report, Exxon Mobil explains that it emitted 126 million metrics tonnes on a CO_2 equivalent from upstream, downstream, and chemical divisions in 2013. The US oil giant publishes detailed information on its gas flaring and on its cogeneration capacity, two factors with major impacts on carbon liabilities in its sector.

Exxon's peers Shell, Chevron, and BP also disclose their quantified data of carbon emissions. Besides, BP has faced another hugely expensive environmental liability, stemming from the huge oil spill in the Gulf Coast in April 2010. In its disclosures of quantified carbon emissions, BP emitted 64.9 million tonnes on a CO_2 equivalent in 2010. But it reduced to 49.2 million tonnes in 2013, 24 % reduction than 3 years before, due to the result of the sale of two refineries, Texas City and Carson in the USA, as part of our divestment program. A huge volume of environmental liabilities, as well as carbon ones, continues to disclose in BP's basic report, as it meets claims arising from the Gulf Coast accident, which is now rated as America's worst ever oil disaster.

Shell emitted 73 million tonnes on a CO_2 equivalent in 2013, which is slightly higher than 72 million tonnes in 2012. The main reasons for this increase were the ramp-up of production in Qatar and the restart of production in Iraq and so on. These increases were partially offset by reduced flaring and lower production in other places.

Those figures show that Exxon has almost double weight of carbon liabilities than other two competitors in absolute quantity. But monetary burdens by the carbon liability are not calculated only by absolute quantity but amount of their assets and provisions to be able to offset. In addition, assets would be stranded as we have already checked (Figs. 3, 4, and 5).

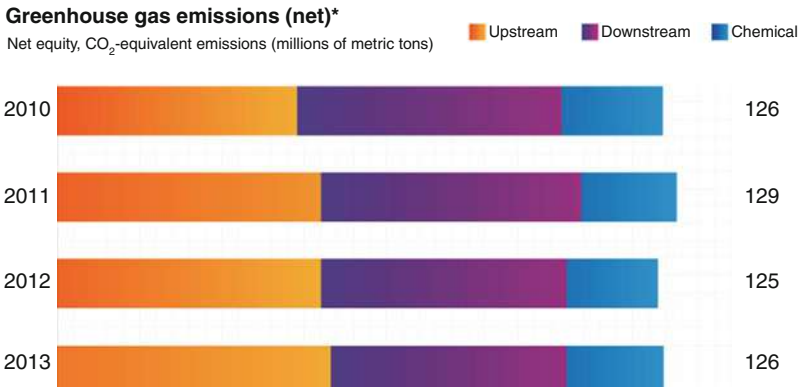

Fig. 3 Direct GHG emissions of Exxon Mobil (Exxon Mobil Corporate Citizenship Report 2013)

Fig. 4 Direct GHG emissions of BP (BP corporate citizenship report 2013)

The Movement for Quantitative Carbon Disclosure

Years of pressure by environmental movements have given strength to regulators seeking quantitative disclosure of CO_2 emissions by companies. Prominent among them are the UK's Carbon Disclosure Project (CDP)[6] and the Climate Disclosure Standards Board (CDSB)[7]. The CDP is a voluntary, nonprofit organization which, through force of argument and through a tailored questionnaire, works to persuade

[6] https://www.cdp.net/en-US/WhatWeDo/Pages/investors.aspx
[7] http://cdsb.net/

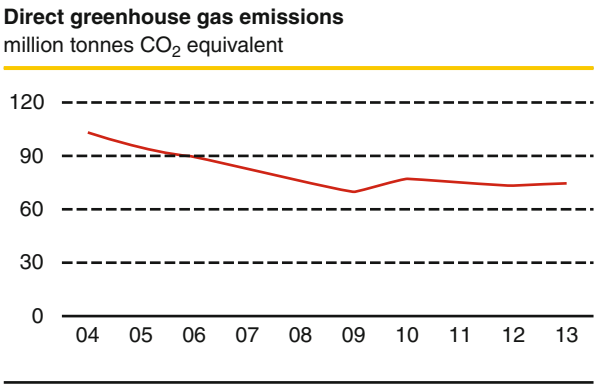

Fig. 5 Direct GHG emissions of Shell

global companies to measure and disclose CO_2 emissions and strategies in relation to climate change. CDP coordinates research on behalf of 767 institutional investors, with combined holdings worth in the region of $92 trillion in 2014. CDP reports include statistics on carbon emissions from its respondent companies plus other analysis. Open to public scrutiny, this information yields important trends and developments in corporate management of carbon emissions.

The Climate Disclosure Standards Board is composed of a pro-environment consortium of global companies, accountancy firms and accounting organizations, and nonprofit lobby groups. CDSB's mission is to develop a global framework for corporate reporting on GHG emissions, with the aim of supporting, strengthening, and harmonizing existing initiatives in climate-related reporting. The board seeks to enhance best practice in the form of a single consistent global framework.

Both the CDP and the CDSB claim that their activities continue to raise standards of corporate accountability toward the environment; neither would claim that their work is complete. Information in companies' financial reports may be useful for investors seeking to select environment-friendly companies for ESG portfolios. But quantified information in financial reports does not necessarily reflect the precise cash values associated with liabilities in relation to carbon emissions, nor the resources which companies must dedicate to meet them.

Quantified disclosure of climate- and carbon-related liabilities is gradually becoming obligation under company law. Participating companies in the EU-ETS are obliged to provide their emission data on a site-by-site basis to EU national governments. Since 2005, enterprises in Japan consuming 1,500 kl per year in fossil fuels must submit emissions data, the legislation stipulates reporting of all six main greenhouse gases.

The Japanese government has published company names over a certain level of quantitative CO_2 emission, in recalculating sum of sites emission data to company basis. Companies who fail to report face fines. In January 2012, US EPA had the first year of GHG Reporting Program (GHGRP) which data can be available to the public.

Carbon Materiality in the Sustainable Accounting Reporting

There are several activities to integrate environmental factors including GHG from economic entities with their conventional financial reporting processes, called as an Integrated Reporting, such as Global Reporting Initiative (GRI), International Integrated Reporting Council (IIRC)[8], Sustainability Accounting Standard (SASB)[9], and so on.

Among them, we would like to focus the SASB's activities, because they are going to set out disclosure guidance and accounting standards on sustainability issues to be included into companies' mandatory financial annual filings. GRI, IIRC, and others are mainly based on voluntary reporting which accompany with mandatory filings but separate from it. SASB is an independent nonprofit organization in the USA and is developing sustainability accounting standards for more than 80 industries in 10 sectors. Their standards are designed for the disclosure of material sustainability issues in mandatory SEC filings, such as the Form 10-K and 20-F.

As we have already seen about SEC's guidance on climate change which recommends on instruction of Regulation S-K, which sets forth certain disclosure requirements associated with SEC filings, SASB has attempted to identify these sustainable information including carbon liability that may be material for all companies based on Regulation S-K and required to describe them in the Management's Discussion and Analysis of Financial Condition and Results of Operations (MD&A) section of Form 10-K.

According to SASB (Sustainable Accounting Standards Board 2013), in determining whether a trend or uncertainty should be disclosed, the SEC has stated that management should use a two-part assessment based on probability and magnitude. The one is a reasonable likelihood that the known trend, demand, commitment, event, or uncertainty will occur. The second part is a reasonable likelihood that occurrence will have a material effect on the registrant's financial condition or results of operation. This approach is consistent with FASB's approach to entity-specific materiality determination.

When companies consider making disclosure on carbon liability including stranded assets in their mandatory financial reports, they should describe them in the MD&A, in a subsection titled "Sustainability Accounting Standards Disclosures." In addition to the MD&A section, companies should consider disclosing sustainability information in other sections of 10-K, as relevant, such as description of business (Item 101 of S-K), legal proceedings (Item 103 of S-K), and risk factors (Item 503(c) of S-K).

SASB's approach to describe sustainable material factors on the mandatory reports is quite pragmatical. They set out and evolve fundamental concepts and procedures by themselves, but for tools for reporting, they recommend existing measurement or guidance developed by other standardizer entities. For instance, in

[8]International Integrated Reporting Council; http://www.theiirc.org/

[9]Sustainable Accounting Standard Board, a 501(c)3 registered nonprofit organization based at San Francisco http://www.sasb.org/

the case of oil and gas exploration and production sector, SASB says companies should disclose their significant direct GHG emissions based on SASB's description, but it recommends to use various tools for accounting metrics to describe their quantitative or narrative information from other standardizer entities (SASB 2014a).

In the case of GHG emissions from companies, they describe GHG emissions should be disclosed Scope 1 level, six GHGs covered under the Kyoto Protocol, calculated them in metric tons of CO_2 equivalent (CO_2-e), and which facilities and equipment should be included as emission sources and so on. To disclose those quantitative and qualitative information, they select relevant tools to disclose, for instance, the Greenhouse Gas Protocol[10] as GHG Scope 1, CDP Guidance and IPIECA GHG Guidelines[11] as financial control approach, and CDSB's Climate Change Reporting Framework (CCRF) as organizational boundary setting.

Sectorial Disclosure Approach

SASB is developing sustainability accounting standards at the industry level, focusing on intractable issues that are closely tied to resource use and business models and other factors at play in the industry that can result in unsustainable outcomes. But traditional industry classification systems do not always group together industries with common sustainability characteristics, making the determination of common sustainability issues difficult. Therefore SASB developed the Sustainable Industry Classification System (SICS), which builds on traditional ones and categorizes 10 sectors and 88 industries in accordance with their resource intensity and sustainability impact as well as their sustainability innovation potential.

One of such industry-specific area is nonrenewable resources sector. We can pick out oil and gas exploration and production industry as an example in the sector. Material impacts of global warming of the activities of this industry are mainly two topics, GHG emissions and reserve valuation and capital expenditures.

Many of the companies' normal operations in the industry involve the combustion of fossil fuels to produce energy and then emit GHG. They are required to report their GHG emissions annually to the EPA under GHGRP at the facility level when emissions of GHG exceed 25,000 metric tons. The sources of these emissions vary based on the activities in which they are engaged and the type of fuel they are using. Therefore they should monitor and disclose their use of energy input as well as their emissions of GHGs, both in accordance with applicable laws and regulations and to improve their overall balance sheets to reduce carbon liabilities.

On GHG emissions, companies should disclose gross amount of GHG Scope 1 emissions of all six gases in metric tons of CO_2-e. These emissions include direct emissions of GHGs from stationary or mobile sources that include, but are not limited to, equipment at well sites, production facilities, refineries, chemical plants,

Table 1 Example of integrated disclosure. Gross Scope 1 emissions (mock data)

Year-end December 31	2012	2013	2014
Gross global Scope 1 emissions (in thousands of metric tons CO_2-e)	6,525	7,765	7,762
Conventional oil operations (%)	63 %	47 %	45 %
Unconventional oil operations	2 %	9 %	11 %
Conventional gas operations	35 %	32 %	31 %
Unconventional gas operations	0 %	12 %	13 %
Percentage covered under a regulatory program	3 %	3 %	3 %

SASB Standard for Oil and Gas Exploration and Production; Example of Integrated Disclosure in Form 10-K

Table 2 Main sources of GHG emissions (mock data)

Thousands of metric tons CO_2-e	2012	2013	2014
Combustion	5,546	6.591	6.598
Flared hydrocarbons	326	388	388
Process emissions	457	543	543
Directly vented releases	326	388	388
Fugitive emissions and leaks	196	233	237

SASB, same as the above

terminals, fixed site drilling rigs, office buildings, marine vessels transporting products, tank truck fleets, mobile drilling rigs, and movable equipment at drilling production facilities.

In addition to those gross figures, they shall provide a breakdown of its emissions by four classifications of hydrocarbon resources: (1) conventional oil, (2) unconventional oil, (3) conventional gas, and (4) unconventional gas. Unconventional oil includes oil shale, oil sands, heavy oil, etc. Unconventional gas includes coal seam gas, shale gas, etc. (SASB 2014b).

The bottom line of the Table 1 shows regulated emission ratio (emission covered under mandatory regulated scheme to the gross emissions they emit). The ratio increases operating cost may also increase.

Their emissions come from various sources as a normal by-product of necessary operational practices. They are involved in diverse exploration and production operations. Therefore they should disclose main sources of emissions among their activities in the mandatory financial report (Table 2).

Oil and gas exploration and production industry also should disclose stranded assets due to acceleration of global warming. Because they usually have huge reserve assets of oil and gas reserves and make significant investments in new reserves. Their activities generate significant direct GHG emissions, contributing to climate change and creating additional regulatory compliance costs and risks for them due to climate change mitigation policies. Also improved competitiveness of renewable energy technologies including policy supports to them through tax breaks and subsidies that have the potential to significantly alter the economic value of reserves, particularly those of oil. The price and cost impacts from climate

Table 3 Sensitivity of reserve levels to future scenarios in which a price is charged on carbon (mock data)

Price case	Proved reserves		Probable reserves	
Scenario	Oil MMbbls	Gas MMsf	Oil MMbbls	Gas MMscf
Current (base)	435	5,828	757	7,200
New policies scenario	415	5,400	723	6,900
450 scenario	378	4,800	701	6,430

SASB, same as the above

regulations and development of alternative energy can affect the net present value of proven reserves that we have already seen as stranded assets.

SASB asks companies belonging to this industry how long they have those assets under several future scenarios, such as BAU, International Energy Agency's New Policies Scenario, and 450 ppm (2 °C) Scenario (Table 3).

In this case, E&P companies have conducted a sensitivity analysis of its proved and probable reserves based on price scenarios outlined by IEA in its World Energy Outlook publication (International Energy Agency, World Energy Outlook 2014). Under this price outlined in IEA's New Policies Scenario, company may see a small reduction in the size of its proved and probable reserves. Under the 450 Scenario, it should reduce its reserves significantly than the former case. Investor can distinguish their targeting companies to compare with these disclosed figures among peer industrial group.

Assets value of E&P companies would be damaged not only by carbon liability but also by social factors, such as security, human rights, and rights of indigenous peoples. Companies face heightened community-related risks when operating in conflict zones with weak or absent governance institutions, rule of law, and legislation to protect human rights or with vulnerable communities such as indigenous peoples. SASB points out that without corresponding enhanced diligence measures to protect human rights and the rights of indigenous peoples in such area, companies could encounter difficulties in accessing reserves or significant operational disruptions with impacts on costs and liabilities (SASB 2014c). We can call these assets as socially stranded assets.

Putting a Price on Carbon

Difficulties in Monetizing a Price for Carbon

Methods are evolving quickly to collect quantified data on carbon emissions from various types and sizes of corporations under various jurisdictions around the world. What are the next steps?

Measuring a corporation's carbon liability means putting a price on it, in other words, monetization. How should this be done? Carbon markets already provide an important tool to measure current prices for carbon in a free market. The emission

trading schemes like the EU's exist to link sellers with buyers, in the process setting of a market-clearing price. Two types of environmental trading systems exist, "cap and trade" and "baseline and credit."

In the EU's cap-and-trade system, carbon emission credits such as the European Union Allowance (EUA) have been traded (the abovementioned Fig. 2). A closing price for this security is reported after every day's trading. The process is identical to that for trading currencies, stocks commodities, or any other form of financial instrument.

As the biggest trading mechanism for corporate carbon credits, the EU-ETS is highly influential in setting a global price for carbon. In consequence, the prices of Certified Emission Reduction (CER) which are issued by the Clean Development Mechanism (CDM) projects in developing countries admitted as one of the emission reduction tools that started under the Kyoto Protocol and have settled on arbitrage trading with EUA markets, although both of them have been struggling with keeping suitable carbon prices due to European economic turbulence after 2010. The effect of such price-setting markets has been that, in general, the more emissions a company causes through its activities, the more it must pay to cover its carbon liabilities.

Complete understanding of techniques to value carbon liabilities will be lacking, however, if they are considered merely as a mean to the end of trading of carbon credits in the market. Three types of carbon risk exist, each presenting its own valuation issues, namely, regulatory risk, physical risk, and market risk. Regrettably, a market mechanism such as trading cannot monetize all three types of risks. Let's consider why.

Firstly, regulation risks are not shared equally between all types of carbon emitters. Proof of this emerges, when it can be examined the composition of the current EU-ETS. Now in its third phase of operations, the EU-ETS expands its targeted eligible sectors in chemicals, aluminum, and aviation, in addition to have been covered heavy-emitting industries including power utilities, energy generation, iron smelting, cement, and oil refining. But it has not yet covered all of CO_2 emitting sectors.

Besides, EU-ETS has faced significant problem which they should solve to put price on carbon. Due to economic downtown during 2010–2013, the so-called European sovereign crisis, demand for carbon credit was fallen sharply as Fig. 2 showed clearly. This means carbon credit is as same economic goods as other goods and services which value goes up and down. But without functional price setting mechanism, we can't rate carbon liability. We need to improve C&T system's more functional ways and integrate fragmented C&T markets in several regions or states into wider ones.

Needs for Integrated Accounting Standards of Carbon Value

We have already seen SASB's attempt to make sectorial disclosure approach on carbon value. We respect their efforts, but at present it is not a mandatory scheme but voluntary one, although there is some possibility that most of listed companies in the USA would use SASB's disclosure standards in their financial statements as de facto standards to describe their own carbon liabilities. To create common accounting

standards to calculate carbon liabilities and carbon vales, there has been repeated trial and error.

The International Financial Reporting Interpretations Committee (IFRIC) is the interpretative body of the IASB (International Accounting Standards Board). In December 2004, just as the EU launched its ETS, the IFRIC committee issued IFRIC3, its formal accounting interpretation on Emission Rights or carbon credits. At that time, it was decided that EU-ETS came into effect from 1 March 2005. In practice, the IFRIC3 thus became the new accounting tool of choice for EU-ETS. But it was withdrawn by the committee themselves after only a month, the victim of wrangles between accounting regulators and business leaders.

The allowances granted by national governments to companies participating in the ETS were at issue. According to IASB, IFRIC3 specified the following (International Accounting Standards Board 2010):

1. Rights (allowances) are intangible assets that should be recognized in the financial statements in accordance with IAS 38.
2. When allowances are issued to a participant by government (or government agency) for less than their fair values, the difference between the amount paid (if any) and their fair value is a government grant that is accounted for in accordance with IAS 20.
3. As a participant produces emissions, it recognizes a provision for its obligation to deliver allowances in accordance with IAS 37. This provision is normally measured at the market value of the allowances needed to settle it.

The issue was how to treat such an allowance on the balance sheet. A consensus among businesses held that an allowance is an asset, because it is acquired at a cost, in the same way as any other factors of production such as raw materials and equipments. IFRIC agreed; however, not all business leaders did so. As the IFRS is an interpretative body of the IASB, it is bound by the IASB Framework on the Preparation and Presentation of Financial Statements ("Framework"). This framework does not assess an asset from the cost evaluation viewpoint. It defines an asset as a "resource controlled by the entity as a result of past events and from which future economic benefits are expected to flow to the entity" (Cook 2009).

As the EU-ETS began trading, the IFRIC standard recognized as an asset the allocation by EU governments of allowances to companies in their own territory. However, IASs set by IASB require assets to be measured at fair value at each reporting date. In consequence, the IFRIC interpreted allowances in an undifferentiated manner, failing to discriminate between allowances purchased from the market or granted by governments. In contrast at that time, the IASB had a long-standing proposal to amend recognition of government-allocated granting of rights in the IAS 20 (Accounting for Government Grants and Disclosure of Government Assistance), and this stipulated that any grant from a government could no longer be considered as income.

The dispute's implication was that any free emission allowances granted by governments would have to be recognized immediately as income. Business leaders

protested that it was impractical for them to recognize fair value at the onset of the trading. Then, IASB withdraw IFRIC3.

Further accounting disputes have followed, concerning the structures of the emission trading schemes and in particular how to establish a scale of values for initial allowances and allocate them among the scheme's members. At question have been competing methods of rights allocation such as the so-called grandfathering approach as used in the first phase of the EU-ETS; alternative methods also considered have included benchmarking approaches, and allocation based on auctions of emission rights. IFRIC3's failure was a direct consequence of the "grandfathering" approach favored by the EU.

In a statement, the Board of the IASB justified its withdrawal of IFRIC3 claiming that "the Board decided to take the time to conduct a broader assessment of the nature of the various volatilities resulting from the application of IFRIC3 to a cap-and-trade scheme and to consider whether and how it might be appropriate to amend existing standards to reduce or eliminate some of those volatilities." The decision was taken by an overwhelmingly vote of 12 in favor, 1 against, and 1 abstention.

After several years, the IASB restarted the debate on limiting free issues in emissions trading schemes. But it chose not to address the controversy surrounding accounting standards for all government grants at December 2007. In May 2008, IASB started joint discussions with the USA counterpart, FASB. But after piled up discussions between them, in December 2012, IASB announced and formally reactivated this project as an IASB-only research project. They didn't explain why the joint discussions met with failure. New IASB-only research project is expected to result in the publication of a discussion paper considering the financial reporting consequences of government-developed schemes designed to encourage reductions in the production of GHGs, which will include an inventory of trading schemes, an analysis of common economic characteristics of those schemes, and an initial assessment of the potential reporting solutions (IFRS).

Calculating Physical Risk to Price

Despite long-standing discussions on setting up comprehensive and intelligible rules in carbon accounting, markets seem to provide the simplest method for setting a carbon price. Companies trading under mandatory emission trading schemes like the EU-ETS can compare carbon prices in the market with their own carbon management on issues such as raw materials purchase, investment in production equipment, identifying a development site, or in decision about production of a new product or service. As described above, accounting standards for reporting carbon values have not been decided, and none will be accepted until the new draft of' "IFRICα" emerges.

Carbon pricing in free markets serves well as one measurement of carbon liability. It is limited, however, in relation to regulatory risk. As described above, the concept of carbon liability comes not only from regulation but also from physical and market risk types. Physical risk may increase carbon damage to the asset side of a company's balance sheet such as stranded assets described above, as opposed to its liabilities.

Some simple examples illustrate the point. Rising sea levels pointed out by AR5 may halt or impede operation of an enterprise's factories and facilities located along coastlines. Companies face operational interruption or damage, due to fiercer storms, heavier rain, more frequent typhoons, or land erosion caused by drought. Firms will be well advised to introduce a climate contingent Business Continuity Plans (BCPs) to prevent deterioration of their fixed assets and operational interruptions caused by climate change. Introducing climate contingent BCPs could work as a form of environmental insurance against carbon impacts.

Applying ARO Method

As companies struggle to calculate climate-related physical risks to their asset base, both now and in future, they have available useful accounting technique. This is the accounting rule for asset retirement obligations (AROs). AROs are legal obligations associated with the retirement of a tangible long-term asset. Such obligations result from the acquisition, construction, development, or normal operation of a long-term tangible asset, as defined in the FAS 143 standard issued in 2002 by the FASB. This accounting rule applies a "fair value" measure of fixed assets which includes environmental damage or other future removable obligations.

For example, the owner of an asset that is subject to environmental laws such as CERCLA is required to recognize their liability as an ARO on their balance sheet in the period in which it is incurred, based on a reasonable estimate of its fair value. Even if it is not possible to estimate with precision, the liability must be recognized whenever a reasonable estimate of fair value can be made.

An ARO is not quite the same as a carbon liability associated with any fixed asset. But it can be said that the nature of the uncertainty surrounding any carbon liability might be quite similar to the processing of evaluating an ARO. Companies have to estimate fair value of a carbon obligation, against the uncertainty of future regulation framework and possibility of physical risk. FIN47 is the FASB's interpretation of FAS 143 issued in March 2005. The US-based environmental accounting consultant C Gregory Rogers (2006) specifies that the fair value of an ARO may be determined based on any of the following methods:

1. The amount of the obligation embedded in the acquisition price of the asset
2. A market quote in an active market for transfer of the obligation (or if neither of these two situations applies)
3. Application of an expected present value technique to estimate fair value

Changing Market Risk to Opportunity

Setting a price on carbon liabilities associated with market risk can be very difficult, not least because this type of risk may be influenced by customers' changes in taste or in buying behavior. One solution may be to apply marketing method such as Customer Related Marketing (CRM). If companies use these carbon marketing techniques, they may persuade their customers that their products are differentiated by virtue of low impact on the environment. Perceptions can be altered by careful marketing.

It is not yet clear how many customers will value, or will react to, perceptions of low carbon positioning, rather than to traditional lower prices and higher quality. But more easily than with the other carbon risk types, market risk can be turned from a liability to into an asset and a source of competitive advantage.

Carbon management entails the full realization and declaration of all costs and liabilities arising from man-made carbon and allocating these costs to appropriate activities both in their production and to the final retail value of a product. In discharging this management obligation more efficiently, corporations must establish a well-planned architecture of mandatory carbon trading which minimizes regulatory risk. Equally desirable and necessary is an agreement on more accurate accounting methods, capable of producing coherent and usable valuations of carbon liabilities, as they effect materially a company's base of fixed assets and related liabilities.

In addition, companies should apply across all key audiences – customers, investors, and other stakeholders – a comprehensive, appropriately designed strategy of carbon marketing. The goal should be to request and to achieve collective changes in patterns of consumption as well production in order to safeguard the interests of future generations.

Abstract

Forest ecosystems have been identified to be the largest land carbon sink and account for more than half of carbon stored in the terrestrial ecosystems. The influences of climate change on forest ecosystems could have significant implications on global carbon cycling. In this chapter, we reviewed research progresses about climate change impacts on forest ecosystem carbon cycling in the past 20 years. Our review is mostly on field experiments and modeling studies. This chapter starts with a brief description of climate change and forest ecosystems. Different experimental studies are then presented. The impacts of global change such as elevated CO_2, global warming, and changes in precipitation and O_3 on carbon cycling in forest ecosystems are synthesized. Next, we present some modeling studies of forest ecosystem carbon cycling at ecosystem, regional, and global scales. At the end of the chapter, we make some recommendations for future studies.

Introduction: Global Climate Change and Forest Ecosystem Carbon Cycling

As a major terrestrial ecosystem, forests occupy 30–43 % of the world's land surface. Forests are an important source for fiber and fuel, for human consumption, and of vital importance for the economy of many regions in the world (Dixon et al. 1994; Pan et al. 2013). In addition, forests provide a suite of services, including habitats for wildlife, clean water and carbon storage, and climate mitigation (Lindquist et al. 2012). Forest biomass is the major pool of vegetation carbon. The total amount of carbon sequestered in forest vegetation is approximately 359 billion tons (Allen et al. 2010). Forest soil is another carbon pool that stores large amount of carbon. Overall, the amount of carbon stored in the forest ecosystems is twice that in the atmosphere (Lal 2005). As forests play an important role in the global carbon cycling and curbing climate change, understanding the types and distribution and assessing the present and future forest ecosystem carbon balance have been of both scientific and policy interest (Nabuurs et al. 2010).

Climate change has been considered as one of the great threatens to the world. Due to fossil fuel burning and deforestation, concentration of atmospheric carbon dioxide (CO_2) has increased from 280 ppm at preindustrial revolution to 394 ppm presently (Peñuelas et al. 2013). As a result, average global surface temperature is

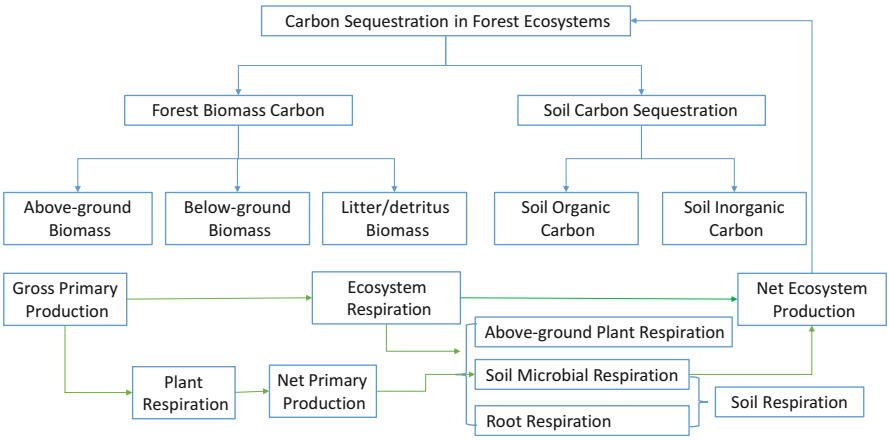

Fig. 1 Carbon sequestration in forest ecosystems, including major carbon pools and fluxes (Lal 2005)

increasing at an unprecedented rate. These changes as well as changes in precipitation, nitrogen deposition are likely to have significant effects on tree growth and forest dynamics, and eventually, carbon accumulation in forest ecosystems (Zuidema et al. 2013). Understanding the accumulated impacts of these climate changes (e.g., global warming, elevated CO_2, precipitation change, and nitrogen deposition) is crucial for predicting ecosystem carbon dynamics in forest ecosystems.

Climate change affects forest ecosystem carbon cycling both directly and indirectly (Hui and Luo 2004). Whether forest ecosystems sequestrate more carbon into ecosystems (carbon sinks) or release more carbon from ecosystems (carbon sources) depends on the net ecosystem carbon exchange, the difference between gross ecosystem primary productivity and ecosystem respiration (Fig. 1). When climate change stimulates photosynthesis process by elevated atmospheric CO_2 or improved growing conditions (i.e., warmer temperatures, more favorable moisture balance, improved nutrient availability, or decreased pollutants such as tropospheric O_3) or decreases plant or microbial respiration process as a result of altered chemical or physical composition of the plants and soil organic matter, the ecosystems act as carbon sinks (Field et al. 2007). Otherwise, the converse processes can make ecosystems act as carbon sources.

Many experimental and modeling studies have been conducted in order to better understand the potential effects of global warming, elevated atmospheric CO_2, and changing precipitation regimes on these forest ecosystem processes (Peters et al. 2013). The effects of climate change on forests have been found to be both positive (e.g., increases in forest growth and water use efficiency under elevated CO_2) and negative effects (e.g., reduced growth due to the combined impacts of

climate change and O_3) and may vary with other factors (Allen et al. 2010; Tian et al. 2012). Increased atmospheric CO_2 concentrations may enhance tree growth, increase NPP, but the effects vary with plant nitrogen conditions and plant species or change over time (Peters et al. 2013). Atmospheric nitrogen deposition is a major factor influencing forest growth under natural conditions (Lu et al. 2011). Both CO_2 and nitrogen deposition may interact with other climate factors such as warming and precipitation to affect tree physiology, carbon allocation, and ecosystem carbon sequestrations (Allen et al. 2010; Tian et al. 2012; Norby and Luo 2004).

Due to the importance of forest ecosystems, many scientific papers have been published on the impacts of climate change on forest ecosystems during the past several decades (Norby and Luo 2004; Deng et al. 2012). Several studies have also reviewed the effects of climate change on forest ecosystems at large spatial scales, such as in Europe and USA, and for specific forest ecosystems such as tropic forests and boreal forests (Lindner et al. 2010). Forest carbon sequestrations have been quantified at small and large scales (Allen et al. 2010), but there are very large uncertainties in the distribution of carbon stocks and carbon exchange in forest ecosystems (Le Toan et al. 2011). Future observations, research, and tool development are needed to further understand the interactions between climate change and forest ecosystems.

In this chapter, we reviewed the existing knowledge about forest ecosystem carbon stocks and dynamics under potential climate change. The following two questions were addressed: (1) What are the estimated carbon stocks in forest ecosystems? (2) What are the main impacts of climate change on forest ecosystem carbon dynamics? We first synthesized the estimations of global forest ecosystem carbon stocks in forest biomass and soil and then presented some typical research studies of climate change on forest ecosystem carbon stocks and fluxes. Two approaches are summarized here. One is the experimental studies considering increased CO_2, global warming, precipitation changes, and nitrogen deposition. Another is a modeling study of forest ecosystem carbon dynamics from past to present and future. We also identify some of the remaining questions warranting further research for better understanding the capacity of forest ecosystems to adapt to climate change, including the interactions with other drivers of global change, and for better understanding the possible feedbacks on climate of these changes in forest ecosystems.

Forest Ecosystems

Forests are the dominant terrestrial ecosystems on the Earth with a total area of more than 4.1×10^9 ha (Dixon et al. 1994; Pan et al. 2013). Forests provide habitats for the majority of species on Earth and produce valuable ecosystem resources and services to human beings, such as food, fiber, timber, clean water, carbon storage, and climate mitigation (Allen et al. 2010).

Forest Types

Forests are dominated by trees and other woody vegetation. At large scale, the major types of forests can be classified by biomes (Dixon et al. 1994). Three major biomes of forests are tropical forests, temperate forests, and boreal forests (Fig. 2).

Tropical forests are characterized by the greatest diversity of species and productivity of trees. They are located between 23° north and south of the Equator, respectively. Temperature is 20–25 °C on average and varies little in a year. Precipitation is high (with annual rainfall exceeding 2000 mm) and evenly distributed throughout the year. Plants can grow during the whole year. Trees are usually 25–35 m tall. Canopy in tropical forests is multilayered and continuous. Tropical forests contain an enormous diversity of hardwood tree species and are important for carbon sequestration. About half of the carbon in rainforests is contained in the vegetation. The remaining carbon is in tropical forest soils: tropical forest soils have only modest carbon levels, because the dead biomass rapidly decomposes in the warm, humid conditions, and the minerals rapidly leach out of tropical forest soils (Table 1) (Gorte 2007).

Temperate forests typically occur in the mid-latitudes, generally ranged between 50° north and south of the Equator. Temperature varies greatly from −30 ° C to 30 ° C, but precipitation (750–1500 mm) is distributed evenly throughout the year. There are a large variety of temperate forests, including hardwood, softwood, and a few mixed forests. Trees are distinguished by broad leaves that are lost annually. Species include oak, hickory, beech, hemlock, maple, etc. Temperate forests have much lower tree species diversity than tropical forests and generally contain less carbon averaging about 1.57×10^5 kg ha^{-1} (Table 1). More than one-third of the carbon is stored in the vegetation and nearly two-thirds in the soil (Gorte 2007).

Boreal forests represent the largest terrestrial biome occurring between 50° and 60° north latitudes. Temperatures are very low and precipitation (400–1000 mm annually) is primarily in the form of snow. Seasons are divided into short, moist, and moderately warm summers and long, cold, and dry winters. Boreal forests are dominated by conifers, including pine, fir, and spruce, with scattered birch and aspen stands. Boreal forests generally contain more carbon than temperate or tropical forests, averaging more than 4.04×10^5 kg ha^{-1} (Table 1), due to very slow decomposition rates owing to short summers and the high acidity of conifer forest soils. Less than one-sixth of boreal forest carbon is in vegetation. The rest 84 % is in boreal forest soils. The high boreal forest soil carbon level is important for carbon cycling, because many believe that management activities and climate change that disturb boreal forest soils can increase their release of carbon (Gorte 2007)

Forest Distributions

The global distributions of forests are mostly determined by the climatic factors, particularly temperature and precipitation. At the regional and local scales, soil type, topography, and other local environmental factors could influence the distributions

Fig. 2 Examples of different forests around the world. (**a**) Temperate Oak forest in Tennessee, USA, photo credit: Brain Stansberry. (Pan et al. 2013). Mapping forest distribution usually involves a combination of two or more of the following methods: field observations and measurements, remote sensing and geographic information system (GIS), and ecosystem modeling (Pan et al. 2013). Global and regional mapping of forest distribution increasingly relies on satellite remote sensing due to the advantages of consistency and automated image processing (Pan et al. 2013). Facilitated by remotely sensed land-cover data (e.g., SPOT and AVHRR) and geographic information system (GIS), various global classifications and maps have been developed (Pan et al. 2013; FAO 2001). At the global scale, MODIS-based observations can currently identify only four physiognomic classes of trees (evergreen needle-leaved, evergreen broad-leaved, deciduous

Table 1 Carbon stock in selected biomes of the world (Dixon et al. 1994; Lal 2005; Fang et al. 2007). Multiple numbers in one cell are estimates from different sources

Biome	Area (Mha)	Carbon density (Mg/ha)		Carbon stock (Pg)

needle-leaved, and deciduous broad-leaved trees) and seven relatively coarse woody biome types based on trees and shrubs (Fig. 3) (Pan et al. 2013).

Forest Ecosystem Functioning and Carbon Cycling in Forest Ecosystems

As we mentioned before, forests are vital to our quality of life and society, as they provide many resources and services including mitigation of climate change (IPCC et al. 2013). Trees take up CO_2 in the atmosphere and release oxygen (O_2) through photosynthesis. The sum of photosynthesis over a year is termed gross primary productivity (GPP) (Nowak and Crane 2002; Pan et al. 2011). The fixed carbon is then transferred to their stems, roots, and leaves for growth. The actual carbon fixed into plants, the net primary productivity (NPP) of an ecosystem, is the balance between GPP and the carbon lost through plant respiration (i.e., the construction and maintenance cost). When leaves and branches fall and decompose, the stored

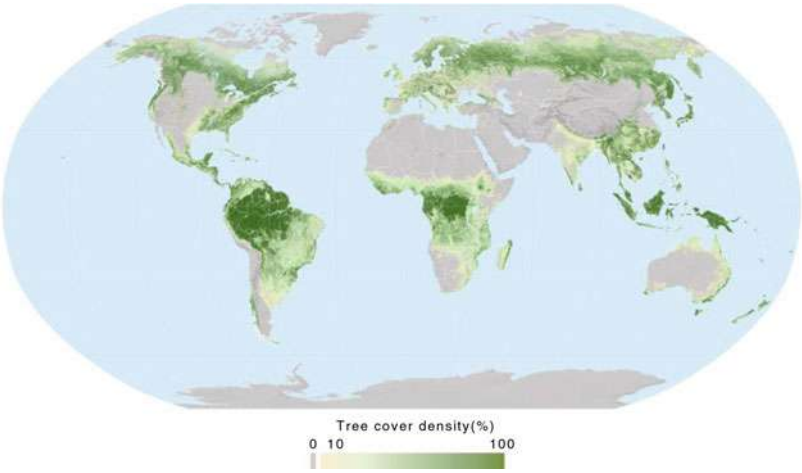

Fig. 3 Global forest cover map (FAO 2010. Forests of the World. http://data.fao.org)

carbon will be released back to atmosphere through respiration. Part of dead organic matter will be transferred to the soil. When carbon losses by microbial respiration (heterotrophic respiration, Rh) in litter and soil are accounted for, we obtain the net carbon balance of an ecosystem. This net balance is termed net ecosystem productivity (NEP). Forest ecosystems play a major role in the global carbon cycle by storing large amount of carbon in live plant biomass, dead plant material, and the soils and are considered as carbon sinks. In order to understand how forest ecosystems respond and feedback to climate change, we need to quantify carbon stocks in vegetation and soil in forest ecosystems.

There are several methods currently used for estimation of forest biomass carbon (Pan et al. 2011, 2013; Brown 2002; Yu et al. 2014): (1) Field measurement-based estimation using forest inventory data (Yu et al. 2014). These methods include (a) the mean biomass density method [MBM] that directly measures biomass in sample plots and uses the average of total plot biomass for each forest type to get biomass for that type, requiring only inventory data on forest area. A biomass expansion factor (BEF) is used to convert stem volume to biomass to account for all components of trees; (b) the continuous biomass expansion factor method [CBM] expands on the MBM by treating BEF not as a constant but as a function of forest age, stand density, and type of site; and (c) continuous BEF method (CBM). Fang et al. (2007) derived an equation that accommodates changing BEF values over time from inventory data on forest area and volume. (2) Remote sensing-based techniques. Remote sensing data such as satellite imagery to aerial photo-imagery from low-flying airplanes may provide a useful means for measuring carbon stocks in forests (Brown 2002). (3) Micrometeorological techniques such as Eddy covariance technique and their

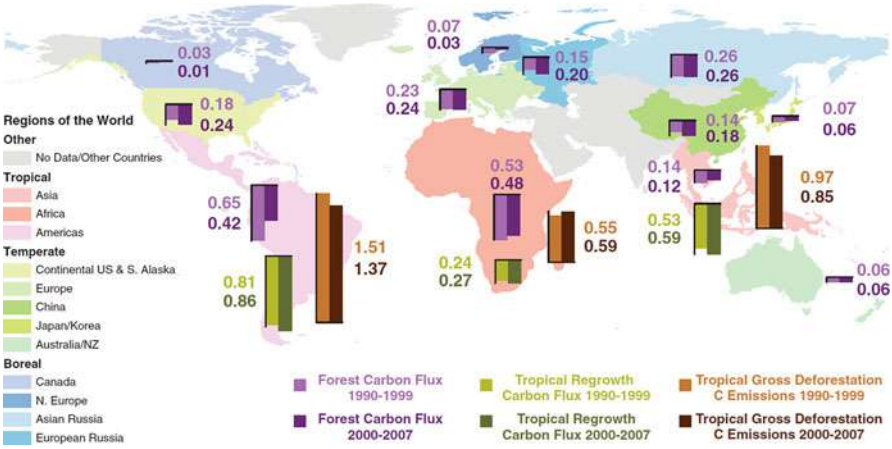

Fig. 4 Carbon sinks and sources (Pg C year^{-1}) in the world's forests. Colored bars in the down-facing direction represent C sinks, whereas bars in the upward-facing direction represent C sources (Adapted from Pan et al. (2011))

upscaling (Nabuurs et al. 2010). (4) Large-scale ecosystem models as BIOME-BGC, LPJ, ORCHIDEE, or DLEM (Tian et al. 2012; Hui et al. 2012).

Each of these methods has its strengths and weaknesses (Nabuurs et al. 2010; Karjalainen et al. 2003). For example, field measurement-based method provides estimates of both the carbon stock changes and the size of the stocks but has limited capability to forecast future changes. Ecosystem models can explore the importance of ecosystem physiological responses to climate variability or increasing CO_2, but most of them do not yet consider natural or human-induced disturbances (Karjalainen et al. 2003). So far, the estimates of the contemporary carbon balance still vary a lot (Nabuurs et al. 2010).

Globally forests store over half of the carbon residing in terrestrial ecosystems (FAO 2001). The total biosphere carbon pool is estimated at 2.19×10^{18} kg C. Of this, approximately 1.0×10^{18} kg is in forests, about 50 % more carbon than now resides in the atmospheric pool. Forests account for 75 % of GPP in terrestrial ecosystems and 80 % of the total plant biomass on the Earth. Forests store about 2.4×10^{12} kg of carbon per year (Pan et al. 2011) and account for almost all of world's land-based carbon uptake (Fig. 4).

In the USA, approximately 33 % (3.03×10^{8} ha) of the land base is forested (Karjalainen et al. 2003). US forests and long-lived wood products accounted for a net sink of 2.51×10^{11} kg of carbon (Karjalainen et al. 2003). Estimates for the European terrestrial biosphere net sink, based on inversion for forest and agricultural lands, vary from 300 to 7.0×10^{11} kg C year^{-1} with large uncertainties (Karjalainen et al. 2003). Estimates based on forest inventories suggest much smaller net sink for European forests, between 1.0 and 1.1×10^{11} kg C year^{-1} (Nabuurs et al. 2010).

Climate Change: From Historical Change to Current and Future

Recent changes in global and regional climate have been well documented and generally show an increase in mean annual temperature, with more extreme events such as hot days and droughts (Peters et al. 2013). Increasing emissions of greenhouse gases such as carbon dioxide (CO_2) are now widely acknowledged by the scientific community as a major cause of current global warming and climate change (Allen et al. 2010). Due to fossil fuel combustion and deforestation, atmospheric carbon is estimated to be increasing by approximately 2.6×10^{12} kg annually (Nowak and Crane 2002). As a result, the concentration of atmospheric CO_2 has risen from 280 ppm at the beginning of the industrial revolution to the current 394 ppm (Peñuelas et al. 2013). An increase in 2.36 ppm of CO_2 in 2010 was reported as one of the largest annual increases in recent decades (Peñuelas et al. 2013; Peters et al. 2013). Atmospheric CO_2 concentration in 2100 is projected to increase to at least 486 ppm or as high as 1000 ppm, depending on different models or model scenarios (Lindner et al. 2010). This rapid increase in the atmospheric CO_2 concentration and other greenhouse gases has the potential to drive current climatic changes more quickly than all previous climatic changes (Peñuelas et al. 2013; IPCC et al. 2013).

Climate observations have demonstrated the existence of a global warming trend: global average air temperature at the Earth's surface has increased by 0.8 °C since 1900 (IPCC et al. 2013) and the 12 hottest years observed globally since 1880 all occurred between 1990 and 2005 (Lindner et al. 2010). Globally, a rapid increase in air temperature was observed. For example, the period of 2001–2010 was 0.477 °C above the 1961–1990 mean annual temperature and was 0.217 °C warmer than the 1991–2000 decade (Morice et al. 2012). Global mean air temperature is expected to increase by 1.0–3.7 °C by the end of this century, with concurrent changes in global and regional precipitation regimes (IPCC et al. 2013). Latest climate change scenario projections for Europe suggest that by 2100 temperatures will increase between about 2–5 °C and by 1.4–5.8 °C globally, depending on the quantity of future greenhouse gas emissions (Peters et al. 2013). Extreme weather events such as heat waves and frequency and severity of extreme droughts are predicted to increase, with spatial differences (IPCC et al. 2013).

These rapid changes in climate may exceed the capacities of trees and forest ecosystems to assimilate them (Peñuelas et al. 2013). Understanding and predicting the consequences of these climatic changes on forest ecosystems is one of the grand challenges for global change scientists, particularly on forest carbon cycling (Allen et al. 2010).

Experimental Studies

Overview

Experimental study is one of the most powerful tools to evaluate the responses of climate change on terrestrial ecosystems and to understand the mechanisms underlying these responses (Rustad 2008). The results from experimental studies can also

be used to parameterize and validate terrestrial ecosystem models (Hui et al. 2012). In the past several decades, numerous manipulative experiments have been conducted on tree seedlings and forests in the laboratory and under field conditions (Rustad 2008; Norby et al. 2010). These experimental studies often use perturbation approaches that create different treatment levels (i.e., magnitudes in changes of treatment factors) to evaluate the effects of climate change in the past, current, and future conditions (Hui et al. 2012). While earlier studies mostly focused on a single climatic factor, now more experiments considered two or more climatic factors in the same studies, which can quantify not only the main effects of climatic factors but also the interactive effects of them (Deng et al. 2010). Some international networks of experimental studies have also been established over the past decade. For example, an international research coordination network – Terrestrial Ecosystem Response to Atmospheric and Climatic Change (TERRAC) – includes 135 field experimental sites of different ecosystems in 25 countries (Rustad 2008). Ecosystems include deciduous forests and coniferous forests, among others. These experimental studies and others have generated large amounts of high-quality data and greatly improved our understanding of the response of terrestrial ecosystems to climate change. In this section, we mainly summarize the findings from experimental studies examining the effects of climate change on carbon sequestration in forest ecosystems.

Effects of CO_2

The effects of rising atmospheric CO_2 concentrations on carbon sequestration in forest ecosystems have been studied for decades. In the early years, researchers used closed chambers such as glasshouse and growth chamber to grow tree seedling or small trees in pots under control and elevated CO_2 levels. These studies were criticized as glasshouse and growth chamber cannot really mimic the real world environment, thus generated responses that are different to these under natural conditions. Open-top chambers provide natural light and precipitation for trees to grow but may modify air and soil temperature inside the chambers. More recently, trees have been exposed to elevated CO_2 using free-air CO_2 enrichment (FACE) technology, which allows the fumigation of intact forest ecosystems with air enriched in CO_2 in large-diameter plots without walls (Norby et al. 2005; Drake et al. 2011).

Experimental studies provide direct evidences of increased vegetation carbon accumulation and ecosystem productivity in forest ecosystems under elevated CO_2. The enhancement of aboveground biomass for trees under elevated CO_2 range from 0 % to 50 %, with the higher values observed in young trees and little to no response observed in the few experiments conducted to date in mature natural forests (de Graaff et al. 2006). For the belowground biomass, the maximum increases by elevated CO_2 can exceed 50 %, hence usually resulting in lower shoot:root ratio (de Graaff et al. 2006). Early results from an open-air CO_2 enrichment experiment in a young North Carolina forest also showed increased ecosystem net primary

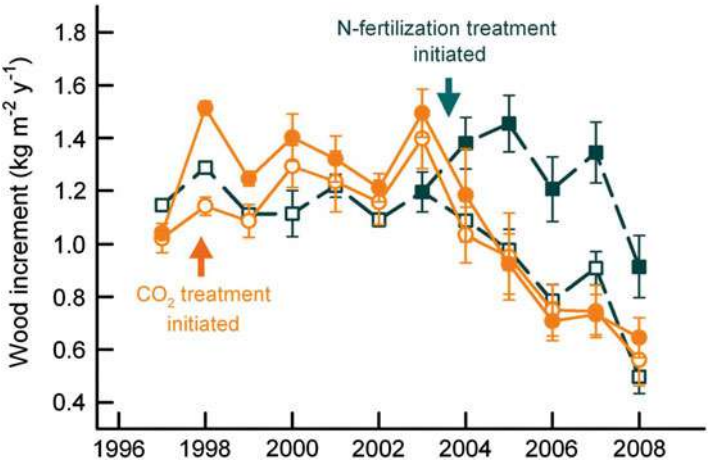

Fig. 5 Growth responses in the FACE and nitrogen addition experiments. Elevated CO_2 (*solid circles*) caused a significant increase in wood increment in the first year after treatment initiation (1998), but the response diminished in subsequent years and in later years was not statistically different from FACE controls (*open circles*). N fertilization (*shaded squares*) caused an immediate and sustained increase in wood increment compared with unfertilized plots (*open squares*) ($p < 0.001$) (Adapted from Norby et al. (2010))

productivity during the first 2 years of exposure, but later findings indicated that this productivity declined with time (Finzi et al. 2002). Experimental studies using FACE technology also indicated that CO_2 enrichment of 550 ppm increased NPP by about 20–25 % across a range of temperate forest sites (Norby et al. 2005), but the long-term outcome was diminishing (Fig. 5) (Norby et al. 2010). Furthermore, some FACE experiments showed lack of CO_2 fertilization effect (Liu et al. 2010). Nutrient limitation is hypothesized as primary cause for reduced or lack of CO_2 fertilization effect observed on NPP (Norby et al. 2010; Luo et al. 2004). For example, experimental studies have shown that elevated CO_2 could stimulate plant nitrogen uptake and enhance tissue carbon:nitrogen ratio (Luo et al. 2006), resulting in progressive nitrogen limitation (PNL) (Luo et al. 2004). In addition, nutrients other than nitrogen may also influence forest NPP responses to elevated CO_2. Some forest ecosystems are limited or co-limited by phosphorus availability, and other nutrients (e.g., potassium), which has received even less attention in experimental study. Thus, carbon accumulated in forest vegetation by the CO_2 fertilization is still uncertain. Interactions between forest vegetation carbon sequestration and nutrient limitation under elevated CO_2 levels should be a focus of future studies. Long-term FACE experiment in old-grown tropical forests will be required, because plant growth in these forest ecosystems is generally limited by phosphorus availability.

Elevated CO_2 should also potentially enhance carbon sequestration in forest soils due to increased aboveground litter, altered C allocation between shoots and roots, enhanced coarse roots production and fine roots turnover, and root exudation.

However, experimental studies of elevated CO_2 suggested a small C sequestration of only average 5.8 % increase in forest soils (Luo et al. 2006), and the magnitudes, sometimes even the direction of the change, vary among different tree species, CO_2 experimental facilities, and length of experiments. This is rather surprising. The newly increased soil C input under elevated CO_2 may stimulate microbial degradation of soil organic matter decomposition, a phenomenon known as a "priming effect" (Bader and Cheng 2007). It has been shown that CO_2-induced priming effect can override environmental effects (such as soil temperature, soil moisture, or soil properties) to accelerate soil organic matter decomposition rates, and hence resulting in expanded soil respiration to offset the extra soil C input due to increased plant growth, and a decrease in soil C content (Bader and Cheng 2007). Several studies have detected priming effects in temperate forests (Bader and Cheng 2007; Carney et al. 2007). Carney et al. (2007) reported that despite higher plant growth, the CO_2-induced priming effect enhanced soil microbial activity and resulted in a double reduction in soil C in scrub-oak ecosystem. Drake et al. (2011) also reported that total quantity of C entering the soil via litter fall and all belowground C inputs increased 17 % from c. 1.50 kg C m^{-2} $year^{-1}$ under ambient CO_2 to c. 1.75 kg C m^{-2} $year^{-1}$ under elevated CO_2. However, these increases in C entering the soil under elevated CO_2 was matched by increased C loss attributable to significant increases in fine and coarse root respiratory fluxes (i.e., autotrophic respiration) and a significant increase in heterotrophic respiration (Fig. 6) (Drake et al. 2011). Furthermore, a recent laboratory study found that shift of soil microbial community by elevated CO_2 could increase soil organic matter decomposition, resulting in a decrease of 9 % in soil carbon (Cheng et al. 2012). These experimental studies have added to the uncertainty about whether the soil C pool would act as a net sink for atmospheric CO_2 under future increasing atmospheric CO_2 concentrations.

Effects of Temperature

Experimental study of warming impacts on forest carbon sequestration is critical for determining the terrestrial carbon feedback to climate change. A number of warming experiments have been conducted in forest ecosystems busing greenhouses, electrical surface soil warming, passive heating, overhead infrared lamps, and closed- and open-top chambers (Hui et al. 2012; Rustad et al. 2001). Since 2001, several of these studies have been completed, new studies have been initiated, and several are ongoing. Of the ongoing studies, the soil warming experiment at the Harvard Forest in Petersham, MA, USA, is one of the longest running. Initiated in 1991, electric heat resistance cables buried at 10 cm depth in the soil warm surface soils to 5 °C above ambient in a mixed northern hardwood forest. Next Generation Ecosystem Experiments-Tropics, or NGEE-Tropics, was initiated to investigate how rising temperatures, shifting precipitation patterns, increasing greenhouse gas levels, and other natural and human-induced changes affect tropical forests' influence on Earth's climate (http://esd1.lbl.gov/research/projects/ngee_tropics/index.html, Accessed June 1, 2015).

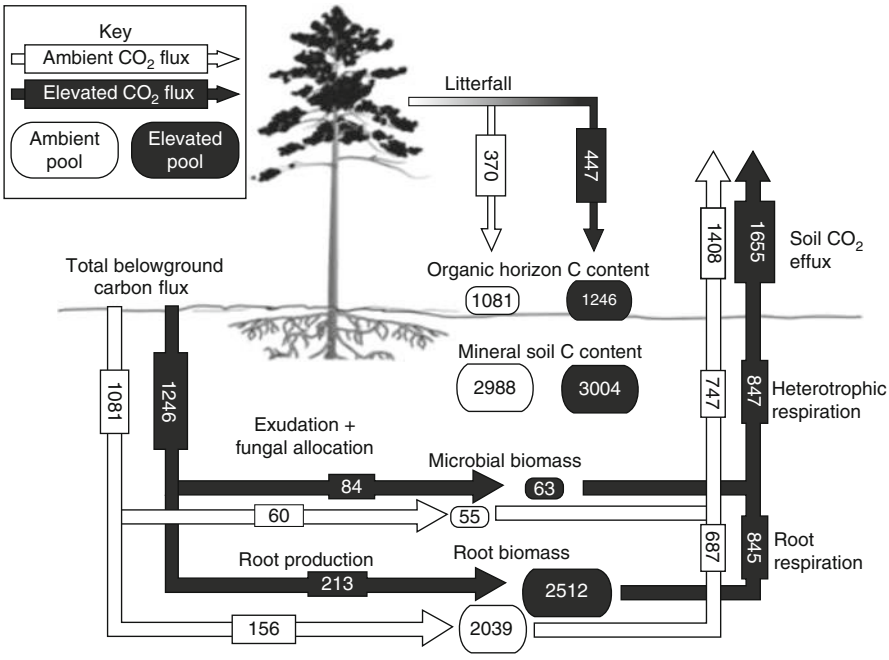

Fig. 6 Belowground carbon budgets for a warm-temperate forest exposed to elevated atmospheric CO_2 at the Duke free-air CO_2 enrichment (*FACE*) site. Ambient CO_2 is shown in white, while elevated CO_2 is shown in black. Ovals reflect pools and have units of g C m^{-2}; squares within arrows reflect fluxes of C and have units of g C m^{-2} $year^{-1}$ (Adapted from Drake et al. (2011), with permission from John Wiley and Sons)

The effects of experimental warming on vegetation carbon accumulation in forest ecosystems are highly variable. Regional environmental factors such as temperature, precipitation, and availability of soil nitrogen may contribute to diverse changes observed in global forest warming experiments. For example, soil warming in a Norway spruce forest at Flakaliden in northern Sweden increased the stem-wood growth of trees in heated plots by 50 % relative to controls after 5 years (Jarvis and Linder 2000). In relatively warmer region, however, the aboveground biomass of sugar maples decreased in response to warming in the open-top chambers. Furthermore, Cunningham and Read (2002) found that Australian tropical trees demonstrate higher physiological temperature optima but narrower photosynthetic temperature tolerances than temperate tree species. Observed growth declines in tropical forests have been attributed to temperature-induced increases in plant respiration and decreased net photosynthesis as a result of increasing temperature beyond the thermal optimum (Doughty 2011). In some environments with pronounced dry spells, the effect of warming may also lead to significantly enhanced moisture limitation, in turn reducing carbon inputs into plant biomass by reduced NPP. Further evidence of warming increasing mortality rates was revealed in several forests

around the world during strong El Niño Southern Oscillation (ENSO) years, which exhibit higher temperatures and lower rainfall than normal years. In addition, Melillo et al. (2002) reported the results from a decade long warming experiment conducted in a hardwood forest. They observed that soil warming also increased the availability of mineral N to plants, which in an N-limited forest may further stimulate carbon storage in plant biomass. Over the 7-year study of warming in a deciduous forest in New England, subsequently, Melillo et al. (2011) found that plant carbon storage increased by up to 7.0×10^6 kg C ha^{-1} in the heated areas relative to control areas (Fig. 7). Increases in vegetation carbon storage in the heated area are likely due, for the most part, to the warming-induced increase in net nitrogen mineralization of about 27 kg N ha^{-1} $year^{-1}$. This represents a 45 % increase relative to the nitrogen mineralization rate in the control area.

The experimental warming studies published to date have suggested significant decrease in carbon from forest soils, although warming-induced increases in plant-derived carbon input (Lu et al. 2013). Warming-induced decrease in forest soil carbon storage should be attributed to a larger carbon loss via soil respiration. As temperature increases, soil respiration generally increases (Melillo et al. 2002), because warming generally directly increases both autotrophic and heterotrophic soil respiration. For example, with 5 °C soil temperature increase above ambient temperature using buried heating cables, Peterjohn et al. (1994) reported an additional C release of 538 g m^{-2} $year^{-1}$ from soil in Harvard Forest. Similarly, Melillo et al. (2011) found that soil warming has resulted in a cumulative net loss of carbon (1.3×10^7 kg C ha^{-1}) from a New England forest relative to a control area over the 7-year study. However, the magnitude of response in soil respiration to soil warming is greater in cold, high-latitude ecosystems than in warm, temperate areas (Lu et al. 2013). Thus, warming has likely caused a great loss of C in boreal forest soils. It is also commonly observed that the magnitude of response in soil respiration to warming decreases over time (Rustad et al. 2001). The experimental warming at the Harvard Forest showed a dramatic 26–75 % increase in soil respiration at the first 4 years (Peterjohn et al. 1994), while 10 years after the initiation of treatments, soil respiration in the warmed plots in 2000 was no longer significantly different from the control, a trend that has continued through the latest period of record. The unchanged soil respiration under warmed treatment can be attributable to acclimatization and/or depletion of substrates (Rustad et al. 2001). In addition, warming caused a shift in the soil microbial community toward more fungi, which are more tolerant to high soil temperature and dry environments than bacteria owing to their filamentous nature. Shifted microbial community structure may partially explain observed decreases in the temperature sensitivity of soil respiration.

Effects of Precipitation

Experiments in which precipitation was manipulated in the field span a wide range of experimental treatments and use a variety of methodologies. Precipitation has been manipulated in a wide range of forest ecosystems through both decreases and

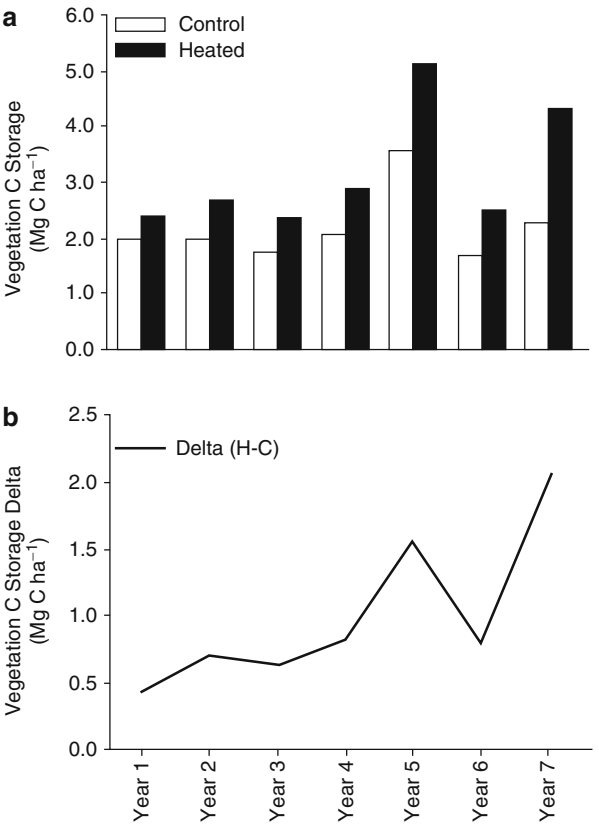

Fig. 7 (**a**) Annual vegetation carbon storage in the heated and control areas (in Mg C ha^{-1}) in a deciduous forest in New England. (**b**) Annual vegetation in carbon storage delta (heated minus control) (in Mg C ha^{-1}) in a deciduous forest in New England (Adapted from Melillo et al. (2011))

increases in rainfall amount and changes in rainfall seasonality. Drought has been often simulated using rainout shelters, while increases in precipitation have been simulated using a combination of rainout shelters and irrigation. Studies at both small and large scales have been conducted. The throughfall exclusion experiment conducted in a mature evergreen forest near Santarém, Brazil, is the largest in scale, reaching 1 ha (Davidson et al. 2008). Because confidence in both historic reconstructions and future global trends in precipitation has lagged behind that for atmospheric CO_2 and temperature, there are fewer precipitation manipulation experiments that have been initiated over the past several decades, and to date, no global synthesis of existing results has been undertaken.

In general, plant production responded positively to experimental increases in precipitation and negatively to experimental decreases in precipitation. However, the magnitude of response in plant to change of precipitation patterns depend on whether water availability is limiting to plant growth and whether the plant community is adapted to drought conditions. In the largest scale throughfall exclusion experiment, Brando et al. (2008) reported that wood production in an Amazon forest was the most sensitive component of aboveground net primary productivity to drought,

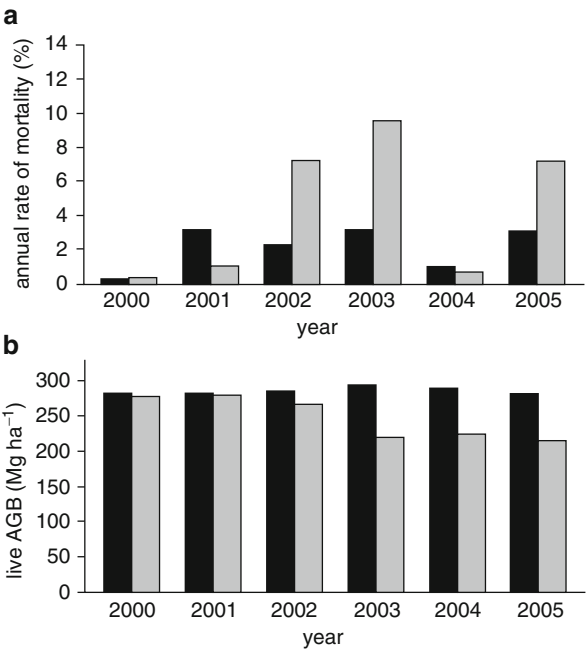

Fig. 8 (**a**) Annual percent of mortality measured on an individual basis for all individuals ≥10 cm dbh in the throughfall exclusion and control plots from Dec. 2000 to Dec. 2005. (**b**) Aboveground standing live biomass of all individuals ≥10 cm dbh from throughfall exclusion and control plots during the same period. *Black bars*, control; *grey bars*, exclusion (Adapted from Brando et al. (2008) with permission)

declining by 13 % the first year and up to 62 % thereafter. Live aboveground carbon declined by 3.25×10^7 kg ha^{-1} through the effects of drought on tree growth and mortality (Fig. 8). In addition, a long-term manipulation of precipitation inputs in a forested ecosystem showed that saplings of *C. florida* and *A. rubrum* grew faster and mortality was less on the wet plot compared with the dry and control plots (Hanson et al. 2001). Conversely, diameter growth of large trees was unaffected by the treatments. However, tree diameter growth averaged across treatments was affected by year-to-year changes in soil water status. Growth in wet years was as much as two to three times greater than in dry years (Hanson et al. 2001). These field growth data also suggest that intra- and interannual variability in precipitation were more important in determining tree growth than large directional changes in the amount of precipitation falling at any given time (Hanson et al. 2001).

There were only a few experimental studies attempted to directly assess the effect of precipitation change on soil carbon storage in forest ecosystems. Meier and Leuschner (2010) observed that soil carbon decreased by approximately 25 % in beech forests with annual precipitation >900 mm year^{-1} compared to those with precipitation <600 mm year^{-1}. However, an experimental study in Mediterranean woodland suggests that minor changes (around 10 % reduction) in precipitation amount are not likely to significantly affect or soil carbon stocks, although enhanced soil moisture during summer significantly accelerates C cycling through stimulated annual stem primary production, litter fall, soil respiration, and net annual plant-

derived C input to soil. Numerous experimental studies of precipitation change impact on soil carbon storage often focus on its impacts on forest soil respiration. Rainfall-manipulation experiments generally showed increased soil respiration following experimental water additions and decreased soil respiration following rain exclusion. However, the response of soil respiration to precipitation change differed according to moisture conditions. In a mixed deciduous forest at the Harvard Forest, Massachusetts, throughfall exclusion significantly decreased soil respiration by 53 mg C m^{-2} h^{-1} over 84 days in 2001 and by 68 mg C m^{-2} h^{-1} over 126 days in 2002, representing 10–30 % of annual soil respiration in this forest and 35–75 % of annual net ecosystem exchange of C (Borken et al. 2006). However, Deng et al. (2012) reported that soil respiration in two of three subtropical forests showed little response to precipitation increase, even when the precipitation was doubled. The precipitation increase treatment only slightly increased soil respiration in the pine forest (15.4 %), where ambient soil moisture level is relatively lower than those in the other two subtropical forests in southern China (Deng et al. 2012). The effect of precipitation on soil respiration is more complex in tropical forests. For example, drought could drive increases in plant root mortality, declines in decomposer activity (or both), and hence lower soil CO_2 emissions in eastern Amazonian rainforest, Brazil (Sotta et al. 2007). Alternatively, increased decomposition of dead roots may more than offset root mortality-related declines in soil respiration, resulting in unchanged soil respiration under throughfall exclusion plots in a mature evergreen forest near Santarém, Brazil (Davidson et al. 2008). However, results from a recent experimental study indicated that experimental drought in a humid tropical rain forest may also increase soil carbon losses to the atmosphere due to higher concentrations in litter dissolved organic matter (Fig. 9) (Cleveland et al. 2010).

Effects of O_3

There has been increased understanding of the effects of O_3 on plants since 1864, particularly during the last half of the twentieth century. Similar to elevated CO_2, ecologists usually use double O_3 concentration or increase it at a specific level in the onset of experiments conducted in greenhouses, growth chambers, open-top chambers, and FACE facilities.

Experimental studies indicated that elevated O_3 generally decreased biomass production, with greater sensitivity of root biomass to elevated O_3. Wittig et al. (2009) using a meta-analysis reported that current ambient O_3 (40 ppb on average) significantly reduced the total biomass of trees by 7 % compared with trees grown in charcoal-filtered (CF) controls, which approximate preindustrial O_3. Elevated O_3 of 64 ppb reduced total biomass by 11 % compared with trees grown at ambient O_3, while elevated O_3 of 97 ppb reduced total biomass of trees by 17 % compared with CF controls (Fig. 10). Similarly, King et al. (2013) found that the mean decrease in biomass production in young trees relative to the control was −12.5 %, with the most responsive parameter being total belowground biomass (−19.1 %) and

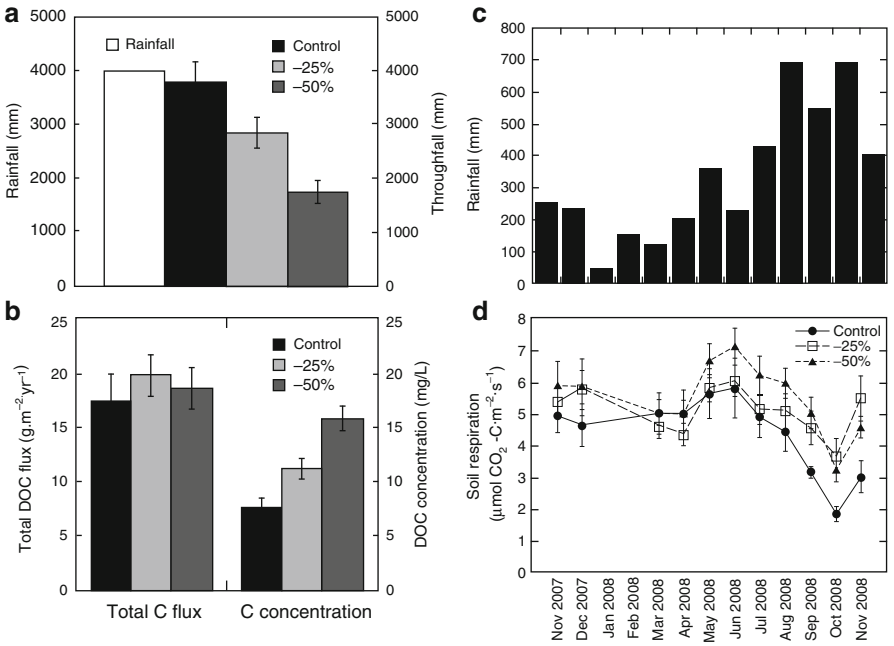

Fig. 9 (**a**) Annual rainfall (*open histogram bar*) and throughfall fluxes and (**b**) total annual dissolved organic carbon (*DOC*) fluxes and concentrations in the control and rainfall reduction (−25 % and −50 %) exclosure plots. (**c**) Monthly rainfall and (**d**) mean monthly surface soil CO_2 fluxes (respiration) from the control and rainfall reduction (−25 % and −50 %) exclosure plots. Values are means ± SD (Adapted from Cleveland et al. (2010))

the least being coarse roots (−2.7 %). For intermediate-age trees, the decrease in biomass production due to elevated O_3 relative to the control averaged −15.0 %.

Decreased allocation to roots under elevated O_3 should potentially reduce soil carbon stock in forest ecosystem. However, the trend of elevated O_3 impacts on soil carbon is poorly characterized. Unlike the total plant production, for example, King et al. (2013) reviewed that fine root biomass in intermediate-age trees (6–12 years) showed a mean stimulation due to elevated O_3 of 1.82 % relative to the control. The extremely large variance occurred because of the 11 observations, six were negative (average of −20.4 %) and five were positive (average of 28.5 %). At the Aspen FACE project, the pure aspen community showed a consistent stimulation in fine root biomass under elevated O_3 over time, whereas the aspen-birch and aspen-maple communities did not, suggesting a strong genetic effect on ecosystem function. Accordingly, soil respiration showed contrasting responses to elevated O_3 in different forest ecosystems. For example, soil respiration decreased from loblolly pine pots exposed to ozone (Edwards 1991). Soil respiration increased in response to elevated O_3 in ponderosa pine seedlings (Scagel and Andersen 1997). A later analysis (Zak et al. 2011) incorporated estimates of turnover with the fine root

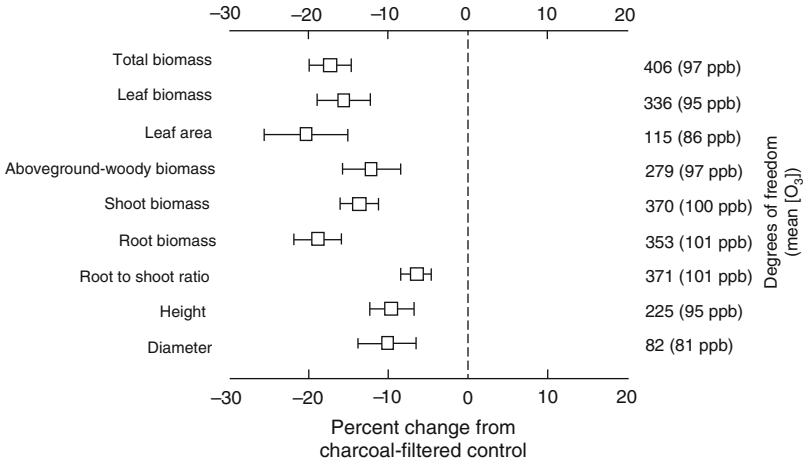

Fig. 10 Percent change in biomass, leaf area, root-to-shoot ratio, height, and diameter of all trees exposed to elevated ozone concentrations relative to charcoal-filtered controls. Symbols are bracketed by 95 % bootstrapped confidence intervals; degrees of freedom and mean O_3 are given along the y-axis (Adapted from Wittig et al. (2009), with permission from John Wiley and Sons)

biomass and estimated a nonsignificant 8 % increase in total NPP in the aspen community in the 12th year of the experiment. The fine root dynamics can have such a large impact on total NPP, and potentially net ecosystem productivity (NEP), in response to air pollution illustrates the continuing need for a much better understanding of belowground processes.

Effects of N Deposition

Atmospheric deposition of reactive nitrogen compounds (i.e., forms of nitrogen that interact with the biosphere and atmosphere) is a byproduct of human activity that can have large impacts on carbon sequestration in forest ecosystems. Since 1980s, numerous experiments of nitrogen addition have been conducted in forest ecosystems using solid or liquid nitrogen fertilization. The types of nitrogen fertilization include NH_4^+, NO_3^-, NH_4NO_3, and urea. Nitrogen fertilization studies usually provide the nitrogen in a single or a few applications, in contrast to atmospheric deposition, which is essentially continuous in the dry form (NOx, HNO_3 vapor) and in small, frequent pulses as wet deposition (NH_4^+ and NO_3^-) in precipitation. Furthermore, in contrast to fertilizer additions where nitrogen inputs are retained primarily in soil, vegetation accounts for most of the retention of nitrogen deposited from the atmosphere.

Experimental evidences in forest ecosystems indicated that plant biomass generally increases with nitrogen additions, and aboveground growth increases more than belowground growth, leading to decreased root/shoot ratios. Using a meta-analysis, Lu et al. (2011) reported that experimental nitrogen addition in forest ecosystems increased aboveground and belowground biomass by about 35 % and 30 %, respectively. However, responses tend to vary depending on tree species and the level of nitrogen availability in soil. In the Harvard Forest Long-Term Ecological Research system, for example, plant productivity increased by 50 % in broadleaf forest after 9 years of nitrogen fertilizer, while it decreased by about 30 % in pine forest at the high nitrogen fertilizer of 30 kg N ha^{-1} $year^{-1}$ (McNulty et al. 1996). In Europe NITREX network, forest NPP increased by 50 % when high nitrogen deposition was removed (Magill et al. 2000). This indicated that excess nitrogen inputs have led to a reduction in plant productivity in Europe NITREX forests. Nitrogen deposition is likely to stimulate fine root production but also increase fine root turnover, resulting in a decrease in fine root biomass. However, fine root production could decrease if chronically elevated nitrogen deposition leads to tree mortality (Nadelhoffer 2000).

Most of nitrogen fertilizer studies suggest a significant increase in soil carbon in forest ecosystems. In 15 long-term (14–30 years) experiments in *Picea abies* and *Pinus sylvestris* stands in Sweden and Finland, for example, Hyvönen et al. (2008) reported that addition of a cumulative amount of N of 600–1800 kg N ha^{-1} resulted in a mean increase in soil C stock of 11 kg (C sequestered) kg^{-1} (N added) ("N-use efficiency"). Nave et al. (2009) conducted a meta-analysis of the responses of soil C storage on north temperate forest and found that N inputs increased soil carbon by 7.7 %, with largest increase in the western conifers forests (Fig. 11). Using isotope technology, Nadelhoffer et al. (1999) reported that nitrogen deposition accounts for 20 % of the annual 1.5 $\pm$ 1.9 Pg CO_2-carbon uptake attributed to forest growth in north temperate forests. Nevertheless, Lu et al. (2011) found that soil carbon did not significantly change in forest ecosystems in response to N addition. They explained that in forest ecosystems, the input of increased plant carbon to the soil was mainly via the aboveground litter fall. Both litter and organic horizon C:N ratios significantly decreased in response to N addition. Unprotected surface litter and organic horizon soil with high substrate quality decomposed quickly. The regression analyses also showed that N-induced variations in soil carbon pools were not significantly correlated with changes in aboveground plant growth but were positively correlated with changes in soil respiration. This is rather surprising. In most of the temperate forests, soil microbial activity is often and also limited by nitrogen; increasing N input can significantly enhance soil respiration (Zhou et al. 2014). However, in some forests such as subtropical forests in southern China where ambient nitrogen deposition is relatively high, increasing N input can significantly reduce soil respiration but still stimulate plant growth (Deng et al. 2010). Nitrogen addition in these forests caused a large increase of about 30 % in soil carbon in subtropical forest in southern China (Chen et al. 2012).

Soil C storage response ratios include pool sizes only. Biogeographic groups are western conifers (*WC*), northeast conifers (*NEC*), and northeast hardwoods (*NEH*) (Reprinted from Geoderma, Vol. 153, Nave et al., Impacts of elevated N inputs on north temperate forest soil C storage, C/N, and net N-mineralization, 231–240, Copyright (2009), with permission from Elsevier)

Multiple Factors Studies

Unlike common single-factor experiments, global change involves simultaneous changes in multiple factors, which could potentially have complex interactive influences on carbon sequestration in forest ecosystems. Currently, more and more experiments now consider more than one climatic factor of elevated CO_2, temperature, precipitation, O_3, and nitrogen. In experimental studies with CO_2 and N manipulations, for example, trees often had greater aboveground growth stimulation by elevated CO_2 at high rather than at low N supply (Norby et al. 2010; Liu et al. 2010). Even in southern China where nitrogen is not the limited factor for tree growth, Liu et al. (2010) reported greater tree growth stimulation by elevated CO_2 at high rather than at low N supply (Table 2). Similarly, the CO_2-induced soil carbon accumulation was larger at high rather than at low N supply (Chen et al. 2012). Deng et al. (2010) also reported that both CO_2 and N treatments significantly affected soil respiration in this subtropical forest in southern China, and there was significant interaction between elevated CO_2 and N addition ($p < 0.001$, $p = 0.003$, and $p = 0.006$, respectively). Deng et al. (2013) further revealed the seasonal importance of environmental controls under elevated CO_2 and N deposition in the assessment of soil C sequestration potential in subtropical forest ecosystems in southern China. Climate warming and elevated CO_2 could interactively alter plant and soil N cycling, which in turn could influence the response of forest carbon sequestration to elevated CO_2. Experimental studies found altered elevated CO_2 fertilization response due to temperature only at temperatures substantially different than typical or optimal thermal environments. For instance, warming increased soil N availability and thereby enhanced relative responses of

Table 2 Tree aboveground biomass and belowground biomass (means ± standard errors) under different CO_2 and N treatments (Liu et al. (2010)). Treatments with the same letter are not significantly different from each other ($p > 0.05$). The treatments were: CK control, N+ high N, C+ high CO_2, and CN high CO_2+high N (Liu et al. 2010)

photosynthesis to elevated CO_2 (Shaw and Harte 2001), which in turn could enhance NPP responses to elevated CO_2.

The interaction of elevated CO_2 and O_3 was generally not statistically significant and resulted in positive stimulation of all biomass production parameters in both young and intermediate-age trees relative to the control. This suggests that the effects of elevated CO_2 and O_3, when occurring together, are generally additive and that the positive effects of elevated CO_2 more than offset the negative effects of elevated O_3 on biomass production (King et al. 2013). All data on changes in soil C were from only two studies conducted at the Aspen FACE Project at different stages of stand development (Loya et al. 2003; Talhelm et al. 2009). Although the mean responses showed elevated CO_2 and O_3 altered total soil carbon in forest ecosystems, the changes were not statistically significant (Talhelm et al. 2009). The 11-year study at Aspen FACE indicated that the effects of elevated CO_2 and O_3 on soil C varied with stand development (King et al. 2013). After the first 4 years of fumigation at the Aspen FACE, Loya et al. (2003) found that the formation of new soil carbon under elevated CO_2 and O_3 treatment was 51 % less than that under elevated CO_2-only treatment. However, a later study by Talhelm et al. (2009) suggested that the initial reduction in new C accumulation in elevated O_3 under elevated CO_2 was only a temporary effect. After 11 years of fumigation, neither elevated CO_2 nor elevated O_3 induced significant impacts on new soil carbon accumulation or total soil carbon content (Table 3).

Thus, evaluating multifactor interactions in influencing carbon sequestration in forest ecosystems is critical to understanding their response to global change in the

Table 3 Pretreatment (1997) of soil carbon (C) traits (means ± SE) and ANOVA P-values (Talhelm et al. (2009)). Carbon dioxide (CO_2) is not a factor in the analyses of $\delta^{13}C$ because only elevated CO_2 plots ($+CO_2$, $+CO_2+O_3$) were later fumigated with $\delta^{13}C$-depleted CO_2. Community is not a factor in this analysis because this sampling predated the establishment of the model communities and did not distinguish between soils in the various parts of the rings. Effects with $P < 0.1$ are in bold whereas those with $P < 0.05$ are in bold and italics (Talhelm et al. 2009)

real world. Indeed, when interactive effects dominate over the main effects of individual factors, results from single-factor experiments become less useful for understanding ecosystem changes. In the case that interactive effects are minor relative to main effects, results from single-factor experiments may become useful in informing us of potential changes of ecosystems in response to multifactor global change.

Conclusion

Responses of forest carbon sequestration to climate change play an important role in regulating future climate change. The current experimental studies, to certain extent, reveal true forest carbon sequestration responses to climate change and help understand mechanisms of these responses. However, the magnitude and direction of these responses may vary with time. Long-term experiments are needed to resolve ecosystem responses to changing climate that occur on decadal or greater time scales. Nutrient limitation is hypothesized as one of the primary causes for the contrasting responses of forest carbon sequestration to climate change (not limited to CO_2). Experimental examples validate this concern (Norby et al. 2010; Melillo et al. 2011), indicating not only plant growth but also soil carbon decomposition can be limited by the nutrient availability under climate change (Cheng et al. 2012). Thus, interactions between forest carbon sequestration and nutrient limitation under climate change should be a focus of future studies. Unlike atmospheric CO_2 concentration and temperature, changes in precipitation include quantity, timing, intensity, and interval of precipitation. However, current precipitation manipulation experiments in forest ecosystems often consider the change in precipitation amount only, and the

response showed relatively complex (Cleveland et al. 2010), highlighting the need to support more types of precipitation manipulation experiments in forest ecosystems particularly in tropical forests. New precipitation manipulation experiments will continue to increase our understanding of the current contrasting results we have seen to date and our ability to quantify the response of large-scale forest ecosystems to realistic precipitation change scenarios. Similarly, technological advances such as large-scale air warming (including ecosystem level) and improved infrared heating can improve our understanding of understudied processes not only belowground but also aboveground vegetation. In addition, multifactor climate change experiments have shown that forest carbon sequestration responses to multiple interacting factors of global change can be nonlinear and nonadditive. It is therefore imperative to continue to initiate and support multifactor experiments to explore these interactions at different locations.

Modeling Studies

Overview

Modeling is an important approach to investigate the effects of global change on forest ecosystems. Ecosystem models can be used to estimate dynamics of forest ecosystem functions, explain the observed changes and the underlying mechanism, and forecast ecosystem carbon cycling in the future climatic conditions (Tian et al. 2012; Hui et al. 2012; Dale and Rauscher 1994; Pan et al. 2014). Ecological models are also useful for assessing the relative importance and the impacts of different environmental change factors on forest ecosystems (Tian et al. 2012).

Ecological models have been developed at different scales, from leaf to plant canopy, ecosystem, regional, and global scales. Most of the models simulate the processes of plant photosynthesis and respiration, stomatal conductance, evapotranspiration, nitrogen uptake, carbon allocation among plant organs, litter production, nitrogen mineralization, and soil organic carbon decomposition and use these processes to calculate the carbon fluxes between vegetation, soils, and the atmosphere (Hanson et al. 2004). At leaf and canopy levels, Farquhar model is widely used to simulate leaf photosynthesis (Tian et al. 2012; Luo et al. 2001). This model considers several key process of CO_2 assimilation including CO_2 diffusion into leaf through leaf stomata and CO_2 uptake by rubisco enzyme. At regional or global scales, some biogeochemical models include Farquhar model while others use a simplified light use efficient model to simulate photosynthesis and ecosystem productivity (Tian et al. 2012; Pan et al. 2014).

At the larger spatial scales, dynamic global vegetation models (DGVMs) have also been developed to simulate carbon dynamics at regional and global scales (Tian et al. 2012; Potter et al. 1993). These models also consider the species composition changes with time under climate change. Several multiple model comparison studies have been conducted to compare model structures, ecological processes, and model performances compared with experimental/observational data. In this section, we

will present a few models as case studies and use several examples to illustrate the climatic effects on ecosystem carbon dynamics as model applications.

Ecological Models at Leaf, Stand, Ecosystem, Regional, and Global Levels

Leaf and Stand Models

Leaf and tree physiology are directly affected by atmospheric CO_2 concentration, temperature and precipitation, particularly leaf photosynthesis, respiration, tree growth, and water use (Galik and Jackson 2009). Photosynthesis is the most important biochemical process that green plants use to incorporate atmospheric CO_2 for plant growth. At the leaf level, Farquhar model can simulate photosynthesis and tree growth (Tian et al. 2012; Luo et al. 2001). Tree growth models are often used to predict the impacts of climate change on tree growth and development, physiology, and forest ecosystem fluxes (Galik and Jackson 2009). These models are often based on a mass balance approach and consider forest ecosystem fluxes, organic matter decomposition, and water balance. As a result, the models can be used to estimate above- and belowground biomass and production, explain decomposition processes, and quantify carbon dynamics and budget for specific sites.

Many models at stand and ecosystem levels have been developed, mostly with similar model structures but different complexity and model parameters (Table 4) (Hanson et al. 2004). For example, Hanson et al. (2004) compared 13 stand level ecosystem models and found that most models use Farquhar equation for photosynthesis calculation but vary greatly in growth cost setting, carbohydrate feedbacks, and soil organic pools, as well as in their spatial, mechanistic, and temporal complexity.

In addition to process-based models, some statistical models are also used to assess the forest carbon fluxes with climatic factors (Hui and Luo 2004; Hui et al. 2012; Dale and Rauscher 1994). These models usually require large calibration data sets and are generally derived from extensive growth records using regression analysis. The models may simulate observations and forecast ecosystem changes in the future with no basis in biological processes. Such statistical models usually work well under given site and stand conditions.

Regional and Global Ecosystem Models

Several ecosystem models have been developed at regional and global scales, such as Carnegie-Ames-Stanford Approach (CASA)-Biosphere (Potter et al. 1993), Terrestrial Ecosystem Model (TEM) (McGuire et al. 1992), and Dynamics Land Ecosystem Model (DLEM) (Tian et al. 2012). Most of the terrestrial ecosystem carbon cycling models start with a leaf-level photosynthesis model, often employing a modified version of the Farquhar et al. (1980) photosynthesis model. Here we used DLEM as an example to illustrate model structure, processes involved, and model functions.

DLEM is a highly integrated process-based ecosystem model that simulates the fluxes and storage of carbon, water, and nitrogen among/within the terrestrial

ecosystem components with consideration of multiple natural and anthropogenic perturbations (e.g., climate change, CO_2 concentration, atmospheric composition, land use and management practices), working at multiple scales in time from daily to yearly and space from meters to kilometers, from region to globe.

The DLEM includes five core components (Fig. 12): (1) biophysics, (2) plant physiology, (3) soil biogeochemistry, (4) dynamic vegetation, and (5) disturbance, land use, and management. Briefly, the biophysics component simulates the instantaneous fluxes of energy, water, and momentum within land ecosystems and their exchanges with the surrounding environment. The plant physiology component simulates major physiological processes, such as plant phenology, C and N assimilation, respiration, allocation, and turnover. The soil biogeochemistry component simulates the dynamics of nutrient compositions and major microbial processes. The biogeochemical processes including the mineralization/immobilization, nitrification/denitrification, decomposition, and methane production/oxidation are considered in this component. The dynamic vegetation component simulates the structural dynamics of vegetation caused by natural and human disturbances. Two processes are considered: the biogeography redistribution when climate change occurs and the recovery and succession of vegetation after disturbances. Like most dynamic global vegetation models, the DLEM builds on the concept of plant functional types (PFT) to describe vegetation distributions. The disturbances, land use, and management component simulates cropland conversion, reforestation after cropland abandonment, and forest management practices such as harvest, thinning, fertilization and prescribed fires. The DLEM has been extensively used to study the terrestrial carbon, water, and nitrogen cycles around the world in response to global change.

Model Applications

Leaf and Stand Models

Effects of climate change on photosynthesis, growth, respiration, and decomposition have been investigated by many studies over the past several decades. Some ecological models specifically simulate the impacts of elevated CO_2 on terrestrial ecosystem carbon processes, while most of the biogeochemical models consider multiple factor impacts and have the capability to simulate the effects of multiple climatic factors on forest ecosystem carbon cycling. Several intermodel comparison studies also compared the features, ecological processes built in the models, and model simulation results among some ecosystem models (Hanson et al. 2004). Due to different model structures and processes implemented, multimodel comparisons typically reveal divergent responses across models. These modeling excises not only quantify model uncertainty but also provide insight to the underlying processes causing the divergent model responses. Below, we summarize some modeling results of climate change impacts on forest ecosystem carbon processes, including elevated CO_2, global warming, precipitation, and nitrogen deposition.

Effects of CO_2 on leaf photosynthesis are very well simulated. Increase in CO_2 concentration generally increases leaf photosynthesis and decrease photorespiration

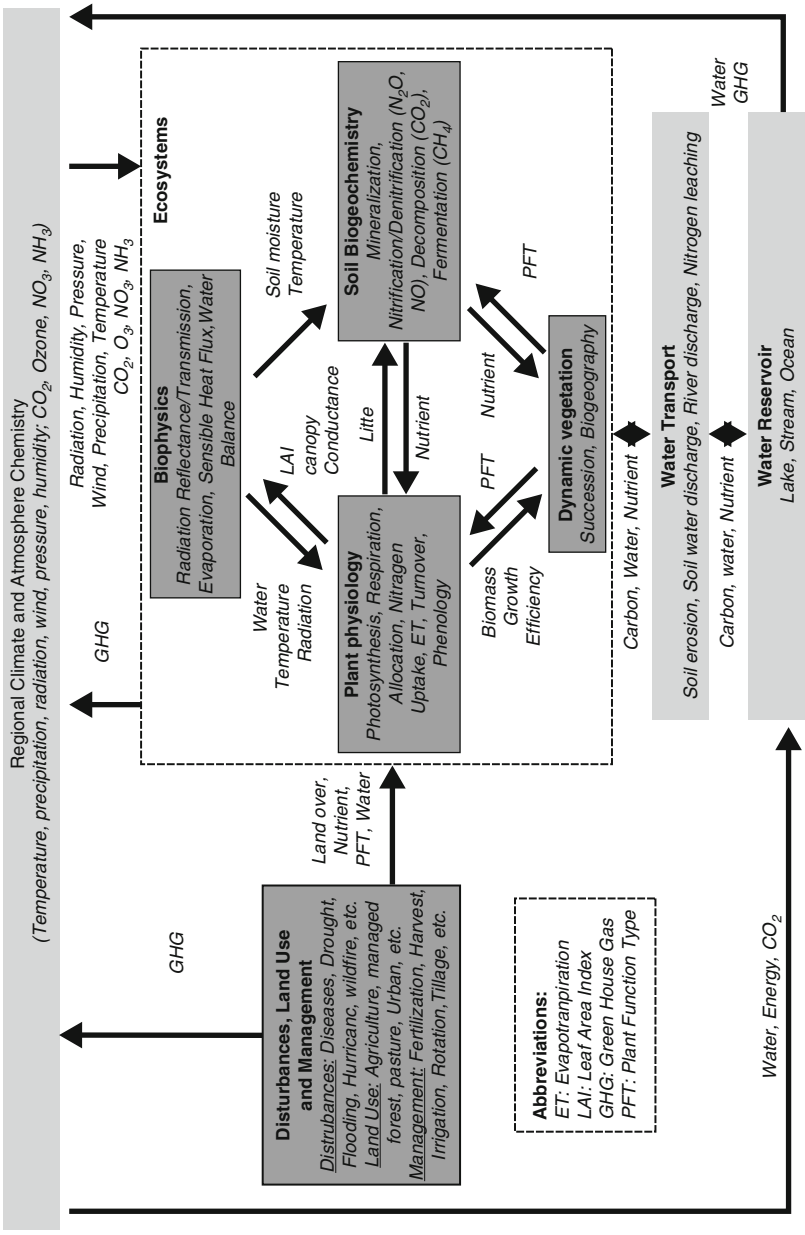

Fig. 12 Framework of the Dynamic Land Ecosystem Model (*DLEM*) (Adapted from Tian et al. (2012) with permission)

(Lloyd and Farquhar 1996), as a result, increases growth of trees and leaf area (Curtis and Wang 1998). Elevated CO_2 also reduces stomatal conductance to water vapor due to partial stomatal closure (Ainsworth and Rogers 2007). Using physiologically based canopy model, MAESTRA, Luo et al. (2001) simulated gross primary productivity of loblolly pine in the Duke Forest and found that elevated CO_2 significantly increased canopy carbon fixation by 35–43 %. At the same forest site, Hui & Luo (Allen et al. 2010) simulated the effects of CO_2 on soil respiration using a process-based model and found that soil respiration was enhanced by 18–26 % by elevated CO_2. In a multiple model evaluation of the response of climate-carbon cycle models to future CO_2 emissions, they applied 11 ecosystem models and found that all models showed an increase in carbon storage with higher atmospheric CO_2, driven by a 12–76 % increase in NPP with CO_2 doubling (Friedlingstein et al. 2006). Bonan (2014) used a process-based model to simulate the biomass production of Norway spruce under both current climate and climate change scenarios. Doubling current ambient CO_2 concentration was projected to increase NPP by 36 %. These modeling studies and many others demonstrated that NPP and GPP will increase under elevated CO_2 conditions but differ in the magnitudes of the enhancement from different stands.

Precipitation is another important factor regulating photosynthesis, respiration, and ecosystem carbon sequestration. For the effects of precipitation, Gerten et al. (2008) used four process-based ecosystem models (TECO, LPJ, ORCHIDEE, and DayCent) to simulate ecosystem carbon and water responses. They found that NPP response to precipitation changes differed not only among different sites/ecosystems but also within a year at a given site. Plants grown at humid sites were least responsive to precipitation change as compared to dry sites. Solomon (1986) simulated the effects of precipitation and temperature on forests across eastern North America using FORENA, an individual-based forest stand model. The model predicted slower growth rates of most deciduous tree species and a universal dieback of the original forest, up to 1000 years from the initial change in climate. Climate-induced drought and heat stress have affected some temperate forests, particularly those in arid regions such as the western United States. Precipitation change has increased tree mortality, suppressed forest productivity, and reduced forest biomass and total carbon stocks (Allen et al. 2010).

Nitrogen availability is often the limiting factor in net primary productivity (Bonan 2014). Nitrogen deposition is one of the major anthropogenic nitrogen inputs to forest ecosystems. Photosynthetic rate is often well correlated with leaf nitrogen content, as photosynthesis is driven by the nitrogen-rich enzyme rubisco. The potential of ecosystems to take up carbon is constrained by the availability of nitrogen (Luo et al. 2004). Without supplemental N additions or decreases in N losses, the availability of mineral N declines with time in ecosystems exposed to elevated atmospheric CO_2 in comparison with N availability at low CO_2 levels (i.e., progressive N limitation) (Luo et al. 2004). Simulation models linking nutrient cycling to plant production and C sequestration consistently predict less terrestrial CO_2 uptake and storage than models that do not incorporate N regulation of carbon-related processes (Wang and Houlton 2009). Zaehle et al. (Lloyd and Farquhar 2008)

used 11 ecosystem models to investigate the effects of N availability on the response of forest productivity to elevated CO_2 at two FACE sites – a deciduous broadleaf forest at Oak Ridge National Laboratory (ORNL) and the evergreen needleleaf (i.e., loblolly pine) Duke Forest. They found that most of the models can reproduce the observed initial enhancement of net primary production (NPP) at both sites, but none can simulate NPP changes in the long term (Fig. 13). Most models showed signs of progressive N limitation.

Warming temperature has proved to have direct physiological effects on photosynthesis and indirect stomatal effects (Meir et al. 2006). Many models included temperature influence on photosynthetic machinery (Doughty 2011). Bonan (2014) simulated the biomass production of Norway spruce in southeastern Norway and reported that NPP was projected to increase by 7 % over the current 1.01×10^4 kg ha^{-1} $year^{-1}$ under a mean annual air temperature elevated by 4 °C over current levels.

Overall, climate change, elevated CO_2, and nitrogen deposition have affected forest productivity and biomass stocks. Nitrogen deposition has a more positive effect on NPP than on other factors, although the positive effect from elevated atmospheric CO_2 is also significant. Climate changes have less obvious effects on average productivity but increased the interannual variability.

Regional and Global Models

At regional and global scales, climate models (general circulation models (GCMs)) have been coupled to terrestrial ecosystem models, dynamic global vegetation models (DGVMs), during the past decade (Smith et al. 1992). Smith et al. (Sitch et al. 2008) compared potential impacts on vegetation distribution of climate change projections from four GCMs. Forest areas increase toward the poles with all scenarios having an increase in the extent of tropical forests into areas that are now occupied by subtropical or warm temperate forests and a shift of the boreal forest zone into area now occupied by tundra. All scenarios suggest an increase in terrestrial carbon storage ranging from 8.5 to 180.5×10^{12} kg.

DGVMs are useful tools for diagnosing the potential responses of forest NPP and biomass to changing climate and atmospheric composition, such as rising CO_2 concentration. Model results have showed that the efficiency of forest carbon uptake under future climate change will decrease, with forests becoming less capable of mitigating the growth in atmospheric CO_2 concentrations (Pan et al. 2014; Friedlingstein et al. 2006). Carbon cycle predictions of different DGVMs are generally consistent with global land carbon budgets but if used to forecast future change, the results diverge considerably. But most models agree that effects of elevated CO_2 counteracts carbon losses caused by climate change, resulting in the forests being a net sink for carbon (Hickler et al. 2008). For example, LPJ model predicted a 35 % increase in NPP for tropical forests under elevated CO_2 at 550 ppm compared to 370 ppm (Galbraith et al. 2010). Galbraith et al. (Fernández-Martínez et al. 2014) tested the importance of precipitation changes relative to other environmental drivers, including CO_2 using three DGVMs (HyLand, LPJ, and TRIFFID) and found that modeled responses to increased temperature are as important, or more

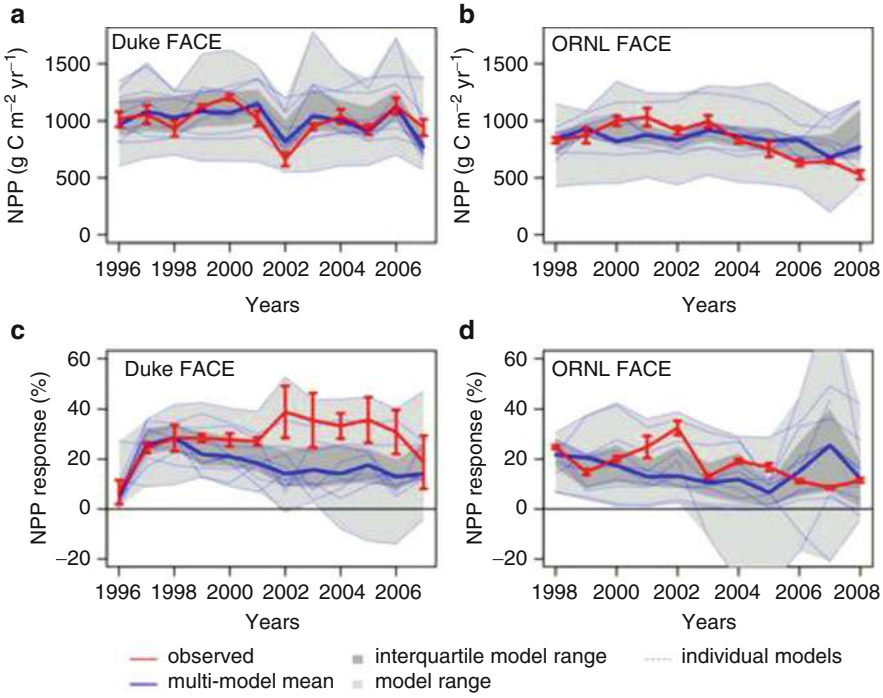

Fig. 13 Ambient net primary production (*NPP*; **a**, **b**) and its response to elevated CO_2 (**c**, **d**) at the Duke (**a**, **c**) and Oak Ridge National Laboratory (*ORNL*) (**b**, **d**) Free-air CO_2 enrichment (*FACE*) experiments. The observations are across-plot averages, and the error bars denote ± 1SE (Adapted from Zaehle et al. (2014), with permission from John Wiley and Sons)

important, than reduced precipitation in causing loss of plant biomass carbon. Model simulated responses of forests to climate change often vary with soil nutrient conditions. Fernández-Martínez et al. (Song et al. 2013) found that forests growing in fertile soils are able to sequester about 30 % of the carbon that they take up during photosynthesis but only 6 % of that carbon if growing in nutrient-poor soils.

Tian et al. (2012) quantified ecosystem NPP in the Southern USA by employing the integrated process-based ecosystem model, DLEM. They found that elevated CO_2 stimulated more carbon uptake in forests than in other land-cover types. Forest NPP was stimulated by 12 % and C storage was stimulated by 6 % from 1895 to 2007. The mean regional total NPP was 1.18×10^{15} g C $year^{-1}$ (525.2 g C m^{-2} $year^{-1}$) during 1895–2007. NPP increased consistently from 1895 to 2007 with a rate of 2.5×10^{12} g C $year^{-1}$ or 1.10 g C m^{-2} $year^{-1}$. Elevated CO2 played an important role in both deciduous broadleaf and evergreen needleleaf forests (Fig. 14). Song et al. (Zaehle et al. 2014) projected terrestrial carbon sequestration of the southeastern USA in the twenty-first century using DLEM model and found that carbon storage will increase from 13.5 kg C m^{-2} in the 2000s to 16.8 kg C m^{-2}

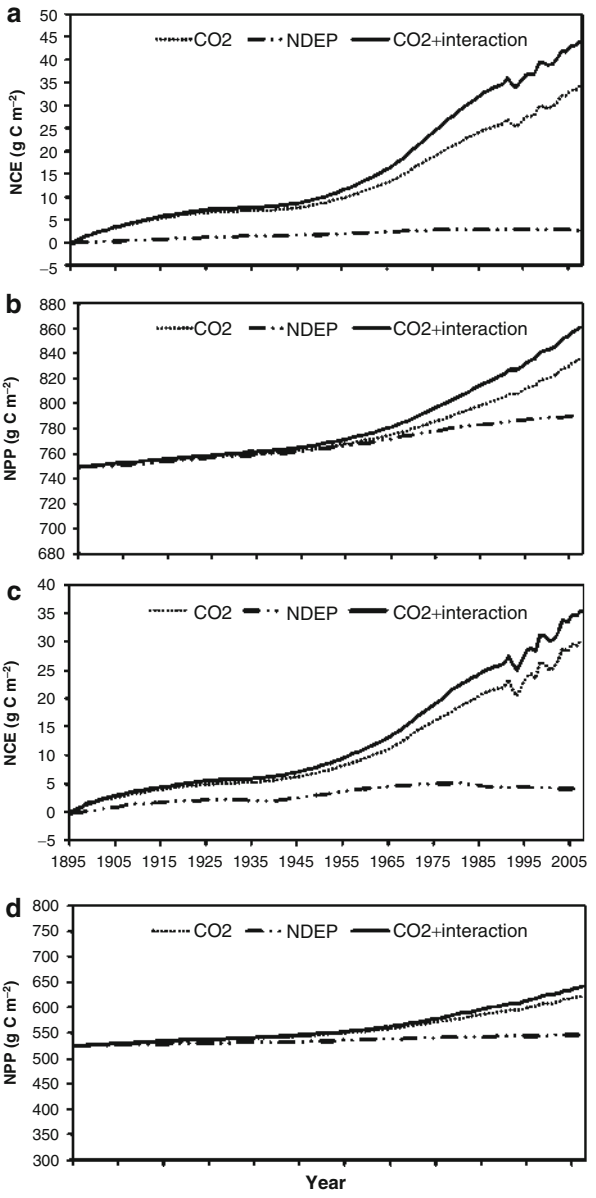

Fig. 14 Interactive effects of CO_2 and N deposition on NCE, NPP for different biomes in the Southeastern USA. (**a**, **b**), deciduous broadleaf forest; (**c**, **d**) evergreen needleleaf forest. CO_2: CO_2 only; NDEP: N deposition only (With kind permission from Springer Science+Business Media: Ecosystems, 15, 2012, Tian et al., Fig. 11. ©2012, Springer Science+Business Media, LLC)

in the 2090s. Both deciduous and evergreen forests show large increases. In the 2000s, the carbon storage in the deciduous forest shows a 42.4 % increase from 14.7 to 20.9 kg C m^{-2} , and the evergreen forests shows a 23.2 % increase from 22.0 to 27.1 kg C m^{-2}. The carbon sequestration is primarily caused by elevated

atmospheric CO_2 and nitrogen deposition. Forests are major contributor to the carbon sink in terrestrial ecosystems.

Conclusion

The forest carbon cycle exerts a large and significant influence over the physical and chemical aspects of the Earth system, but we still have limited understanding of this influence (Smith et al. 1992). Until now, most ecological models to predict forest carbon sequestration at large scales had only considered the effect of nitrogen but did not take into account other constraints such as phosphorus or the pH of the soil, which is related to the availability of nutrients. The frontiers of global terrestrial biosphere modeling, such as phosphorus cycling, microbial models of decomposition, and photosynthetic and respiratory temperature acclimation, should be included in these models (Lloyd and Farquhar 2008). New measurements as well as new modeling studies are needed to assess fully the importance of forest ecosystem–climate interactions for future climatic change. Greater attention must be given to understanding processes, rather than model projections of the future (Lloyd and Farquhar 2008). Better-constrained predictions of future changes in forest ecosystems and climate will also require improved links between data and models, perhaps through the application of formal data assimilation techniques (Meir et al. 2006; Smith et al. 1992).

Closing Remarks and Future Research

Considerable progresses have been made during the past several decades to better understand forest ecosystem responses to climate change using both experimental and modeling approaches. While the manipulative field studies provide useful insight into how forests respond to individual climate change factors, logistical constraints often prevent the examination of some climatic factors, and more importantly, the complex interactions between multiple and changing climatic factors (Norby et al. 2010; Deng et al. 2010; Shaw and Harte 2001; Fisichelli et al. 2012). Due to the facility limitation, the early studies on the elevated CO_2 effects mostly used growth chamber or open-top chamber on tree seedlings. Only after the FACE facility is constructed, the effect of CO_2 on mature trees can be investigated. Due to the cost of construction and fire concerns, warming studies in forests are often limited to soil warming (Rustad 2008; Melillo et al. 2002; Lu et al. 2013). The whole ecosystem warming studies have seldom been done. Temperature and precipitation forcings are also codependent, requiring a complex systems approach to understand the impact on forest ecosystem carbon dynamics and their feedbacks. Increases in productivity under elevated CO_2 can be partially offset by reductions in productivity from warming-induced drought stress (Rustad et al. 2001; Lu et al. 2013), and experimental studies incorporating more climatic factors are needed. Additionally, experimental studies typically conducted at plot or stand scales

and over relatively short time scales leave gaps in our understanding about the long-term effects of climate change at landscape and regional scales. The long-term and multifactor experiments should be conducted. For ecosystem biogeochemical modeling study, data model need to be better integrated. Inverse modeling techniques need to be applied to better parameterize the models. Uncertainty analysis in term of measurement error, model structures, model parameters, and parameter combinations need to be conducted to improve confidence of model estimation and prediction (Tian et al. 2012; Reyer et al. 2013). As more data are accumulating in long-term manipulative experiments, inverse modeling and data assimilation will play a more important role in global change ecology. Besides climate variability, climate disturbances such as drought, cold spell, heat wave, and fire and biological disturbances such as disease, insect outbreak need to be built into biogeochemical models. At large scale and for long-term prediction, dynamic changes of vegetation need to be considered in the models (Tian et al. 2012). Thus, great effort will be required to integrate previous and new data from experimental results and process knowledge into ecosystem models. Further development of data-model assimilation tools, analytical methods, and ecosystem models to improve understanding of climate change effects on forests will be needed in order to actually predict the carbon sequestration in forest ecosystems, inform policy makers, and provide guidelines for conservation and forest management (Zuidema et al. 2013).

Impact of Climate Change on Biodiversity

David H. Reed

Contents

Abstract

Biodiversity, the diversity of living things on Earth, is a critical measure of the Earth's health. Biodiversity provides immense direct benefits to humans, with at least 40 % of the world's economy being derived from biological resources. Maintaining biodiversity provides greater food security, opportunities for economic development, and provides a foundation for new pharmaceuticals and other medical advances. Ironically, maintaining biodiversity levels and functioning ecosystems is critical to ameliorating climate change; yet, climate change is expected to cause serious disruptions to Earth's ecological systems, resulting in an overall loss of biodiversity and a reduction in the goods and services provided

to humans. Extinction rates in the future are very difficult to predict. However, with immediate and decisive action to mitigate climate change, losses of biodiversity can be minimized and humans can continue to reap many of the benefits nature provides; business as usual scenarios will likely lead to the loss of >50 % of all plant and animal species on Earth and the collapse of many ecosystems worldwide. Such losses will drastically lower the quality of life for humans and will take millions of years to reverse.

Introduction

Biodiversity refers to the sum variation of all living organisms (animal, plant, fungal, and microbial) on Earth, including their genetic diversity, species diversity, and the diversity in the ecosystems (e.g., rainforests, coral reefs, estuaries) they help build and regulate. There is a hierarchical structure to biodiversity. Genetic diversity is the most fundamental level of diversity and the one on which all other levels of biodiversity depend, and all levels of biodiversity contribute to the amount and diverse types of ecosystem services provided and the utilitarian and aesthetic value of biodiversity (Reed 2010).

Biodiversity contributes to human welfare in innumerable ways. Examples of ecosystem services include the regulation of climate from a local to global level, purification of the fresh water supplies necessary for human survival, the storage and recycling of the nutrients on which all life depends, and the formation of soil necessary for agriculture. Biodiversity also provides resources such as foods, medicines, and wood products. At least 40 % of the world's economy, and 80 % of the economy of less-industrialized nations, is derived directly from biological resources (1992). Biodiversity enriches the lives of humans in very tangible and utilitarian ways, but also provides us with emotional gratification and inspiration.

Given the importance of biodiversity to human well-being and the irreversibility of its loss, the depletion of biodiversity is one of the most important environmental threats that humanity faces (Millennium Ecosystem Assessment (MEA) 2005). The golden toad (*Bufo periglenes*) is thought to be the first species to go extinct due primarily to global warming (Pounds and Crump 1994), and climate change has already been implicated in numerous population extinctions and at least one other species extinction (Pounds et al. 2006). However, this is just the tip of the iceberg. Examination of past extinction events and current warming predictions suggests that global climate change alone could drive more than half of the known species on Earth to extinction (Fig. 1).

This chapter will cover some of the many reasons why biodiversity is vital to human life and well-being, briefly describe global warming scenarios, present the results of data and models suggesting how many species are likely to go extinct in the near future if steps are not taken to sharply decrease greenhouse gases, and conclude with suggestions for what needs to be done to ameliorate global climate change in a way that is compatible with minimizing biodiversity loss and maintaining the critical ecosystem functions that nature provides.

Fig. 1 The golden toad vanished from Costa Rica's Pacific coastal-mountain cloud forest in the late 1980s. Several researchers have linked outbreaks of the chytrid fungus that drove the golden toad to extinction, and threatens dozens of other species of frogs and toads in the same region, to climate change (Pounds et al. 2006)

Importance of Biodiversity: Ecosystem Services

Biodiversity and healthy ecosystems are vital to life and to human well-being. Biodiversity underlies everything from food production to medical advances. Humans, the world over, use at least 40,000 species of plants and animals on a daily basis (Primack 2002). Many people still depend on wild species for some or all of their food, shelter, and clothing. All of our domesticated plants and animals, including our closest companion the dog, came from wild-living ancestral species.

Ecosystem services are the services provided for humans by natural ecosystems (Daily 1997). These ecosystem services can be divided into four major categories: supporting, regulating, provisioning, and cultural (Millennium Ecosystem Assessment (MEA) 2005). As an example, mature forests help regulate local and regional climates by contributing to rainfall and temperature in the areas they occupy. They do this in part by extracting carbon dioxide from the air and producing oxygen as a byproduct of photosynthesis. The health of ecosystems depends on having viable populations of the species that make up those ecosystems (Reed et al. 2003a) and maintaining viable populations of plants and animals will require immediate and strong actions to limit global climate change and a commitment to biodiversity friendly land use changes and conservation efforts.

Supporting Ecosystem Services

These are the biogeochemical and biological processes underlying all other ecosystem processes, such as nutrient cycling, oxygen production, pollination, seed dispersal, primary productivity, and soil formation. Three of these are elaborated on in more detail below.

Net primary productivity (NPP) is the amount of organic material generated through the process of photosynthesis. This underlies the capacity of all ecosystems to provide ecosystem services, as well as provisioning and regulating much of what humans use. Humans currently consume or forego about 35 % of global terrestrial NPP (see Fig. 2 for one example) (Vitousek et al. 1986; Rojstaczer et al. 2001; Imhoff et al. 2004; Helmut et al. 2007). Forego means that our altering of the natural environment diminishes the potential NPP of the planet, for example, by covering potentially productive land with asphalt and concrete, overgrazing and overfarming many formerly productive areas of the Earth's surface until they become desert, and polluting many rivers and lakes. Thus, because we have already exceeded the carrying capacity of the planet the foundational productivity of the planet is slowly being eroded.

Nitrogen is the single largest component of the Earth's atmosphere. However, atmospheric nitrogen is unavailable for biological use, leading to a scarcity of usable nitrogen in many types of ecosystems. The nitrogen cycle is crucial for life on Earth and affects the rate of key ecosystem processes, including primary production and decomposition. Alteration of the nitrogen cycle by human activities is global and pervasive (Galloway and Cowling 2002; Gruber and Galloway 2008; Duce et al. 2008; Galloway et al. 2008). Human activities now convert more N_2 from the atmosphere into reactive forms than all of the Earth's terrestrial processes combined, mostly via the creation and use of fertilizers to enhance food production. Agricultural runoff and the burning of fossil fuels have boosted the supply of reactive nitrogen in the open oceans 50 % above preindustrial levels. This excess nitrogen causes great harm to marine and freshwater ecosystems, contributes to global warming, and harms human health (Galloway and Cowling 2002; Gruber and Galloway 2008; Duce et al. 2008; Galloway et al. 2008).

Pollination and seed dispersal of both domestic and wild plants is another essential ecosystem service provided free of charge by many diverse animal species. Approximately 80 % of wild plants, and about 35 % of the agricultural crop species that feed the world, require animal pollination for successful reproduction (Fig. 3) (Klein et al. 2007; Ricketts et al. 2008). Similarly, without animal species acting as seed dispersers, many plants would fail to reproduce successfully. Animal seed dispersers, such as bears, birds, elephants, and monkeys play a central role in the structure and regeneration of forests (Lanner 1996; Nathan and Muller-Landau 2000; Seidler and Plotkin 2007). Disruption of these complex services may leave large areas of forest devoid of seedlings and younger age classes of trees, and are thus unable to recover swiftly from human impacts such as land clearing. The great importance of forests will be expounded upon at several points in the chapter (Fig. 4).

In the USA alone, the agricultural value of wild pollinators is estimated in billions of dollars per year. Meanwhile, the diversity of natural pollinators available to both wild and domesticated plants is diminishing and negative effects on plants clearly visible (Buchmann and Nabhan 1996; Rodríguez-Cabal et al. 2007; Anderson et al. 2011). As an example of the value of pollinators, experiments preserving tropical forest fragments around coffee farms boosted crop yields roughly by 7 %, as coffee plants near forested areas received twice as many visits from bees and produced 20 % more coffee beans (Ricketts et al. 2004a, b).

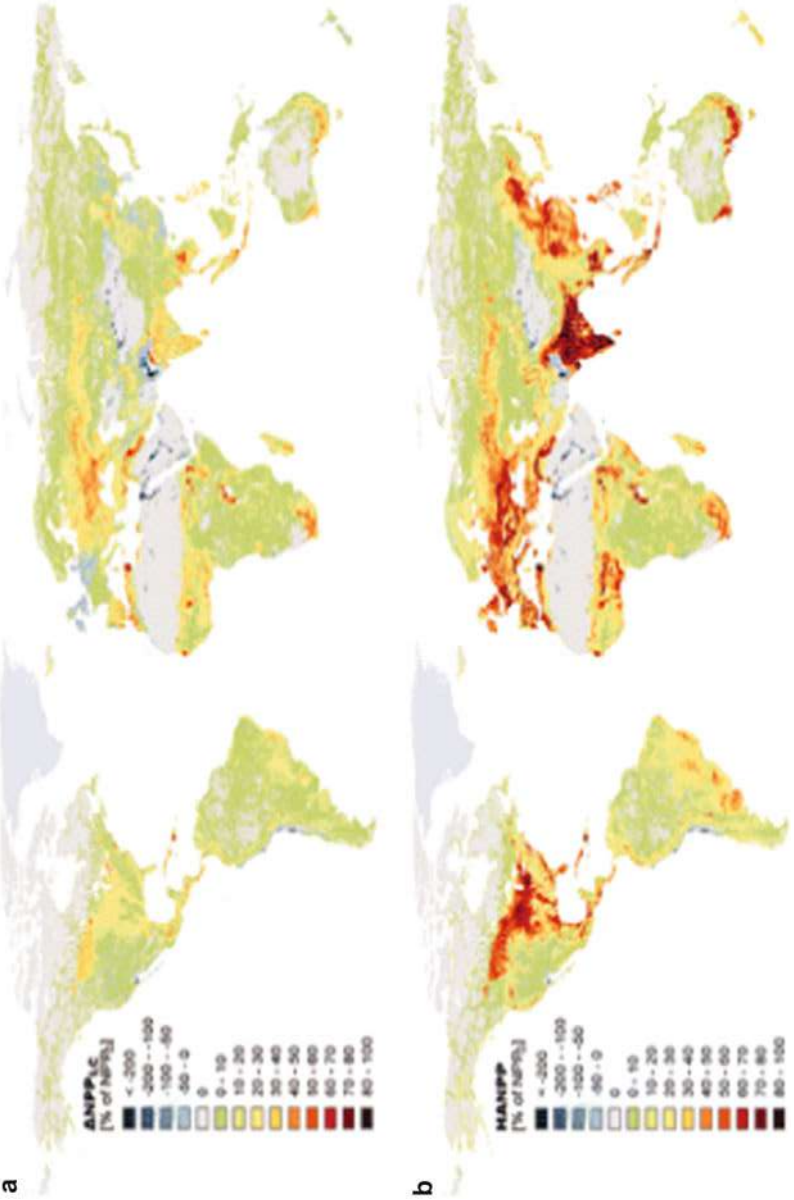

Fig. 2 Maps of the human appropriation of net primary production (*NPP*), excluding human-induced fires. (**a**) Land-use-induced reductions in NPP as a percentage of NPP_0. (**b**) Total NPP as a percentage of NPP_0. *Blue* (negative values) indicates increases of NPP_{act} (**a**) or NPP_t (**b**) over NPP_0, *green* and *yellow* indicate low HANPP, and *red* to *dark* colors indicate medium to high HANPP (Reprinted from Fig. 1 of Helmut et al. (2007))

Fig. 3 Iridescent green sweat bee (*Agapostemon* sp.) covered in pollen. Bees are the best known pollinators. Pollination by bees and other animals increases the quality and/or yield of harvests for 70 % of leading global crops (Jackson and Overpeck 2000) (Photo courtesy of Jon Sullivan, pdphoto.org)

Fig. 4 Old-growth forests, such as the tropical rainforest around San Rafael Falls in Yasuni National Park (Ecuador) pictured below, provide a vast array of ecosystem services such as carbon storage and mitigation of climate change, micro- and macro-climate control, oxygen production, water purification, regeneration of nutrients, and maintenance of soils. They also provide food, fibers, timber, and other renewable resources for humans. Old-growth forests also contain a vast array of plants, animals, fungi species, along with their almost infinite variety of genes, which provide huge benefits to humans. The forests are also spectacularly beautiful

Regulating Ecosystem Services

Examples of regulating ecosystem services include climate regulation, flood regulation, nutrient retention, pest control, protection from soil erosion, and purification of both air and water. A few of these examples are elaborated on in greater detail below.

Plants, trees in particular, have a major influence on local, regional, and even global climate. Approximately half of the annual rainfall in the Amazon basin is recycled by the forest itself. Extensive deforestation can dramatically reduce rainfall in a region, raise temperatures (via loss of shade and reduced evapotranspiration), increase fire frequency, and negatively affect agriculture and access to clean potable water (Webb et al. 2005; Werth and Avissar 2004; Lavelle et al. 2006; Foley et al. 2007). According to the Intergovernmental Panel on Climate Change, and others, deforestation probably accounts for more than 20 % of total anthropogenic carbon dioxide emissions (IPCC 2007a). Living trees extract carbon dioxide and other pollutants from the air, slowing the buildup of carbon dioxide in the atmosphere, while the burning of forests to clear land for agriculture releases large amounts of CO_2 into the atmosphere, which contributes to global warming (Korner 2000; Fearnside and Laurance 2004).

The conversion of wetlands increases flooding rates, and deforestation of uplands and flood plains also increases the frequency and severity of flooding events, at least in some areas (Hey and Philippi 1995; Bradshaw et al. 2007; Ward et al. 2008; Chang et al. 2009). Wetlands store and slowly release surface water, rain, snowmelt, groundwater, and flood waters. Trees and other vegetation impede the movement of flood waters and distribute them more slowly over floodplains. This combined water storage and slowing action lowers flood heights and reduces soil erosion downstream and on adjacent lands. Preserving and restoring wetlands typically provides flood protection at a lower cost than dredging operations and levees and also serves as excellent wildlife habitat and carbon sinks. Flooding in Asia, Europe, and North America over the past several decades has claimed thousands of lives, destroyed hundreds of thousands of homes, and damaged more than 13 million hectares of farmland (Fig. 5). Increased flooding rates along the Mississippi River are due to drainage of floodplain wetlands, the construction of levees, and the loss of beaver dams (Fearnside and Laurance 2004). Though there are a number of factors impacting flooding severity and economic losses, it is worth noting that Missouri, Illinois, and Iowa suffered the most damage from the 1993 floods and all three have less than 15 % of their original wetlands left (Ward et al. 2008). Europe has seen a number of devastating floods over the past 15 years. For the River Meuse, an analysis suggests that landscape changes brought on by humans, especially deforestation and draining of wetlands are the primary causative agents for the increase in flooding, along with increased variability in rainfall (Chang et al. 2009). Recent catastrophic flooding in Korea has been determined to be due to increased frequency of severe rainfall events with deforestation also contributing (US Geological Survey 1999). Note that the increases in severe rainfall events is a prediction of climate change models and their implication in recent flooding events is foreshadowing even more severe events in the future.

Fig. 5 Flooding in Thailand (2010) killed 232 people (*top photo*), flooding in Brazil (2011) killed 702 people (*center photo*), and flooding of the Mississippi River in the U.S. (2011) has killed at least 400 people (*bottom photo* is from Mississippi River flooding of 1993). Draining of wetlands, deforestation, and deleterious changes in rainfall patterns due to climate change will make floods like these more common in the future (*Center photo* courtesy of Agência Brasil, permission does not imply that Agência Brasil endorses this use of their photo)

In addition to inland flooding from rivers, coastal areas are also prone to flooding. Mangrove forests and coral reefs buffer the coast against ocean storm surges and prevent coastal erosion. The building of levees, along with the destruction of freshwater wetlands, contributed to the massive flooding of New Orleans following Hurricane Katrina (Stokstad 2005). Evidence suggests that mangrove forests are more effective than concrete sea walls in controlling floodwaters from tropical storms (Raven and McNeely 1998) and that areas with intact mangrove forests and/or coral reefs were less damaged during the Southeast Asian Tsunami of 2004 than areas without them (Marris 2005; Kunkel et al. 2006; Wells and Kapos 2006). However, both salt marshes and mangrove forests are rapidly being destroyed and coral reefs may be functionally extinct by 2050 due to climate change (Carpenter et al. 2008; Veron et al. 2009). Besides buffering from storms, coral reefs and mangrove forests harbor vast amounts of biodiversity and are among the most productive breeding grounds for commercially important fish.

Studies have confirmed intense periods of soil erosion associated with the rise and subsequent decline of civilizations in the Middle East, Greece, Rome, Central and South America, as well as other regions around the world (Judson 1968; Pope and van Andel 1984; Beach 1998; Van Andel et al. 1990; Beach et al. 2006). The high

rates of soil erosion are due both to deforestation and agriculture (Ponting 1993; Williams 2003; Montgomery 2007). When vegetation is removed, the rates of soil erosion increase rapidly. Clear cutting slopes lead to landslides that have killed tens of thousands of people across the world over the past few decades. Soil runoff into rivers and oceans kills freshwater and marine animals. Erosion and flooding can make the water supplies along rivers undrinkable. The UN Food and Agricultural Organization estimated that from 1990 to 1999, erosion damaged or destroyed more than 600,000 km (1992) of the world's cropland. In China, erosion has forced the abandonment of one third of all formerly arable land. China's Loess Plateau was cleared of trees about 1,000 years ago, since then it has been eroding, causing 40 % declines in agricultural output and flooding and landslides in the lower reaches of the river that killed thousands in 2010. Data from studies worldwide strongly suggest that erosion rates from conventionally plowed agricultural fields are 10–100 times greater than rates of soil production (Montgomery 2007).

Provisioning Ecosystem Services

Provisioning ecosystem services consist primarily of food, pharmaceuticals, and wood, but also include a number of other services such as use in biofuels, bioremediation of pollution, natural insecticides, and providing materials for building shelters and producing clothing. The focus of this section will be on food security and pharmaceuticals.

It is obvious that humans rely on plants and other animals for food. For example, the world's aquatic ecosystems are the leading source of animal protein for human consumption (Kareiva and Marvier 2011). Three species of plant, wheat, corn, and rice provide about 60 % of the calories humans consume. However, few realize the importance of biodiversity (both at the genetic and species level) for food security.

The dangers of relying on genetically depauperate crops are illustrated by the Great Irish Potato Famine. Potatoes were introduced into Ireland from the New World and eventually most of the Irish people became dependent on this one crop. In 1845, the windborne Potato blight (*Phytophthora infestans*) spread throughout the country and caused almost complete failure of the potato crop over the next 3 years. It is estimated that at least one million people died of starvation and another million emigrated out of the country, reducing the population by 20–25 %. The severity of the famine was greatly exacerbated by the lack of genetic variation in the potatoes, which made them particularly vulnerable to disease. More than a century later a wild relative of the potato would be discovered in Peru, that when hybridized with the standard crop plant, produces a variety of potato resistant to potato blight. Another wild potato species, *Solanum fendleri*, is used in breeding for resistance to a nematode species that attacks cultivated potatoes. A potato species from Mexico, *Solanum bulbocastanum*, has been used to genetically engineer the potato to resist new strains of the potato blight (Song et al. 2003).

Despite evolutionary theory and history, much agriculture continues to depend on genetically uniform crops. For example, in most less-industrialized nations, more

than half of the rice varieties come from a single mother plant. In the past century, about 75 % of the genetic diversity of our most important domestic crops has been lost (Fowler and Mooney 1990). The widespread planting of a single corn variety contributed to the loss of over a billion dollars worth of corn in 1970, when the US crop was overwhelmed by a fungus (*Bipolaris maydis*). In 1991, the genetic similarity of Brazil's orange trees made them easy targets for the worst outbreak of a citrus disease in the country's history.

And wild relatives of our domestic crops continue to come to the rescue of current food production. Agriculture and genetic resources are critically interdependent and agricultural production relies on continuing infusions of genetic resources from wild relatives for maintaining or increasing yield. A wild barley plant from Ethiopia (*Hordeum bulbosum*) provided a novel gene conferring complete resistance to the yellow dwarf virus that causes huge losses in barley, oats, wheat, maize, and rice worldwide. In the 1970s, an outbreak of grassy stunt virus decimated rice harvests across Asia. Scientists from the International Rice Research Institute screened 6,273 samples of rice plants looking for genetic resistance to the disease. They found it in a wild relative, *Oryza nivara*, which grows in India. The gene has been incorporated into most new rice varieties since the discovery. In fact, rice is protected from most major rice diseases and much more by genes brought in from at least a dozen wild species (Table 1). The list of examples of wild species improving domesticated crops is very long, wild species genes contribute more than US$100 billion per year to profits from agriculture.

Historically, agricultural varieties of cereals have had a life expectancy of only 5–10 years before diseases or insect pests evolve to take advantage of them and the crop must be replaced with a different genetic variety because the old one is no longer productive. With global climate change, increasing water shortages, increasing pollution, decreasing amounts of arable land, and increasing dispersal of insect pests and diseases, we need these wild species now more than ever. Unfortunately many of them have likely already gone extinct and thousands more face imminent extinction. In fact, not only have we tapped only a small amount of the genetic diversity within species already cultivated, we also only use a very small proportion of the edible species. About 30,000 species of plants are thought to be edible, but only about 150 are used as human food (Wilson 1992). Of those species, only 15 species make up more than 90 % of the food we eat. Genetic diversity is most important when environments are changing rapidly (Reed 2008) and the environment may never have changed more rapidly during the history of life on Earth than it is changing right now.

The pharmaceutical industry is very dependent on natural products (Fig. 6). About a quarter of all prescription drugs in the USA (and up to 80 % of pharmaceuticals in developing nations) are taken directly from plants and 73 % of them are modeled on natural compounds (Farnsworth et al. 1988; Grifo et al. 1997; Newman et al. 2003). These include artemisinin (antimalarial and a potential treatment for cancer), aspirin, atropine, codeine, cyclosporine (the immunosuppressive which transformed the field of human organ transplantation), digitalis, morphine, penicillin, pilocarpine (used to treat glaucoma), quinine (model for modern antimalarial drugs),

Fig. 6 Poison Dart Frogs, such as *Dendrobates tinctorius* and *D. azureus* shown above, may hold the key to improved pain-relief drugs and other medications. However, their habitat is rapidly disappearing

and warfarin. Most of these come from tropical forests, but less than 1 % of rainforest plants have been tested for medicinal uses and at current rates of deforestation almost all rainforest will be gone within 40 years (Wilson 2002).

Several examples of potential cures, for diseases that kill hundreds of thousands of people, being lost or nearly lost due to the extinction of the plant or animal

supplying it are available. In 1987, leaves were collected from *Callophylum lanigerum* in Malaysian Borneo. Years later, the National Cancer Institute determined that extract from the leaves completely stopped the replication of HIV-I (Wilson 1992). A return trip was made to find the original tree, but the area had been clear cut and leaf samples from other *C. lanigerum* in the region failed to yield any of the original compound (calanolide). Luckily, a related species (*C. teysmannii*) also produced a slightly less potent anti-HIV drug called calanolide B. Calanolide B is currently in preclinical trials in the United States and seems to have low potential for cross-resistance with other therapies (Newman et al. 2008; Currens et al. 1996).

The gastric-brooding frogs consisted of only two species (*Rheobatrachus vitellinus* and *R. silus*), both native to Australia. The genus was unique because it contained the only known frog species that incubated tadpoles inside the stomach of the mother. Preliminary studies with gastric-brooding tadpoles demonstrated that the tadpoles secreted a substance, or substances, that both inhibits the secretion of stomach acids and prevents stomach emptying so that the tadpoles do not end up being digested by the mother. In the 1980s, both species became extinct, terminating studies which might have led to important new insights for treating human peptic ulcers (Newman et al. 2008).

The Pacific Yew tree (*Taxus brevifolia*) is a rare and slow-growing tree found only in old-growth forests of the Pacific Northwest, an area that is currently being logged under generous concessions to logging companies at US tax-payer's expense. The tree also used to be the only source of a drug called paclitaxel, which appears to be very effective in treating ovarian cancer and has great promise for treating lung, prostrate, and breast cancer as well. Clinical trials were delayed for this drug as it takes six Pacific yew trees to extract enough paclitaxel to treat one patient and there were not that many trees. Fortunately, paclitaxel is now being produced by semi-synthetic conversion of precursor compounds found in a variety of yew trees (Newman et al. 2008).

Gastric-brooding frogs are not the only amphibians that produce(d) compounds of potential medical benefit to humans. The skin secretions of the phantasmal poison frog (*Epipedobates tricolor*), listed by the IUCN as endangered, yield a nonaddictive painkiller (epibatidine) that is 200 times stronger than opium and does not lead to tolerance (Newman et al. 2008). Because of the very small difference between a therapeutic dose and a lethal dose, epibatidine has never been used in humans. However, research is under way to invent derivatives of epibatidine that are less toxic, but still have the desired qualities of being an extremely powerful and nonaddictive analgesic (Donnelly-Roberts et al. 1998; Drisdel et al. 2008; Sun et al. 2008). Epibatidine and other derivatives from the poisonous secretions of the frog are also being investigated for a number of other medical uses. In fact, 50 species within the family Dendrobatidae, many of which are critically endangered, have yielded 500 structurally complex compounds new to science and of medical interest (Newman et al. 2008; Daly et al. 2002). One drug investigated in clinical trials and a subject of much further research (Daly et al. 2002; Decker et al. 2001; Baraznenok et al. 2005; Zhang et al. 2006; Bunnelle et al. 2007; Arneric et al. 2007), tebanycline, was almost lost when one of the two sites of Ecuadorian forest from which the frog

was originally collected were cleared for a banana plantation (Plotkin 2000). Amphibians as a whole are more endangered than any other group of vertebrates and more than 200 antimicrobial and antifungal compounds from the skin of frogs and toads have been discovered (Wilson 2002). Given that the world now faces a severe problem due to the widespread resistance of pathogenic bacteria to multiple antibiotics, amphibian compounds can serve as powerful models for drug invention because they have novel forms of function.

There has never been a comprehensive assessment of the risk of extinction for cone snail (*Conus*) species. However, 50 % of the Earth's coral reefs are close to collapse and at least 33 % of mangrove habitat is already destroyed. These two habitats are the primary centers for cone snail diversity. Warming ocean temperatures, acidification of the ocean, coastal development, and direct exploitation of snails for their shells are all threats to this group. The species *Conus magus* produces a peptide that the commercial medication ziconotide is based on. It is about 1,000 times more powerful than morphine and relieves pain in 50 % of advanced cancer and AIDS patients whose pain is unresponsive to opiates, and results in neither addiction nor tolerance (Newman et al. 2008). At least seven other medicines derived from cone snail poisons are in clinical trials and others show promise for treatment of neurodegenerative diseases and epilepsy (Newman et al. 2008). However, only about 100 of the estimated 70,000 cone snail toxins have been characterized (Herndon and Butler 2010).

Six species of bear are threatened with extinction, including a species I study, the Asian Black Bear (*Ursus thibetanus*) (Fig. 7). The threats to bears are habitat destruction and fragmentation, direct harvesting, and global climate change. Several medical benefits have already arisen from the study of bears and others are being investigated (Newman et al. 2008). For example, denning bears appear to produce a substance that inhibits cells that break down bone and promote substances that encourage bone and cartilage production; determining the mode of action of these substances could lead to breakthroughs in treating osteoporosis and cartilage damage. Denning bears can survive for a period of 5 months or more without excreting their urinary wastes, whereas humans would die from the buildup of these toxic substances after only a few days. An estimated 1.5 million people worldwide are receiving treatment for end-stage renal disease, and the hope is that by studying bears, we may be able to learn how to treat them more effectively (Herndon and Butler 2010).

Cultural Services

Biodiversity is worth conserving because it is beautiful, interesting, and provides inspiration to inventers, artists, and people all over the globe. Wild animals, plants, and natural areas contribute to our emotional and physical well-being (Louv 2005). Hundreds of millions of people visit natural areas or zoos each year and billions of dollars are spent on hunting, fishing, and nature tourism. Other living things have also contributed greatly to human progress by providing scientific and educational

Fig. 7 The Asiatic black bear (*Ursus thibetanus*) is one of six bear species threatened with extinction from sources as varied as habitat destruction, poaching, and climate change. Bears not only serve as important models for medical uses, but Asian black bears are important seed dispersers and polar bears (*Ursus maritimus*) are top carnivores helping to structure their ecosystems. The photo is of mother Asiatic black bear and her cub. The photograph was taken by remote camera in Khao Yai National Park, Thailand (Photo courtesy of Dusit Ngoprasert)

services that are usually overlooked. For example, most of what we know about genetic diseases in humans comes from studies on the fruit fly (*Drosophila melanogaster*) or the laboratory mouse/rat. Rats (*Rattus norvegicus*) have been used in many experimental studies, which have added to our understanding of disease processes, the effects of drugs, physiology, psychology, and genetics, and other topics in health and medicine.

Summary

By this point you should be convinced that if all ecosystem services provided by Earth's biodiversity were to stop, life on Earth would be impossible. Also, by this time it should be obvious that biodiversity makes a huge and undervalued contribution to the quality of life that humans enjoy. However, you might well say to yourself, *We have already identified the organisms most valuable to humans and the species we rely on for food, and the ones that perform many of the more important ecosystem functions are in no danger of becoming extinct.*

This statement has some element of truth to it. However, it has two major weaknesses. First, we never know what species will turn out to be valuable in the future. Could you have predicted that discovery of a fluorescent protein from a bioluminescent species of jellyfish (*Aequorea victoria*) would be worthy of a 2008 Nobel Prize, a fungus (*Amycolatopsis orientalis*) found in soil samples from the rainforests of Borneo would yield the powerful antibiotic vancomycin, saliva from the canine hookworm (*Ancylostoma caninum*) would provide an anticoagulant (NAP_{c2}) that has potential use in heart attack victims and the treatment of Ebola (Newman et al. 2008), ingredients from the venom of a pit viper *Bothrops jaracara* would yield a model for hypertension drugs, vincristine and vinblastine would be isolated from the rosy periwinkle plant (*Catharanthus roseus*) and increase the chances of remission to 99 % in childhood leukemia and to 70 % in Hodgkin's disease, leech (*Hirudo medicinalis*) saliva would yield a powerful blood anticoagulant, the silk of a spider (*Nephila clavipes*) would prove useful in regenerating neurons (Allmeling et al. 2006), a bread mold (*Penicillium notatum*) would be the source of one of the most useful antibiotics and that other molds in the same genus would have statins isolated from them that may potentially reduce the risk of having a heart attack or stroke by 25 % (Wilson 2002), the synthesis of the first effective antiretroviral drug AZT would be guided by compounds isolated from a sponge (*Tethya crypta*) (Newman et al. 2000), or that a revolution in the field of molecular biology would be achieved through isolation of a DNA polymerase from a bacterium (*Thermus aquaticus*) collected out of a Yellowstone hot spring? Thus, uncertainty surrounding the value of millions of yet undescribed species suggests that we should be cautious in our destruction of habitats and the short-sighted extirpation of species that have taken millions of years to evolve their specific characteristics.

We also do not know how many species can be removed from an ecosystem before it collapses, though there is good evidence that such collapses will occur and the concomitant loss of ecosystem services (May et al. 1995; Carpenter et al. 2011).

Impact of Global Climate Change on Biodiversity

Current Rates and Causes of Extinction

In the fossil record, an individual vertebrate (amphibian, bird, fish, mammal, or reptile) species lasts on average at least one million years before it becomes extinct. Thus, in an average year, no more than one out of one million species should go extinct. The current observed extinction rate since 1,600, for vertebrates, is 2.6 per 10,000 species per year. That is at least 260 times the background rate of extinction. At this rate, it would take less than 15,000 years to equal the extinction event that killed the dinosaurs over several million years. Further, because we know that the primary cause of modern extinctions is the loss, degradation, and fragmentation of habitat, and because we know the response to habitat loss is not linear, we expect that background rate to continue to increase and probably become an order of magnitude greater than it is currently (Whiteside and Ward 2011; Pimm and Raven 2000).

The reason for this increased and increasing rate of extinction is not difficult to fathom. Humans have been strongly implicated in global extinctions for tens of thousands of years (Jetz et al. 2007; Brook et al. 2008), but the current mass extinction is due to the fact that in the last 50 years we have used more of Earth's resources than we have for the entire history of humanity before that point. We are losing topsoil at least ten times faster than it can be replaced (Montgomery 2007), about 10 % of the Earth's agricultural land has become unfit for agriculture in the past 40 years while the population continues to expand, 80 % of the world's fish stocks for which assessment information is available are reported as fully exploited or overexploited, we are using more than 20 % of the world's renewable fresh water just for irrigation (Cassman and Wood 2005), and about 40 % of the world's rainforests have been lost in the past 50 years. The human population has increased from 3.0 to 6.9 billion during those same 50 years and we are expecting another two billion over the next 40 years.

However, the current rate of extinction might pale compared to what anthropogenic climate change threatens (Pimm and Raven 2000; Jetz et al. 2007). If we do not do something about climate change then all the money and the effort that has gone into saving species from extinction will likely be lost. This is particularly true because the current threat from habitat destruction and fragmentation interacts with climate change in a nonlinear way so that the negative impacts are greater than expected by looking at the threats independently.

Current and Future Rates of Global Climate Change

Over the past century the Earth has warmed approximately 0.74 °C, averaged over all land and ocean surfaces (IPCC 2007a). This warming of the Earth has clear effects on the species that live there. By the 1990s data started being published showing that 1,700 species had shifted their ranges an average of 6.1 km per decade toward the poles and that the timing of spring activities (e.g., breeding, migration, egg laying, flowering of plants) were occurring several days earlier each decade over the past 50 years. There is now a vast amount of data showing changes in the biology of plants and animals which are in accordance with expectations under a warming climate (Cassman and Wood 2005; Walther et al. 2002; Parmesan and Yohe 2003; Root et al. 2003; Hickling et al. 2006; Parmesan 2006; IPCC 2007b). Predictions for the next century are for increases in average global temperature of anywhere from 1.1 °C to 6.4 °C (Hickling et al. 2006), due mostly to unprecedented increases in the atmospheric concentrations of the three most important greenhouse gases, carbon dioxide, methane, and nitrous oxide. However, growth in emissions continues to far exceed expectations and it is possible that predicted increases in temperature are conservative. Further, temperatures are expected to increase for at least several centuries beyond this one, because of the half-life of CO_2 in the atmosphere, loss of polar ice which reflects rather than absorbs the sun's energy (Albedo effect), release of energy from the ocean into the atmosphere, and interactions between atmospheric warming and release of CO_2 from sources such as melting permafrost.

Another major impact of climate change includes effects on rainfall patterns and water storage. Rainfall is expected to become more variable with longer droughts and more flooding. Drought areas have more than doubled over the past 40 years (Leadley et al. 2010). In many parts of the world more precipitation will fall as rain instead of snow, snows at higher elevations will melt earlier, and this will cause deleterious changes in river flow. These changes are already causing a looming water crisis in the western USA (Dai et al. 2004). Similarly, the Tibetan plateau and the Himalayas are sources for the five major rivers of Asia, all of which are vitally important to already threatened biodiversity and to 1.4 billion people. Changes in temperature and precipitation are expected to drastically alter snow melt patterns over the next 40 years, so that the Indus, Brahmaputra, and Mekong basins are likely to experience severe negative effects owing to the dependence on irrigated agriculture and meltwater in these areas (Barnett et al. 2008; Immerzeel et al. 2010).

In terms of temperature, sea levels, and other climatic factors, we are headed towards conditions that have not existed for millions or probably tens of millions of years. Even the most rapid changes in the Earth's climate that led to those conditions in the past took at least 100,000 years to occur, not a couple of centuries or less.

Climate Change and Biodiversity

There are three possible fates for populations and species making up the current biodiversity of Earth, in a rapidly changing environment: (1) Plants and animals can migrate in order to leave unfavorable environmental conditions in one area and take up residence in an area with environmental conditions that are more conducive to survival and reproduction. The evidence that plants and animals have migrated long distances during past warming and cooling periods over the past 250,000 years is irrefutable. We already see such movement in extant species and can expect to see much more in the future. (2) Adapt to changing conditions through selection on genetic diversity present or arising in the population during the period of climatic change. (3) Go extinct when some combination of the first two are not sufficient to keep the population or species extant. Over hundreds of millions of years, the Earth has experienced innumerable cooling and heating periods of different magnitudes and rates. Periods of rapid change are usually accompanied by increases in extinction rates.

Projections of species extinction rates during the current period of global climate change are controversial because of uncertainty concerning how much the climate will change and how fast, because of methodological challenges especially concerning species ability to migrate through a human-dominated habitat matrix, and because of imperfect data from past extinctions. However, much is known and reasonable estimates can be made by looking at past extinctions under global climate change. An analysis of the fossil record over the past 520 million years provides a consistent relationship between global temperatures and biodiversity levels. During warm phases, extinction rates have been relatively high in both terrestrial and marine environments (Fig. 8) (Västilä et al. 2010). Extinction rates may increase

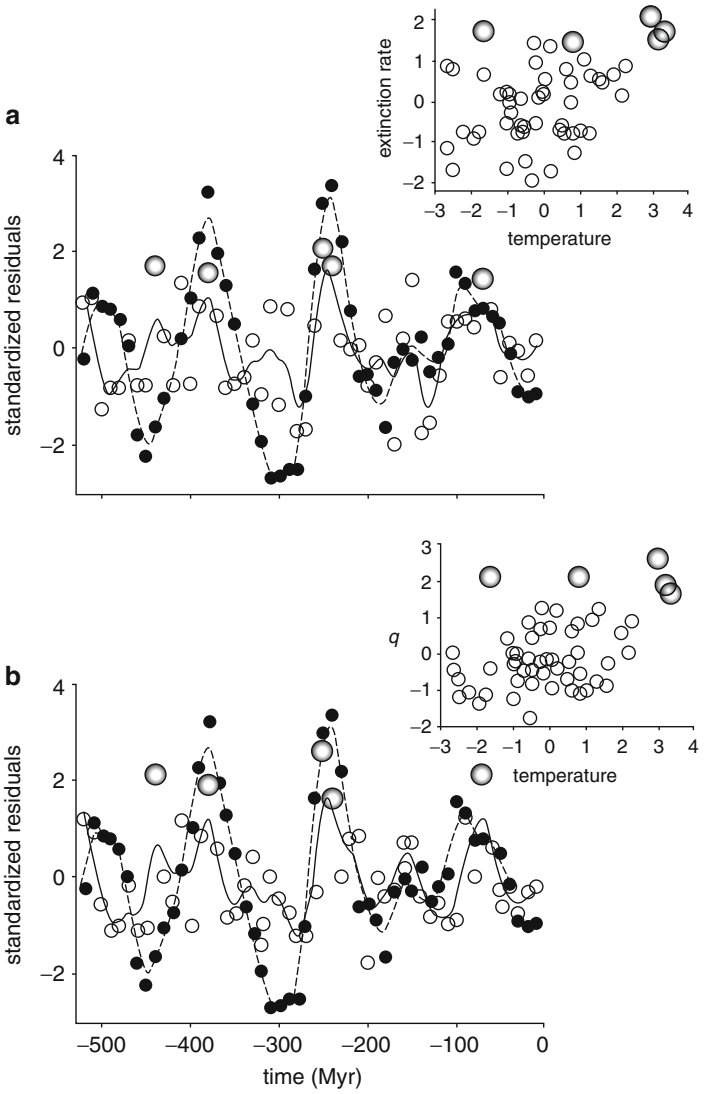

Fig. 8 Increase in extinction rates, over the past 520 million years, with increases in temperature. (**a**) the per-taxon rate of extinction for families (Myr^{-1}) using the maximum dating assumption and (**b**) the estimated *per capita* rate, *q*, of extinction (Myr^{-1}) for marine animal genera. Rates and temperature were transformed, detrended and mean standardized. Closed circles and dashed lines represent temperature and open circles and continuous lines extinction rates. Large double open symbols represent periods of mass extinction, defined as the five largest positive extinction residuals (in order of decreasing age: end Ordovician; Late Devonian; end Permian; Early Triassic, end Cretaceous). Insets show the positive association between extinction rate and temperature residuals across the time series (Reprinted with permission of the Proceedings of the Royal Society B. Fig. 3 from Mayhew et al. (2008))

approximately 10 % for every 1 °C increase in temperature. The end-Permian event that caused the extinction of approximately 95 % of all species on Earth was accompanied by a 6 °C increase in global temperatures over a few million years (Mayhew et al. 2008; Benton and Twitchett 2003). An increase in temperature of approximately 5 °C over several million years caused a great loss of plant biodiversity in Greenland (Västilä et al. 2010).

The biodiversity currently extant on Earth faces a much more difficult situation than does biodiversity during past periods of rapid climate change. There are two major reasons for this: (1) Species habitats are smaller than in the past. Smaller habitats support smaller populations which harbor less genetic diversity and have less evolutionary potential (Reed 2008). This evolutionary potential is critical for species' ability to adapt to the changing environmental conditions. (2) Species habitats are more fragmented than in the past. The fragmentation prevents individuals from being able to shift their distribution in response to climate-related impacts as easily as in the past. Recall, these are the two fates available to species other than going extinct: adapt to climate change or migrate in response to climate change in order to track environmental conditions favorable to survival. The current rate of climate change is probably unprecedented and would present extreme challenges to the biota of the planet under normal circumstances (McElwain et al. 2009). However, the combination of the magnitude of change, the extreme fragmentation of habitats, and the fact that there are 6.9 billion people using a very large proportion of the Earth's resources means that neither evolution nor migration will be sufficient to allow many species to cope with current rates of global climate change. They will go extinct and their value to humans and their beauty lost.

Many of the extinction may not be due directly to global climate change alone. The interactions between climate change and other factors will likely be extremely important. Habitat destruction and conversion continues in Southeast Asia and the Amazon, both places where I have done research and both areas rich in biodiversity. The continued fragmentation and loss of these forested areas alone is cause for grave concern. However, when you factor in that destruction of forests in these areas further limits movement of species trying to track a changing environment and that this continues to fuel further climate change by dumping more CO_2 into the atmosphere, it starts to appear catastrophic. Warmer temperatures will cause novel diseases to spread into naïve populations and will act as a general stress causing species to be susceptible to diseases their immune systems once were able to fight. The interaction between global climate change and diseases is already manifest in the widespread extinction of amphibians (Primack 2002). Increases in the frequency of drought and the introduction of novel diseases form an almost perfect combination for driving populations extinct, as these are the two biggest causes for population collapse among vertebrates (Reed et al. 2003b). Temperature stress, and other forms of environmental stress incurred through climate change, will interact with declining population size and loss of genetic diversity in a way that makes populations more vulnerable than either factor independently (Reed et al. 2007; Liao and Reed 2009; Fox and Reed 2011).

Table 2 Several million species of plant and animals face extinction due to global climate change, perhaps as early as 2050. Species most affected would be poor dispersers or those for which anthropogenic habitat fragmentation prevents dispersal and those with very narrow thermal tolerances and/or low genetic variation that prevent(s) evolution of new tolerances. The table below is based on the results of Thomas et al. (2007), who predicted extinction under different warming and movement scenarios. Migration rates are certainly somewhere between the extreme of no movement and the ability to track moving habitats perfectly, and current data suggests that warming trends will be close to the warmest predictions of Thomas et al. (2007). Consequently, ≥33 % of known species may be doomed to extinction by 2050

Warming level	No movement (%)	Perfect movement (%)
Low	34 extinction	11 extinction
Medium	45 extinction	19 extinction
High	58 extinction	33 extinction

Exactly how bad will it get? The prediction from a team of experts is that if temperatures increase by >3.5 °C, 40–70 % of plant and animal species will face extinction (Rosenzweig et al. 2008). One prominent study suggests that about 25 % of known plant and animal species will be committed to extinction by 2050 under current warming predictions (Table 2) (Thomas et al. 2004). A recent study suggests that 20 % of lizards may be extinct by 2080 as a direct result of increasing global temperatures (Sinervo et al. 2010). Exact predictions are of course impossible, but the combination of extremely rapid climate change, reduced population sizes, and fragmented habitats suggest that a very large proportion of Earth's biodiversity (>50 % of plants and animals) suffers a very high risk of extinction, particularly if definitive measures are not taken rapidly to ameliorate climate change. This level of species extinctions will be associated with an even larger percentage loss of populations and genetic diversity. This represents a very large proportion of the biodiversity and biological resources that humans need now more than ever.

Future Directions

In order to stave off huge losses in biodiversity and to save vast amounts of human suffering, humans will have to change the way they live and use their boundless innovation to produce a high quality of life in a way that does not endanger the planet. The following are some urgent and important general suggestions for directions human societies need to head in to mitigate climate change:

- Limit land-use change and make intelligent choices in land-use changes that balance agriculture against biodiversity loss (Koh and Ghazoul 2010; Lambin and Meyfroidt 2011). This is especially urgent in tropical and subtropical regions, but also in boreal and temperate forests (Bradshaw et al. 2009). Zero-loss of old-growth forests must be the immediate goal and this be combined with reforestation. Manage forests more efficiently and create/enforce laws that protect

forests from illegal logging and pillaging from corporations at the expense of the general populace.

- Aggressive climate change mitigation, including immediate implementation of existing cleaner energy technologies (Pacala and Socolow 2004), increased research to develop cleaner energy sources, and immediate legislation to increase fuel efficiency for motor vehicles.
- Place a global cap on greenhouse gas emissions and sell permits up to that cap in a global auction. Use the profits to finance the other mitigation measures discussed. Include the economic price for land-use emissions (Thomson et al. 2010). Economic models must begin to include all costs associated with production of goods, governments must regulate rather than subsidize corporations and their impacts on the public, and people must hold their governments accountable for lack of enforcement or collusion with corporations.
- Stabilize and eventually reduce human population size through intense family planning, education, and a change in societal norms.
- Make human-dominated landscapes more hospitable to biodiversity. Reclamation of degraded lands and reintroduction of extirpated species.
- Education of people, especially in the rural tropics, concerning biodiversity and the value of nature. Shift in the education and reward systems of developed nations away from short-term profiteering and financial markets toward science, engineering, innovation, and longer-term good to society.
- Create space and opportunities for ecosystems to self-adapt and reorganize because novel climates without current analogs will appear (Williams et al. 2007).

Sea-Level Rise and Hazardous Storms: Impact Assessment on Coasts and Estuaries

Yan Ding

Contents

Abstract

Sea-level changes in coasts and estuaries may differ substantially from global mean sea-level variations, showing complex spatial patterns which result from coastal-ocean dynamic processes, movements of the sea floor, and changes in gravity due to water mass redistribution. Because dominant hydrodynamic and

morphodynamic processes in coastal and estuarine zones are unsteady and of multi-scale, assessment of hazardous storms under the future sea-level rise heavily relies on numerical simulations of dynamic responses to sea-level rise and storm conditions. Thus, this chapter focuses on the following three objectives: (1) investigation of the impacts of hazardous storms/hurricanes and sea-level rise on coasts and estuaries, (2) review of impact assessment approaches by using numerical simulation models, and (3) demonstration of impact assessment of coastal floods and erosions under the combined conditions of hazardous storms (extreme events) and the future sea-level rise scenarios. It emphasizes a systematic approach for the impact assessment of sea-level rise by using integrated coastal process models which are widely used to simulate coastal/estuarine hydrodynamic and morphodynamic processes to predict flooding/inundation and coastline erosion/deposition under complex hydrological, morphological, oceanographic, and meteorological conditions. It also demonstrates an application of an integrated coastal model, CCHE2D-Coast, to simulate waves, tides, sediment transport, and morphological changes in an estuary and to predict the hydrodynamic and morphodynamic impacts of hazardous storms and five hypothetical sea-level rise scenarios. It shows that the integrated physical process modeling technique is the most effective method to predict the impact of spatially varying mean sea-level changes in coasts and estuaries and to facilitate coastal flood management, erosion protection, and infrastructure designing/planning against extreme hydrological conditions and climate changes.

Introduction

The increasing trend of atmospheric concentrations of carbon dioxide and other gases in the past decades, especially due to anthropogenic greenhouse gas emissions, leads to increase in the Earth's temperature, thermal expansion of the upper ocean, and the melting of small ice caps (Church et al. 2001). Consequentially, a primary effect of global warming is an increase in the global volume of the ocean and accelerated global mean sea-level (GMSL) rise, which will speed up permanent inundation, shoreline erosion and retreat, and land loss of low-lying coastal/estuarine areas. Historically, global mean sea level has risen over 120 m at some locations from the low stand of the last glacial maximum 20,000 years ago when temperatures were between 5 °C and 10 °C cooler than today (Jouzel et al. 1989; Church et al. 2001). Geologic evidence suggests a global mean sea-level rise rate of 0.1 to 0.2 mm/year over last 3,000 years with a significant acceleration that may have occurred around the mid-nineteenth century (Church et al. 2001). Based on global tide-gauge data, global mean sea levels are estimated to have risen 10–20 cm during the twentieth century (or 1.0–2.0 mm/year) (Douglas 1991, 1997; Church et al. 2001). It has since been argued that an estimated average of a 20-cm rise during the past century is most consistent with the available data (Douglas and Peltier 2002). Thus, a significant sea-level rise during the twentieth century occurred,

which has been arguably one stress factor contributing to many of the existing coastal problems. Predictions from the Fourth Assessment Report (AR4) by Intergovernmental Panel on Climate Change (IPCC) suggest that sea level may rise by as much as 60 cm by 2100 (IPCC 2007). The Fifth Assessment Report (AR5) of IPCC presented the latest results on the GMSL rise that may rise 74 cm of a median value by 2100 with a likely range from 52 to 98 cm (Church et al. 2013). Uncertainty, however, remains about how projected melting of the Greenland and Antarctic ice sheets will contribute to sea-level rise.

Based on the selected long-term tide gauges on the East Coast of the United States, it has been found that along the US Atlantic coast, over the last century, relative sea-level rise rates have ranged from 1.8 mm/year to as much as 4.4 mm/year (US-CCSP 2008). The lowest rates (1.75–2.00 mm/year) are close to the present global rate of 2.0 mm/year and occur along coastal New England and from Georgia to northern Florida. The highest rates (4.42 ± 0.16 mm/year) have been observed in the mid-Atlantic region between northern New Jersey and southern Virginia. It is also found that subsidence of the land surface due to a range of factors contributes to the high rates of relative sea-level rise observed in this region.

GMSL rise does not translate into a uniform rise in sea level around the world. Considerable variation often exists between global and local changes over a range of time/spatial scales. For example, based on available tide-gauge data collected by the National Oceanic and Atmospheric Administration (NOAA) on the mid-Atlantic coast (NOAA 2011), Cooper et al. (2005) obtained an approximate relative sea-level rise trend of 3.53 mm/year during the twentieth century, which is almost double the global mean value of sea-level rise. In general, the local sea-level change at any coast location can be determined by the sum of GMSL rise, regional sea-level change due to meteo-oceanographic factors (i.e., atmospheric pressure, storm surge, wave setup, and ocean circulations), and vertical land movement (i.e., subsidence and/or uplift) due to various geological processes such as tectonics, glacial isostatic adjustment, sediment consolidation, groundwater withdrawal, etc. (Nicholls 2003).

The development of a coastal zone management plan considering a local/relative sea-level rise and its impact area is of utmost importance. Due to existing multi-scale and unsteady physical processes driven by waves, tides, storm surge, sediment transport (erosion and deposition), and tectonic movement (subsidence and rise), a local sea-level rise is not equal to the estimate by the IPCC and generally varying with time and locations from coast to coast. For coastal hazard management and coastal defense planning in a specific coastal/estuarine zone, it is essential to predict the dynamic impacts of the local/relative sea level under local hydrological conditions such as waves, storm surges, and morphology, especially generated by hazardous weather.

The surface water motion in coasts and estuaries encompasses various hydrodynamic processes driven by astronomical tides, waves, river flows, wind-induced currents, turbulence, etc. Morphodynamic processes include the evolutions of landscapes and seascapes (erosion and deposition) due to sediment transport. Because unsteady and multi-scale hydrodynamic and morphodynamic processes are dominant in coastal/estuarine zones, numerical simulation of dynamic responses to

sea-level rise and storms, in fact, becomes the only effective approach to systematically assess the impacts of storms under the future sea-level rise scenario conditions. Thus, the objectives of this chapter are (1) to investigate the impacts of sea-level rise due to climate change on coasts and estuaries; (2) to review impact assessment approaches for flood water management, coastal erosion protection, and infrastructure designing/planning against extreme hydrological conditions; and (3) to demonstrate impact assessment of coastal floods and erosions under the combined conditions of hazardous storms and the future sea-level rise scenarios. It focuses on the regional-scale assessment of the dynamic impacts of hazardous storms (i.e., extreme events in ocean) including hurricanes and typhoons under the conditions of sea-level changes, using numerical simulation techniques, which are applicable to directly predict flooding/inundation and morphological changes in coastal zones and estuarine regions. By employing an integrated coastal process modeling system, CCHE2D-Coast, simulations of waves, tides, sediment transport, and morphological changes in an estuary are demonstrated under these natural physical conditions and sea-level rise scenarios. Assessment of impacts of a hazardous storm combined with sea-level rise scenarios in the estuary is discussed accordingly.

This chapter in the following context is organized as follows: At first, the GMSL scenarios, as well as some regional relative sea-level rise projections in the United States, are briefly reviewed. Second, the relationship between regional/local sea-level rise and hydrological, meteorological, and oceanographic conditions is discussed; accordingly, geophysical and socioeconomic impacts of local sea-level rise on coasts and estuaries are summarized. For coastal zone management, general impact assessment approaches under sea-level rise scenarios are discussed. Then, a more detailed review on numerical modeling, using global circulation models (GCM), coastal process models (or inundation models), and downscaling techniques, for predicting coastal hazards under sea-level rise conditions in the future is given. By applying an integrated coastal process simulation model, a case study on the assessment of sea-level rise impacts in an estuary located at the west coast of Taiwan is demonstrated. Finally, concluding remarks and discussions on the future research directions are presented.

Future Global Main Sea-Level Projection/Scenarios

In the IPCC Third Assessment Report, the projected sea-level rise from 1990 to 2100 was between 9 and 88 cm with a mid estimate of 48 cm (Church et al. 2001), which however does not include the contribution from Antarctica. Based on the emission scenarios in the twenty-first century, the Fourth Assessment Report (AR4) of IPCC on Emission Scenarios (SRES) has projected the six SRES marker scenarios (IPCC 2007), i.e., the SRES B1, A1T, B2, A1B, A2, and A1FI, as shown in Table 1. The SRES scenarios represent mutually consistent characterizations of how the world might evolve during the twenty-first century. Each scenario is a short narrative of a possible pathway of future development from the current world. They explore what might happen if political, economic, technical, and social developments take specific

Table 1 Projected global surface warming and sea-level rise at the end of the twenty-first century by the IPCC AR4 (IPCC 2007)

Scenario	Approximate carbon dioxide CO_2-equivalent concentration (ppm)	Likely range of temperature change (°C at 2090–2099 relative to 1980–1999)	Sea-level rise (m at 2090–2099 relative to 1980–1999)
B1	600	1.1–2.9	0.18–0.38
A1T	700	1.4–3.8	0.20–0.45
B2	800	1.4–3.8	0.20–0.43
A1B	850	1.7–4.4	0.21–0.48
A2	1,250	2.0–5.4	0.23–0.51
A1FI	1,550	2.4–6.4	0.26–0.59

alterative directions at the global level, including consideration of potential differences and interactions. Approximate CO_2-equivalent concentrations corresponding to the computed radiative forcing due to anthropogenic greenhouse gases (GHGs) and aerosols in 2100 for the six SRES scenarios are about 600, 700, 800, 850, 1,250, and 1,550 ppm, respectively. (Radiative forcing is a measure of the influence a factor has in altering the balance of incoming and outgoing energy in the Earth-atmosphere system and is an index of the importance of the factor as a potential climate change mechanism (IPCC 2007, p. 36). In the IPCC AR4 report, radiative forcing values are for changes relative to preindustrial conditions defined at 1750 and are expressed in watts per square meter [W/m^2].) Based on these GHG emission scenarios, estimates about temperature change and sea-level rise are assessed from a hierarchy of models that encompass a simple climate model, several Earth models of intermediate complexity, and a large number of atmosphere-ocean general circulation models (AOGCMs) as well as observation constraints (IPCC 2007). The model-based results of sea-level rise, excluding future rapid dynamic changes in ice flow, show that the bottom line of GHG emission (i.e., 600 ppm) will cause a global mean sea-level rise at 2090–2099 within a range from 18 to 38 cm. The top line (1,550 ppm), however, will give the sea-level rise about 26–59 cm, relative to 1980–1999. Following the SRES scenarios, Nicholls (2004) has investigated coastal flooding and wetland loss in the twenty-first century corresponding to only four SRES scenarios (i.e., A1FI, A2, B1, and B2) with a GMSL rise range from 22 to 34 cm by the 2080s, relative to 1990. The conclusion is that sea-level rise increases the flood impacts in all cases, and coastal wetland will be lost due to sea-level rise in all scenarios with 5–20 % losses by the 2080s in the A1FI scenario.

For the Fifth Assessment Report (AR5) of IPCC, instead of the six scenarios used the IPCC AR4 report (IPCC 2007), the IPCC work group has defined a set of four new scenarios, which are denoted Representative Concentration Pathways (RCPs) (IPCC 2013). As given in Table 2, for the Coupled Model Intercomparison Project Phase 5 (CMIP5), the four new scenarios reflect by their approximate total radiative forcing in year 2100 relative to 1750: 2.6 W/ m^2 for RCP2.6, 4.5 W/ m^2 for RCP4.5, 6.0 W/ m^2 for RCP6.0, and 8.5 W/ m^2 for RCP8.5. These four RCPs include one mitigation scenario leading to a very low forcing level (RCP2.6), two stabilization

Table 2 Projected global surface warming and sea-level rise for the late twenty-first century (2081–2100) relative to the reference period of 1986–2005 by the IPCC AR5 (IPCC 2013)

Scenario	Radiative forcing in year 2100 relative to 1750 (W/m^2)	Approximate carbon dioxide (CO_2)-equivalent concentration (ppm)	Median value and likely range of temperature change (°C)	Median value and likely range of sea-level rise (m)
RCP2.6	2.6	475	1.0 [0.3–1.7]	0.40 [0.26–0.55]
RCP4.5	4.5	630	1.8 [1.1–2.6]	0.47 [0.32–0.63]
RCP6.0	6.0	800	2.2 [1.4–3.1]	0.48 [0.33–0.63]
RCP8.5	8.5	1,313	3.7 [2.6–4.8]	0.63 [0.45–0.82]

scenarios (RCP4.5 and RCP6), and one scenario with very high greenhouse gas emissions (RCP8.5). The RCPs can thus represent a range of twenty-first-century climate policies, as compared with the no-climate policy of the Special Report on Emissions Scenarios (SRES) used in the Third Assessment Report and the Fourth Assessment Report. Including the prescribed concentrations of CH_4 and N_2O, the combined CO_2-equivalent concentrations are 475 ppm (RCP2.6), 630 ppm (RCP4.5), 800 ppm (RCP6.0), and 1,313 ppm (RCP8.5). Those scenarios represent a possible range of the mean global mean surface temperature from 1.0 °C to 3.7 °C. The peak value of this surface temperature may reach 4.8 °C in the case of RCP8.5.

Projections of GMSL rise in the IPCC AR5 are larger than in the AR4, primarily because of improved modeling land-ice contributions (Church et al. 2013). As shown in Table 2, for the period of the late twenty-first century (2081–2100), compared to 1986–2005, GMSL rise is likely (medium confidence) to be in the 5–95 % range of projections from process-based models, which give 0.26–0.55 m for RCP2.6, 0.32–0.63 m for RCP4.5, 0.33–0.63 m for RCP6.0, and 0.45–0.82 m for RCP8.5. At 2100, the median and likely ranges of GMSL rise are 0.44 [0.28–0.61] m (RCP2.6), 0.53 [0.36–0.71] m (RCP4.5), 0.55 [0.38–0.73] m (RCP6.0), and 0.74 [0.52–0.98] m (RCP8.5) (Church et al. 2013, p.1182).

In all scenarios, the rate of GMSL rise at the start of the RCP projections (2007–2013) is about 3.7 mm/year, slightly above the observational range of 3.2 [2.8–3.6] mm/year for 1993–2010. In RCP2.6, it becomes roughly constant (central projection 4.5 mm/year) before the middle of the century and subsequently declines slightly. The rate of rise becomes roughly constant in RCP4.5 and RCP6.0 by the end of the century, whereas acceleration continues throughout the century in RCP8.5, reaching 8.0–16.0 mm/year in 2081–2100.

In all scenarios, thermal expansion is the largest contribution, accounting for about 30–55 % of the projections. Glaciers are the next largest, accounting for 15−35 % of the projections. By 2100, 15–55 % of the present volume of glaciers outside Antarctica is projected to be eliminated under RCP2.6 and 35–85 % under RCP8.5.

Local/Regional Sea-Level Rise Scenarios

Local/regional sea-level changes may differ substantially from a GMSL average, showing complex spatial patterns which result from ocean dynamical processes, movements of the sea floor, and changes in gravity due to water mass redistribution (land ice and other terrestrial water storage) in the climate system (IPCC 2013). The local/regional distribution is associated with a dynamical redistribution of water masses and a change of sea water properties caused by spatiotemporal variations of winds and air pressure, air-sea heat, and freshwater fluxes and ocean currents.

IPCC AR5 (IPCC 2013) concludes that it is very likely that in the twenty-first century and beyond, sea-level change will have a strong regional pattern, with some places experiencing significant deviations of local and regional sea-level change from the global mean change. Over decadal periods, the rates of regional sea-level change as a result of climate variability can differ from the global average rate by more than 100 % of the global average rate. By the end of the twenty-first century, it is very likely that over about 95 % of the world ocean, regional sea-level rise will be positive, and most regions that will experience a sea-level fall are located near current and former glaciers and ice sheets. About 70 % of the global coastlines are projected to experience a relative sea-level change within 20 % of the global mean sea-level change.

Local/regional sea-level change can be estimated from long-term tide-gauge data measured at tide gauges over a century. Tide gauges, usually placed on piers, measure the mean sea-level change relative to a nearby geodetic benchmark. Therefore, the local sea-level rise trends usually do not follow the abovementioned IPCC SRES or RCP storylines. Due to tectonic uplift or subsidence, tide gauges may also move vertically with the region. These vertical crustal movements greatly complicate the problems of determining local/regional sea-level change from tide-gauge data.

For instance, using available tide-gauge data in the New Jersey coast (NOAA 2011), Cooper et al. (2005) estimated that the New Jersey coast may have a local component of sea-level rise of 2 mm/year attributed to land subsidence and sediment compaction. Based on the range of GMSL rise from 9 to 88 cm between 1990 and 2100 (Church et al. 2001), adding the local estimation of subsidence and consolidation (2 mm/year), they suggested a local/relative sea-level rise for the New Jersey coast will be between 31 and 110 cm, giving a central value of approximately 71 cm. Furthermore, in the study of the sea-level rise and land use using 7.5 min digital elevation models (DEMs) with 10-m horizontal resolution, they provided the assessment results on two specific (median-projected) sea levels, 61 cm (2 ft) and 122 cm (4 ft), for 2050 and 2100, respectively, by means of the so-called contour-line projection approach. On the other hand, some studies of sea-level rise only evaluated the impact of hypothetical sea-level rise. For example, the US-CCSP (2008) used three assumed sea-level rise scenarios (30, 50, and 100 m of sea-level rise by 2100) to evaluate several aspects of their impacts for the Mid-Atlantic US coast using a range of elevation data sets which have large variations in vertical resolution and horizontal accuracy.

In the New Orleans region, land-surface altitude data collected in the leveed areas of the New Orleans metropolitan region during five survey epochs between 1951 and 1995 indicated mean annual subsidence of 5 mm per year (Burkett et al. 2003). By considering this rate of land subsidence and the IPCC mid-range estimate of sea-level rise (48 cm), Burkett et al. (2003) suggested a net 1.0-m decline in elevation during the next 100 years relative to present mean sea level in the New Orleans region. They estimated accordingly that the areas of New Orleans and vicinity that are presently 1.5–3.0 m below mean sea level will likely be 2.5–4.0 m or more below mean sea level by 2100.

Global Warming, Sea-Level Rise, Hurricanes, and Storm Surges

Climate variability and any resulting change in the characteristics of tropical cyclones (tropical storms, subtropical storms, and hurricanes) have become topics of great interest and research within the past years. An emerging focus is how the frequency of tropical cyclones has changed over time, and whether any changes could be linked to anthropogenic global warming. A special attention to Atlantic hurricane activity and its relation with tropical Atlantic warmth has been paid, because the Atlantic is the one tropical cyclone basin that has quantitative records back to the mid-nineteenth century for the whole basin (i.e., North Atlantic Ocean, Caribbean Sea, and Gulf of Mexico) (Landsea 2007). Mann and Emanuel (2006) analyzed those data to conclude that there is a strong historical relationship between tropical Atlantic sea surface temperature (SST) and tropical cyclone frequency for the period of 1871–2005. Similarly, Holland and Webster (2007) investigated Atlantic tropical cyclone frequency and found a doubling of the number of tropical cyclones over the past 100 years. With no conclusions about the existence of the Atlantic Multidecadal Oscillation (AMO) which is a natural climate cycle, both papers linked these changes of Atlantic tropical cyclone frequency to anthropogenic greenhouse warming. However, Landsea (2007) pointed out that both analyses, with no indication of uncertainty or error bars, presumed that tropical cyclone counts are complete or nearly complete for the entire basin going back in time for at least a century. And this presumption is not reasonable and that improved monitoring in recent years is responsible for most, if not all, of the observed trend in increasing frequency of tropical cyclones. Through reanalyzing the historical data of Atlantic basin storms, Landsea (2007) indicated that large, long-term "trends" in tropical cyclone frequency are primarily manifestations of increased monitoring capabilities and likely not related to any real change in the climate in which they develop.

From the point of view of coastal hazard (flooding and erosion) management, increasing tropical storm and hurricane activity may cause more frequent flooding and inundation in the current coastal floodplains. Even if it is assumed that the strength of storms shows no change in the future, under the future conditions of sea-level rise, current flood levels and inundation areas will be exceeded, and low-lying lands will still be permanently inundated. For example, Cooper et al. (2005) studied the future sea-level rise in the New Jersey coast by introducing

only two sea-level rise scenarios, i.e., 0.61 m (1 ft) and 1.22 m (2 ft). By comparing with the US Federal Emergency Management Agency (FEMA) tidal surge frequency for 5-, 10-, 20-, 30-, 50-, and 100-year flood water levels for Atlantic City, New Jersey, they found that sea-level rise will allow current flood levels to be exceeded and low-lying lands to be flooded with increase frequency. In the case of 0.61 m rise in sea level, the current 30-year storm will produce a flood water elevation of 2.96 m, which exceeds the current 100-year FEMA flood level (2.90 m at Atlantic City). After a 1.22 m rise in sea level, the current 5-year storm will cause water levels above the current 100-year flood level. In other words, provided that other factors being equal, New Jersey's current 100-year flood levels could become the 30-year flood level after a 0.61 m sea-level rise and the 5-year flood level after a 1.22 m rise. Cooper et al. (2005) further estimated that 6.5 % of the state's total land area will be inundated in the case of the current FEMA 100-year flood level due to storm; the inundation area due to the same storm after 0.61 m rise in sea level will increase up to 9 % of the state's total land area.

In low-lying areas, subsidence and uplift play an important role in flood management. As mentioned above, an average 5-mm per year land subsidence in the New Orleans region and IPCC mid-range estimate of sea-level rise (480 mm) suggests a net 1.0-m decline in elevation during the next 100 years relative to present mean sea level (Burkett et al. 2003). A storm surge from a category 3 hurricane (estimated at 3–4 m without waves) at the end of this century, combined with global mean sea-level rise and land subsidence, would place storm surge at 4–5 m above the city's present altitude. The effect of such a storm on flooding in the New Orleans Metropolitan Statistical Area (MSA) will depend upon the height and integrity of the regional levees and other flood-protection projects at that time (Burkett et al. 2003).

The US-CCSP (2008) examined the effects of sea-level rise on coastal floodplains and on coastal flooding management issues confronting the US FEMA, the floodplain management community, the coastal zone management community, and the public, including private industry. From the analysis of historical tide station records for the highest storm tides in the Mid-Atlantic Coast, this report shows that storms today with slightly lesser storm surge than historical storms have had slightly higher storm tide elevations relative to the land due to sea-level rise. This suggests that any given storm could have higher flooding potential in the future due to higher sea levels than it would if it occurred today.

During storm events, local water elevations at coastal zones will significantly increase due to nonlinear physical processes such as storm surges, high tides, wave setup, and their combinations. These combinations largely determine temporally/spatially varying flooding/inundation, coastal erosion, and overwash in barrier islands in coastal regions. Additionally, sea-level rise will lift up flood levels by providing a higher base for a storm surge to build upon. Even if the frequency and strength of storms will keep no change in the future, sea-level rise undoubtedly will cause flooding/inundation over a wider coastal area due to shoreline retreat, higher wave setup, and storm surges. Because of the nonlinear and unsteady behavior of storms, the linear contour-line project approach can lead to poor depiction of reality of sea-level rise impacts. It is, therefore, essential to assess the dynamic, interactive,

and nonlinear impacts of hazardous storms under conditions of sea-level rise for the purpose of better coastal protection management in a local or regional area.

Coupled coastal and ocean process models have been applied to assess the impacts of local/regional sea-level rise and storm/hurricane events. Using a numerical storm surge model, Smith et al. (2010) investigated potential impacts of 0.5 and 1.0 m of local sea-level rise on hurricane surges waves in southeast Louisiana. They found that in the regions of large surges, the effect of mean sea-level (MSL) rise added linearly to the simulated surges. However, in the regions of moderate surges (2–3 m), particularly in wetland-fronted areas, the increase in surge height was 1–3 m larger than the increase in mean sea-level rise. They showed that sea-level rise alters the speed of propagation of surges and their amplification in different regions of the coast. For lower Texas coast bays in the Gulf of Mexico, Mousavi et al. (2011) developed a simple relationship between storm surges, sea-level rise, and hurricane intensification for three major historical hurricanes, concluding that the dynamic interaction of surge and sea-level rise lowered or amplified the surge at different points within a shallow coastal bay. For the Mississippi and Alabama coast, Bilskie et al. (2014) introduced a modeling procedure to simulate the response of storm surges to changes in sea level, land use and land cover, and land-surface elevations for past (1960), present (2005), and future (2050) conditions. The results show that the storm surge response to SLR is dynamic and sensitive to changes in the landscape.

Geophysical and Socioeconomic Impacts of Sea-Level Rise on Coast and Estuary

Human populations have a tremendous impact on the quality of coastal and estuarine environments. The ultimate goal of assessment of sea-level rise and climate change is to quantify these impacts on coastal communities as human society. In 2001 just over half the world's population – around 3.2 billion people – lived within 200 km of a coastline (Hinrichsen 2009). The rate of population growth in coastal areas is accelerating and increasing tourism adds to the pressure on the environment. In the United States, around 37 % of the total US population lives in the 364 "coastal counties," including the Great Lakes, which contains V zones (a coastal hazard zone defined by FEMA (2009)) (Crowell et al. 2007). In their recent publication (Crowell et al. 2010), it is shown that about 8.2 % of the coastal population (86,541,000 people) live in 1 % annual chance (or 100-year) coastal flood hazard areas as defined by FEMA. Therefore, the impacts of sea-level rise on coastal and estuarine area are, in principle, closely related to its geophysical and socioeconomic effects to the natural habitat of human being in the areas. In general, there are four primary geophysical impacts of sea-level rise, i.e.:

- Permanent inundation and displacement of coastal lowlands, including loss of wetland
- Increased flood and storm damage

Table 3 The physical impacts of sea-level rise and other relevant factors

Impact of sea-level rise	Other relevant interacting factors			
	Meteorology	Oceanography	Hydrology	Geomorphology
Permanent inundation and displacement of coastal lowlands	Wind, temperature, storm, hurricane, rainfall	Wave, storm surge, tide, ocean current	Runoff, river flood, backwater effect	Sediment supply, morphological changes, land claim, subsidence
Increased flood and storm damage	Wind setup, rainfall	Wave setup, storm surge, strong surge, tide current	Runoff, river flood, backwater effect	Morphological changes
Increased erosion	Rainfall	Wave, storm surge, tide, current	River flood	Sediment supply, subsidence, land claim
Salinization of surface and increased waters	Temperature, storm, hurricane, rainfall	Tide, surge, ocean current	Runoff, groundwater table change, catchment management	Morphological change, subsidence

- Increased erosion
- Salinization of surface and increased waters

In Table 3, the geophysical impacts of sea-level rise and relevant interacting factors are summarized. This table indicates that the relevant interacting factors of the impacts of sea-level rise are related to multi-scale physical processes including meteorology, oceanography, hydrology, and geomorphology. Assessment of the impacts of sea-level rise strongly depends on the understanding of nonlinear behavior of the integrated coastal system driven by these multi-scale physical processes. Considering specific coastal regions, more detailed categories on the geophysical impacts of sea-level rise can be identified as follows:

- Increased wave energy in the nearshore area (shoreline erosion and land erosion)
- Upward and landward migration of beaches (shoreline retreats)
- Accelerated coastal retreat and erosion
- Saltwater intrusion into coastal freshwater aquifers and rivers (upstream)
- Damage to coastal infrastructure due to increased wave energy
- Broad impact on coastal economy of coastal communities (coastal resilience)

Assessment of socioeconomic impacts of sea-level rise is an ultimate goal for building resilient coastal communities to alleviate coastal hazards generated from severe storms together with sea-level rise. Readers may find a large number of publications such as government reports and academic papers on the assessment of socioeconomic impacts and management policies on this issue, e.g., IPCC report

(IPCC 2007), US-Climate Change report (US-CCSP 2008), and Nicholls et al. (2007). Although discussions of the socioeconomic impacts are out of this chapter's range, potential socioeconomic impacts of sea-level rise summarized by Nicholls (2003) are listed as follows:

- Increased loss of property and coastal habitats
- Increased flood risk and potential loss of life
- Damage to coastal protection works and other infrastructure
- Loss of renewable and subsistence resources
- Loss of tourism, recreation, and transportation functions
- Loss of nonmonetary cultural resources and values
- Impacts on agriculture and aquaculture through decline in soil and water quality

In the following contents, the impact of sea-level rise means its geophysical impact if there is no special explanation.

Assessment of Impact of Local Sea-Level Rise for Coastal Zone Management

The impacts of sea-level rise can be assessed in different ranges of spatial scales, i.e., global, regional, and local scales, in which some case studies are driven by policy making (e.g., Nicholls et al. 1999; Nicholls 2004; Schleupner 2007), and some are more science orientated to examine the methodologies that can transfer scientific knowledge into decision-making tools (e.g., Cooper et al. 2005; Capobianco et al. 1999). Sea-level rise may significantly change the areas of coastal hazard maps in a specific coast. Therefore, coastal hazard management in coastal zones requires local assessment of impacts of sea-level rise. Figure 1 presents a general procedure for assessment of impacts of sea-level rise from global scale to local scale. As for the sea-level rise assessment methodologies, since the contour-line projection approaches to assess sea-level rise only can give an average estimation (most likely underestimation) of the impacts, further accurate numerical simulations are needed to include the nonlinear variations of other physical factors such as storm surge, wave, tide, etc., along with sea-level rise. In fact, direct numerical modeling plays an important role on predicting multi-scale physical processes including storm track, weather change, ocean volume increase, surge, tide, wave, and inland flood in atmosphere, ocean, and coast, as well as quantitative evaluation of sea-level rise impacts in time and space. It also has to point out that the reliability of the sea-level rise assessment results strongly depend on the accuracy of the coupled physical models.

In order to assess the impacts of sea-level rise in a specific coast, coastal zone management is usually practiced through defining coastal flood plain and coastal flood hazard zones based on coastal processes. In general terms, a floodplain is any normally dry land surrounding a natural water body that holds the overflow of water during a flood. The US federal regulations governing FEMA (2009) define

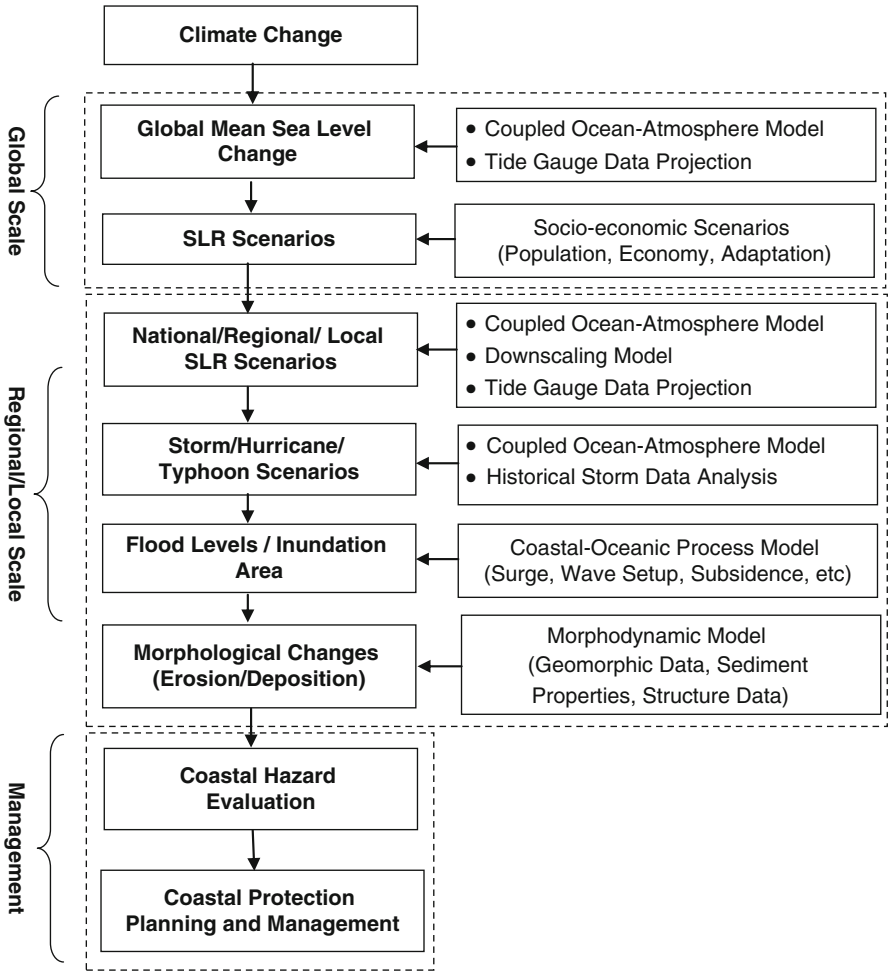

Fig. 1 Assessment of sea-level rise in global/regional/local scale

floodplains as "any land area susceptible to being inundated by flood waters from any source." The National Oceanic and Atmospheric Administration (NOAA) National Weather Service (NWS) defines a floodplain more specifically as the portion of a river valley that has been inundated by the river during historic floods. None of the formal definitions of floodplains include the word "coastal." However, as river systems approach coastal regions, river base levels approach sea level, and the rivers become influenced not only by stream flow but also by coastal processes such as tides, waves, and storm surges (Ding and Wang 2008b). Coastal areas are periodically inundated by tides, waves, and surges. The slope and width of the coastal plain determine the size and inland extent of coastal influences on river systems. The US-CCSP (2008) has given a good working definition of a coastal

floodplain, borrowing from the river floodplain definition, which is any normally dry land area in coastal areas that is susceptible to being inundated by water from any natural source, including oceans (e.g., tsunami run-up, coastal storm surge, relative sea-level rise) in addition to rivers, streams, and lakes. (Tsunami run-up occurs when a peak in the tsunami wave travels from the nearshore region onto shore. Run-up is a measurement of the height of the water onshore observed above a reference sea level. For more information, one may refer to USGS (2011).)

FEMA (2009) has defined four coastal zones in cross shore for management of coastal flood hazards: *Offshore zone* is the area, usually in the deep water, influenced by waves and water levels that are not substantially influenced by bathymetry (i.e., the water depth relative to sea level) or topography (i.e., the elevations above sea level). Dominant processes in this zone include swell, seas, astronomical tides, storm surge, and large-scale climate perturbations such as El Niño. *Shoaling zone* is the area outside the surf zone where offshore conditions (mainly waves) are transformed by interaction with bathymetry or topography. This transformation of wave in the shoaling zone includes refraction, diffraction, dissipation, and generation of waves by wind. *Surf zone* is defined as the area where waves break as they interact with the bottom. Dominant processes in the surf zone include wave setup, run-up, overtopping, erosion/deposition, and interaction with structures. *Backshore zone* represents the area that is outside the normal surf zone but may be subject to inundation during coastal flooding events. This area is subject to development and is the critical area for determination of flood hazards. As for coastal hazard management, on the other hand, FEMA generally divided coastal flood hazard zones into three categories: (1) *VE zone*: the coastal high hazard area where wave action and/or high-velocity water can cause structural damage during the 1 % annual chance flood including wave run-up zone, wave overtopping splash zone, high-velocity flow zone, breaking wave zone, and primary frontal dune zone; (2) *AE zone*: where flood hazards are not as severe as in VE zones; and (3) *X zone*: which is only subject to flooding by flood more severe than the 1 % annual chance flood.

Numerical Modeling for Assessing Dynamic Impacts of Local Sea-Level Rise and Hazardous Storms

Numerical modeling plays a decisive role in assessing various impacts of sea-level rise in different spatial scales. Since climate change is a global-scale phenomenon, a global circulation model (GCM) is the first choice to predict the thermodynamic motion of atmosphere layers due to greenhouse gas emission. By coupling with ocean models which represent oceanographic processes, a coupled ocean-atmosphere model (OAM) is able to predict the variation of ocean water volume in response to the changes of atmospheric temperature. Usually, GCMs and OAMs can predict global-scale temporal-spatial variations of various physical variables such as air temperature, precipitation, concentration of greenhouse gases, sea-level change, etc. However, the spatial resolution of the numerical results is in general

several hundred kilometers on the Earth's surface. So far, there is not a numerical model capable of directly simulating sea-level changes under local hydrological conditions with a local coastal scale (which can be several meters to several kilometers). As shown in Fig. 1, a number of numerical models for different spatial scales are usually employed to obtain the sea-level rise scenarios in response to greenhouse gas concentrations on the global scale, to downscale the GCM model results to a local/regional scale, and then to use a coastal-ocean process model to predict the impacts of the sea-level rise scenarios together with a hazardous storm condition in a specific local coast/estuary.

Projection Approach and Numerical Simulation

Other than numerical simulation modeling based on physical principles, projection approach (e.g., Cooper et al. 2005) is a simple but quick way to delineate flood hazard areas due to mean sea-level scenarios by projecting the corresponding contour lines on terrain maps within GIS models. But its demerit is the underestimation of the impacts of sea-level rise such as area of inundation and erosion. The only way to predict the day-to-day weather and changes to the climate over longer timescales is to use numerical simulation models, such as a GCM or OAM. These models solve complex mathematical equations that are based on well-established physical laws that define the nonlinear and unsteady behavior of weather and climate. According to the 2001 IPCC Third Assessment Report, a total of seven GCMs were used for assessing the global climate change. In the 2007 IPCC Fourth Assessment Report, as many as 23 GCMs were adopted to predict the global climate change including sea-level variations in response to eight greenhouse gas emission scenarios (IPCC Data Distribution Centre 2010).

Owing to computer capacity limitations, it is highly impossible to represent all the detail in the real world in a computer model, so approximations have to be made. The models are tried and tested in a number of ways: (1) They are used to reproduce the climate of the recent past, both in terms of the average and variations in space and time (John et al. 1997). (2) They are used to reproduce ancient climates that have been known (which are more limited) (John et al. 2003). These climate models typically have three-dimensional representation of the ocean and sea ice, an interactive carbon cycle, interactive atmospheric chemistry models, and the coupled atmosphere-ocean-carbon-cycle-chemistry model (White and Bromley 1995; Gordon et al. 2000). The global-scale climate simulations are extensive and usually carried out in high-performance parallel computers.

In a regional/local scale, 2D or/and 3D coastal/estuarine models are used to simulate and to predict physical processes under a set of given conditions which typically represent storm/hurricane events and sea-level rise scenarios (e.g., Ding et al. 2013). Coastal/estuarine models are to compute coastal and estuarine processes such as wave transformation, storm surge, tide, sediment movement, erosion/deposition, water quality, etc., so as to predict hydrological variables, e.g., water levels, velocities, bed changes, biomass properties, etc. Those process-based models can

predict complex unsteady physical processes to provide a set of dynamic results (basic databases) for engineering assessment and coastal hazard mapping. They enable to handle various data inputs such as hydrological data (wave, wind, tide, runoff, river inflow, storm track, etc.), bathymetry/topography (e.g., DEM data from GIS application), boundary condition data, etc. So far, coastal/estuarine numerical modeling is the most accurate methodology to predict/plan coastal hazards and sea-level rise impacts on coasts and estuaries. They have been extensively adopted in coastal storm water management.

Downscaling Techniques

GCMs are in general three-dimensional climate models which are based on physical principles and take into account as many physical variables as possible that could affect global climate. They are the only capable tools for predicting global-scale climate patterns in response to the increase of greenhouse gas emission. They are therefore widely applied to assess climate change impacts for various climate change scenarios. IPCC has provided all the output results generated by the selected IPCC GCMs in the online site of IPCC Data Distribution Centre at www.ipcc-data.org for public data download service. However, the horizontal resolution of the GCM model results is very coarse, up to several hundred kilometers in grid. For a regional assessment of climate change, a downscaling technique is needed to nest a higher-resolution local/regional climate model within a coarse resolution GCM. Wilby et al. (2002) categorized downscaling methodologies into four main types: (1) dynamic climate modeling, (2) synoptic weather typing, (3) stochastic weather generation, and (4) regression-based approaches. They give a detailed description and review on the downscaling techniques. Among them, dynamic downscaling together with a regional climate change model can resolve smaller-scale atmospheric features such as orographic precipitation (i.e., rain, snow, or other precipitation produced when moist air is lifted as it moves over a mountain range) or low-level jets better than the host GCM. Regression-based downscaling methods, which are relatively simpler, rely on empirical relationships between local-scale predictands and regional-scale predictors. Individual downscaling schemes differ according to the choice of mathematical transfer function, predictor variables, or statistical fitting procedure.

Challenges to Planning and Management of Coastal Zone Under Conditions of Sea-Level Rise and Hazardous Storms

Planning and management of coastal zone are facing more new challenges due to sea-level rise and increasingly frequent storms and hurricanes in order to alleviate the damage of flooding, inundation, and erosion. Under the conditions of climate change and sea-level rise, these difficulties could happen to coastal zone management and planning to:

- Find new design criteria of coastal infrastructure, e.g., design parameters for storm, wave, surge, and tide
- Redefine extreme storm events, e.g., the 1 % annual chance storm (i.e., 100-year storms due to global climate change)
- Update out-of-date flooding/inundation maps for most of coastal communities
- Redefine storm surge zones, evacuation route and evacuation zones, emergency shelter, etc.
- Reevaluate coastal resiliency, hazard preparedness, coastal emergency management, first responding planning, coastal infrastructure planning, etc.
- Establish and maintain a premier data collection and delivery system such as a GIS- and Internet-based system.

Brief Review on Coastal and Estuarine Process Modeling

Understanding the nonlinear and unsteady features of coastal and estuarine processes driven by astronomical tides, storm surge, wind-generated waves, and river flows is essential to quantify the impacts of sea-level rise with hazardous storms for the purposes of coastal flood prevention, sediment management, shoreline erosion control, navigation channel maintenance, and designing coastal infrastructure. Sediment transport, consisting of longshore and cross-shore sediment movements and river sediment supply into coasts and estuaries, leads to complex morphological changes such as shoreline erosion/accretion, levee/barrier breaching, river bank erosion, variations of river mouth bar, navigation channel refilling, migration of offshore bar, etc. (A levee breach or levee failure is a situation where a levee fails and the water that was retained by that levee is allowed to flood the land behind the levee. A barrier breach happens in barrier islands in a coast when storm surges and/or high waves breached barrier.) Under increase of sea levels and shoreline retreat, some bathymetrical changes during storm and flood period may aggravate the problem of coastal flood and inundation.

Numerical modeling is the only way to predict the temporal-spatial variations of sea-level rise impacts in a specific coast under naturally complex hydrological conditions. In the past decades, significant progress has been made in the studies of coastal and estuarine processes by means of physical experiments and computational simulations. Due to the complexities of physical processes, direct simulation of long-term (daily to yearly) hydrodynamic and morphodynamic responses to sea-level changes and storm events in a large-scale coast driven by astronomical tides, unsteady irregular waves, storm surges, wave-induced currents, and sediment transport has been a challenging goal. In recent years, with the process-based approach having been employed to the development of the coastal and estuarine process model, the long-term simulation of multi-scale hydrodynamic and morphodynamic changes has become feasible (e.g., Shimizu et al. 1996; Zyserman and Johnson 2002). In general, this multi-scale simulation is accomplished by computing sequentially the wave field, the current field, and the seabed changes under the given boundary conditions and sea-level changes. Then a new bathymetry

will be fed back to affect the computations of the wave and current fields in the next time step. By this iterative procedure going through the wave-current-morphological models, it is possible to simulate the morphodynamic process by using an empirical sediment transport model for the time-scale morphological process (e.g., Ding and Wang 2008a).

According to the existence of different spatial scales, the practical numerical model for simulating hydrodynamic and morphodynamic processes in coasts and estuaries has the following four types: (1) one-dimensional (1D) longshore coastline models, (2) two-dimensional (2D) cross-shore coastal profile models, (3) 2D horizontal coastal/estuarine/oceanic process models, and (4) fully three-dimensional (3D) models. 1D coastline models can only describe behaviors of the longshore sediment transport and shoreline evolutions by using the sand budget approach; 2D cross-shore coastal profile models are able to predict the vertical variations of coastal profiles, but not the variations of the longshore sediment transport; 2D horizontal coast/estuary/ocean models can simulate hydrological and morphological variations over a coastal area with a rather wide range of spatial scales (e.g., 100 m^2 to 100 km^2) with the vertical variations of waves and currents ignored. Nevertheless, only fully 3D morphological models are expected to take into account both the vertical and horizontal variations of wave and current (e.g., Lesser et al. 2004; Warner et al. 2008). However, due to the time-consuming nature for practical problems, 3D models are restricted generally to predict the temporal-spatial hydrological and morphological changes in a relatively small near-field and in a short duration. On the other hand, the horizontal 2D models have the potential to assess the impacts of storms and sea-level rise in local/regional/global scales. Therefore, a quasi-3D model with the efficiency of the 2D depth-averaged model and better accuracy than 2D models would be a feasible tool for the long-term morphodynamic simulations in large-scale coastal engineering problems. Zyserman and Johnson (2002) and Ding et al. (2006b) have presented, respectively, two quasi-3D coastal process models in which an empirical 3D shear stress distribution was used to take into account a quasi-3D effect of sediment transport. They concluded that quasi-3D coastal/estuarine process models enable to compute accurately free-surface water motions, cross-shore sediment transport, and morphological changes under natural hydrological conditions with high computing efficiency.

Recently, semi-empirical numerical approaches were presented by means of tide-averaging currents to assess long-term morphological changes on both the meso- and macro-scale in coastal inlets and tidal lagoons in estuaries, e.g., rapid assessment of morphology (RAM) by Roelvink (2006). But these tidal-phase-averaging approaches are not able to simulate nonlinear and highly unsteady hydrodynamic and morphodynamic processes during a short-term storm, as they cannot capture the peak surge and maximum flood inundation in storms/hurricanes. Nevertheless, due to the concern of computing time for assessing long-term impacts of sea-level rise over a few decades in the future, a similar approach based on tide-averaging hydrodynamic variables for rapid assessment of impacts of sea-level rise may be needed.

Table 4 Summary of computer codes of phase-averaged wave models

Models	Wave processes included	Steady or unsteady	Mesh coordinates	References

[a]Note: Wave whitecapping is a situation that wave is blown by the wind so its crest is broken and appears white

As an example of quasi-3D coastal and estuarine process models, CCHE2D-Coast is capable of simulating tides, waves, currents, sediment transport, and morphological changes in various coasts and estuaries (Ding et al. 2006b; Ding and Wang 2008a). It has been applied to assess the impacts of hazardous hydrological forcings including sea-level changes during storms and hurricanes (or typhoon) on coastal flood inundation, erosion and deposition, and navigation maintenance (Ding et al. 2007, 2013; Ding and Wang 2008b). This model has systematically integrated three major submodels for simulating irregular wave deformations, astronomical tides, river inflows, wave-induced currents, sediment transport due to combined waves and currents, and morphological changes in coasts and estuaries. A validated algorithm in the CCHE2D (Jia et al. 2002) for the treatment of wetting/drying was directly used for predicting tidal flat variations and coastal inundations. This process-based model has been extensively validated by simulating waves, wave-induced currents, and morphological changes in coastal applications in various laboratory and field scales (Ding et al. 2004, 2006a, b; Ding and Wang 2005, 2008a).

Some other commercial and in-house numerical models capable of modeling coastal and estuarine processes are briefly reviewed as follows: Table 4 gives a short list of computer codes of phase-averaged irregular wave models, in which the wave transformation and deformation processes and mesh coordinates are evaluated. In Table 5, some 2D hydrodynamic models have been compared with each other in respect to their numerical methods, grid systems, wetting/drying modeling capability, consideration of irregular waves, modeling capability for complex quasi-3D flow structures, and the

effects of coastal structures. The different capabilities of the models available for modeling sediment transport and morphological changes are shown in Table 6. In addition, there are some other storm surge models which can be used to predict storm surge and coastal inundation due to sea-level rise and storms, but incapable of simulating sediment transport and morphological change together with coastal hydrodynamic simulation, e.g., POM model (Blumberg and Mellor 1987), SLOSH model (Jelesnianski et al. 1992), and SHORECIRC model (Svendsen et al. 2003).

A Case Study: Assessment of Impacts of Sea-Level Rise and Hazardous Storm in an Estuary

This case study is to demonstrate the assessment of impacts of sea-level rise and hazardous storms by simulating hydrodynamic variations and morphological changes in an estuary located in the west coast of Taiwan by using CCHE2D-Coast. This study did not estimate how much the sea-level rise will be; instead, it used several sea-level rise scenarios which are broadly based on recent sea-level rise forecasting studies and combined with historical storms as hydrological forcings. In this study, four scenarios, i.e., 0.5, 1.0, 1.5, and 2.0 m sea-level rise by 2100, were adopted to assess the impacts of sea-level rise in the estuary. CCHE2D-Coast was used to predict hydrodynamic processes (water elevations and velocities) and morphological changes under the conditions of the four scenarios and a storm flood event.

Information of the Study Estuary and Model Validations

The estuary of study site is located at the west coast of Taiwan called Touchien Estuary, facing to Taiwan Strait. As shown in Fig. 2, this estuary has a 2.0-km wide river mouth, a river mouth bar, two islands inside the bay, and two rivers (Touchien

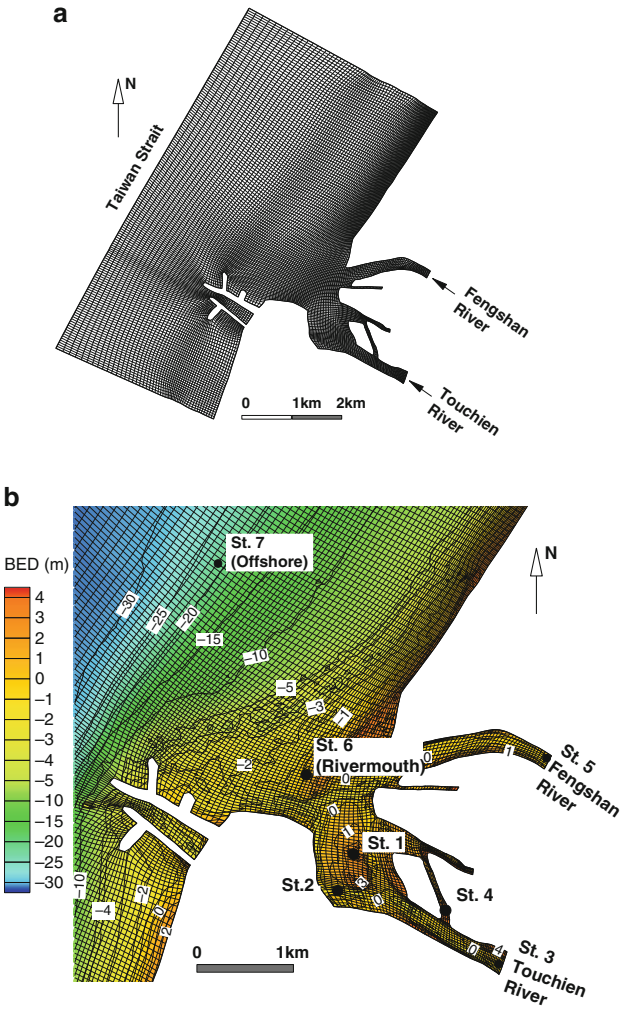

Fig. 2 Grid and bathymetry in Touchien Estuary. (**a**) Overview of the computational domain. (**b**) Close-up view of the estuary

and Fengshan Rivers). A highly dense population lives in the coastal communities very close to the beaches. And the coastal zone is vulnerable facing storm (typhoon) attack and river floods and meanwhile is sensitive to sea-level rise. During storms or typhoons, this small estuary has equally important hydrodynamic and morphodynamic processes driven by tides, storm waves, surges, and river floods. The morphodynamic processes are therefore driven by multi-scale physical forcing such as river flows, tidal currents, nearshore currents, and wave breaking across the surf zone. Morphological changes in the estuary are generally complex. To investigate floods and morphological changes in the estuary, a computational domain, as

shown in Fig. 2a, was used in the simulations. A non-orthogonal structural grid was generated by the CCHE2D mesh generator (Zhang and Jia 2005) to cover this entire estuarine and its adjacent coastal area. Figure 2b shows a close-up view of the estuarine area in which several stations are marked for output of model results. Through simulating morphological changes during a 3-year period from 2004 to 2006 in which nine typhoon events (i.e., Mindulle, Aere, Haima, Haitang, Matsa, Talim, Longwang, Bilis, and Kaemi) were included, the CCHE2D coastal model has been validated in this study area (Ding et al. 2008). The boundary conditions of tidal elevations and wave properties at offshore in the 3-year simulation were prepared beforehand using a regional storm surge model (a POM model) (POM 2011; Blumberg and Mellor 1987) and the SWAN wave model (SWAN 2011). (The Princeton Ocean Model (POM) is an ocean model that is able to simulate hydrodynamic processes of free-surface flows such as circulation and mixing processes in rivers, estuaries, shelf and slope, lakes, seas, and ocean. SWAN is a wave model that computes random, short-crested wind-generated waves in coastal regions and inland waters. For more information, one may refer to SWAN (2011).) The offshore incident wave properties, i.e., the significant wave heights, the periods, and the mean directions, were provided by field observations and the extracted results from the simulations by the SWAN model. The significant wave heights were usually lower than 2.0 m in most typhoons landed at the east coast and flood events in the coast. According to the grain size measurements, a uniform grain size, $d_{50} =$ 0.2 mm, was used for representing the coastal sediments in the domain. A total load sediment transport formulation was used to calculate sediment fluxes and morphodynamic process from river to coast. Ding et al. (2008) have shown that the computed morphological changes induced by all the storms during the 3-year validation period are in good agreement with the observations. As a result, CCHE2D-Coast was validated in the estuary using the field observation data. For the details on this site-specific model validation, one may refer to Ding et al. (2008).

Hydrodynamic and Morphodynamic Responses to Sea-Level Rise and Storm

As mentioned above, sea-level rise may cause disastrous flooding and inundation during storm periods in the low-lying areas of coasts and estuaries. In order to examine the impacts of sea-level rise together with a storm event, a real storm (typhoon Talim which occurred in August 2005), which attacked the Touchien Estuary from 8/31/2005 to 9/2/2005, was used as the extreme event for this case study. As shown in Fig. 3, two hydrographs, which represent respectively time series of flood flow discharges from the two rivers caused by rainfall of the typhoon, were applied to the two river inlets as the river inflow boundary conditions. These two hydrographs at the inlets of the two river upstreams were obtained beforehand by simulating respectively the storm flood flows in the two rivers from far upstream down to the estuary using a one-dimensional river flow model. The peak discharge was 2,013.67 m^3/s in the Touchien River and 992.66 m^3/s in the Fengshan River, respectively.

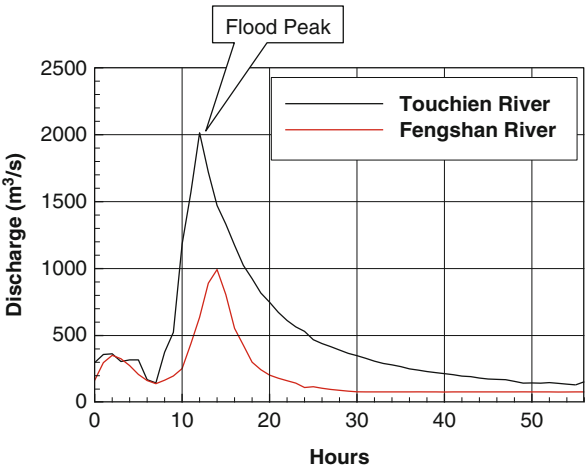

Fig. 3 Hydrographs at two river upstream inlets during a storm flood event

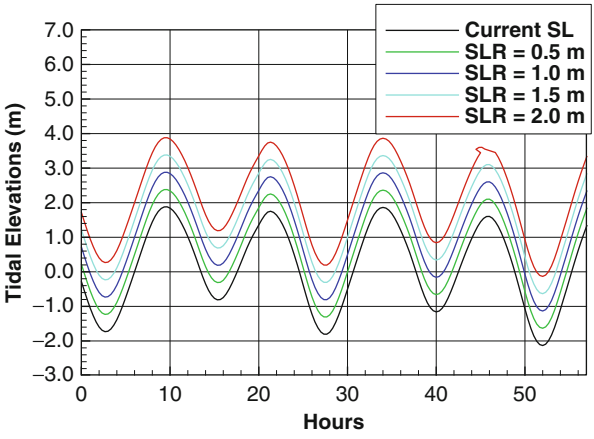

Fig. 4 Tidal elevations boundary conditions at the offshore

Then, the site-specifically validated CCHE2D-Coast was applied to simulate flood flows and sediment transport driven by this selected storm combined with the five sea-level rise scenarios (i.e., 0.5, 1.0, 1.5, 2.0 m sea-level rise, and a case without mean sea-level change). The mean sea-level changes were considered as the different scenarios of tidal elevations at the open sea. So the sea-level changes were added into the tidal elevations during the storm event to create new tidal elevation time series with the mean sea-level rise. Figure 4 shows the five time series of tidal elevations at the offshore which represent the tides under the conditions of the five sea-level rise scenarios. As the boundary conditions of a wave action model at offshore of the estuary, the wave properties (i.e., significant heights, averaged periods, and mean directions) at the offshore were specified on the offshore boundary for simulation of wave transformation from the offshore to the coast zone and the estuarine area. The offshore incident significant wave heights varied in the range

from 0.5 to 1.6 m during the storm event (Ding et al. 2013). In addition, the time series of prevailing wind speed and direction observed during the storm event were used in this study as the surface wind forcing over the estuary, in which the wind speed varies from 0.3 to 16.4 m/s.

Under these boundary conditions of tides and waves with the combined sea-level rise and storm, hydrodynamic and morphodynamic processes in the estuary were simulated using the site-specifically validated CCHE2D-Coast. The numerical simulations were performed by sequentially computing waves, currents, sediment fluxes, and morphological changes driven by the given hydrological conditions such as tides, waves, and river inflows at the five sea-level rise scenarios. To do so, the wave fields were updated every 1 h to reflect the changes of the offshore incident wave climate. And the sediment fluxes in the alluvial river reaches, the estuary, and the coastal area were calculated by an empirical sediment transport formulation which has taken into account the variations of sediment transport due to waves and currents over the entire estuarine region from the river-flow-dominant upstream to the wave-dominant coast (Ding and Wang 2008a).

Figure 5 shows the spatial distributions of computed significant wave heights and mean wave directions at the flood peak under the different conditions of sea-level rise. Along with the increase of the flooding area in the estuary from the current sea level (i.e., no sea-level rise) to 2-m rise, numerical results show that the offshore waves could invade the estuarine area from the river mouth toward the upstream river reaches. In comparison with the case for the current sea level (Fig. 5a), sea-level rises from 0.5 to 2.0 m would promote the invasion of offshore waves inside the estuary and could further change the morphological features in the bay area.

Figure 6 shows the comparisons of the computed currents and water elevations at the flood peak in the five cases over a range from the current sea level to 2.0 m rise. The results indicate that significant increases in water elevations, offshore surge water invasion inside the estuary, and widening inundation areas occur when the sea-level rise is more than (and equal to) 1.0 m.

In order to investigate the water elevation increases in the estuary which respond to the sea-level rise and the storm event, the time series of water elevations at seven selected monitoring stations are plotted in Fig. 7. As the locations of the stations are shown in Fig. 2b, these stations represent respectively the offshore, river mouth, cross sections inside the estuary, and two rivers upstream. Intercomparisons of these water elevation changes clearly show that the tidal variations will affect the two river upstreams if sea-level rises up to 1.0 m. With the sea-level rise up to 2.0 m, the entire river reaches will become tidal reaches and therefore possibly receive the saline water from ocean. Furthermore, the differences of water elevations at a same station generated by the five sea-level scenarios are shown in Fig. 8. It also can be concluded that all the computational area could become tide-influenced estuary if there is 2.0-m sea-level rise, and most of the coastal community will be exposed to the attack of high tides, storm waves, and river floods. As it can be seen from Fig. 8a, there is an increasing inundation area at the river mouth bar due to the sea-level rise, and the river mouth area behaves like the offshore after the rise is equal to and higher than 1.5 m. And the upstream river area is more susceptible to the tidal effect as it is

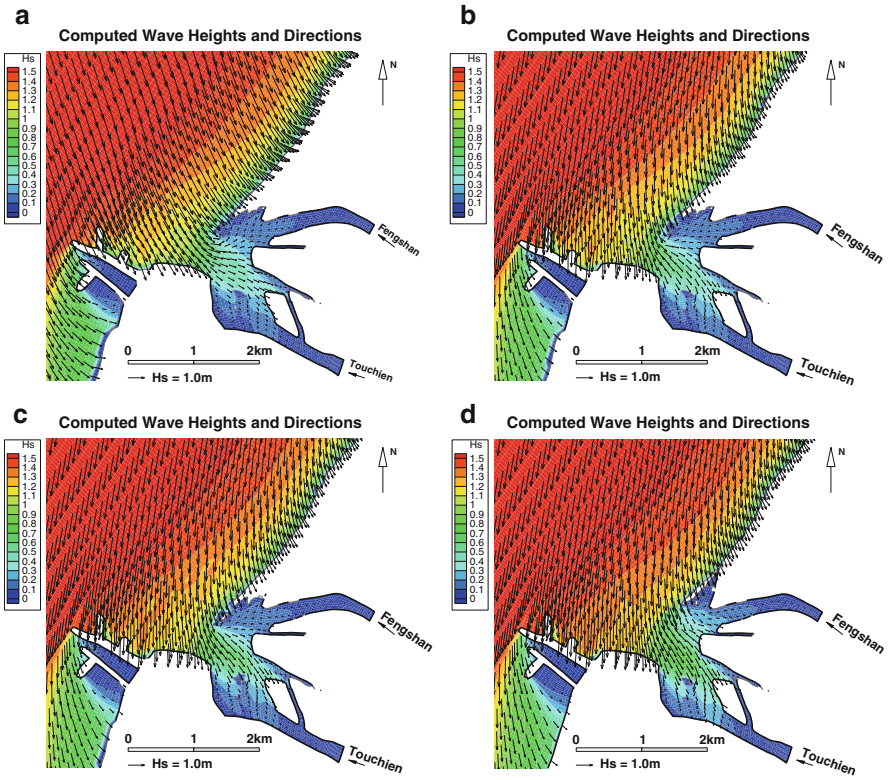

Fig. 5 Comparison of computed wave height (unit: m) and directions at the flood peak for different sea-level rise scenarios. (**a**) Current sea level, (**b**) 0.5-m rise, (**c**) 1.0-m rise, and (**d**) 2.0-m rise

shown in Fig. 8d. The increase of sea level promotes the invasion of tidal waves inside the rivers and elevates the water levels in river reaches, and the tidal effect may even influence farther upstream.

The morphodynamic processes are complicated in the estuary due to the highly irregular bathymetry and hydrological conditions. In particular, the existence of the two interior islands affects river courses and sediment transport. As depicted in Fig. 9, the simulated morphological changes indicate erosion/deposition areas in the estuary, river mouth, and the adjacent coasts due to the storm and the sea-level changes. They show the gradually reducing areas of deposition in the offshore when sea-level rise increasing from current sea level to 2.0 m mean sea level. This is because the increased water depth causes wave-breaking zone (or the surf zone) shifting to upstream (or landward), and the current surf zones turn to be shoaling zones where wave breaking may no longer occur. Therefore, sediment transport at the offshore becomes less active. Figure 9 also shows that with the increasing of sea levels, the river mouth bar is increasingly eroded, which consequently will cause a

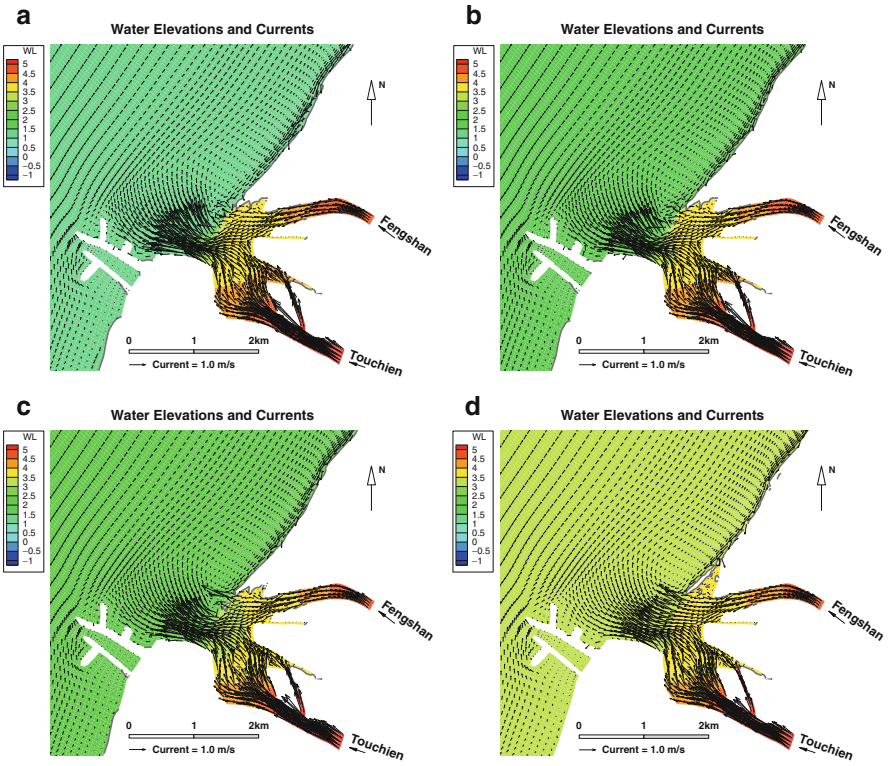

Fig. 6 Comparison of computed water elevations and currents at the flood peak due to sea-level rise scenarios. (**a**) Current sea level, (**b**) 0.5-m rise, (**c**) 1.0-m rise, and (**d**) 2.0-m rise

landward displacement of the shoreline. And the river mouth bar may migrate to the junction area of the two rivers in the estuary. Figure 10 presents the profiles of computed bed elevations and bed changes at the river mouth along with the transect A-A', of which the location is shown in Fig. 9d, after the storm flood with the conditions of the sea-level rise scenarios. The profiles clearly show that the erosion process in the river mouth is not linearly increasing, but typically nonlinearly varying with the sea-level changes; in fact, 1.0-m sea-level rise will cause a river mouth to be narrowed (turning to close), and the river mouth widening process could be accelerated only after the sea-level rises up to 2.0 m.

Discussions on the Impacts of Sea-Level Rise in Touchien Estuary

In this case study, the site-specifically validated coastal process model, CCHE2D-Coast, was applied to compute hydrodynamic and morphodynamic responses to a set of hypothetical sea-level rise scenarios combining with a real storm event happened

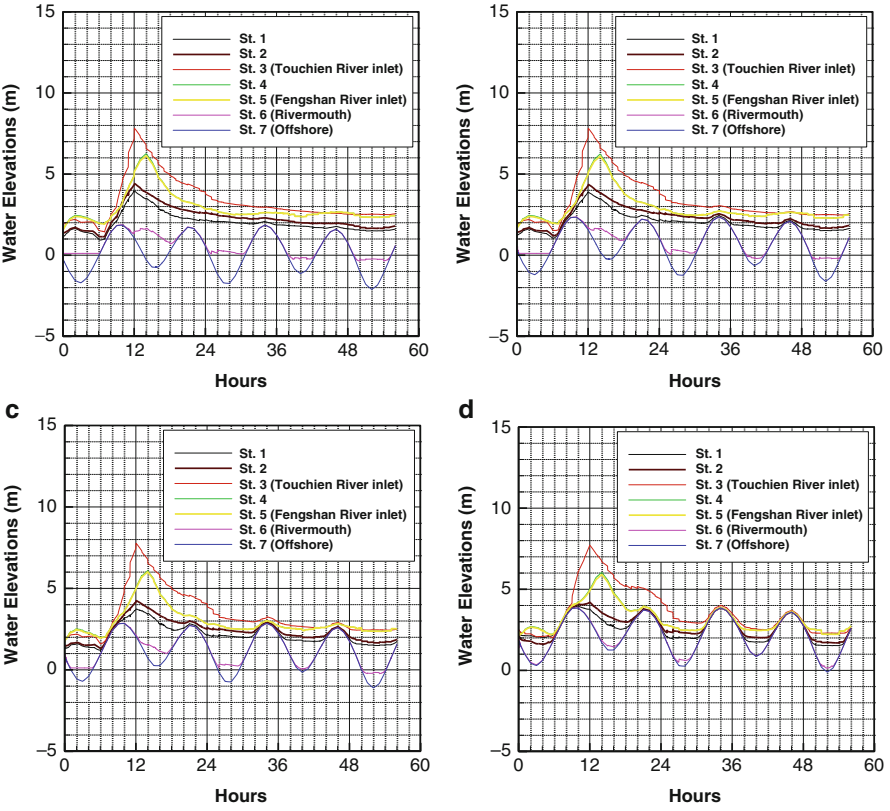

Fig. 7 Comparison of computed water elevation time series at seven stations under the same sea-level rise scenarios. (**a**) Current sea level, (**b**) 0.5-m rise, (**c**) 1.0-m rise, and (**d**) 2.0-m rise

in Touchien Estuary located in the west coast of Taiwan. The hydrodynamic results show that there are obvious wet/dry cycle changes at all the upstream monitoring stations. And there is an increasing inundation effect at the river mouth bar in case of the mean sea level higher than 1.5 m. The river area is more susceptible to the tidal effect at the 1.5-m mean sea-level rise. In addition, the morphodynamic results show that there is apparent change in erosion/deposition areas due to sea-level rise. Especially, the river mouth bar is more exposed to be eroded, which consequently could cause landward retreat of shoreline and displacement of rivermouth bar due to inundation and waves approaching inland. The preliminary test results in the case study demonstrate that the CCHE2D-Coast model is able to effectively simulate the nonlinear and unsteady hydrodynamic and morphodynamic processes in the coastal and estuarine area under different mean sea-level scenarios. Therefore, this model can be used for coastal/estuarine planning and management to assess the impacts of sea-level rise and storm events under naturally temporal-spatial varying hydrological conditions.

Concluding Remarks and Future Research Topics

This chapter investigates the dynamic impacts of sea-level rise by assessing hydrodynamic and morphodynamic responses to storms (hurricanes or typhoons) under natural physical conditions of coastal and estuarine processes which are induced by astronomical tides, waves, storm surges, river inflows (floods), sediment transport, and morphological changes in coasts and estuaries. It also presents a review on the impact assessment approaches such as projection and numerical modeling to assess the impacts of sea-level rise in local/regional/global scales. A special attention in the chapter has been paid to emphasize the importance and applicability of numerical modeling to quantify the dynamic impacts of hazardous storms after sea-level rise occurs, since simulated results on flooding/inundation areas and erosion are the

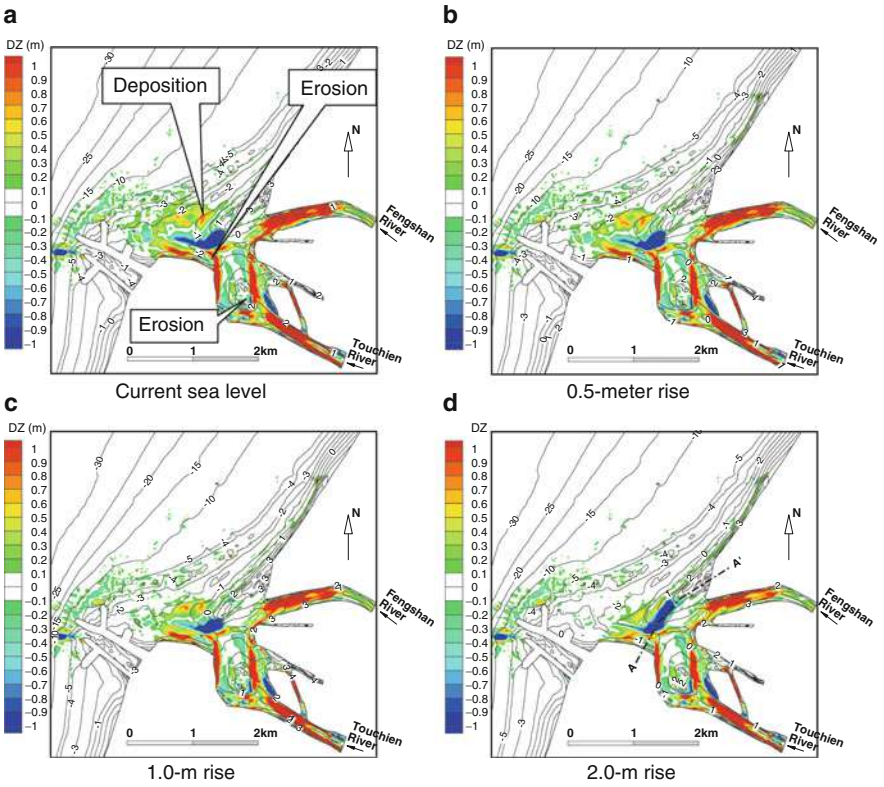

Fig. 9 Comparisons of computed bed changes after the storm flood under the conditions of different sea-level rise scenarios. (DZ is bed change. The contour lines are computed bed elevations.) (**a**) Current sea level, (**b**) 0.5-m rise, (**c**) 1.0-m rise, and (**d**) 2.0-m rise

firsthand data base to engineers, managers, and decision makers to practice flood water management, shoreline erosion protection, and design/planning of coastal infrastructure against hazardous storms.

It also gives a brief review on the existing coastal/estuarine process models which are applicable to simulate/predict hydrodynamic and morphodynamic responses to the complex hydrological conditions in coasts and estuaries. Finally, using an integrated coastal/estuarine process model called CCHE2D-Coast, the simulations of flows and morphological changes in an estuary located in the west coast of Taiwan under the conditions of several sea-level rise scenarios and a selected extreme storm are demonstrated. It shows that numerical modeling of coastal/estuarine processes can predict temporal-spatial variations of flows (water elevations and current velocities), sediment transport, and morphological changes due to the combined physical conditions from waves, tides, surges, and river floods. These numerical simulation results indicate that this integrated process model is capable of predicting the dynamic impacts of sea-level rise with storm events such as inundation of

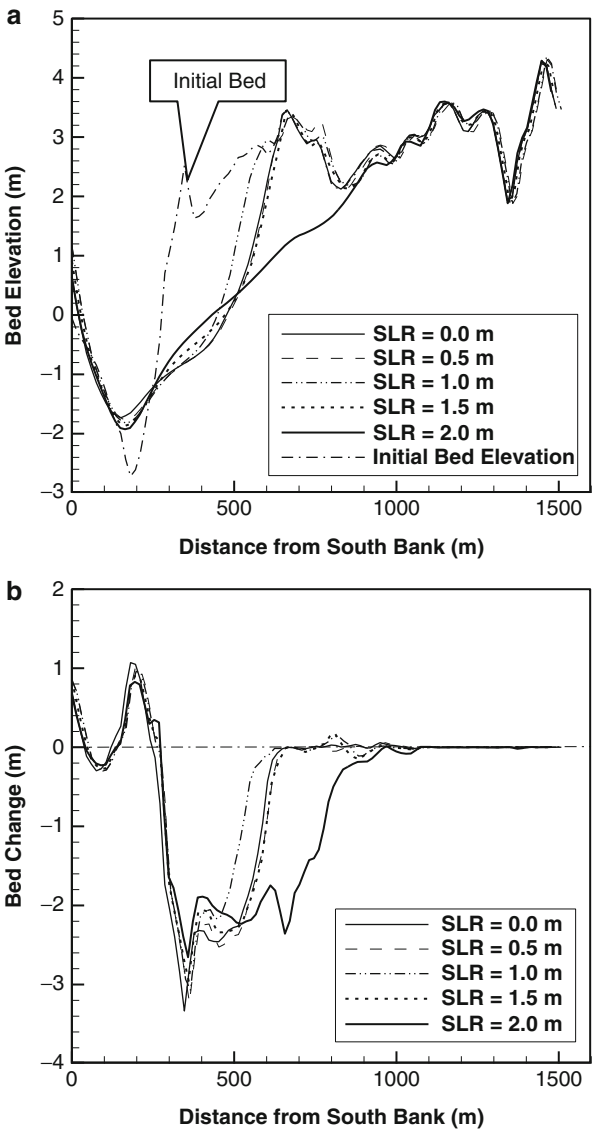

Fig. 10 Comparisons of profiles of computed bed elevations and bed changes after the storm flood at the river mouth along with the transect A-A' shown in Fig. 9d. (**a**) Bed elevations and (**b**) bed elevation changes

low-lying area, shoreline retreat, changes of coastal zones, tidal water intrusion, etc. These models enable to facilitate the assessment of dynamic impacts of sea-level rise and storms in different time and spatial scales (local/regional scales) for various practical engineering application purposes such as flood management, coastal erosion protection, and coastal community development/planning. By integrating with other numerical models for prediction of water quality and ecological processes in the future, this kind of integrated physical process model will also be applied for

assessment of the environmental impacts of sea-level rise such as saline water intrusion and pollutant transport in coasts and estuaries.

As for the potential future research topics for better assessment of impacts of sea-level rise and hazardous storms (extreme events), basically, there are three aspects that need to be enhanced in the future:

1. Improve understanding of sea-level rise and coastal hazardous events or extreme events including other extreme events such as tsunami and large-scale oil spill.
2. Improve assessment tools by advancing all scale-level numerical modeling techniques with more accurate, efficient, and higher-resolution numerical simulations.
3. Develop mitigation and adaptation to sea-level rise and extreme storms with increasing storm strength and frequency.

Nicholls et al. (2007) pointed out that the level of knowledge and understanding on sea-level rise, storms/hurricanes, and their interactions is not consistent with the potential severity of the problem of climate change and coastal zones. Key uncertainties in the climate drivers and responses of coasts and oceans increase with the largest uncertainties concerning in their interactions. It is vital to establish better baselines of actual sea-level changes and coastal changes in morphology and ecology through observations and expanded monitoring. In addition to traditional tide-gauge measurements, there is a need to collect more accurate data from altimetric satellites, such as TOPEX/Poseidon (launched in 1992 and still operating), which observe almost the entire planet and determine the absolute, not relative, sea level because they make measurements with respect to Earth's center of mass (without uncertainty of subsidence existing in some tide-gauge data) (Douglas and Peltier 2002). For a better assessment of impact of sea-level rise and storms, it is also of vital importance to improve understanding of extreme tropical storms/hurricanes, particularly their strength and frequency increasing with global climate change. Better knowledge about occurrence of coastal extreme events will definitely facilitate a more accurate impact assessment and building a stronger coastal defense community. Assessment of human vulnerability in coastal and low-lying areas is an ultimate goal to build a sustainable coastal community, which though is out of the scope of this chapter; one may refer to Nicholls et al. (2007) for detailed assessment of socioeconomic impacts of sea-level rise due to climate changes.

Numerical modeling is the only assessment tool to evaluate impact of sea-level rise with various spatial scales and to predict time-dependent variation patterns of physical variables including climate driving factors and coastal/oceanographic factors. It is essential to continue to develop numerical models with higher accuracy by including improved knowledge on climate changes and coastal/ocean processes so that uncertainties from natural processes can be reduced as much as possible. Detailed model validation/verification is always requested to control the quality of numerical simulations before a model can be applied to a real-world problem. The models with different scales should be validated by the observation data sets obtained from relevant field measurements. To make the multi-scale assessment more effective, multi-scale modeling techniques have to be developed to meet the

increasing demand for assessing local/regional impact of sea-level rise with the conditions of storms and hurricanes. Development of high-performance computing techniques is critical to improve the computing efficiency of climate models and local assessment models, especially due to multidimensional and unsteady physical problems in the interactions of climate changes and coastal/ocean processes. It is undoubted that an integrated modeling system with better accuracy and efficiency will be a unique powerhouse to help scientists, engineers, and policy/decision makers to better assess coastal vulnerability and provide the cost-effective plan for mitigation and adaptation against the impacts of sea-level rise and extreme coastal events, as well as their interactive impacts.

Acknowledgment This work was a product of the research partially sponsored by the National Center for Computational Hydroscience and Engineering in the University of Mississippi. The authors would like to thank Dr. Keh-Chia Yeh in National Chiao Tung University, Hsinchu, Taiwan, for his help to provide the boundary conditions for the case study. Special thanks are given to Mr. Moustafa Elgohry for his research assistance.

Abstract

Water quality and fish habitat models were developed and applied to investigate impacts of future climate change on cisco oxythermal habitat in Minnesota lakes. Long-term daily water temperature (T) and dissolved oxygen (DO) profiles were simulated for different types of representative lakes (surface area from 0.05 to 50 km^2) in Minnesota under the past climate conditions (1961–2008) and projected future climate scenarios. A process-oriented, dynamic, and one-dimensional year-round lake water quality model was developed and applied for the temperature and DO simulations, which were run in daily time steps over a 48-year simulation period. The lake parameters required as model input were surface area (A_s), maximum depth (H_{max}), and Secchi depth (as a measure of radiation attenuation and trophic state). Weather records from eight stations in Minnesota and North Dakota were used for model simulations. Two projected future climate scenarios were based on the output of the third-generation Canadian Centre for Climate Modeling and Analysis coupled general circulation model (CCCma CGCM 3.0) and the Model for Interdisciplinary Research on Climate (MIROC 3.2). The climate scenarios lead to a longer period of hypoxic hypolimnetic conditions in stratified lakes that will result in various negative environmental and ecological impacts in lakes. The study has identified potential refuge lakes important for sustaining cisco habitat under climate warming scenarios. Cisco *Coregonus artedi* is the most common cold-water stenothermal fish species in lakes over the several northern states in the USA such as Minnesota. To project its chances of survival under future warmer climate conditions, using simulated daily T and DO profiles in 44 representative and 30 virtual lake types, three oxythermal habitat modeling options were used: (1) constant lethal T and DO limits, (2) lethal-niche-boundary curve, and (3) an oxythermal habitat variable, TDO3, i.e., water temperature at DO = 3 mg/L. The fish habitat models using constant and variable lethal limits were validated in the 23 Minnesota lakes of which 18 had cisco mortality while five had no cisco mortality in the unusually warm summer of 2006. Cisco lethal and habitable conditions in the 23 lakes simulated by the models had overall good agreement with observations in 2006. Cisco lethal days were simulated in the 44 representative lake types. Polymictic shallow lakes with lake geometry ratio $A_s^{0.25}/H_{max} > 5.2\ m^{-0.5}$ (A_s in m^2 and H_{max} in m) were simulated to typically not support cisco oxythermal habitat under past climate conditions and the future climate scenario (MIROC 3.2). Medium-depth lakes are projected to be most vulnerable to climate warming with most

increase in the number of years with cisco kill. The mean daily TDO3 values over a 31-day fixed and variable benchmark periods were calculated for each of simulated years and then averaged over the simulation period for each lake type. Projected increases of the multiyear average TDO3 (called AvgATD3) under the two future climate scenarios and relative to the 47-year simulation period from 1962 to 2008 had averages from 2.6 °C to 3.4 °C. Isopleths of AvgATD3 were interpolated for the 30 simulated virtual lakes on a plot of Secchi depth versus lake geometry ratio used as indicators of trophic state and summer mixing conditions, respectively. Marking the 620 Minnesota lakes with identified cisco populations on the plot of AvgATD3 allowed to partition the 620 lakes into three tiers depending on where they fell between the isopleths: lakes with AvgATD3 $\leq$ 11 °C (tier 1 lakes) were selected to be most suitable for cisco; lakes with 11 °C $<$ AvgATD3 $\leq$ 17 °C (tier 2 lakes) had suitable habitat for cisco; and non-refuge lakes with AvgATD3 $>$ 17 °C (tier 3 lakes) would support cisco only at a reduced probability of occurrence or not at all. About 208 (one third) and 160 (one fourth) of the 620 lakes that are known to have cisco populations are projected to maintain viable cisco habitat under the two projected future climate scenarios using the fixed and variable benchmark periods, respectively. These selective lakes have a Secchi depth greater than 2.3 m (mesotrophic and oligotrophic lakes) and are seasonally stratified (geometry ratio less than 2.7 $m^{-0.5}$). Management strategies were developed and implemented for some of the refuge lakes.

Introduction

The potential significance of climate change for inland aquatic ecosystems (e.g., streams, lakes, reservoirs) caught the attention of water resource professionals and scientists in the early 1990s. An increase of carbon dioxide (CO_2) and/or other greenhouse gases in the atmosphere is projected to cause climate warming (NRC 1983; IPCC 2007), which would alter water temperature (T), ice/snow cover, and dissolved oxygen (DO) characteristics in lakes (Blumberg and Di Toro 1990; Stefan et al. 1996). These changes are in turn expected to have an effect on indigenous fish populations: cold-water, cool-water, and warmwater fish species (Coutant 1990; Magnuson et al. 1990; Chang et al. 1992; Stefan et al. 1995; De Stasio et al. 1996). Chapter 16 in the previous edition of the handbook has summarized some basic information on effects of climate change on water quality (water temperature, dissolved oxygen, snow and ice covers) and fish habitat for three fish guilds (8, 7, and 14 species of cold-water, cool-water, and warmwater fish guilds, respectively) in lakes in Minnesota and the contiguous USA (Fang and Stefan 2012). This chapter summarizes simulation results and model validation of cisco oxythermal habitat in Minnesota lakes that were used to identify cisco "refuge lakes" under future climate scenarios and develop management strategies for them. A "refuge lake" is a cisco lake that is projected to provide suitable cold-water habitat under future climate scenarios.

Cisco *Coregonus artedi* is the most common cold-water stenothermal fish in northern lakes in Minnesota, Wisconsin, and other northern states, and it is a common forage fish for walleye *Sander vitreus* and northern pike *Esox lucius* among other prized sport fishes. The Minnesota (MN) Department of Natural Resources (DNR) has sampled cisco from 648 lakes in netting assessments since 1946 (MN DNR files). These lakes are typically deeper and more transparent than average lakes in Minnesota (Fang et al. 2009). The lakes are scattered throughout much of the central and northern portions of the state (Fig. 1) and cross several land uses (agricultural, urban, and forested). The wide distribution suggests that ciscoes are somewhat more eurythermal than other native, lentic cold-water stenotherms such as lake whitefish *Coregonus clupeaformis* (sampled in 155 Minnesota lakes), lake trout *Salvelinus namaycush* (124 Minnesota lakes), and burbot *Lota* (233 Minnesota lakes). Cisco physiologically requires cold, well-oxygenated water to survive, grow, and reproduce (Cahn 1927; Frey 1955). The combination of a wide distribution (Fig. 1) and a requirement for cold, oxygenated water (Frey 1955) make cisco an excellent "canary in a mineshaft" species that is a sensitive indicator of ecological stresses such as eutrophication and climate warming. For example, 18 lakes in north-central Minnesota experienced cisco mortality in the unusually hot summer of 2006 (Jacobson et al. 2008), and one example of cisco mortality is given in Fig. 2.

The climate warming is projected to warm the water and increase hypolimnetic oxygen depletion during periods of stratification in lakes (Blumberg and Di Toro 1990; Fang and Stefan 1999, 2000, 2009). Fish habitat is constrained by water temperature, available DO, food supply, human interference, and other environmental factors (Frey 1955; Fry 1971). In lakes, water temperature and DO are the two important water quality parameters that affect survival and growth of cold-water fishes (Magnuson et al. 1979; Coutant 1985, 1990; Christie and Regier 1988; Jacobson et al. 2010; Fang et al. 2012a, b; Jiang et al. 2012). Therefore, projected changes of water temperature and DO characteristics due to climate warming have the potential to reduce cold-water fish habitat (such as cisco) in lakes (Magnuson et al. 1990; Schindler et al. 1996; Stefan et al. 1996; Fang et al. 2004b). Ciscoes have been declining in recent years in Minnesota lakes, likely because of climate warming (Jacobson et al. 2012). Recently, Sharma et al. (2011) estimated that 30–70 % of the cisco population in about 170 of Wisconsin's deepest and coldest lakes could become a climate change casualty and disappear from most of the Wisconsin cisco lakes by the year 2100.

The goal of the study was to simulate daily water temperature and DO profiles in different cisco lakes to project the quality of cold-water fish habitat in 620 known cisco lakes in Minnesota under future climate scenarios and to identify potential cisco refuge lakes and impacts of climate change on cisco habitat. To make projections of water quality and fish habitat in lakes under future climate scenarios, numerical simulation models of daily temperature and DO profiles are useful. It is infeasible to simulate 620 cisco lakes in Minnesota using MINLAKE2010/MINLAKE2012 (Fang et al. 2012a). In this study, simulations of daily water temperature and DO profiles were made for the 30 virtual lakes

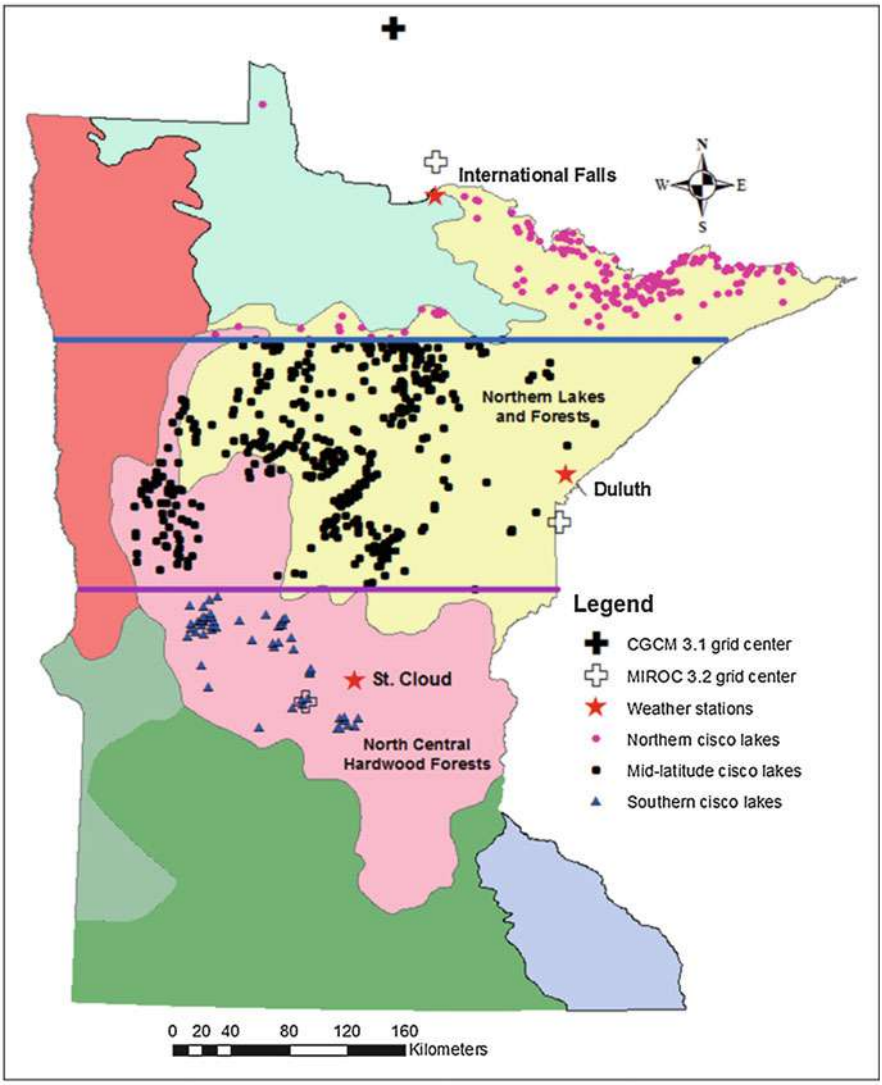

Fig. 1 Geographic distribution of 620 cisco lakes grouped by latitude, three weather stations (stars), and associated grid center points (crosses) of CGCM 3.1 and MIROC 3.2 used for model simulations. Background shades identify ecoregions of Minnesota. Cisco lakes are essentially in two ecoregions: (1) Northern Lakes and Forests and (2) North Central Hardwood Forests (modified from Jiang et al. 2012)

(Fang et al. 2012b; Jiang et al. 2012) and 44 representative lakes (Fang et al. 2014) in Minnesota before cisco oxythermal habitat and lethal conditions were examined in these lakes. The overall modeling methodology for the study is discussed in detail in the next section (Fig. 3).

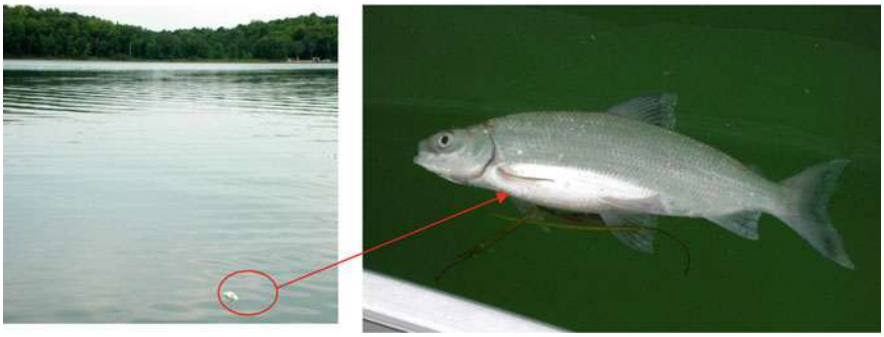

Fig. 2 Lake Andrusia in Minnesota had cisco mortality in July 2006 (Photo: Peter C. Jacobson, Minnesota Department of Natural Resources)

In this study, cold-water oxythermal fish habitat was identified using three different methods (Fig. 3): (1) constant lethal limits (lethal temperature, LT and DO survival limit), (2) lethal-niche-boundary curve (Jacobson et al. 2008) (also called variable lethal limits), and (3) a single oxythermal habitat variable TDO3, temperature at 3 mg/L of DO (Jacobson et al. 2010). Depths at the good-growth temperatures and lethal limits and TDO3 values were calculated day by day from simulated daily lake water temperature and DO profiles obtained from the process-oriented, one-dimensional year-round water quality model MINLAKE2010/MINLAKE2012 (Fang et al. 2012a). The model was run in daily time steps over a continuous 48-year simulation period for past (1961–2008) climate conditions and for two projected future climate scenarios (CGCM 3.1 and MIROC 3.2). Monthly (31-day) fixed and variable benchmark periods (Fang et al. 2012b; Jiang et al. 2012; Jacobson et al. 2010) were used to identify future cold-water fish habitat in lakes based on projected future temperature and DO profiles.

Overall Modeling Methodology

Figure 3 shows a flowchart of the study to project impacts of climate changes on cisco oxythermal habitat in Minnesota. Past climate conditions (1961–2008, 48 years) and two future climate scenarios at different weather stations were assembled and used as model inputs (atmospheric boundary conditions) to the deterministic, unsteady, one-dimensional (vertical) lake water quality model MINLAKE2010/MINLAKE2012 which can simulate T and DO profiles in cisco lakes continuously for 48 years over the open-water seasons and winter ice-cover periods.

A cisco habitat model with three different modeling options were developed, validated, and used for the study. The first option is to use the constant lethal limits to model cisco habitat in Minnesota lakes. The constant limits for fish survival (lethal) and good growth do not change with time, and the method was previously used to

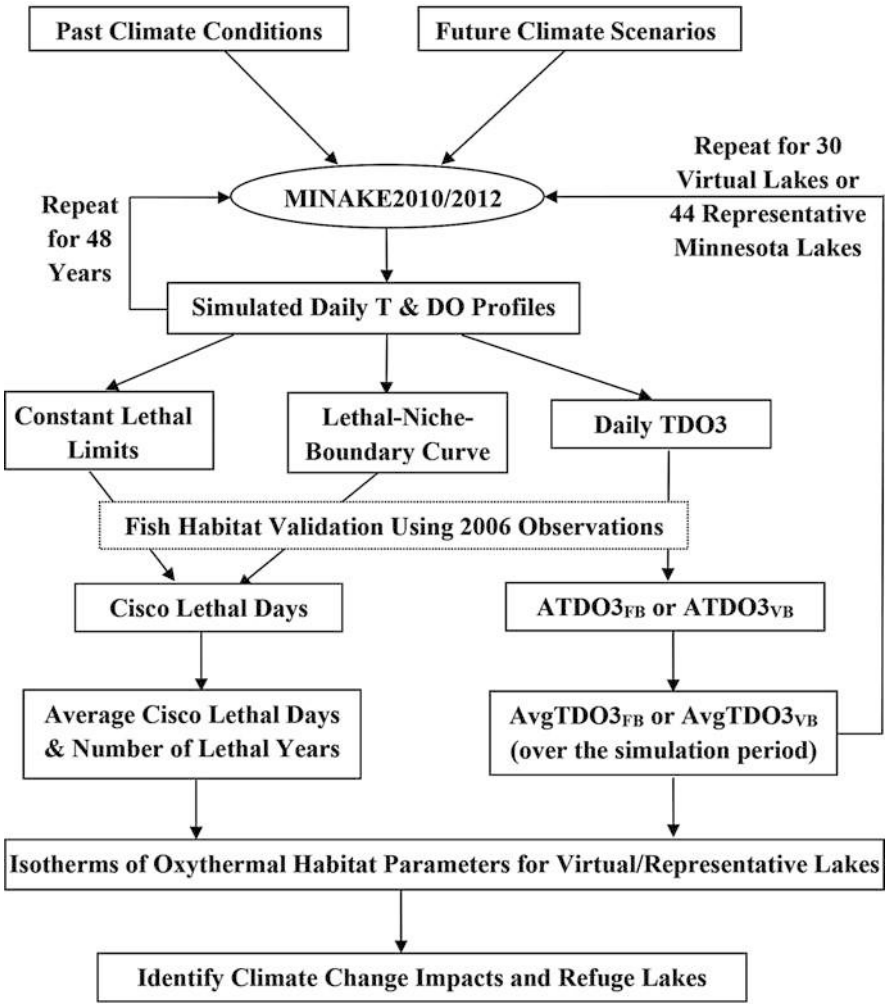

Fig. 3 Flowchart of the study to project impacts of climate changes on cisco oxythermal habitat in Minnesota lakes

project cold-water, cool-water, and warmwater fish habitat in small lakes in Minnesota and over the contiguous USA (Stefan et al. 2001). The constant lethal limits of cisco were calculated from the lethal-niche-boundary curve of adult cisco (Jacobson et al. 2008) and then determined through model validation in 23 Minnesota lakes using cisco mortality and survival data in the summer of 2006. The second option is to use a fitted regression equation as the lethal niche boundary of adult cisco. The equation was developed by Jacobson et al. (2008) and gives DO survival limits at different temperatures, which are temperature-varying lethal limits. The third option is to use a single oxythermal variable TDO3 to identify cisco refuge lakes

(Fang et al. 2012b; Jiang et al. 2012). TDO3 has been a useful parameter for quantifying the oxythermal niche of cold-water fish (Jacobson et al. 2010). TDO3 was calculated from simulated daily T and DO profiles for every simulated day except days in 1961 to avoid effects of initial conditions. In the third option of cisco oxythermal habitat modeling, the daily TDO3 values were averaged over either the fixed benchmark (FB) period ($ATDO3_{FB}$) (Fang et al. 2012b) or the variable benchmark (VB) period ($ATDO3_{VB}$) (Jiang et al. 2012) for each simulated lake and year. Using the variable benchmark periods for each simulated year gave the maximum average TDO3 over a 31-day period in different years and different lake types (Jiang et al. 2012).

The oxythermal habitat options 1 and 2 determine which day lethal conditions can occur. In the first option, when the LT isotherm and the DO limit isopleth for cisco intersect in a particular day (Stefan et al. 2001; Fang et al. 2004a; Fang and Stefan 2012), the entire depth of a stratified lake is under lethal conditions on that day. The lethal conditions are because water temperature is higher than LT from the water surface to or below the intersecting depth and DO is lower than the DO limit from the lake bottom to or above the intersecting depth. In the second option, lethal conditions for cisco are assumed to occur if the simulated DO is less than the DO_{lethal} value in all water layers (from the lake water surface to the lake bottom) on that day when DO_{lethal} is calculated from simulated water temperature using the lethal-niche-boundary curve (Jacobson et al. 2008).

To understand climatic variability, the water quality model and fish habitat model were run using the weather data from 1961 to 2008 for the past climate conditions in 30 virtual deep lakes and 44 representative lakes (Table 1) in Minnesota (Fig. 3). A number of years with cisco kill and number of cisco lethal days were determined during the simulation period for the habitat modeling options 1 and 2. The cisco kill was assumed to occur when the continuous lethal days of cisco last 3 or 7 days (Fang et al. 2014). To assess the quality of cisco habitat in a lake and identify refuge lakes, the 47-year averages of annual $ATDO3_{FB}$ and $ATDO3_{VB}$ values in the 1962–2008 simulation period (i.e., $AvgATD3_{FB}$ and $AvgATD3_{VB}$) were calculated in 30 virtual deep lakes (Table 2) and compared to TDO3 limits (11 °C and 17 °C determined by the analysis of field data) to divide cisco lakes into three tiers: tiers 1 and 2 refuge lakes and tier 3 non-refuge lakes (Fang et al. 2012b; Jiang et al. 2012).

To implement the above modeling approach, 44 "representative" Minnesota lake types (Table 1 and Fig. 3) and 30 "virtual" cisco lake types (Table 2 and Fig. 3) were chosen as representative of the entire set of Minnesota lakes in general and 620 cisco lakes, respectively; a similar approach using 27 "generic" lake types had been used to study climate warming impact on fish habitat in small lakes in Minnesota (Stefan et al. 1996) and in the contiguous USA (Stefan et al. 2001; Fang et al. 2004a, b), because it was not viable to run the deterministic model for all 620 cisco lakes over 47 years. To apply the oxythermal habitat results to the hundreds of cisco lakes that could not all be simulated, the virtual and representative simulated lakes had to be characterized in a generic way. Following previous practice (Stefan et al. 2001; Fang et al. 2004a, b), two parameters were chosen for this purpose: a lake geometry ratio (GR) as an indicator of a lake's potential for strong or weak summer stratification (Gorham and Boyce 1989) and mean summer Secchi depth (SD) as an indicator of

Table 1 Morphometric characteristics and "names" of the 44 representative or regional lake types in Minnesota simulated with the MINLAKE2010/MINLAKE2012 model

Maximum depth (m)	Surface area A_S (km^2)	Secchi depth, *SD* (m)				Geometry ratio (GR)

lake trophic state and transparency. These virtual and representative lakes are described in detail in a separate section.

Simulation Models for Year-Round Water Quality

To make projections of water quality and fish habitat in small lakes under future climate scenarios, numerical simulation models of daily temperature and DO profiles are indispensable. The one-dimensional (vertical) year-round lake water quality model MINLAKE2010 was developed to run continuously over many simulation years for both the open-water season and the ice-cover period (Fang and Stefan 1996a). The model uses a stacked layer system (Fig. 4); the layers consist of lake water and lake sediments during the open-water season and additional ice cover and snow cover during the winter ice-cover period (Fang and Stefan 2009). It simulates daily water temperature profiles in a lake using daily weather data as input. Figure 4 is a schematic of a stratified lake including heat transfer components, oxygen sources and sinks for the year-round water temperature and DO models, and typical temperature and DO profiles in the summer and winter (Fang and Stefan 1996a, b, c). MINLAKE2010 uses a mixed layer approach (Chapra 1997), which considers a mechanical energy balance (kinetic and potential energy), to predict the thickness of the mixed layer (epilimnion) after the heat diffusion equation is solved and convective mixing is considered (Ford and Stefan 1980).

A lake is divided into a series of well-mixed horizontal water layers (Fig. 4) because the horizontal variations of water quality parameters are typically much smaller than the vertical variations in a small stratified lake. The one-dimensional, unsteady heat transfer equation in a lake is solved for daily vertical water temperature profiles (Hondzo and Stefan 1993):

$$\frac{\partial T}{\partial t} = \frac{1}{A}\frac{\partial}{\partial z}\left(K_{zT} A \frac{\partial T}{\partial z}\right) + \frac{H_w}{\rho C_p} \tag{1}$$

where $T(z, t)$ is the water temperature (°C) in a horizontal layer, t is the time (day), $A(z)$ is the horizontal area (m^2) as a function of depth z (m) based on lake bathymetry

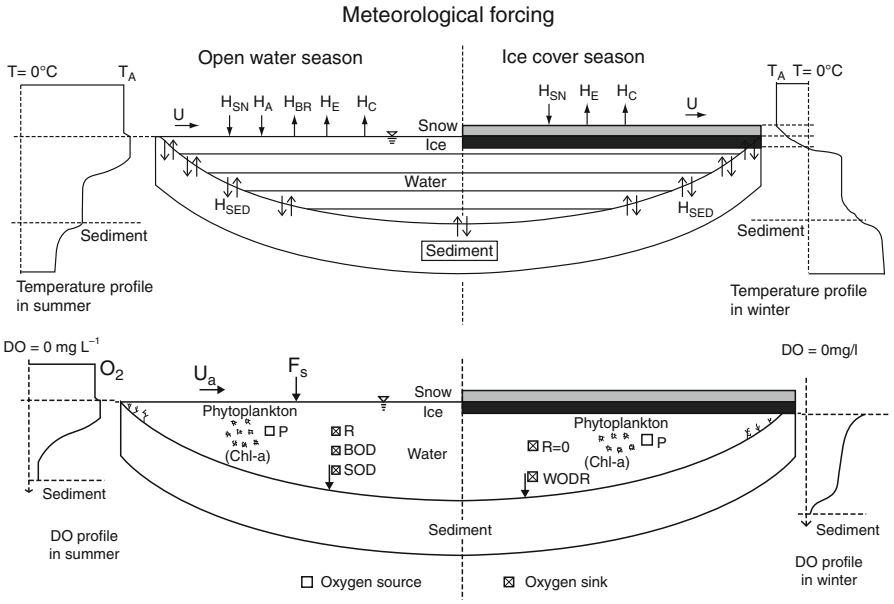

Fig. 4 Schematic of a stratified lake showing heat transfer components, oxygen sources and sinks for the year-round water temperature and DO model MINLAKE96/MINLAKE2010/MINLAKE2012, and typical temperature and DO profiles in summer open-water season (*left*) and winter ice-cover period (*right*) including sediment, water, ice, and snow layers (Fang and Stefan 2009)

input data, K_{zT} is the vertical turbulent heat diffusion coefficient ($m^2\ day^{-1}$), ρC_p is the density of water (ρ) times heat capacity of water (C_p) and represents heat capacity per unit volume ($J\ m^{-3}\ °C^{-1}$), and H_w is the internal heat source strength per unit volume of water ($J\ m^{-3}\ day^{-1}$). Solar radiation absorption in the water column is the main contributor to the heat source term during the open-water season (Stefan and Ford 1975). Heat exchange with the bottom sediment layer included in MINLAKE2010 can be important in the shallow water layers and during the winter ice-cover periods (Fang and Stefan 1996b).

Heat exchange between the lake and the atmosphere is treated as a source or sink term (Fig. 4) for the topmost water layer of a lake during the open-water season due to the surface wind mixing, i.e., $H_w(1)$ in Eq. 1 $= A_s/V(1) \times (H_{SN} + H_A - H_{BR} - H_E - H_C)$, where A_s is the lake surface area and $V(1)$ is the volume of the topmost/first water layer. It includes surface heat fluxes in $J\ m^{-2}\ day^{-1}$ such as net incoming heat from shortwave solar radiation (H_{SN}), long-wave radiation (H_A), outgoing heat from back radiation (H_{BR}), evaporation/condensation (H_E), and conduction/convection (H_C) related to wind speed (U, Fig. 4). The computation of above surface heat fluxes and the internal heat source term (H_w) using daily weather input data has been discussed by Hondzo and Stefan (1993), among others. During the ice-cover period (Fang and Stefan 1996b, c), the model first simulates snow/ice thicknesses

and sediment temperature profiles (heat conduction equation), then determines the heat source/sink terms, and finally solves the heat transfer equation to obtain water temperature profiles below the ice. The heat budget components through the water surface are directly linked to climate parameters that are related to future climate changes.

Dissolved oxygen concentration is viewed as one of the most important lake water quality parameters which indicate a lake's overall ecological health. The vertical DO profiles in the lake are computed from a balance between oxygen sources (surface reaeration and photosynthesis, Fig. 4) and oxygen sinks (sedimentary oxygen demand (SOD), biochemical oxygen demand (BOD), and plant respiration (R)). The numerical simulation model for daily DO profiles in a lake solves the one-dimensional, unsteady transport equation:

$$\begin{aligned}\frac{\partial C}{\partial t} &= \frac{1}{A}\frac{\partial}{\partial A}\left(AK_Z\frac{\partial C}{\partial z}\right) - \frac{S_b}{A}\frac{\partial A}{\partial z}\,\theta_s^{T-20} + P_{\mathrm{MAX}}\,\theta_p^{T-20}\mathrm{Min}[L]\;\;\mathrm{Chla} \\ &- \frac{1}{YCHO2}\,k_r\theta_r{}^{T-20}\,\mathrm{Chla} - k_b\,\theta_b{}^{T-20}\mathrm{BOD}\end{aligned} \tag{2}$$

In Eq. 2, $C(z, t)$ is the DO concentration in mg/L as a function of depth (z) and time (t), $K_z(z, t)$ is the DO vertical turbulent diffusion coefficient in $m^2\ day^{-1}$, and S_b is the coefficient for SOD at 20 °C in mg $O_2\ m^{-2}\ day^{-1}$. P_{MAX} is the maximum specific oxygen production rate by aquatic plants at 20 °C under saturating light conditions in mg O_2 (mg Chla)$^{-1}$ day^{-1}. Min[L] is the light limitation determined by Haldane kinetics (Megard et al. 1984). Chla is the chlorophyll-*a* concentration in mg/L to represent the biomass of aquatic plants in a lake. *YCHO2* is the yield coefficient, i.e., the ratio of mg chlorophyll-*a* to mg oxygen. The first-order decay rate coefficients are k_b and k_r for BOD and plant respiration (day^{-1}), respectively. The temperature adjustment coefficients for SOD, photosynthesis, BOD, and plant respiration are θ_s, θ_p, θ_b, and θ_r, respectively. Typical values and ranges of temperature and DO model parameters have been summarized elsewhere (Fang and Stefan 2012).

Oxygen production is related to chlorophyll-*a* concentration and limitation of available light determined by Haldane kinetics. In the DO model, chlorophyll-*a* is specified by a mean annual value which depends on the specified trophic state of a lake and a function that calculates typical seasonal chlorophyll-*a* cycles (Stefan and Fang 1994a) based on observational data from 56 lakes and reservoirs in Europe and North America (Marshall and Peters 1989). Annual mean chlorophyll-*a* concentration that represents biomass or phytoplankton in the MINLAKE2010 model was calculated from the relationship between chlorophyll-*a* and Secchi depth used in the Carlson trophic index (Carlson 1977) for virtual and representative lakes in Minnesota (Tables 1 and 2) or measured data for calibration lakes.

In the model, the oxygen transfers through the water surface (reaeration) during the open-water season is used as an oxygen source or sink term in the topmost water (surface) layer of the lake after the reaeration is multiplied by the surface area and divided by the layer volume, and the surface oxygen transfer coefficient is calculated as a function of wind speed. SOD is treated as a sink term for each water layer

because each water layer is in contact with lake sediments. BOD occurs in the water column along all water depths, and plant respiration for all water layers is a function of chlorophyll-*a* concentration. BOD (mg/L) is used to reflect biodegradable detritus in lake water column. Diffusive oxygen flux at the lake bottom is set equal to zero as a boundary condition (the flux is not explicitly modeled, but SOD is used as surrogate of the flux).

For the DO simulations in a lake during the ice-cover period (Fig. 4), modifications must be made to account for the presence of an ice cover and low temperatures. For example, reaeration is zero because the lake ice cover prevents any significant gas exchange between the atmosphere and the water body. The water column oxygen demand (WOD in Fig. 4) is set at 0.01 g O^2 m^{-3} per day after model calibration. DO concentrations are simulated after water temperature and snow/ice covers have been simulated. Equations 1 and 2 are solved numerically for time steps of 1 day and layer thicknesses from 0.02 m (near the water surface and the ice-water interface) to 1.0 m (when $z > 1.0$ m) for small lakes using an implicit finite difference scheme and a Gaussian elimination method. Model parameters and detailed formulations of the year-round DO model (Eq. 2) have been described elsewhere (Stefan and Fang 1994a; Fang and Stefan 1997).

Several modifications and refinements were made to develop MINLAKE2010 from MINLAKE96 for relative deep cisco lakes in Minnesota and have been reported by Fang et al. (2012a). Most recent version MINLAKE2012 (Fang et al. 2014) used in a part of the study is a spreadsheet model developed from MINLAKE2010. The most important upgrades of MINLAKE2012 compared to MINLAKE2010 are the conversion to a user-friendly Excel spreadsheet (for data input and displaying basic graphic results) and the introduction of variable temporal resolution, allowing the model to run at hourly and daily time steps.

The MINLAKE model was calibrated and validated against extensive Minnesota lake data: first, using 5,378 water temperature and DO measurements for 48 lake years in 9 lakes for MINLAKE96 (Fang and Stefan 1996) and then using 7,384 water temperature and DO measurements for 439 lake years in 28 lakes for MINLAKE2010 (Fang et al. 2012a). Twenty-one cisco lakes and seven non-cisco lakes were selected for model calibration of MINLAKE2010 based on multiyear data availability; more than half of these 28 lakes had maximum depths greater than 24.0 m, which is H_{max} used for the 30 virtual lakes in Table 2, and 23 of the 28 lakes were either mesotrophic or oligotrophic lakes (Fang et al. 2012a). After calibration, the average standard error of estimates against measured data for all 28 lakes was 1.47 °C for water temperature (range from 0.8 °C to 2.06 °C) and 1.50 mg/L for DO (range from 0.88 to 2.76 mg/L) (Fang et al. 2012a).

Cisco Lakes in Minnesota

The modeling analysis was conducted for 620 known cisco lakes in Minnesota (Fig. 1); the MN DNR had netting assessments for these lakes since 1946. On average, Minnesota cisco lakes are deeper and more transparent (larger Secchi

depth) and have lower chlorophyll-*a* concentrations than other lakes in Minnesota (Fang et al. 2009). The 620 cisco lakes vary in mean Secchi depth (SD) and lake geometry ratio (GR) as shown in Fig. 5. The lake GR is defined as $A_s^{0.25}/H_{max}$ in $m^{-0.5}$ when surface area A_s is in m^2 and maximum depth H_{max} in m. The strength of the seasonal lake stratification is related to the GR (Gorham and Boyce 1989). Polymictic lakes such as large shallow lakes have the highest GR numbers, while strongly stratified lakes have the lowest GR numbers; the transition from weakly to strongly stratified lakes occurs when GR is between 3 and 5 (Gorham and Boyce 1989). Lake geometry ratios of Minnesota cisco lakes range from 0.47 to 22.7 $m^{-0.5}$ (Fig. 4), and about 73 % of these lakes have GR less than 3.0 $m^{-0.5}$ (Fang et al. 2009). Only 6 % or 39 of these lakes have GR greater than 5.0 $m^{-0.5}$; these are very weakly stratified or unstratified lakes during the summer. Lake of the Woods is located at the border of the USA and Canada and has the largest surface area (3847.8 km^2) with the largest GR = 22.7 $m^{-0.5}$ and a maximum depth of 10.97 m. Mille Lacs Lake has the second largest GR = 11.9 $m^{-0.5}$ with a maximum depth of 12.8 m and surface area of 536.5 km^2.

Maximum depths of the 620 cisco lakes range from 3.0 to 64.9 m, and 25 % of these lakes have maximum depth greater than 24 m (Fang et al. 2009). For these 620 cisco lakes in Minnesota, there are 14 shallow lakes with $H_{max} < 5.0$ m, 385 medium-depth lakes (Fig. 5 top) with 5.0 m $\leq H_{max} <$ 20.0 m, and 221 deep lakes with $H_{max} > 20.0$ m (Fig. 5 bottom) based on regional lake classifications in Minnesota (Stefan et al. 1996). Surface areas of these lakes range from 0.04 to 3,847.8 km^2 (Fang et al. 2009) and mean summer Secchi depths from 0.7 to 9.5 m. Nineteen percent and 81 % of the 620 cisco lakes (Fang et al. 2009) have mean summer Secchi depth greater than 4.5 m (oligotrophic lakes) and 2.5 m (mesotrophic lakes), respectively, based on regional lake classifications in Minnesota (Stefan et al. 1993).

For modeling purposes, the 620 Minnesota cisco lakes were grouped by either shortest distance or latitude to associate with three Class I National Weather Service (NWS) weather stations in Minnesota (International Falls, Duluth, and St. Cloud; Fig. 1). Weather data from only these three Class I NWS weather stations were useful and available for cisco lake long-term simulations for the period from 1961 to 2008. Three options (methods) were used to associate each lake with one of the three weather stations: (1) association by shortest distance (Fang et al. 2012b), (2) association by latitude (Jiang et al. 2012), and (3) association of one single weather station with all lakes simulated (Fang et al. 2010b). Refuge lakes were determined using each of the three options (Fang et al. 2010b), but results were similar; simulation results by methods (1) and (2) are presented here.

Representative Lake Types in Minnesota

Simulations of daily water temperature and DO profiles and oxythermal habitat parameters were made for 30 virtual cisco lakes and 44 representative lakes (lake types or classes) in Minnesota before fish habitat was examined in 620 cisco lakes. The 44 representative lake types in Table 1 were expanded from the 27 lake types

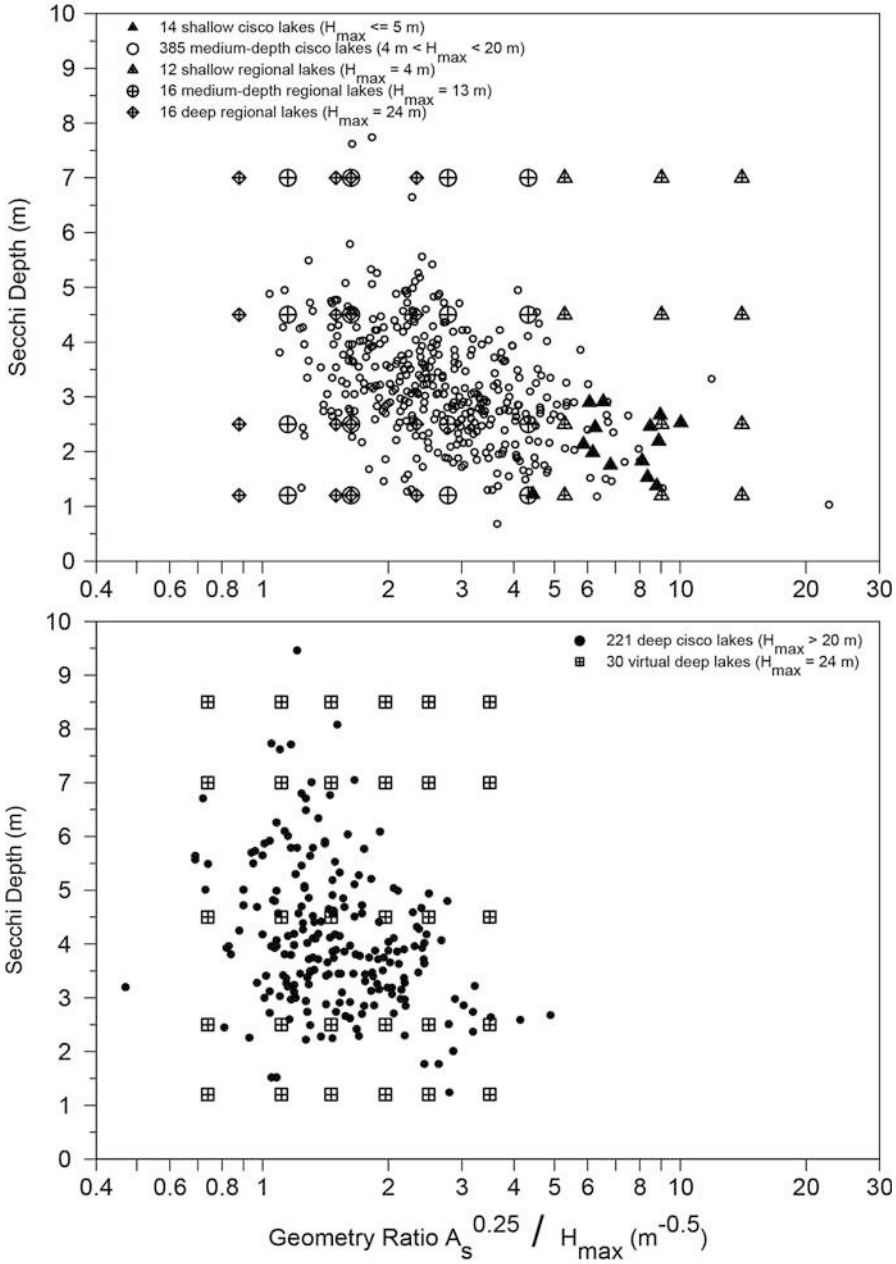

Fig. 5 Distribution of 14 shallow and 385 medium-depth cisco lakes (*top*) and 221 deep cisco lakes (*bottom*) from 620 cisco lakes in Minnesota including 44 regional or representative lakes (Table 1) and 30 virtual deep lakes (Table 2) plotted using Secchi depth and lake geometry ratio as axes

used to study fish habitat in Minnesota (Stefan et al. 1996) and in the contiguous USA (Fang et al. 2004a). Lakes were classified by lake geometry (surface area A_s and maximum depth H_{max}) and trophic state as related to Secchi depth (SD in Tables 1 and 2). The representative surface areas chosen for the 27 lake types were 0.2, 1.7, and 10.0 km^2 for small, medium-size, and large lakes (Stefan et al. 1996; Fang et al. 2004a), respectively. The representative maximum depths chosen were 4, 13, and 24 m for shallow, medium-depth, and deep lakes (Stefan et al. 1996; Fang et al. 2004a), respectively. With these numbers for A_s and H_{max}, nine lake types were obtained ranging from relatively large and shallow lakes to relatively small and deep lakes.

Secchi (disk) depth (SD) is a common limnological parameter to measure transparency of a lake (Hutchinson 1957; Horne and Goldman 1994). It was used in previous fish habitat studies (Stefan et al. 1996; Fang et al. 2004a) to represent both trophic state (primary productivity of biomass or photosynthesis of plants) and solar radiation attenuation in a lake, which is used to quantify how much solar energy reaching the water surface can penetrate through a water column to heat water and to support photosynthesis of aquatic plants (Fig. 4). Lake turbidity from suspended inorganic sediment is relatively rare in Minnesota, and total phosphorus or chlorophyll-*a* in most Minnesota lakes is well correlated with SD (Stefan and Fang 1994b). Therefore, SD is a representative parameter to characterize trophic state of each of the 620 cisco lakes in the database. Contours (isotherms or isopleths) on plots with SD versus GR as axes have been previously used successfully by the authors to give/present generic, but regional, patterns or variations of different characteristic parameters in lakes, e.g., maximum surface water temperatures, maximum lake bottom temperatures, minimum DO at the sediment/water interface, and various fish habitat parameters in lakes (Stefan et al. 1996; Fang and Stefan 1997, 1999).

The representative Secchi depths of 1.2, 2.5, and 4.5 m were previously selected for eutrophic, mesotrophic, and oligotrophic Minnesota lakes (Stefan et al. 1996; Fang et al. 2004a), respectively, using Carlson's trophic state index (Carlson 1977). Ten percent or 62 lakes of 620 cisco lakes have mean summer Secchi depths of 5.0–9.5 m. Therefore, the fourth Secchi depth of 7.0 m was added creating nine new representative lake types for the study. A set of virtual cisco lakes (Table 2) with SD = 7.0 m was first used before to study cisco refuge lakes in Minnesota (Jiang et al. 2012). Therefore, the first 36 representative lake types (Table 1) were characterized by a 3 × 3 × 4 matrix consisting of (a) three different lake surface areas, (b) three lake maximum depths, and (c) four Secchi depths.

The first 28 shallow and medium-depth lakes in Table 1 were used for fish habitat modeling of the constant lethal limits method (Fang et al. 2014). Four medium-depth lakes LakeR37–LakeR40 were added to have a lake geometry ratio of 1.15 to reflect some of the medium-depth cisco lakes with smaller GR (Fig. 5). Four deep lakes (LakeR41–LakeR44) were added to have the same geometry ratio but different surface areas as four medium-depth lakes LakeR10–LakeR12 and LakeR31 to compare fish habitat parameters in these two groups of lakes (Fang et al. 2014). With above eight additional regional lakes, there

are a total of 44 representative lakes (Table 1 and Fig. 5 top) used for cisco habitat modeling in Minnesota. These representative or regional values for each parameter (As, Hmax, and SD in Table 1) were selected from the data analysis of these parameters in the Minnesota Lakes Fisheries Database containing lake survey data for 3,002 lakes (Hondzo and Stefan 1993) and 620 cisco lakes (Fang et al. 2009). The lake bathymetry of these 44 lakes (the shape of the lake basin as part of model input data) is characterized by three functions $A(z)/A_s$ versus $z/H_{\max}$ for small, medium-size, and large lakes, which are regression equations developed from 122 Minnesota lakes by Hondzo and Stefan (1993). More important than the geometric characteristics of each lake type is the likelihood of relating a strong or weak stratification in a lake to the lake's geometry ratio $\mathrm{GR} = {A_s}^{0.25}/H_{\max}$ (Gorham and Boyce 1989). The above 44 lake types cover geometry ratios from 0.88 to 14.06 $\mathrm{m}^{-0.5}$ (Table 1). Polymictic lakes, i.e., large shallow lakes, have the highest geometric ratio, while strongly stratified lakes, i.e., small deep lakes, have the lowest geometry ratio. Hence, these 44 lake types selected for the study include the full range of stratification behavior.

The set of 30 virtual cisco lakes (Fig. 5 bottom) comprised lakes with five different SD values (1.2, 2.5, 4.5, 7.0, and 8.5 m) and six different surface areas (0.1, 0.5, 1.5, 5.0, 13.0, and 50 km^2). The maximum depth of all 30 virtual lakes was set at 24 m (Fang et al. 2009, 2012; Jiang et al. 2012). Combinations of the maximum depth and surface areas gave six different geometry ratios for the 30 virtual lakes, i.e., 0.74, 1.11, 1.46, 1.97, 2.50, and 3.50 $\mathrm{m}^{-0.5}$ (Table 2). Twenty of the 30 virtual cisco lake types were strongly stratified with $\mathrm{GR} < 2\ \mathrm{m}^{-0.5}$; the other ten lake types were weakly stratified (Table 2). The 30 virtual cisco lakes (Table 2) did not include any polymictic lakes because they likely would not provide suitable cold-water habitat in Minnesota after climate warming. For example, Fang et al. (2012a) studied the oxythermal habitat variable TDO3 in 21 study cisco lakes in Minnesota and found that two cisco lakes with $\mathrm{GR} > 4.0\ \mathrm{m}^{-0.5}$ (White Iron Lake and South Twin Lake) had high annual maximum TDO3 values indicating unfavorable conditions for cisco survival and growth. Values of TDO3 extracted from observed temperature and DO profiles were lowest in lakes with small geometry ratios ($\mathrm{GR} < 2\ \mathrm{m}^{-0.5}$); a geometry ratio of 4 $\mathrm{m}^{-0.5}$ effectively marked the transition between stratified and unstratified lakes (Jacobson et al. 2010).

Even though the lake bathymetry (surface area and maximum depth) and Secchi depth of the 30 virtual cisco lakes were subjective, the selected values were representative of most of the 620 Minnesota cisco lake database (Fang et al. 2009). The 30 virtual cisco lakes were all stratified lakes based on geometry ratio and included eutrophic to oligotrophic lakes (Table 2). The 30 virtual cisco lakes were more or less uniformly distributed on the plot of SD vs. GR (Fig. 5 bottom) (Fang et al. 2012b). None of the 30 virtual cisco lakes in Table 2 have the same lake surface areas as 44 representative Minnesota lakes in Table 1. These two groups of generic lake classes (types) were used in the different fish habitat modeling options (Fig. 3): 44 representative lakes for the oxythermal model options 1 and 2 using lethal limits (Fig. 5) and 30 virtual lakes for the model option 1 (constant lethal limits) and the model option 3 using TDO3 (Fig. 3) during different study periods.

Past Climate and Future Climate Scenarios

Climate conditions control water temperature and DO distribution in a lake. Climate scenarios are model inputs of MINLAKE2010/MINLAKE2012 for producing water temperature and DO concentration scenarios for the simulated lakes (Tables 1 and 2), which are used to assess potential changes in cisco habitats in these lakes. To identify refuge lakes, we need to project whether a lake that currently has a cisco population can support cisco habitat under future climate scenarios, i.e., after climate warming. To make the projection, the model outputs from two coupled general circulation models (CGCMs) of the earth's atmosphere and oceans (i.e., CGCM 3.1 and MIROC 3.2) were used as input to the MINLAKE2010 model to calculate a range of future water quality conditions.

Forty-eight years (1961–2008) of recorded daily weather data, which were obtained from the Solar and Meteorological Surface Observation Network (SAMSON) and Midwestern Regional Climate Center, were used to describe past climate conditions for the study lakes. Weather data used for lake modeling consist of daily air temperature, dew point temperature, wind speed, solar radiation, percent sunshine, and precipitation (both rainfall and snowfall).

The CGCM 3.1 (Kim et al. 2002, 2003) is the third generation of CGCMs from the Canadian Centre for Climate Modeling and Analysis (CCCma). The CCCma CGCM 3.1 uses the ocean component from the earlier second-generation CGCM (McFarlane et al. 1992) and applies a substantially updated atmospheric component – the third-generation atmospheric general circulation model. Output of the CGCM 3.1 model with a coarse global surface grid resolution of roughly 3.75° latitude and longitude or approximately 410 km in Minnesota was used for the study because it was available to be downloaded from the Intergovernmental Panel on Climate Change (IPCC) data center in 2008. When CGCM 3.1 is used for the study, there is one grid center point within Minnesota and another grid center point in Canada that is the closest grid point to International Falls weather station (Fig. 1).

The MIROC 3.2 (Hasumi and Emori 2004) was developed by the Center for Climate System Research, University of Tokyo; the National Institute for Environmental Studies; and the Frontier Research Center for Global Change – Japan Agency for Marine-Earth Science and Technology. Output of the MIROC 3.2 model with a high spatial surface grid resolution of roughly 1.12° latitude and longitude or approximately 120 km in Minnesota was used. The MIROC 3.2 model has 17 grid center points in Minnesota, and Fig. 1 shows three grid center points from MIROC 3.2 that are the closest to three weather stations (St. Cloud, Duluth, and International Falls) used for the model study.

At all CGCM grid center points, the differences or ratios known as "change fields" were produced and reported at a monthly interval. The 2070–2099 change field data, 30-year averages compatible with the Third Assessment Report of the IPCC (2007), were downloaded from the IPCC's website and used in the study. These monthly climate parameter differences or ratios predicted by CGCM models were then applied to measured daily climate conditions (1961–2008) month by month to produce the projected daily future climate scenario. Monthly increments

from the grid center point closest to a weather station were used to specify the future climate. For the MIROC 3.2 future climate scenario, each of the three Class I NWS weather stations (International Falls, Duluth, and St. Cloud) used for the study had a closest grid center point (Fig. 1); for the CGCM 3.1 future climate scenario, Duluth and St. Cloud used the grid center point in Minnesota (Fig. 1), and International Falls used a grid center point in Canada (Fig. 1).

Monthly air temperature increases projected by MIROC 3.2 range from 3.53 °C to 4.70 °C with annual averages of 4.00–4.24 °C for the three weather stations (Table 3); CGCM 3.1 projection has a range from 2.89 °C to 8.09 °C with annual averages of 4.07–4.14 °C for the three weather stations (Fang et al. 2010b). The average monthly increases in air temperature range from 3.6 °C to 4.7 °C (3.6–3.8 °C from July to September) in Bemidji, Minnesota, which was also used for the oxythermal habitat option 2 (lethal-niche-boundary curve).

Simulation and Validation of Cisco Oxythermal Habitat Using the Constant Lethal Limits

The physiological response of adult populations of different fish species to T and DO levels has been the subject of numerous laboratory and field studies, e.g., by Coutant (1970), McCormick et al. (1972), and Hokanson et al. (1977). These studies correlated fish survival, growth, reproduction, and other responses to chronic levels of T and DO exposure. Simulation of oxythermal fish habitat in lakes was conducted in small lakes (up to 10 km^2 surface area) in Minnesota and the contiguous USA using constant survival limits (Stefan et al. 1996; Fang et al. 2004a, b). The oxythermal habitat approach commonly used in cold-water fish niche modeling (Dillon et al. 2003) defines an upper boundary for T and a lower boundary for DO, which are lethal temperature (*LT*) and DO survival limit (DO_{lethal}). These oxythermal habitat models determine the water volume or layer thickness in a stratified lake between the upper temperature and lower DO bound that represent either optimal thermal habitat (Dillon et al. 2003) or nonlethal/useable habitat (Stefan et al. 2001). The "uninhabitable spaces" or "lethal conditions" for a fish species in a lake are where temperature is above or DO is below the survival limits (Stefan et al. 2001). This study uses the oxythermal habitat approach to investigate the lethal conditions and fish kill in summer for a cold-water fish species – cisco *Coregonus artedi* in Minnesota lakes. The goals of the study were to first validate cisco survival and lethal conditions in 23 Minnesota lakes (Tables 4 and 5) under 2006 weather conditions and then simulate daily T and DO profiles in 58 lake types (28 shallow and medium-depth lakes in Table 1 and 30 virtual lakes in Table 2) to project cisco survival and potential lethal conditions in 620 cisco lakes in Minnesota under future climate scenarios. The 28 shallow and medium-depth lakes include LakeR01–LakeR18, LakeR28–LakeR33, and LakeR37–LakeR40 in Table 1.

Prediction of Cisco Lethal Conditions Using Constant Lethal Limits

Cisco habitat (survival) and lethal conditions were determined using simulated daily T and DO profiles in lakes, similar to the approach by Christie and Regier (1988). Temperature and DO limits of lethal conditions for adult cisco were applied to simulated water temperature and DO profiles day by day to examine whether lethal conditions occur or not in each specific day, as shown in Fig. 6 for Pine Mountain Lake. Simulated T and DO profiles were not averaged during the simulation period as was done in previous studies (Stefan et al. 1996; Fang et al. 2004a, b). When the *LT* isotherm and the DO_{lethal} isopleth for cisco intersect in a particular day, the entire depth of a stratified lake is under lethal conditions on that day. The lethal conditions are because water temperature is higher than *LT* from the water surface to or below the intersecting depth and DO is lower than the DO_{lethal} from the lake bottom to or above the intersecting depth. When the maximum daily water temperature is lower than the *LT*, the *LT* isotherm does not show up in the plot of depth-time contours of cold-water habitat (the upper and lower good-growth temperature contours used in previous

studies were not used/shown in Fig. 6). Therefore, the DO lethal/survival limit becomes the only lethal criterion during the early spring, late fall, and winter ice-cover period, but the study only deals with lethal conditions of cisco during the summer months. Figure 6 shows cisco habitat results from April 15 to October 31, i.e., the day of year (DOY) 105–304, which is during the typical open-water season in Minnesota.

The *LT* is the water temperature to which fish cannot be acclimated without causing death. In early publications by authors, it was called as the upper survival temperature limit (Stefan et al. 1996), which was the 95th percentile of the weekly mean temperatures from an updated national fish/temperature database (Stefan

Table 5 Maximum depth (H_{max}), lake geometry ratio (GR), and fish habitat validation results using constant lethal limits ($LT = 22.0$ °C and $DO_{lethal} = 3$ mg/L) for 23 Minnesota lakes. Simulated and observed days with lethal conditions or mortality for cisco are given

Lake name (H_{max} in m, GR in $m^{-0.5}$)	Lethal conditions			Simulated lethal days in 2006	Observed mortality day in 2006	Model agreement

et al. 1996) that includes observed stream temperature and fish observations. The LT values compared favorably with laboratory test results involving exposures of fish in several days (Stefan et al. 1992). The $LT = 23.4$ °C used for the cold-water fish guild in previous studies (Stefan et al. 1996, 2001) was the mean value of LT values for nine cold-water fish species (pink salmon, sockeye salmon, chinook salmon, chum salmon, coho salmon, brown trout, rainbow trout, brook trout, and mountain whitefish), which do not include cisco. The LT of cold-water fish species ranged from 22.1 °C (brook trout) to 26.6 °C (brown trout) in the 1992 study (Stefan et al. 1996). Eaton et al. (1995) updated the LT values that ranged from 19.8 °C (chum salmon) to 24.1 °C (brown trout) with guild mean of 22.9 °C. The DO concentration of 3.0 mg/L requirement for the cold-water fish guild, below which mortality is more likely to occur or growth is impaired (US EPA 1976), was developed from an available US EPA database (Chapman 1986). Jacobson et al. (2010) selected a benchmark oxygen concentration of 3 mg/L which is probably lethal or nearly so for many cold-water species. Frey (1955) also used an oxygen concentration of 3 mg/L in his definition of cisco habitat. Several benchmark DO concentrations (2, 3, 4, and 5 mg/L) were considered by Jacobson et al. (2010), and they were highly correlated (Table 4).

Before appropriate LT and DO limits for adult cisco were determined/used for cisco oxythermal modeling, a sensitivity analysis using 22.0 °C and 23.4 °C as LT and 2, 3, and 4 mg/L as DO survival limit was performed. The lethal temperature of 22.0 °C used for the sensitivity analysis was determined from the lethal-niche-boundary curve (Jacobson et al. 2008) (Eq. 3) at $DO_{lethal} = 3$ mg/L. The 22.0 °C

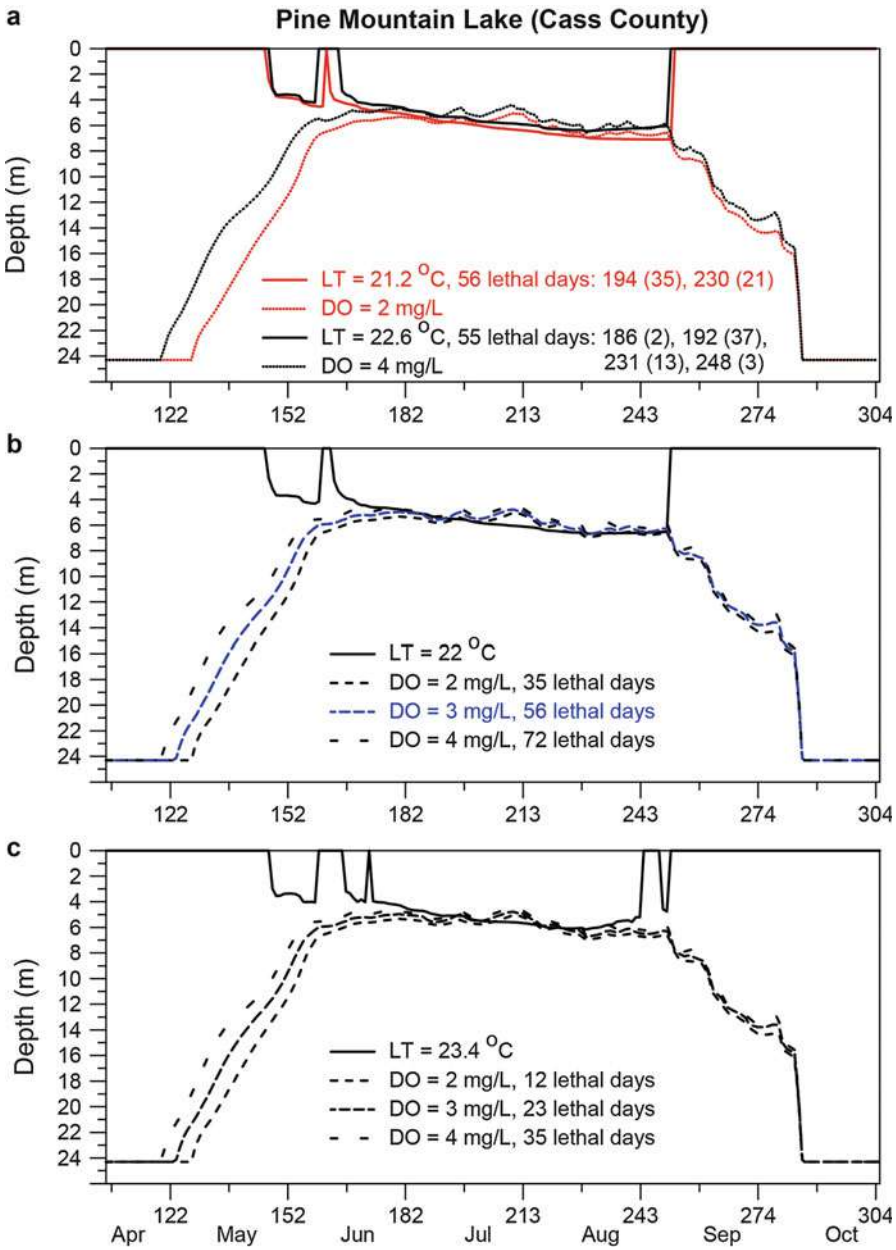

Fig. 6 Simulated isopleths of lethal temperatures (*LT*) and DO_{lethal} limits in 2006 for Pine Mountain Lake for eight LT-DO limit combinations. Selected LT are 21.2 and 22.6 °C (*top*) 22.0 °C (*middle*) and 23.4 °C (*bottom*), and selected DO survival limits are 2, 3, and 4 mg/L

LT compares favorably with lower LT values for other cold-water fish species in previous studies (Stefan et al. 1992, 1996; Eaton et al. 1995). Using the lethal-niche-boundary curve (Jacobson et al. 2008), the lethal temperatures were 21.2 °C and 22.6 °C for $DO_{\text{lethal}} = 2$ and 4 mg/L, respectively, and these two LT-DO combinations were also used for the sensitivity analysis (Table 4). The combinations of four LTs and three DO limits resulted in eight constant LT-DO criteria for the sensitivity analysis of the fish habitat model. The final LT-DO criteria, $LT = 22.0$ °C and $DO_{\text{lethal}} = 3$ mg/L, were chosen according to fish habitat model validation based on the cisco mortality field data in 2006 (Table 5) as discussed below.

Fish Habitat Model Validation in 23 Lakes Against 2006 Observations

The fish habitat model uses simulated daily temperature and DO profiles in a lake to check day by day whether cisco habitable or lethal conditions occur. When the LT isotherm and the DO limit isopleth for cisco do not intersect in a day, cisco is survivable in that day; otherwise, the entire depth of a stratified lake is under lethal conditions (too warm temperature or lower DO) in that day. A number of days with cisco lethal conditions in 2006 under eight different criteria are given in Fig. 5 for Pine Mountain Lake as an example. Pine Mountain Lake located in Cass County, Minnesota, has a maximum depth of 23.8 m (deep lake) and a surface area of 6.36 km^2. Pine Mountain Lake is a mesotrophic stratified lake because of its mean Secchi depth 2.4 m, mean chlorophyll-a concentration 6.5 μg/L, and GR = 2.11.

The total number of lethal days in 2006 increases from 35 to 72 days (Fig. 5b and Table 4) when LT = 22.0 °C and the DO survival limit changes from 2 to 4 mg/L. The 35 lethal days were not continuous as shown in Fig. 5b and were 2 days from DOY 196 (July 15–16, 2006), 26 days from 199 (July 18–August 12), 1 day from 227 (August 15), 2 days from 235 (August 23–24), and 4 days from 238 (August 26–29). When LT increases to 23.4 °C (mean LT for cold-water fish species not including cisco), the total number of lethal days in 2006 decreases to 12–35 days (Fig. 5c), respectively, when DO survival limits are 2–4 mg/L.

With $LT = 21.2$ °C and $DO_{\text{lethal}} = 2$ mg/L limits (Fig. 5a) from the lethal-niche-boundary curve, Pine Mountain Lake was simulated to have 56 lethal days: 196 (37 continuous lethal days) and 230 (21); with $LT = 22.6$ °C and $DO_{\text{lethal}} = 4$ mg/L limits, Pine Mountain Lake was simulated to have 55 lethal days: 186 (2), 192 (37), 231 (13), and 248 (3). With $DO_{\text{lethal}} = 4$ mg/L, lethal days started 10 days early, but prevalent lethal conditions occurred after DOY 196 (July 15) for all three LT-DO limit combinations from the lethal-niche-boundary curve.

Results of the sensitivity analysis using eight *LT* and DO survival limits in all 23 lakes are summarized in Table 4. The period of lethal conditions (lethal days) simulated using $LT = 22.0$ °C is typically longer than the lethal days using $LT = 23.4$ °C. When DO survival limits increase from 2 to 4 mg/L, cisco lethal days increase also (Fig. 5 and Table 4) when *LT* is fixed. Using $LT = 23.4$ °C, Star, Little Pine (Otter Tail County), Bemidji, Gull, Straight, Long, and Carlos lakes were simulated to have zero or a few days with lethal conditions in 2006, which indicates

that $LT = 23.4$ °C used in previous studies for the cold-water guild is little too high for cisco. Three LT-DO combinations, where LT was computed using DO_{lethal} and the cisco lethal-niche-boundary curve, resulted very similar values on lethal days in 23 lakes (Table 4), but starting days of lethal conditions could be somewhat different as shown in Fig. 5 for Pine Mountain Lake. Detailed simulation results of $LT = 22.0$ and $DO_{\text{lethal}} = 3$ mg/L are given in Table 5 for 23 Minnesota lakes for model validation against cisco mortality observations in 2006.

Table 5 lists the first DOY, the last DOY, and the total number of days with cisco lethal conditions predicted by the model (using constant lethal limits) in 2006 (hindcast or backtesting). It also lists the DOYs and the number of continuous days from DOYs with cisco lethal conditions predicted in 2006. For example, Little Turtle Lake has "180(62)" under "simulated lethal days in 2006" in Table 5 that means lethal conditions were simulated on DOY 180 (June 29, 2006) and the number of continuous cisco lethal days is 62 (DOYs 180–241). The DOY and month/day in 2006 inside brackets when cisco mortality was reported in each lake is listed under "observed mortality date in 2006" in Table 5 and used to examine model agreement. In the last column of Table 5, the first Yes/No gives the agreement of cisco lethal prediction and reported cisco mortality in 2006, and the second Yes/No inside brackets gives the agreement whether or not cisco lethal days from the model include reported date with cisco mortality. For example, for Mille Lacs Lake, the fish habitat model predicted a total of 49 days from July 22 (DOY 203) to September 8 (DOY 251) having cisco lethal conditions, which agree with reported cisco mortality in 2006, and the period of predicted cisco lethal conditions includes the reported day with cisco mortality, i.e., July 23 or DOY 204. Therefore, the model agreement with mortality observation is "Yes (Yes)" as listed in Table 5. The fish habitat model predicted the "Yes (Yes)" agreement in 13 of the 18 lakes that experienced cisco mortality in 2006 (Table 5).

For four lakes (Bemidji, Star, Seventh Crow Wing, and Long), the model predicted cisco lethal conditions, but the predicted lethal periods did not include corresponding reported cisco mortality days in 2006; these lakes have the "Yes (No)" agreement (Table 5). For two lakes (Bemidji and Star), cisco lethal conditions were predicted to occur after the reported cisco mortality days in 2006. For Seventh Crow Wing Lake, cisco lethal conditions were predicted to occur from DOY 196 to 215 (August 3) in 2006, and the cisco mortality was reported on August 4. For Long Lake, cisco lethal conditions were predicted to occur from DOY 213 to 216 (August 4) in 2006, and the cisco mortality was reported on August 6. These two cases can be considered as "Yes (Yes)" agreement because cisco mortality might be reported one or a few days after cisco mortality occurred when study lakes were not constantly monitored and observed. Long Lake was predicted with only 4 days of lethal conditions. Long Lake located in Otter Tail County, Minnesota, has a maximum depth of 39.0 m (deep lake) and a surface area of 5.1 km^2. Long Lake is a mesotrophic strongly stratified lake because of its mean Secchi depth 3.0 m, mean chlorophyll-a concentration 7.2 μg/L, and GR = 1.22. There was only 1 day in 2006 with observed temperature and DO profiles in Long Lake for model calibration.

For Lake Carlos, the model did not predict cisco lethal conditions, but they had cisco mortality in 2006; the model has the No agreement with mortality observation (Table 5). Lake Carlos located in Douglas County, Minnesota, has a maximum depth of 49.7 m and a surface area of 10.5 km^2. Lake Carlos is a mesotrophic strongly stratified lake because of its mean Secchi depth 3.0 m, mean chlorophyll-*a* concentration 5.0 μg/L, and GR = 1.15. The late summer cisco mortality event that occurred on August 27 (DOY 239) in Lake Carlos did not fit the lethal-niche-boundary curve developed from the midsummer events in 16 lakes (Jacobson et al. 2008). Based on the lethal-niche-boundary curve and measured profiles on September 1, 2006 (Jacobson et al. 2008), cisco could exist in some surface layers with low temperatures and high DO, but could not exist in the hypolimnion with anoxic conditions.

Jacobson et al. (2008) also studied the five reference lakes that did not experience cisco mortality in 2006. These five reference lakes are all deep strongly stratified lakes (GR < 1.4). The fish habitat model using constant LT and DO_{lethal} limits predicted no lethal conditions for cisco in all five reference lakes (Table 5). Therefore, the fish habitat model has an overall good agreement in the 23 study lakes with and without cisco mortality reported in 2006.

With $LT = 21.2$ °C and $DO_{\text{lethal}} = 2$ mg/L limits, Straight Lake changed the agreement from "Yes (Yes)" to "Yes (No)" and Seventh Crow Wing from "Yes (No)" to "Yes (Yes)"; with $LT = 22.6$ °C and $DO_{\text{lethal}} = 4$ mg/L limits, Star Lake changed the agreement from "Yes (No)" to "Yes (Yes)" when comparing with cisco mortality observations in 2006. Therefore, three LT and DO_{lethal} limit combinations derived from the lethal-niche-boundary curve (Jacobson et al. 2008) had similar overall agreement with cisco mortality observations in 2006, and all of them could be used for constant lethal limits for adult cisco when there is no additional laboratory and field data support on survival limits. To be consistent with previous studies with DO survival limit (Stefan et al. 1996, 2001; Fang et al. 2004a, b) or benchmark DO (Jacobson et al. 2010; Fang et al. 2012b; Jiang et al. 2012) of 3 mg/L, $LT = 22.0$ °C and $DO_{\text{lethal}} = 3$ mg/L limits were used for remaining of the oxythermal habitat modeling with constant lethal limits.

Simulation Results of 28 Regional Lakes and 30 Virtual Lakes

Both 28 regional lakes (LakeR01–LakeR18, LakeR28–LakeR33, and LakeR37–LakeR39 in Table 1) and 30 virtual lakes (Table 2) were first simulated using MINLAKE2010 to generate daily temperature and DO profiles over 48 simulation years (1962–2008 under the past climate conditions) and then simulated using the fish habitat model to determine number of days with cisco lethal conditions year by year (excluding the first year 1961) using constant lethal limits. Results for shallow or medium-depth lakes and deep lakes were grouped and analyzed separately as recommended by Fang et al. (2014).

Figure 7 shows contour plots of total number of years with cisco lethal days and average cisco kill days for the years with lethal conditions under past (left frames)

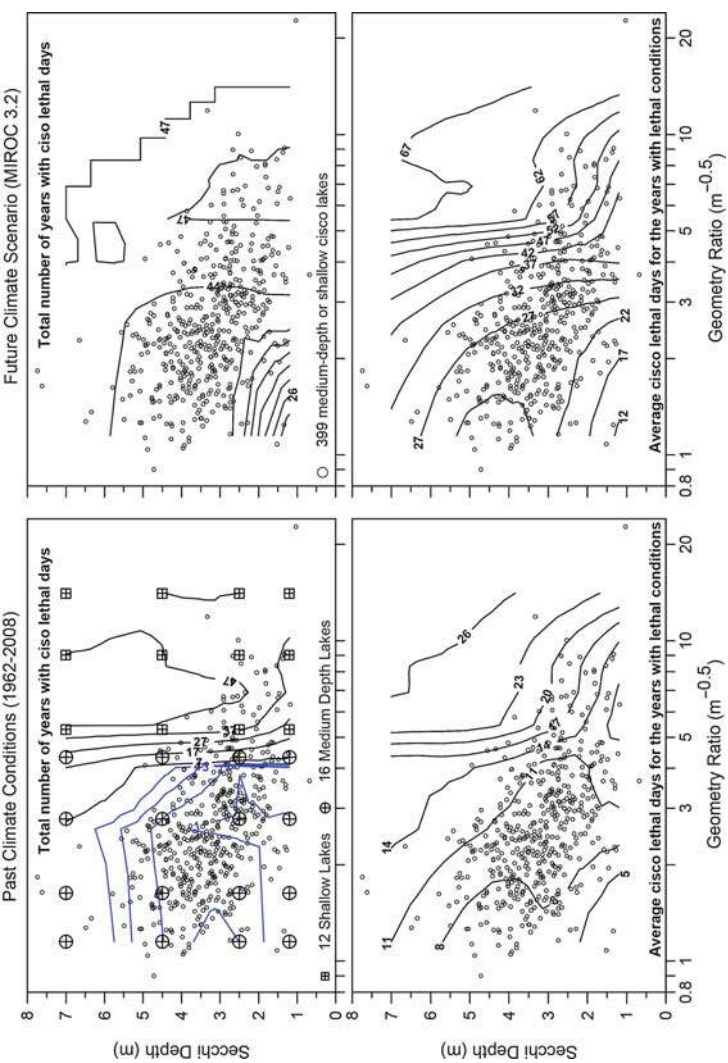

Fig. 7 Contour plots of total number of years with cisco lethal days (*top*) and average cisco lethal days for the years with lethal conditions (*bottom*) under past (1962–2008) and future (MIROC 3.2) climate scenarios. Duluth weather data were used for model simulations. Contours were derived by interpolation from simulated points for 28 regional lakes

and future (right frames for MIROC 3.2) climate scenarios. Duluth weather data over 47 years were used for model simulation results presented in Fig. 7. Contours were derived by interpolation from simulated points for 28 regional/representative lakes (Fig. 7). Under the past climate conditions, shallow lakes with a geometry ratio >5.2 $m^{-0.5}$ had 23–47 years with lethal conditions and are projected to have all 47 years with lethal days under MIROC 3.2 (Fig. 7). Average cisco lethal days for the years with lethal conditions under the past climate conditions ranged from 11 to 26 days and are projected to range from 38 to 65 days in shallow lakes under MIROC 3.2 climate scenario. Therefore, 12 shallow regional lakes simulated (Fig. 7) and 14 shallow lakes in the 620 cisco lake database (Fig. 5) do not provide suitable habitat conditions to support cisco.

For 16 medium-depth lakes simulated under the past climate conditions, there were 0 (GR = 1.63 $m^{-0.5}$) to 8 (GR = 4.33 $m^{-0.5}$) years with lethal conditions with average lethal days ranging from 0 to 14 days (Fig. 7). Under future climate scenario (MIROC 3.2), they are projected to have 20–47 years with lethal conditions with average lethal days ranging from 12 to 52 days (Fig. 7). It seems medium-depth lakes are most vulnerable to climate change with largest increases in lethal days and the number of years with lethal conditions.

When simulated under past climate conditions, none of the 30 virtual deep lakes (H_{max} = 24 m) have cisco lethal conditions; therefore, deep lakes provided relatively good fish habitats compared with shallow and medium-depth lakes. The results for virtual deep lakes under past climate conditions seem to have certain disagreement with cisco mortality observations (Table 5). Minnesota lakes with H_{max} < 20.0 m were classified as deep lakes (Stefan et al. 1996), and 7 of the 18 study lakes with cisco mortality in 2006 are deep lakes with GR ranging from 1.15 to 3.26 $m^{-0.5}$ (Table 5). Generalized model parameters (Fang et al. 2010a) were used for simulations in the 30 virtual lake types, but for the 23 lakes (Table 5), model parameters were first calibrated against measured profiles before the cisco habitat model was applied. Differences in model parameters are one of the major reasons for disagreement in habitat projections and suggest that other oxythermal habitat parameters, e.g., TDO3 (Jacobson et al. 2010), should be used for studying cisco fish habitat in relatively deep lakes.

Under the future climate scenario (MIROC 3.2), projected number of years with lethal conditions are up to 20 years with average lethal days up to 23 days (Fig. 8). Distributions of total number of years with cisco lethal days and average cisco kill days for the years with lethal conditions under MIROC 3.2 are given in Fig. 8, which shows eutrophic deep lakes are projected with more lethal days. Figure 8 was not used to divide 221 deep cisco lakes into tier 1 to tier 3 refuge lakes as it was done using TDO3 (Fang et al. 2012; Jiang et al. 2012). Under MIROC 3.2 climate scenario, those lakes with 0–2 years (Fig. 8 top) and 0–3 days (Fig. 8 bottom) with lethal conditions provide most suitable habitat for cisco, and lakes with 2–5 years (Fig. 8 top) and 3–6 days (Fig. 8 bottom) with lethal conditions also provide suitable habitat for cisco. Good-growth habitat areas and volumes used in previous studies (Stefan et al. 1996, 2001; Fang et al. 2004a, b) may be used to classify refuge lakes in the future.

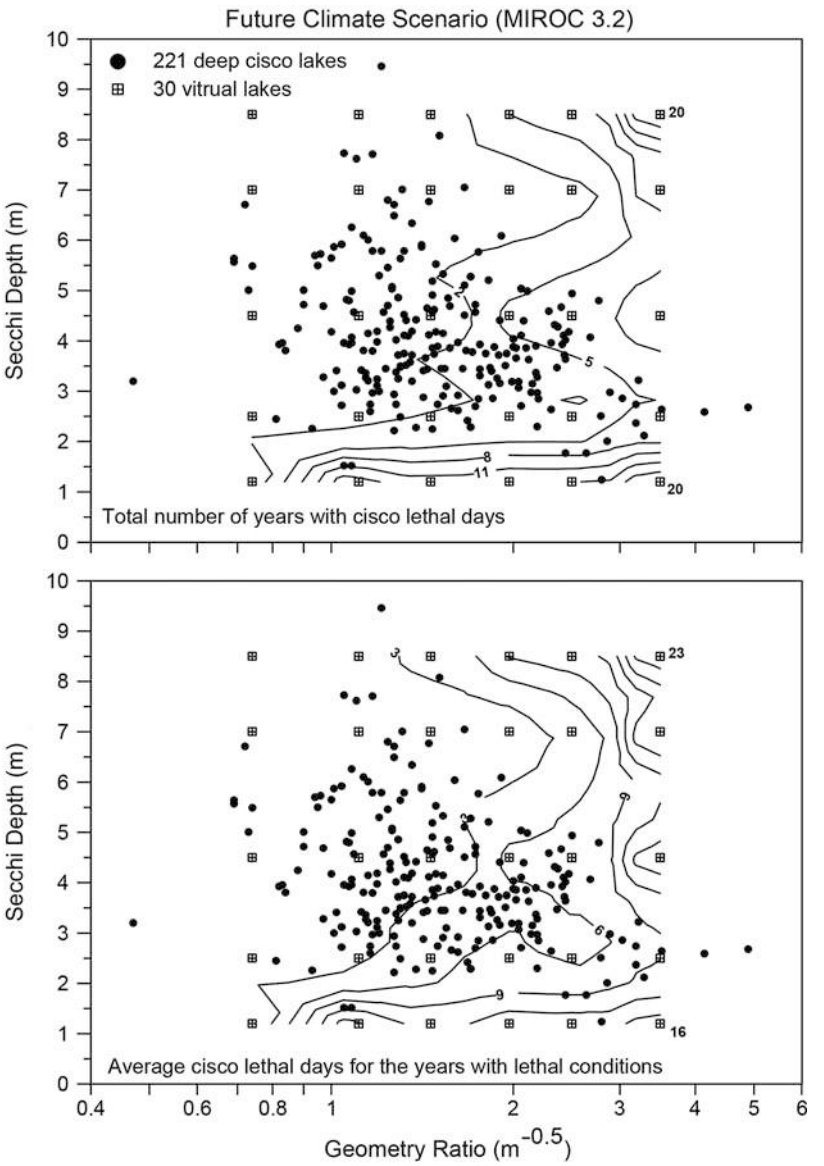

Fig. 8 Contour plots of total number of years with cisco lethal days (*top*) and average cisco lethal days for the years with lethal conditions (*bottom*) in deep lakes under future (MIROC 3.2) climate scenarios. Duluth weather data were used for model simulations. Contours were derived by interpolation from simulated points for 30 virtual lakes ($H_{max} = 24$ m)

Simulation and Validation of Cisco Oxythermal Habitat Using the Lethal-Niche-Boundary Curve

For oxythermal habitat modeling of cisco, the second option is to use temperature-varying lethal DO limits. The fish habitat model uses a fitted regression equation as the lethal niche boundary of adult cisco developed by Jacobson et al. (2008). The equation mapped the DO concentrations and water temperatures from the profiles measured in 16 Minnesota lakes that experienced cisco mortality in 2006 (Table 6). One profile was measured in each of the 16 lakes on the same day or a few days after reported mortality. The shifted exponential function given in Eq. 3 is a fit of the 99th quartile nonparametric regression line bracketed the lethal combinations of observed oxygen and temperature in 16 lakes with midsummer (July 19 to August 6) mortality events in 2006 (Jacobson et al. 2008). First, the fish habitat model (the option 2) was validated in 23 Minnesota lakes (Table 6) and then used to project cisco lethal conditions in 36 representative lake types under past (1992–2008) climate conditions and a future climate scenario (MIROC 3.2) at Bemidji, Minnesota. Based on the number of years with cisco kill and the number of annual cisco lethal days, lake types that most likely could not support cisco were identified, and lake types that can support cisco under both the past climate and the future climate scenarios were identified as potential cisco refuge lakes.

Fish Habitat Projection Model

There were 18 Minnesota lakes with reported cisco mortality in 2006, but no temperature and DO profiles were measured in Mille Lacs Lake, which had automated temperature recorder data at 2 m below the surface (Jacobson et al. 2008). Measured temperature and DO profiles in Lake Carlos, which had late summer cisco mortality event occurred on August 27, were not used to fit the lethal-niche-boundary curve (Jacobson et al. 2008). The lethal-niche-boundary curve of adult cisco developed from measured temperature and DO profiles in 16 Minnesota lakes is given as

$$DO_{\text{lethal}} = 0.40 + 0.0000060 \ e^{0.59T} \tag{3}$$

where DO_{lethal} and T are the DO concentrations (in mg/L) and the water temperatures (in °C), respectively, which define the lethal niche boundary (Jacobson et al. 2008). The computed DO_{lethal} is the required minimum DO concentration at a given water temperature T for cisco to survive. For the regression Eq. 3, the coefficients 0.40 and 0.0000060 are in mg/L, and the coefficient 0.59 for the exponent is in $^{\circ}C^{-1}$.

Equation 3 indicates the DO survival limit for adult cisco is not constant but depends on water temperature. The lethal-niche-boundary curve for cisco (Eq. 3)

Table 6 Fish habitat validation results using the lethal-niche-boundary curve for 23 Minnesota lakes. Simulated and observed days with lethal conditions for cisco are given as DOYs

Lake name	Lethal conditions			Simulated lethal days in 2006	Observed mortality day in 2006	Model agreement
	First day	Last day	No. of days			
Little Turtle	181	222	38	182(4)[a], 187(4), 193(30)	200 (7/19)[b]	Yes (Yes)[c]
Andrusia	192	234	39	192(37), 233(2)	202 (7/21)	Yes (Yes)
Little Pine (Otter Tail)	199	216	17	199(1), 201(16)	203 (7/22)	Yes (Yes)
Cotton	188	225	36	188(1), 190(1), 192(34)	205 (7/24)	Yes (Yes)
Pine Mountain	192	241	49	192(45), 238(4)	207 (7/26)	Yes (Yes)
Leech	189	217	22	189(1), 195(6), 203(15)	211 (7/30)	Yes (Yes)
Itasca	189	222	31	189(1), 193(30)	209 (7/28)	Yes (Yes)
Gull	209	227	19	209(19)	210 (7/29)	Yes (Yes)
Woman	183	224	36	183(2), 187(1), 190(1), 193(32)	210 (7/29)	Yes (Yes)
Little Pine (Crow Wing)	183	240	48	183(5), 190(39), 233(3), 240(1)	214 (8/2)	Yes (Yes)
Eighth Crow Wing	195	222	28	195(28)	216 (8/4)	Yes (Yes)
Bemidji	212	217	6	212(6)	208 (7/27)	Yes (No)
Mille Lacs	216	241	26	216(26)	204 (7/23)	Yes (No)
Star	212	216	5	212(5)	200 (7/19)	Yes (No)
Seventh Crow Wing	196	215	20	196(20)	216 (8/4)	Yes (No)
Long	216	216	1	216(1)	218 (8/6)	Yes (No)
Carlos			0	No kill	239 (8/27)	No
Straight			0	No kill	213 (8/1)	No
Reference lakes without cisco kill in 2006						
Big Trout			0	No kill	No kill	Yes
Kabekona			0	No kill	No kill	Yes
Scalp			0	No kill	No kill	Yes
Ten Mile			0	No kill	No kill	Yes
Rose			0	No kill	No kill	Yes

Note:
[a]Stands for a DOY in 2006 and the number of continuous cisco lethal days from the lethal day predicted by the fish habitat model
[b]DOY followed by month and date in 2006 inside brackets
[c]The first Yes/No gives the agreement of cisco lethal prediction and reported cisco mortality in 2006, and Yes/No inside brackets gives the agreement whether or not cisco lethal days from the model include reported date with cisco mortality

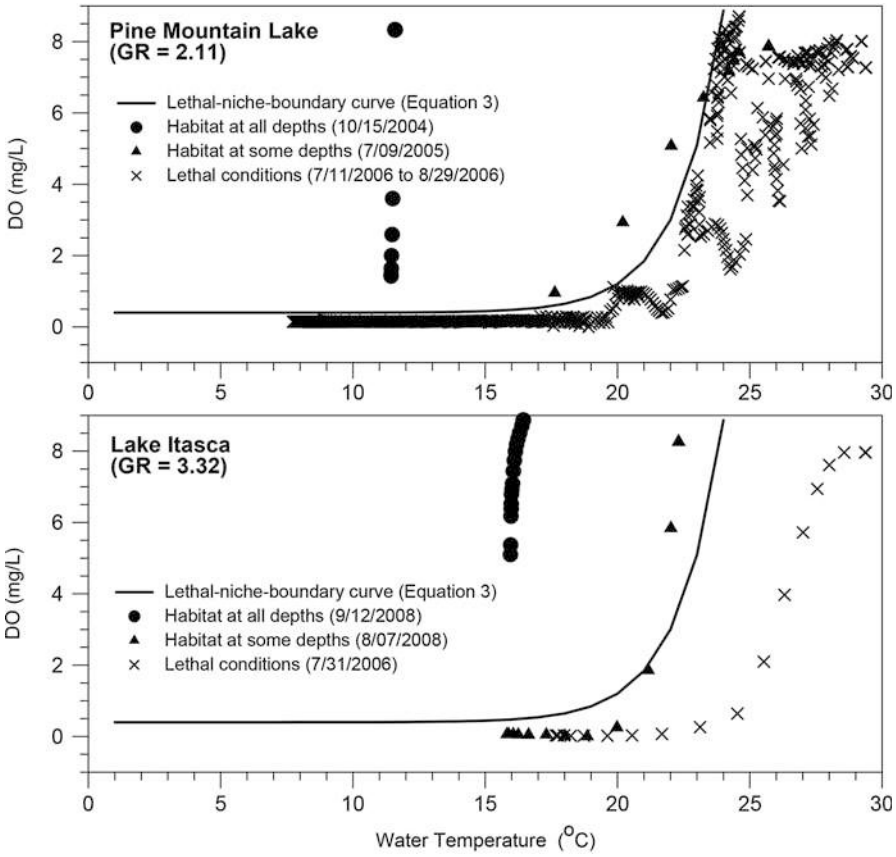

Fig. 9 Simulated DO versus simulated temperature for selected days to show three different types of fish habitat in Pine Mountain Lake and Lake Itasca (Table 6) and the lethal-niche-boundary curve of adult cisco (Eq. 3)

was plotted in Fig. 9 for two Minnesota lakes (Pine Mountain Lake and Lake Itasca). In comparison with the previous constant lethal temperature for cold-water fish species, i.e., 23.4 °C (Eaton et al. 1995), the lethal temperature from Eq. 3 is only 22.0 °C when 3.0 mg/L is used as the DO survival limit (Jacobson et al. 2008). In this study, the required DO concentration DO_{lethal} was computed from the simulated water temperature in each water layer of a lake for each simulated day using Eq. 3. The computed DO_{lethal} value was then compared with the simulated DO concentration in the same layer; lethal conditions for cisco were assumed to occur if the simulated DO concentrations were less than the DO_{lethal} values in all water layers (from the lake water surface to the lake bottom) on that day. In Fig. 9, simulated DO was plotted against simulated temperature for selected days in the two lakes. In Pine Mountain

Lake, from July 11, 2006 (DOY 192 in Table 6) to August 29, 2006 (DOY 241), there were 49 days (Table 6, one discontinuous lethal day) that all simulated T-DO data points (shown by the crosses) are located at the right side of or below the lethal-niche-boundary curve when simulated DO concentrations were below computed DO_{lethal} values at simulated temperatures at all water depths. The same situation of cisco lethal conditions was predicted to occur on July 31, 2006 in Lake Itasca.

If simulated DO concentrations are less than the DO_{lethal} values in only some of the water layers, lethal conditions for cisco are not assumed to occur on that day because cisco can swim to other water layers having suitable T and DO condition. These days with habitat at some depths are shown as filled triangles in Fig. 9. Pine Mountain Lake on July 9, 2005 had lower DO at higher temperatures near the surface and near anoxic DO (0.2 mg/L) in the hypolimnion. Therefore, layers near the surface and in the hypolimnion could not support cisco habitat, but some intermediate layers had high enough DO at simulated temperatures to support cisco habitat. Lake Itasca on August 7, 2008 had suitable cisco habitat in the surface layers and no cisco habitat in the bottom layers (Fig. 9). Lake Itasca located in Clearwater County, Minnesota, has a maximum depth of 13.7 m and a surface area of 4.3 km^2. Lake Itasca is mesotrophic due to its mean Secchi depth 2.8 m and mean chlorophyll-a concentration 10.4 μg/L and has relatively weak stratifications because of its GR = 3.32 (Gorham and Boyce 1989; Stefan et al. 1996).

When simulated DO concentrations are greater than the DO_{lethal} values in all water layers, fish can live in any depth of the lake, i.e., filled circles in Fig. 9 (e.g., October 15, 2004 in Pine Mountain Lake and September 12, 2008 in Lake Itasca).

Validation of Fish Habitat Model

Figure 9 shows simulated DO versus simulated temperature during two periods (July 11, 2006–August 24, 2006 and August 26–29, 2006) in Pine Mountain Lake when cisco lethal conditions were predicted by the fish habitat model using the cisco lethal-niche-boundary curve. Surface water temperatures in Pine Mountain Lake ($A_s = 6.36$ km^2, $H_{\max} = 23.77$ m, and $GR = 2.11$ $m^{-0.5}$) reached 29.4 °C on July 31, 2006. When the lethal temperature of 22.0 °C for adult cisco was used, for the 49 days in Pine Mountain Lake (Fig. 9), 43 % of water depths had temperatures greater than 22.0 °C, and 58 % of water depths had DO < 3 mg/L. The cisco mortality in Pine Mountain Lake was reported on July 26, 2006 (Jacobson et al. 2008) when the fish habitat model predicted continuous 16 days of lethal conditions starting from July 11, 2006.

The fish habitat modeling using the cisco lethal-niche-boundary curve was validated in the 23 Minnesota lakes that Jacobson et al. (2008) studied first in 2006. Validation results are summarized in Table 6 for each lake, which shows similar information as Table 5 does but using different oxythermal lethal limits. For example, Lake Andrusia has "192(37), 233(2)" under "simulated lethal days in 2006" in Table 6 that means lethal conditions were simulated on DOY 192 (July 11, 2006) with the number of continuous cisco lethal days of 37 (DOYs 192–228)

and on DOYs 233–234 (August 21–22, 2006). Lethal conditions were not simulated for DOYs 229–232 (August 17–20, 2006) in Lake Andrusia. In comparison to "Observed mortality day in 2006" in Table 6, the model agreement with mortality observation is "Yes (Yes)" for Lake Andrusia (Table 6).

Using the lethal-niche-boundary curve, for five lakes (Bemidji, Mille Lacs, Star, Seventh Crow Wing, and Long), the model predicted cisco lethal conditions, but the predicted lethal periods did not include corresponding reported cisco mortality days in 2006; these lakes have the "Yes (No)" agreement (Table 6). For three lakes (Bemidji, Mille Lacs, and Star), cisco lethal conditions were predicted to occur after the reported cisco mortality days in 2006. In the Seventh Crow Wing Lake, cisco lethal conditions were predicted to occur from DOY 196 to 215 (August 3) in 2006, and the cisco mortality was reported on August 4. This case can be considered as "Yes (Yes)" agreement because cisco mortality might be reported one or a few days after cisco mortality occurred when study lakes were not constantly monitored and observed. Long Lake was predicted with only 1 day of lethal conditions.

There are two lakes (Straight Lake and Lake Carlos) that the model did not predict cisco lethal conditions, but they had cisco mortality in 2006; the model has the No agreement with mortality observation (Table 6). Lake Carlos had a late summer cisco mortality event occurred on August 27, which might be due to the formation of the metalimnetic oxygen minimum during part of the summer (Smith et al. 2014).

The five reference lakes (deep strongly stratified) that Jacobson et al. (2008) studied did not experience cisco mortality in 2006. The fish habitat model using simulated temperature and DO profiles predicted no lethal conditions for cisco in all five reference lakes (Table 6). Therefore, the fish habitat model using the lethal-niche-boundary curve has overall good agreement in the 23 study lakes with and without cisco mortality reported in 2006. The overall good agreement is very similar but not exactly the same as the agreement using the constant lethal limits ($LT = 22.0$ °C and $DO_{\text{lethal}} = 3$ mg/L, Table 5).

Fish Habitat Simulations in 36 Representative Lake Types

To understand cisco habitat and to determine cisco kill in 36 different lake types (LakeR01–LakeR36 in Table 1), daily water temperature and DO profiles were simulated using MINLAKE2012 under past (1991–2008) climate conditions from Bemidji weather station and the corresponding future climate scenario (MIROC 3.2). Bemidji weather station is close to most of the 23 study lakes (Tables 5 and 6) and has 18 years of weather data. The fish habitat model for cisco was applied every day year by year from 1992 to 2008 using simulated daily water temperature and DO profiles. Results for the first simulation year (1991) were not used for cisco modeling in order to remove the possible effect of initial conditions.

Total Days of Cisco Lethal Conditions in Each Year

Total days of lethal conditions for cisco in each year over 17 simulation years were used to create box plots showing the maximum and minimum and 25 %, 50 %, and

75 % quartile values simulated for each of the 36 representative lake types in Minnesota under past climate conditions and MIROC 3.2 future climate scenario (Fang et al. 2014). Lethal conditions may be continuous for many days or discontinuous for some days (Fig. 9 and Table 6). For the 12 shallow lakes with GR $\geq$ 5.29 $m^{-0.5}$, median annual days of cisco lethal conditions ranged from 13 to 22 days under past climate conditions and are projected to range from 47 to 55 days under the future climate scenario (Fang et al. 2014). These results indicate again that shallow lakes typically cannot support cisco habitat. In the MN DNR cisco lake database, there are a total of 620 cisco lakes, of which 37 lakes have GR $\geq$ 5.29 $m^{-0.5}$ and maximum depths less than 11.0 m. There are 14 lakes with $H_{max} < 5.0$ m that are classified as shallow lakes in Minnesota (Stefan et al. 1996), of which 13 lakes have GR $>$ 5.29 $m^{-0.5}$ and one lake has GR $=$ 4.4 $m^{-0.5}$. These lakes had cisco observed in the past, but, most likely, they cannot sustain cisco habitat.

For the 12 medium-depth lakes with $H_{max} = 13.0$ m (LakeR10–LakeR18 and LakeR31–LakeR33), GR values are 1.63, 2.78, and 4.33 $m^{-0.5}$ (Table 1). Median annual days of cisco lethal conditions ranged from 0 to 1 day under past climate conditions and are projected to range from 19 to 49 days under the future climate scenario. Under past climate conditions, cisco lethal conditions reached a maximum of 30 days for medium-depth lakes during the unusual hot summer in 2006. These lakes are vulnerable to climate warming because lethal conditions are projected up to 80 days (Fang et al. 2014).

For the 12 deep lakes with $H_{max} = 24$ m (LakeR19–LakeR27 and LakeR34–LakeR36), eutrophic deep lakes (LakeR19, LakeR22, and LakeR25) and mesotrophic large deep lake (LakeR26 with GR $=$ 2.34 $m^{-0.5}$) are projected to have some cisco lethal days under the future climate scenario (Fang et al. 2014). Cisco lethal conditions, however, were not simulated to occur under past climate conditions (1992–2008). Large deep lakes with GR $=$ 2.34 $m^{-0.5}$ seem to require Secchi depth more than 2.5 m to have nonlethal conditions under the future climate scenario. Other strongly stratified mesotrophic and oligotrophic deep lakes (LakeR20, LakeR21, and LakeR34 with GR $=$ 0.88; LakeR23, LakeR24, and LakeR35 with GR $=$ 1.50; and LakeR27 and LakeR36 with GR $=$ 2.34 in Table 1) are possible to support cisco habitat under both past and future climate conditions. These deep lakes are good candidates of cisco refuge lakes (Fang et al. 2012b; Jiang et al. 2012).

Annual cisco lethal days are strongly dependent on lake stratification characteristics (i.e., GR) but vary relatively weakly with trophic status (i.e., SD). The four lakes with the same GR but different Secchi depths were grouped together to compute mean and standard deviation of annual cisco lethal days under past climate conditions and the future climate scenario (Fig. 10). There are consistent patterns of average annual lethal days for each group of lakes with the same maximum depth (shallow, medium-depth, and deep). Shallow lakes (GR $>$ 5.2 $m^{-0.5}$) have large numbers of cisco lethal days, medium-depth lakes (GR $=$ 1.63, 2.78, and 4.33 $m^{-0.5}$) have cisco lethal days increasing with geometry ratio (Fig. 10), and deep lakes (GR $=$ 0.88, 1.50, and 2.34 $m^{-0.5}$) have little or no cisco lethal days.

The four lakes with GR $=$ 1.63 $m^{-0.5}$ (LakeR10–LakeR12 and LakeR31) are small medium-depth lakes ($A_s = 0.2$ km^2 and $H_{max} = 13.0$ m). Cisco lethal days

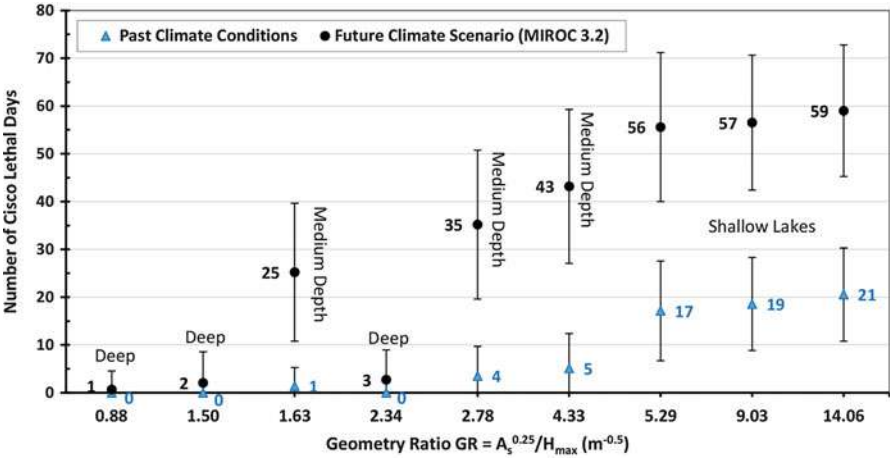

Fig. 10 Number of annual cisco lethal days (mean ± standard deviation) simulated for the 36 representative lake types with nine GR values under past climate conditions and the future climate scenario (Fang et al. 2014)

projected for these four lakes (especially under the future climate scenario) are different from deep lakes with GR just less or greater than 1.63 $m^{-0.5}$ (Fig. 10). These results may indicate that fish habitat modeling for deep lakes should be separated from the modeling for medium-depth lakes. To further prove the point, four deep lakes (LakeR41–LakeR44, Table 1) having GR = 1.63 $m^{-0.5}$ with larger A_s = 2.32 km^2 and deeper H_{max} = 24.0 m were created, and daily temperature and DO profiles were simulated using MINLAKE2012 under past climate conditions and the future climate scenario. The simulated number of annual cisco lethal days in these four deep lakes is zero for all years (1992–2008) under past climate conditions and is projected to be zero under the future climate scenario except for LakeR41, which is an eutrophic deep lake having 1 year with 4 days of cisco lethal projection. Therefore, simulations of cisco lethal days in these deep lakes (LakeR41–LakeR44) are consistent with other deep lakes but different from medium-depth lakes with the same geometry ratio. Other fish habitat parameters, e.g., good-growth period for cold-water fish in 27 Minnesota lake types, had similar discontinuous patterns in some medium-depth and deep lakes in a previous study (Fang et al. 2004b). In the MN DNR cisco lake database, there are 385 medium-depth lakes with 5 m $\leq H_{max} <$ 20 m and 221 deep lakes with $H_{max} \geq$ 20 m. Therefore, it is recommended to model cisco habitat and survival separately for medium-depth lakes and deep lakes in the future.

Number of Years with Cisco Kill

It is still uncertain how many days that exceed non-survival or lethal niche limits are necessary to result fish mortality. In previous regional fish habitat projections (Stefan et al. 1996) when daily water temperature and DO concentration profiles used for fish habitat simulations were long-term (30-year) averages, fish kill was assumed to occur when the number of non-survival days (either consecutive or discontinuous) totaled at

least seven. In this study, a sensitivity analysis on the number of continuous lethal days for determining cisco kill was performed when daily profiles were not averaged over 17 years (1992–2008), but cisco lethal conditions were checked in each day year by year. A cisco kill was assumed to occur if the number of continuous lethal days was greater than 3, 7, and 14 days for the sensitivity analysis. The 3 days are the half of 7 days used before, and 14 days are the double of 7 days. For the 11 Minnesota lakes (Table 6) in which the simulated lethal days included the reported cisco mortality days in 2006, the number of continuous lethal days to the mortality day was calculated and ranged from 2 (Gull Lake) to 25 (Little Pine Lake in Crow Wing County) days. Median value of the number of continuous lethal days to the mortality day was 14 days (mean value 13 days with a standard deviation 7 days). This result provides another reason to use 14 days for the sensitivity analysis.

When 3, 7, and 14 continuous lethal days were used for determining cisco kill, Fig. 11 shows the numbers of years with cisco kill simulated for the 36 representative lake types in Minnesota for 17 simulation years under past (1992–2008) climate conditions (blue triangles) and the future climate scenario (red circles). The x axis gives lake's geometry ratio, and the four lake types with the same geometry ratio (Table 1) were grouped together to compute mean and standard deviation of the number of years with cisco kill. Under past climate conditions, the 12 shallow lakes (LakeR01–LakeR09, LakeR28–LakeR30, GR = 5.29, 9.03, and 14.06 $m^{-0.5}$) were simulated to have cisco kills on average in 14–15 years when 3 continuous lethal days were used to determine whether cisco kill happens or not. Under the future climate scenario (MIROC 3.2), the 12 shallow lakes are projected to have cisco kills in all 17 simulation years. These results provide strong evidence to indicate that shallow lakes cannot sustain cisco habitat under future warmer weather. The shallow lakes in MN cisco database are weakly stratified or polymictic with relatively high temperatures from surface to bottom during the summer which caused summer cisco kill almost every year from 1992 to 2008. Although cisco was observed in these 14 lakes in the past, whether cisco still exists in them is unknown. The projection under the future climate scenario shows they are not favorable to support cisco habitat every year.

When 7 continuous lethal days were used to determine whether cisco kill happens, the 12 shallow lakes were simulated to have cisco kills on average in 11–12 years (range from 9 to 13 years) under past climate conditions and are projected to have 17 years of cisco kills under the future climate scenario. When 14 continuous lethal days were used to determine whether cisco kill happens, the 12 shallow lakes were simulated to have only 1 year (2006) with cisco kill under past climate conditions and are projected to have 11–12 years of cisco kills under the future climate scenario. It projects there are more years with cisco kills in some medium-depth lakes than in the 12 shallow lakes under the future climate scenario (Fig. 11). This finding may indicate that 14 continuous lethal days for determining cisco kill may be longer than how many lethal days would be needed for cisco mortality to occur because it gives inconsistent results on fish habitat projections.

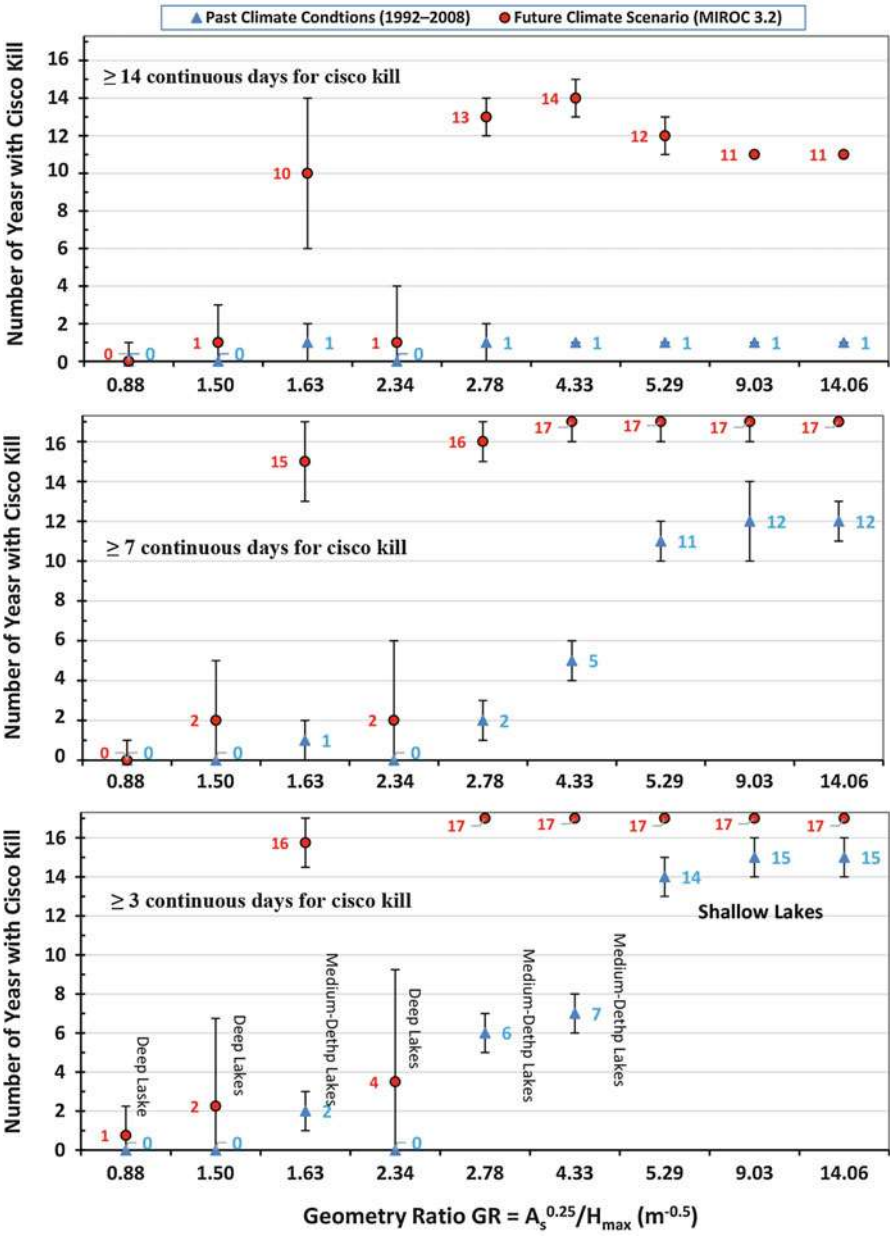

Fig. 11 Numbers of years with cisco kill simulated for the 36 representative lake types in Minnesota under past climate conditions (*triangles*) and the future climate scenario (*circles*) using 3, 7, and 14 continuous lethal days for determining cisco kill (Fang et al. 2014)

Therefore, the 14 continuous lethal days for determining cisco kill are not recommended for further fish habitat study.

Using 3 continuous lethal days for determining cisco kill, the 12 medium-depth lakes were simulated to have cisco kills on average in 2–7 years (range from 1 to 8 years) under past climate conditions and are projected to have 16–17 years of cisco kills under the future climate scenario. Using 7 continuous days for determining cisco kill, the 12 medium-depth lakes were simulated to have cisco kills on average in 1–5 years (range from 0 to 6 years) under past climate conditions and are projected to have 15–17 years (range from 13 to 17 years) of cisco kills under the future climate scenario. Figure 11 shows medium-depth lakes are most vulnerable to climate warming with average increase of 13 years with cisco kill (range from 9 to 15 years).

The 12 deep lakes (LakeR19–LakeR27, LakeR34–LakeR36) were simulated to have no cisco kill under past climate conditions using either 3, 7, or 14 continuous lethal days for determining cisco kill (Fig. 11). The 12 deep lakes are projected to have on average 1–4 years (range from 0 to 9 years) or 0–2 years (range from 0 to 6 years) of cisco kills under the future climate scenario when 3 and 7 continuous lethal days were used for determining cisco kill, respectively. Only eutrophic deep lakes ($SD = 1.2$ m, LakeR19, LakeR22, and LakeR25) and large mesotrophic deep lake ($A_s = 10$ km^2, $SD = 2.5$ m, LakeR26) are projected to have a few years with cisco kill under the future climate scenario. Figure 11 shows most mesotrophic and oligotrophic deep lakes can support cisco habitat under both past climate conditions and the future climate scenario and are good candidates for cisco refuge lakes, as supported by previous studies (Fang et al. 2012b; Jiang et al. 2012). It seems that 3 or 7 continuous lethal days for determining cisco kill provide quite reasonable results for cisco kill simulations in shallow, medium-depth, and deep lakes in Minnesota.

The box plots of the numbers of annual continuous lethal days greater than or equal to 3 and 7 days simulated for the 36 lake types in Minnesota under past climate conditions (1992–2008) and the future climate scenario (MIROC 3.2) were presented elsewhere (Fang et al. 2014). Those lethal days that are not continuous for 3 or 7 days were excluded. Under past climate conditions, 1 to a few years with cooler summers did not result in cisco kills in the 12 shallow lakes, but most other years had cisco kills with annual continuous lethal days up to 36 days (Fang et al. 2014). Under the future climate scenario, projected annual continuous lethal days are up to 94 days and 40 days in shallow lakes and eutrophic deep lakes, respectively. Medium-depth lakes are projected to have relatively large change in annual continuous lethal days.

Identification of Cisco Refuge Lakes Using the Fixed Benchmark Period

Cisco Habitat Criteria and Selection of Cisco Refuge Lakes

The oxythermal habitat approach used in the oxythermal fish niche modeling options 1 and 2 (Fig. 3) uses lethal limits for temperature and oxygen. In the third option, the quality of oxythermal habitat for cisco was determined using a single variable,

TDO3, i.e., water temperature at 3 mg/L of DO, proposed by Jacobson et al. (2010). A higher TDO3 value represents higher oxythermal stress for the cold-water fish. For example, if TDO3 is high, then fish must choose between well-oxygenated water that is too warm and live in hypoxic water that is of a proper temperature. The oxygen concentration of 3 mg/L is probably lethal or nearly so for many cold-water species (Frey 1955; US EPA 1986; Evans 2007) and therefore represents a desirable benchmark for a presence/absence niche model.

Oxythermal habitat niche relationships developed for several cold-water fish (including cisco) by Jacobson et al. (2010) were used to identify potential refuge lakes for cisco under future climate scenarios. Niche breadth measures, i.e., central response borders used by Heegaard (2002), were used by Jacobson et al. (2010) to identify values of TDO3 measured in the period of greatest oxythermal stress in late summer ($maxT_{DO3}$) useful for describing the quality of cold-water habitat for cisco. Central response borders essentially bracket the core range of a habitat variable required for a species to thrive (Heegaard 2002). The central species response borders for cisco ranged from $maxT_{DO3}$ of 4.0 °C to 16.9 °C (Jacobson et al. 2010).

TDO3 can be determined by interpolation from measured or simulated (vertical) temperature and DO profiles in a stratified lake. When non-monotonic profiles generate low oxygen concentrations with more than one TDO3 value, the coldest TDO3 was used (Jacobson et al. 2010). Temperature and DO profiles simulated for the first year (1961) were not used to compute TDO3 in order to avoid possible effects of assumed initial conditions. Figure 12 illustrates the procedure how TDO3 can be extracted from either measured or simulated temperature and DO profiles. Elk Lake (Fig. 12) has a maximum depth of 27 m and mean summer Secchi depth of 3.6 m (mesotrophic lake). Elk Lake has a lake geometry ratio of 1.16 and is a strongly stratified (dimictic) lake; it has excellent cold-water oxythermal habitat with TDO3 = 5.8 °C on June 24, 2008 (using observed temperature and DO profiles) and is projected to have a TDO3 value of 6.3 °C on June 24 under the future climate scenario MIROC 3.2. There were 99 measured T and DO profiles that had adequate data to extract TDO3 values for the 21 cisco lakes (Fang et al. 2010b). The standard error of TDO3 determined from simulated profiles against TDO3 from 99 measured profiles was 2.19 °C with correlation coefficient R = 0.88 (Fang et al. 2010b).

Through cisco habitat modeling, cisco refuge lakes were selected and identified in two categories: tier 1 refuge lakes and tier 2 refuge lakes. Tier 1 refuge lakes have TDO3 less than or equal to 11 °C, and tier 2 refuge lakes have TDO3 less than or equal to 17 °C but greater than 11 °C. Lakes having TDO3 greater than 17 °C are classified as tier 3 or non-refuge lakes. The limit of 17 °C corresponds to the upper cisco central response border of TDO3, and the limit of 11 °C is near the midpoint of the cisco central response borders of TDO3, as well as the upper central response border of TDO3 for lake whitefish *Coregonus clupeaformis* (Jacobson et al. 2010). Therefore, tier 1 refuge lakes identified for cisco in this study are also useful to the management of lake whitefish in Minnesota.

The multiyear average TDO3 over a fixed benchmark (FB) period was used to identify cisco refuge lakes in Minnesota. The benchmark period is the period of greatest oxythermal stress for cold-water fish. It is defined as the month (31-day

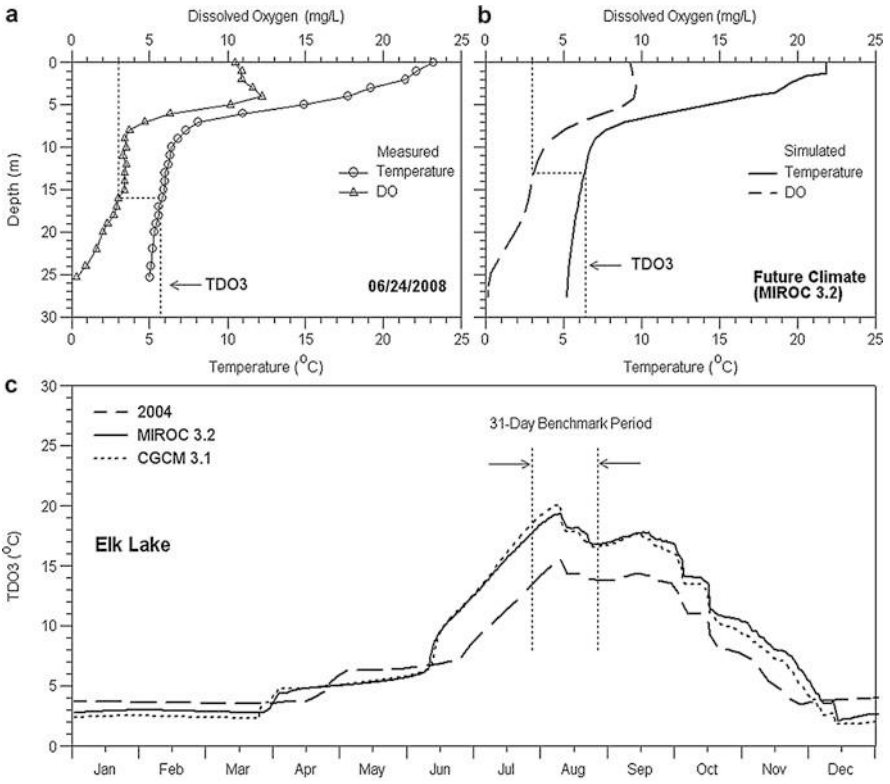

Fig. 12 Examples of measured (**a**) and simulated (**b**) temperature and DO profiles in Elk Lake for past (**a**) and a future (**b**) climate to show the determination of TDO3 (temperature at 3 mg/L DO) and (**c**) time series of simulated daily TDO3 values for Elk Lake in 2004 and for future climate scenarios CGCM 3.1 and MIROC 3.2. The fixed benchmark periods for stratified lakes are between the vertical dashed lines (Fang et al. 2012b)

period) with the highest value of TDO3 and typically occurs in late summer (Jacobson et al. 2010). From a total of 9,521 T and DO profiles measured in 1,623 Minnesota lakes in the years 1993 through 2005, associated maximum TDO3 values were computed in summer periods, and then Jacobson et al. (2010) determined that the period of greatest oxythermal stress for cold-water fish differed by stratification status of a lake. The stress occurred earlier in unstratified lakes. In this study, the fixed benchmark (FB) period from July 28 through August 27 proposed by Jacobson et al. (2010) was chosen to calculate the monthly (31-day) average of daily TDO3, called $ATDO3_{FB}$, in each simulated year over the 47-year simulation period because the 30 simulated virtual cisco lakes (Table 2) are strongly stratified lakes.

The overall modeling approach of the option 3 was depicted in Fig. 3 and discussed in detail by Fang et al. (2012b). To pursue the overall objective, we had to (1) review how the T and DO habitat constraints on cold-water fishes in lakes can be quantified (oxythermal fish habitat criteria), (2) develop a method to quantify

oxythermal fish habitat under past climate and by how much climate warming will change it in existing cisco lakes, (3) validate that the methods under (1) and (2) would give results for past climate conditions that would match actual cisco observations in lakes, (4) apply the method to make projections for a representative number of lakes in the future, and (5) extrapolate those results to 620 cisco lakes of Minnesota. To implement the above modeling approach, 30 "virtual" cisco lake types (Table 2) were chosen as representative of the entire set of 620 lakes. For step (4), to assess the quality of cisco habitat in 30 virtual cisco lakes and to identify refuge lakes, the 47-year average of annual $ATDO3_{FB}$ values in the 1962–2008 simulation period (i.e., $AvgATD3_{FB}$, Fig. 3) was calculated and compared to TDO3 limits (11 °C and 17 °C determined by the analysis of field data) to divide 620 Minnesota cisco lakes into three tiers.

It is impossible to validate the projected number of refuge lakes for future climate scenarios, but a model validation on 23 cisco study lakes was performed (Table 7). Adult cisco mortality was reported in 18 lakes in Minnesota during the unusually hot summer of 2006, and no cisco mortality was reported in five reference lakes (Jacobson et al. 2008), which is shown in the last column "Reported 2006 cisco mortality" of Table 7. Water temperature and DO profiles in all 23 lakes were simulated under 2006 weather data from the closest weather station after necessary model calibration (Fang et al. 2014). $ATDO3_{FB}$ in 2006 was calculated for each lake and used to classify the lake into tier 1 and tier 2 refuge lakes or tier 3 non-refuge lake. The $ATDO3_{FB}$ values in 2006 range from 13.2 °C (Lake Carlos) to 25.3 °C (Little Turtle Lake) for 18 Minnesota lakes with cisco mortality (Table 7). Except Lake Carlos (tier 2 refuge lake), all other 17 cisco lakes with 2006 cisco mortality are classified as tier 3 non-refuge lakes because their $ATDO3_{FB}$ values in 2006 are greater than 17 °C. The $ATDO3_{FB}$ values in 2006 for five reference lakes range from 6.4 °C (Big Trout Lake) to 14.3 °C (Rose Lake): four references are classified as tier 1 refuge lake, and only Rose Lake is classified as tier 2 non-refuge lake in 2006 (Table 7). Rose Lake has one profile for model calibration. Out of 23 cisco study lakes, there are two lakes (Lake Carlos and Rose Lake) having sort of disagreement with 2006 observations. Overall, there is a remarkable agreement between model predictions of refuge lake classification using $ATDO3_{FB}$ and observed adult cisco mortality and survival lakes in 2006 (Table 7).

This study was to develop a method to rank the quality of fish habitat for cisco in Minnesota lakes and the identification of potential refuge lakes if and when projected future (warmer) climate scenarios become reality. When a fish species is eliminated by changes in water temperature, it is not only a loss but also opens the habitat for other, exotic invasive species. For these reasons, a method to identify potential refuge lakes is important.

Multiyear Average of Oxythermal Stress ($AvgATDO3_{FB}$)

From the time series of daily TDO3 for each year in the 47-year (1962 to 2008) simulation period, different TDO3 statistics can be extracted, e.g., the annual

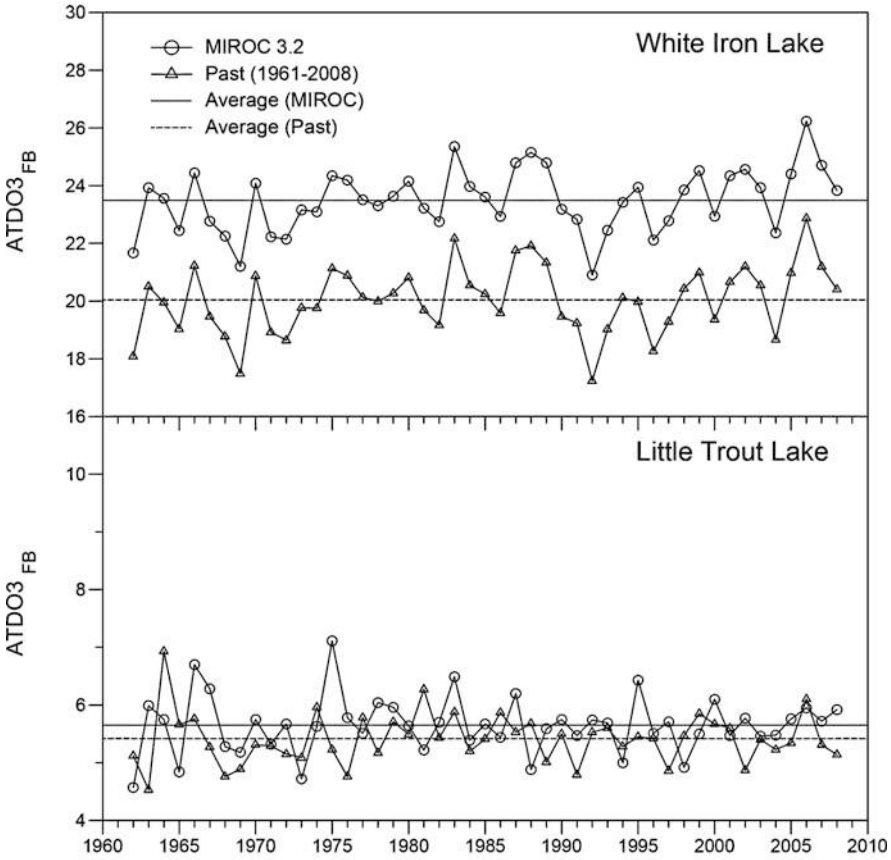

Fig. 13 Examples of annual time series of mean daily TDO3 values for the fixed benchmark periods for past climate (1962–2008) and for the future climate scenario MIROC 3.2. Averages ($AvgATDO3_{FB}$) over the 47-year simulation period are presented as dashed horizontal lines. Weather data from the closest Class I NWS weather station were used for the model simulations (Duluth for White Iron Lake and International Falls for Little Trout Lake)

maximum of daily TDO3 ($TDO3_{AM}$), monthly (31-day) averages over fixed benchmark periods ($ATDO3_{FB}$), multiyear averages of the above, etc. Twelve options of TDO3 characteristic values or statistics were calculated and explored (Fang et al. 2010b). Examples of daily TDO3 time series for Elk Lake are given in Fig. 12. The $TDO3_{AM}$ value was 15.5 °C in 2004 for Elk Lake (bottom of Fig. 12); the day of occurrence of $TDO3_{AM}$ was DOY = 222 (August 10). The $TDO3_{AM}$ value is projected to increase by 3.8 or 4.3 °C in Elk Lake under the future climate CGCM 3.1 and MIROC 3.2 scenarios, respectively (Fig. 12).

Two of the 21 cisco study lakes (Fang et al. 2012a, b), White Iron Lake and Little Trout Lake, were selected to illustrate examples of time series of mean daily TDO3 in the 31-day FB periods, $ATDO3_{FB}$ (Fig. 13). Lake geometry ratios for White Iron

Lake and Little Trout Lake are 4.27 and 1.08 $m^{-0.5}$, respectively. White Iron Lake is a weakly stratified lake or a relatively shallow, large, and eutrophic lake (maximum depth $H_{max} = 14.3$ m, surface area $A_s = 13.9$ km^2, Secchi depth SD = 1.4 m). Little Trout Lake ($H_{max} = 29.0$ m and SD = 6.3 m) is a strongly stratified and oligotrophic lake. Values of $ATDO3_{FB}$ ranged from 17.2 °C to 22.9 °C for White Iron Lake (using fixed benchmark period for unstratified lakes) and from 4.5 °C to 6.9 °C for Little Trout Lake under past climate conditions. $ATDO3_{FB}$ values in weakly stratified eutrophic White Iron Lake are much larger than $ATDO3_{FB}$ in strongly stratified oligotrophic Little Trout Lake. Under the future climate scenario MIROC 3.2, values of $ATDO3_{FB}$ are projected to range from 20.9 °C to 26.2 °C for White Iron Lake and from 4.6 °C to 7.1 °C for Little Trout Lake (Fig. 13).

Mean daily TDO3 values over the fixed benchmark ($ATDO3_{FB}$) period for each simulated year were averaged over the simulation period to obtain the parameter value $AvgATDO3_{FB}$, which had been chosen as the TDO3 characteristic parameter for the selection of cisco refuge lakes (Fang et al. 2010b, 2012b). The $AvgATDO3_{FB}$ value is one value for the 47-year simulation period (1962–2008) for each lake and each climate scenario, whereas $ATDO3_{FB}$ has one value for each simulated year and 47 values in the simulation period. The $AvgATDO3_{FB}$ values were 20.0 °C (standard deviation STD = 1.19 °C) for White Iron Lake and 5.4 °C (STD = 0.44 °C) for Little Trout Lake under past climate conditions (1962–2008). $AvgATDO3_{FB}$ is typically higher for weakly stratified lakes (e.g., White Iron Lake) than for stratified lakes (Little Trout lakes, Fig. 13). Values of $AvgATDO3_{FB}$ for the future climate scenario MIROC 3.2 are projected to be 23.5 °C for White Iron Lake and 5.7 °C for Little Trout Lake; the projected increases of $AvgATDO3_{FB}$ are 3.5 °C and 0.2 °C for these two lakes, respectively.

Simulated $AvgATDO3_{FB}$ values in 23 Minnesota lakes using available climate data (ranging 17–50 years) from a closest weather station are listed in Table 7. Based on $AvgATDO3_{FB}$, the tier of the refuge lake is signed for each lake. Results of the refuge lake classification based on $ATDO3_{FB}$ and $AvgATDO3_{FB}$ are almost the same except Straight Lake. Straight Lake has $AvgATDO3_{FB}$ of 16.7 °C, which is slightly less than 17 °C, and is classified as tier 2 refuge lake based on $AvgATDO3_{FB}$ instead of tier 3 non-refuge lake based on $ATDO3_{FB}$ in the warmer summer of 2006. Overall agreement between refuge lake classification using $AvgATDO3_{FB}$ and observation of cisco mortality and suitable habitat in 2006 is very good. Table 7 also lists the maximum TDO3 in 2006 ($TDO3_{AM}$) for each lake that was used to determine whether lethal days could occur or not based on the constant lethal limits ($LT = 22$ °C and $DO_{lethal} = 3$ mg/L). The projection of having lethal days based on $TDO3_{AM}$ in 2006 has almost perfect agreement with 2006 cisco mortality observation except Lake Carlos (Table 7).

Simulated $AvgATDO3_{FB}$ values are affected by lake bathymetry and trophic state (Fig. 14) for stratified lakes, but they are less dependent on Secchi depth (trophic status) when a lake is weakly stratified, e.g., GR > 4. This is very similar to the findings by Jacobson et al. (2010) that lake productivity did not significantly affect TDO3 in the unstratified lakes. Simulated $AvgATDO3_{FB}$ values are lower in northern Minnesota (International Falls, Fig. 14) than in north-central and central

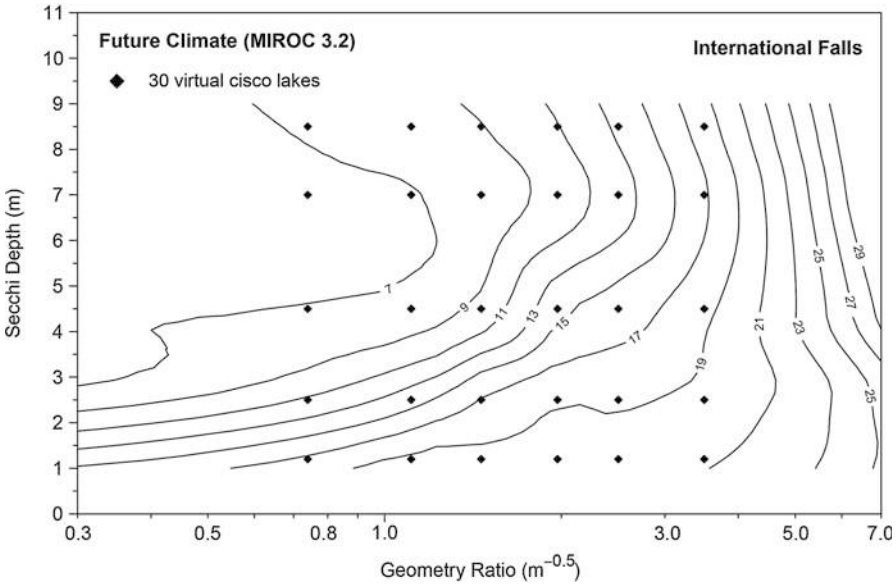

Fig. 14 Contour plots of AvgATDO3$_{FB}$ values under the future climate scenario MIROC 3.2 at International Falls, Minnesota. Contours were derived by interpolation from simulated data points for 30 virtual cisco lakes

Minnesota (Duluth and St. Cloud), but they have similar relationships (patterns) as function of GR and SD at all three locations (Fang et al. 2012b).

The AvgATDO3$_{FB}$ values ranged from 6.1 °C to 19.6 °C under past climate conditions and from 6.3 °C to 23.3 °C under two future climate scenarios at three weather stations for the 30 virtual cisco lakes (Fang et al. 2012). The projected increases of AvgATDO3$_{FB}$ values from past climate to future scenarios were from 0.0 °C to 6.5 °C in the 30 virtual lakes, and average increases are projected to be from 2.6 °C to 2.9 °C (Fang et al. 2012b), which is about 1.0–1.5 °C less than projected annual air temperature increases under the climate scenarios MIROC 3.2 and CGCM 3.1 (Table 3), respectively.

Identified Cisco Refuge Lakes in Minnesota

The selection of cisco refuge lakes was based on TDO3 parameters projected under the CGCM 3.1 and MIROC 3.2 future climate scenarios using the temperature boundaries derived from 30 simulated lakes (e.g., AvgATDO3$_{FB}$ in Fig. 14). Cisco refuge lakes were also determined by simulations for past climate conditions (1962–2008) because the results would be expected to match actual cisco lakes in Minnesota and would be a useful reference to gage both the reliability of the selection procedure and the impact of climate warming on cisco lakes in Minnesota.

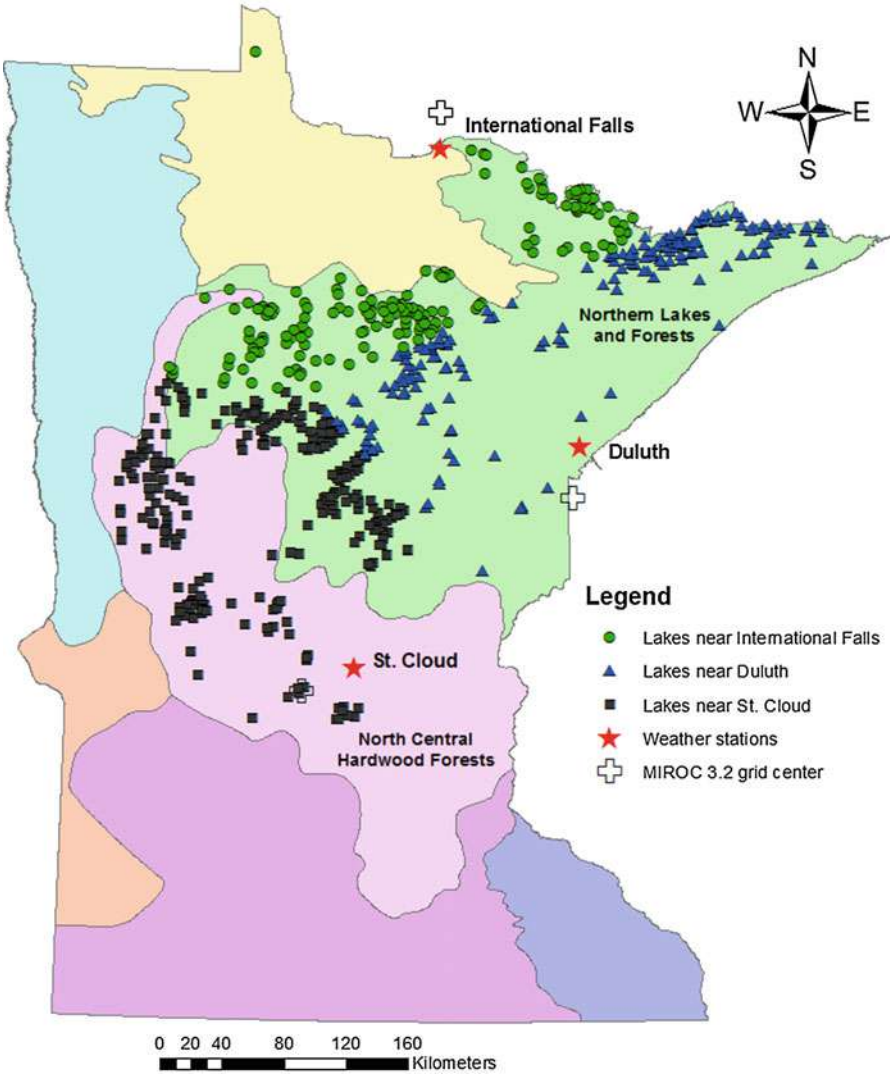

Fig. 15 Geographic distribution of 620 cisco lakes in Minnesota assigned by shortest distance to one of the three weather stations (International Falls, Duluth, and St. Cloud). The three weather stations (stars) and the grid center points (crosses) of MIROC 3.2 GCM are shown. Background shades identify ecoregions of Minnesota. Cisco lakes are found in two ecoregions: (1) Northern Lakes and Forests and (2) North Central Hardwood Forests

For the 620 cisco lakes, lakes were grouped by the shortest distance to one of the three Class I NWS weather stations in Minnesota; 169, 189, and 262 lakes were associated with International Falls, Duluth, and St. Cloud, respectively (shown by different symbols, Fig. 15).

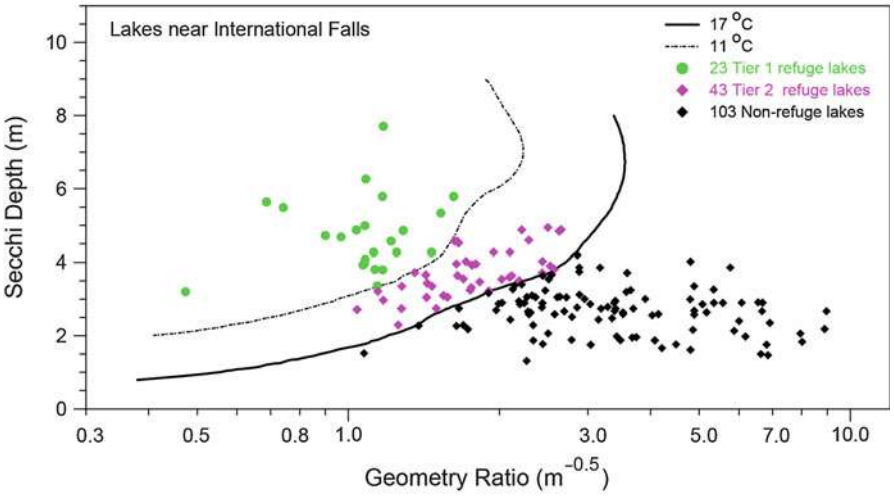

Fig. 16 Distribution of tier 1 and tier 2 refuge lakes and tier 3 non-refuge lakes on a plot of Secchi depth versus lake geometry ratio for 169 cisco lakes close to International Falls. The boundary contour lines between tiers 1, 2, and 3 are for $AvgATDO3_{FB} = 11$ °C and 17 °C, respectively, and were determined by the fixed benchmark method for the future climate scenario MIROC 3.2

The cisco lakes assigned to International Falls, Duluth, and St. Cloud weather stations were divided into tier 1 and tier 2 refuge lakes and tier 3 non-refuge lakes by the 11 °C and 17 °C isotherms of $AvgATDO3_{FB}$ simulated using corresponding climate input. The selection of refuge lakes shown in Fig. 16 was based on contour lines of $AvgATDO3_{FB}$ for the fixed benchmark period simulated under the future climate scenario MIROC 3.2. It was projected that 66 (23 + 43 in Fig. 16), 89, and 56 lakes associated with International Falls, Duluth, and St. Cloud, respectively, would be tier 1 plus tier 2 refuge lakes. A total of 211 or 205 lakes of 620 cisco lakes were identified as refuge lakes (tier 1 plus tier 2) under the future climate scenarios MIROC 3.2 and CGCM 3.1, respectively (Fang et al. 2012b). It means that about one third of the 620 lakes that currently have cisco populations are projected to maintain cisco habitat under future projected warmer climate scenarios.

Under past climate conditions (1962–2008), 483 lakes or 78 % of the 620 lakes with documented cisco populations were classified as refuge lakes (tier 1 plus tier 2) (Fang et al. 2012b). Mean values of gillnet catch per unit effort (CPUE, number of cisco gillnet) were determined from standard MN DNR netting assessments of cisco in 474 lakes. The CPUE is used as a measure of relative abundance. Mean CPUE values were 5.1, 4.1, and 3.6 for 49 tier 1 (out of total 474 lakes MN DNR studied), 97 tier 2, and 328 tier 3 refuge lakes, respectively. The netting assessment data show that there is a correlation between the tier and relative abundance, i.e., cisco abundance diminishes from tier 1 to tier 3 lakes.

The geographic distribution or a division of the 620 Minnesota cisco lakes into 84 tier 1 refuge lakes (large green circles), 127 tier 2 refuge lakes (medium-size pink pentagons), and 409 non-refuge cisco lakes (small black hexagons) is projected for

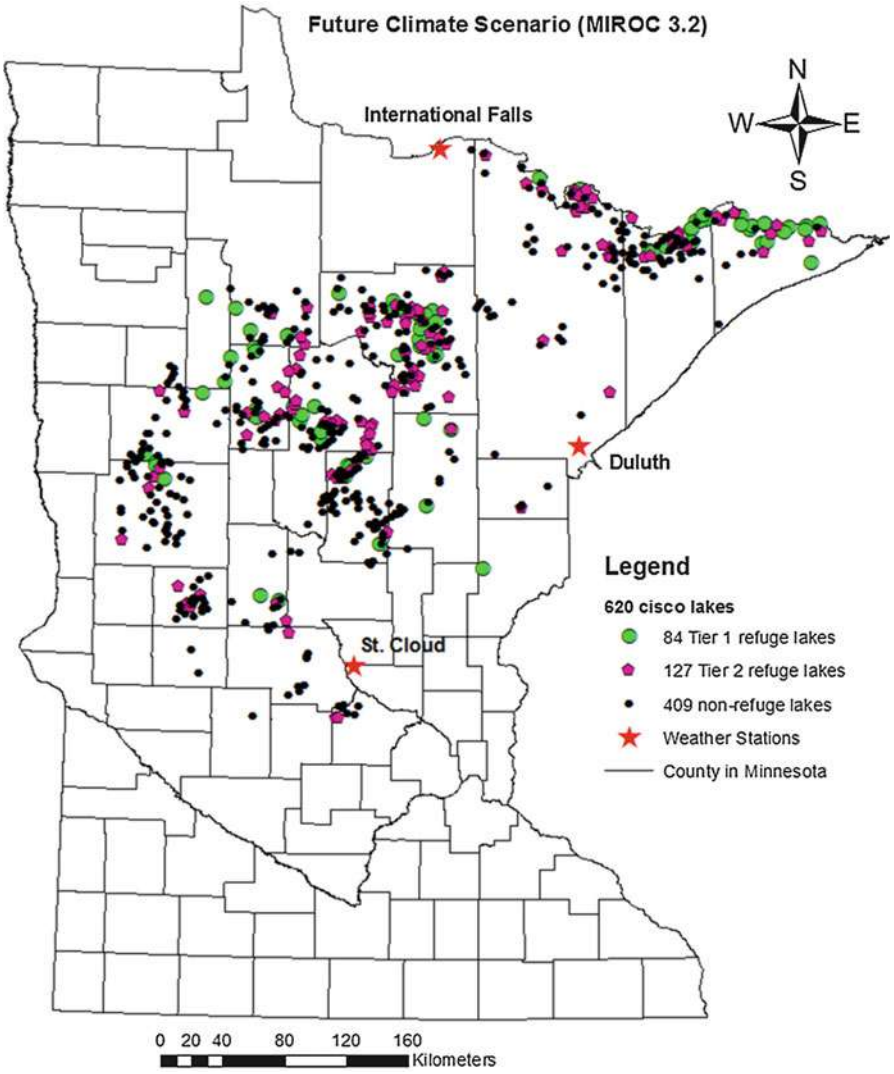

Fig. 17 Geographic distribution of tier 1 and tier 2 cisco refuge lakes and tier 3 non-refuge cisco lakes obtained from simulations for the future climate scenario MIROC 3.2. The boundary limits for tier 1 and tier 2 refuge lakes were contour lines of $\mathrm{AvgATDO3_{FB}} = 11\ ^{\circ}\mathrm{C}$ and 17 °C, respectively. The fixed benchmark method and weather data from principal weather stations in International Falls, Duluth, and St. Cloud, Minnesota, were used

the future climate scenario MIROC 3.2 (Fig. 17). Twenty-three (23) tier 1 and 43 tier 2 cisco refuge lakes (Fig. 16 and Table 8) are associated with International Falls where there is little urban or agricultural development (protected by the Superior National Forest); 39 tier 1 and 50 tier 2 refuge lakes (Table 8) are near Duluth where more development pressure exists and more protection may be necessary; and there

Table 8 Number (%) of lakes selected as tier 1 and tier 2 refuge lakes and tier 3 non-refuge lakes from cisco lakes partitioned by shortest distance to weather stations in International Falls, Duluth, and St. Cloud, Minnesota. The total number of lakes considered is 620

Closest weather station	Climate scenario	Tier 1 refuge lakes	Tier 2 refuge lakes	Total number of refuge lakes	Non-refuge lakes	Total number of lakes
International Falls	Past	49 (8)	88 (14)	137 (22)	31 (5)	169 (27.2)

	CGCM 3.1	19 (3)	37 (6)	56 (9)	206 (33)	262 (42.3)
	MIROC 3.2	22 (4)	34 (5)	56 (9)	206 (33)	262 (42.3)
All three stations	Past	176 (28)	307 (50)	483 (78)	137 (22)	620 (100)
	CGCM 3.1	78 (13)	127 (20)	205 (33)	415 (67)	620 (100)
	MIROC 3.2	84 (14)	127 (20)	211 (34)	409 (66)	620 (100)

are 22 tier 1 and 34 tier 2 refuge lakes (Table 8) associated with the St. Cloud area and its moderate development pressure.

It was found that 84 tier 1 refuge lakes have mean summer Secchi depths from 3.20 to 9.46 m (oligotrophic lakes), lake geometry ratios from 0.47 to 1.83 $m^{-0.5}$ (strongly stratified lakes), maximum depths from 13.7 to 64.9 m, and surface areas from 0.08 to 21.27 km^2 (Fang et al. 2012b). The upper 50 % of the 127 tier 2 refuge cisco lakes have a mean summer Secchi depth greater than 3.89 m, a geometry ratio from 1.56 to 2.66 $m^{-0.5}$, and a maximum depth greater than 21.3 m (Fang et al. 2012b). On the other hand, the lower 50 % of the 409 tier 3 non-refuge lakes have a mean summer Secchi depth less than 2.9 m, a geometry ratio from 2.72 to 11.89 $m^{-0.5}$, and a maximum depth less than 13.4 m.

Tier 1 plus tier 2 refuge lakes selected under the MIROC 3.2 climate scenario have a Secchi depth greater than 2.3 m, a lake geometry ratio less than 2.7 m, and a maximum depth greater than 11.6 m (Fang et al. 2012b). The geographic distribution of the projected cisco refuge lakes in Minnesota was surprisingly uniform (Fig. 16). Refuge lakes are not exclusively found in the northern and colder region; in fact, many non-refuge lakes are in the north, and a few refuge lakes are near St. Cloud in the south. This is because stratification characteristics related to lake geometry ratio

and trophic status play an important role in determining cold-water habitat for cisco in addition to climate conditions.

Identification of Cisco Refuge Lakes Using the Variable Benchmark Periods

In the third option of the oxythermal habitat modeling for cisco, single variable TDO3 can be determined by interpolation from simulated temperature and DO profiles in a stratified lake such as Elk Lake shown in Fig. 12. To determine refuge cisco lakes, average TDO3 in each simulation year can be quantified in two different periods, i.e., fixed benchmark period (Fang et al. 2012b) and variable benchmark periods (Jiang et al. 2012). Jacobson et al. (2010) determined that the period of greatest oxythermal stress for cold-water fish differed by stratification status of a lake. The 31-day fixed benchmark period of greatest oxythermal stress went from July 13 through August 12 (DOY 194 to DOY 224) for unstratified lakes and from July 28 through August 27 (DOY 209 to DOY 239) for stratified lakes; these benchmark periods explained 65 % of the deviance in TDO3 for the stratified lakes and 68 % for the unstratified lakes (Jacobson et al. 2010). However, fixing the benchmark period in time may introduce a bias for some lakes (Jiang et al. 2012). The highest average daily TDO3 value in any 31-day sliding (variable) benchmark (VB) period, called $ATDO3_{VB}$ (Fig. 3), was calculated for each simulated lake and year. Multiyear average of annual maximum oxythermal stress $ATDO3_{VB}$, i.e., $AveATDO3_{VB}$ (Fig. 3), was then used to compare with the TDO3 limits of 11 °C and 17 °C to identify cisco refuge lakes.

Figure 18 shows time series of daily TDO3 values in Big Trout Lake under 2006 and future climate scenarios (CGCM 3.1 and MIROC 3.2). The annual maximum daily TDO3 ($TDO3_{AM}$) was 9.8 °C, and the day of its occurrence was at DOY = 283 (October 10) in 2006 in Big Trout Lake. The $TDO3_{AM}$ value is projected to increase by 1.2–1.8 °C in Big Trout Lake under the future climate CGCM 3.1 and MIROC 3.2 scenarios, respectively (Fig. 18). Big Trout Lake, with a maximum depth of 39.0 m and a lake geometry ratio of 1.24, is a seasonally stratified (dimictic) lake and is projected to have a smaller increase in TDO3 under the future climate scenarios than White Iron Lake which has a maximum depth of 14.3 m and a geometry ratio of 4.27 and is a weakly stratified lake (Jiang et al. 2012).

The variable benchmark periods were determined using sliding window of 31 days to find the highest average daily TDO3 (called $ATDO3_{VB}$) over any 31-day period in each simulated year. The variable (sliding) 31-day benchmark period retained for each simulation year must not only have the highest mean daily $ATDO3_{VB}$ but must also contain the maximum daily TDO3 in that year (i.e., $TDO3_{AM}$). Using time series of daily TDO3 in each simulated year, the mean daily TDO3 over each sliding benchmark period of 31 days was calculated, and only the highest mean value in any of the sliding benchmark periods of a year (i.e., $ATDO3_{VB}$) was retained in the fish habitat program. For example, the beginning date of the VB period in Big Trout Lake was DOY 262 (September 19) in 2006 (Fig. 18),

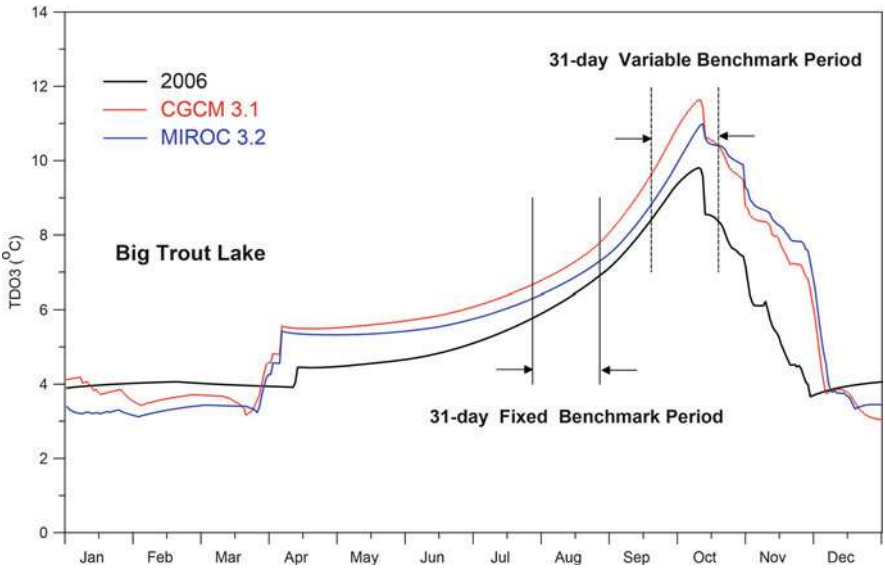

Fig. 18 Time series of simulated daily TDO3 for Big Trout Lake in 2006 and for future climate scenarios CGCM 3.1 and MIROC 3.2. The beginning dates of variable benchmark periods of highest mean daily TDO3 in 2006 for Big Trout Lake are DOY 262 (September 19)

which was quite different from the fixed benchmark period (DOYs 209 to 239). Under the future climate scenarios MIROC 3.2 and CGCM 3.1, the beginning dates for the $ATDO3_{VB}$ period are projected (simulated) to be DOYs 273 and 265 in Big Trout Lake, respectively; these dates are not much different from the beginning dates of the $ATDO3_{VB}$ for the past climate conditions. The VB period in White Iron Lake was DOY 199 (July 18) in 2006, which was about 2 months earlier than the VB period in Big Trout Lake.

To further illustrate the variability of the VB periods that give the annual $ATDO3_{VB}$ values, the beginning dates of these VB periods for virtual cisco LakeC06 and LakeC08 were determined for past climate (1962–2008) and for the future climate scenario MIROC 3.2 (Jiang et al. 2012). Duluth weather data were used as model simulation input. The beginning dates of these VB periods ranged from DOY 192 to 226 for LakeC06 and from DOY 241 to 271 for LakeC08 under past climate conditions. Average beginning dates were DOY 210 (July 29) for LakeC06 and DOY 253 (September 10) for LakeC08 under past climate conditions (1962–2008). These two small virtual lakes have the same lake geometry but different Secchi depths (Table 2); LakeC06 is an eutrophic lake with SD = 1.2 m, and LakeC08 is an oligotrophic lake with SD = 4.5 m. Isolines that give simulated average beginning dates of the VB periods of greatest oxythermal stress over the 47-year simulation period as a function of Secchi depth and lake geometry ratio were developed and studied (Jiang et al. 2012). Averages of the beginning dates of the VB periods for $ATDO3_{VB}$ ranged from DOY 207 (July 26) to DOY 269 (September 26)

for the 30 virtual lakes under past climate conditions (1962–2008). It was found that the beginning date of greatest oxythermal stress for cisco can vary considerably from year to year depending on weather, but it can also vary by lake type, i.e., stratification characteristics and trophic status (Jiang et al. 2012). Later dates occur in lakes with lower geometry ratio and higher Secchi depth, i.e., stratified oligotrophic lakes produce oxythermal stress for cisco later in the season than other lakes. The differences between the latest and earliest average beginning dates of the greatest oxythermal stress period for cold-water fish in Minnesota lakes were ranged from 59 to 89 days under past and future climates using weather data from three Class I weather stations. Therefore, variable (sliding) benchmark periods ($ATDO3_{VB}$) performed better than fixed benchmark periods to quantify the maximum oxythermal stress to cisco. The differences in average beginning dates of VB periods are much smaller (nearly negligible) between projected future climate and past climate than the differences between different lake types and the differences from year to year (Jiang et al. 2012).

Oxythermal Parameters ($ATDO3_{VB}$ and $AveATDO3_{VB}$) for VB Periods

To evaluate oxythermal stress for cisco in different lake types and under different climate scenarios, the $AvgATDO3_{VB}$ was chosen as the TDO3 parameter to identify and select cisco refuge lakes for the study (Fang et al. 2010b). The time series of $ATDO3_{VB}$ for virtual cisco LakeC06 and LakeC08 (Table 2) were analyzed under past climate (1962–2008 at Duluth) and the future climate scenario MIROC 3.2 (Jiang et al. 2012). Over the simulation period (1962–2008), $ATDO3_{VB}$ values ranged from 7.3 °C to 12.1 °C for LakeC06 and from 11.8 °C to 19.9 °C for LakeC08 under past climate conditions. Averages of $ATDO3_{VB}$ over the 47-year simulation period (i.e., $AvgATDO3_{VB}$) were 9.3 °C with standard deviation of 1.0 °C for LakeC06 and 15.6 °C with standard deviation of 1.5 °C for LakeC08 under past climate conditions (1962–2008). Values of $AvgATDO3_{VB}$ for the MIROC 3.2 future climate scenario are projected to be 12.6 °C for LakeC06 and 20.7 °C for LakeC08; the projected increases are 3.3 °C and 5.1 °C, respectively (Jiang et al. 2012).

Figure 19 shows contour plots of $AvgATDO3_{VB}$ under the past climate conditions and the CGCM 3.1 and MIROC 3.2 future climate scenarios using Duluth weather data. Contours were derived by interpolation from simulated $AvgATDO3_{VB}$ data points for the 30 virtual cisco lakes (dots in top frame of Fig. 19). Statistics of $AvgATDO3_{VB}$ values under past climate and future scenarios for three weather stations (International Falls, Duluth, and St. Cloud) were summarized by Jiang et al. (2012). The $AvgATDO3_{VB}$ values ranged from 7.48 °C to 19.91 °C under past climate conditions and from 8.02 °C to 23.28 °C under two future climate scenarios for the 30 virtual cisco lakes (Jiang et al. 2012). The projected increases of $AvgATDO3_{VB}$ values from past climate to future scenarios are from 0.30 °C to 5.11 °C, and average increases are projected to be from 2.79 °C to 3.40 °C. These increases are crucial, when cisco refuge lakes for future climate scenarios are identified and selected. Values of $AvgATDO3_{VB}$ vary by lake type depending on

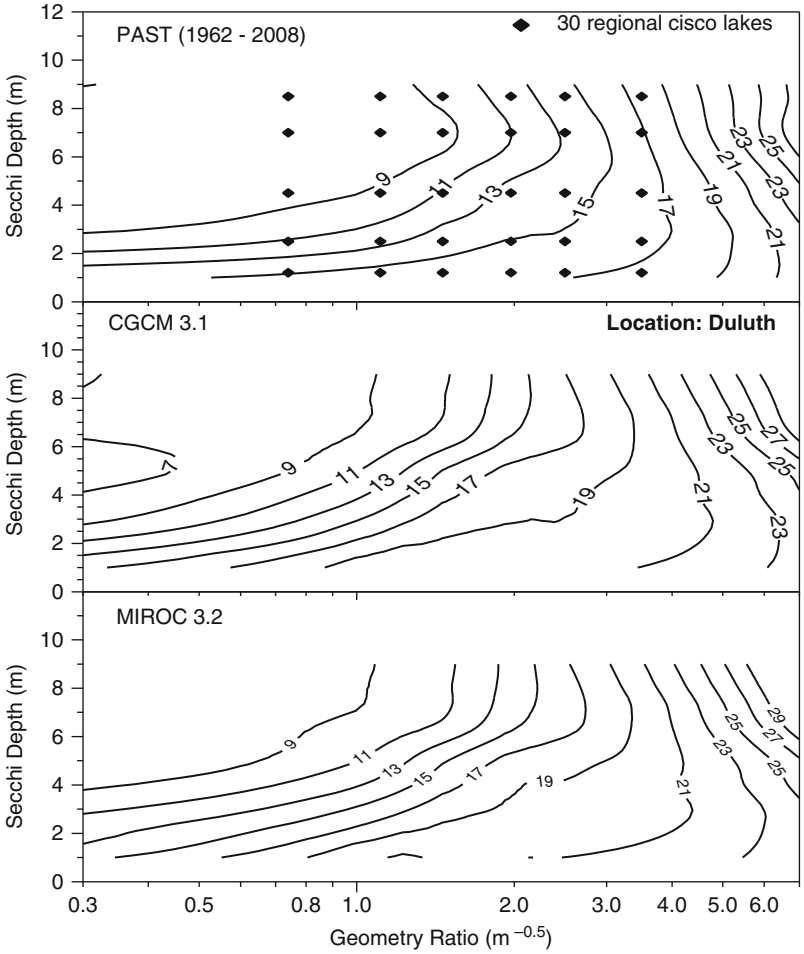

Fig. 19 Contour plots of averages of mean TDO3 over variable benchmark periods ($AvgATDO3_{VB}$) under past (1962–2008), CGCM 3.1, and MIROC 3.2 future climate scenarios. Duluth weather data was used for past climate condition. Contours were derived by interpolation from simulated data points for 30 virtual lakes

stratification characteristics and trophic status (Fig. 19); stratified oligotrophic lakes produce lower $AvgATDO3_{VB}$ values or lower oxythermal stress for cisco.

Cisco Refuge Lakes in Minnesota

Contour lines of 11 °C and 17 °C in the contour plots of $AvgTDO3_{VB}$ in Fig. 19 were used to identify cisco refuge lakes in the database of 620 Minnesota cisco lakes. The final selection of cisco refuge lakes was based on $AvgTDO3_{VB}$ projected under

Table 9 Number (%) of lakes selected as tier 1 and tier 2 refuge lakes and tier 3 non-refuge lakes from cisco lakes grouped by latitude (Fig. 1). Weather input data from three principal weather stations (International Falls, Duluth, and St. Cloud) are each assigned to a different range of latitudes for use in the simulations (Jiang et al. 2012)

Weather station by latitude	Climate scenario	Tier 1 refuge lakes	Tier 2 refuge lakes	Total number of refuge lakes	Tier 3 non-refuge lakes	Total number of lakes
Northern (International Falls)	Past	41 (7)	96 (15)	137 (22)	29 (5)	166 (27)
	CGCM 3.1	24 (4)	43 (7)	67 (11)	99 (16)	166 (27)
	MIROC 3.2	19 (3)	43 (7)	62 (10)	104 (17)	166 (27)
Mid-latitude (Duluth)	Past	52 (8)	285 (46)	337 (54)	62 (10)	399 (64)
	CGCM 3.1	10 (2)	83 (13)	93 (15)	306 (49)	399 (64)
	MIROC 3.2	10 (2)	84 (14)	94 (15)	305 (49)	399 (64)
Southern (St. Cloud)	Past	1 (<1)	31 (5)	32 (5)	23 (4)	55 (9)
	CGCM 3.1	0	4 (1)	4 (1)	51 (8)	55 (9)
	MIROC 3.2	0	4 (1)	4 (1)	51 (8)	55 (9)
All three latitudes	Past	94 (15)	412 (66)	506 (82)	114 (18)	620 (100)
	CGCM 3.1	34 (5)	130 (21)	164 (26)	456 (74)	620 (100)
	MIROC 3.2	29 (5)	131 (21)	160 (26)	460 (74)	620 (100)

the CGCM 3.1 and MIROC 3.2 future climate scenarios. Under past climate conditions (1962–2008), 506 lakes or 82 % were classified as "refuge" lakes (tier 1 plus tier 2). It means that the proposed methodology using VB periods identified current cisco lakes with an 82 % success ratio (Jiang et al. 2012).

The results of refuge lake selection using $AvgATDO3_{VB}$ are summarized in Table 9. Figure 20 shows the division of the 166 northern cisco lakes (Fig. 1) into tier 1 and tier 2 refuge lakes and tier 3 non-refuge lakes based on contour lines of 11 °C and 17 °C for $AvgATDO3_{VB}$ under the future climate scenario MIROC 3.2. It is projected that 19, 43, and 104 lakes out of 166 northern cisco lakes would be tier 1, tier 2, and tier 3 refuge lakes (Table 9 and Fig. 20) under MIROC 3.2. A total of 164 and 160 lakes or about 25 % of 620 cisco lakes were identified as tier 1 plus tier 2 refuge lakes under the future climate scenarios MIROC 3.2 and CGCM 3.1, respectively (Table 9). Thus, under fairly stringent selection criteria ($AvgATDO3_{VB} \leq 17$ °C), about one fourth of the 620 lakes that currently have cisco populations are projected to maintain viable cisco habitat (tier 1 plus tier 2) under projected future climate scenarios. In other words, climate warming under the MIROC 3.2 future

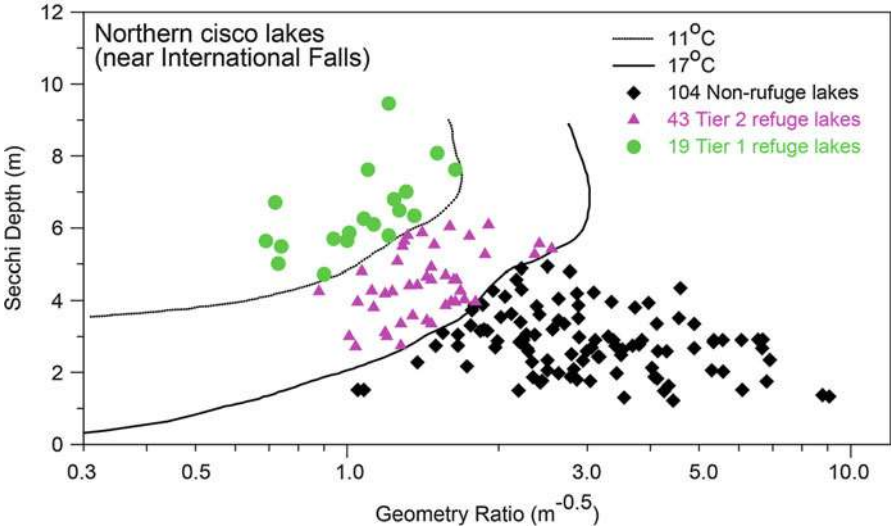

Fig. 20 Distribution of tier 1 and tier 2 refuge lakes and tier 3 non-refuge lakes on a plot of Secchi depth versus lake geometry ratio for 166 northern lakes using $AvgATDO3_{VB} = 11\ °C$ and 17 °C, as boundary lines

climate scenario is projected to potentially decrease the number of Minnesota cisco refuge lakes (tier 1 plus tier 2) by 346 (= 506 − 160) from past climate conditions (Table 9).

Table 7 summarizes the refuge lake classification in 23 Minnesota lakes based on $ATDO3_{VB}$ and $AvgTDO3_{VB}$. Except Lake Carlos, all lakes with cisco mortality in 2006 are classified as tier 3 non-refuge lakes. For five reference lakes, Kabekona and Scalp were classified as tier 2 refuge lakes using $AvgTDO3_{VB}$ (Table 7). Using VB period, $TDO3_{VB}$ does represent better actual oxythermal stress that occurs at different time periods in different lakes. Overall, there is a good agreement between refuge lake classifications using $ATDO3_{VB}$ or $AvgTDO3_{VB}$ and observed adult cisco mortality and suitable habitats in 2006 (Table 7).

The projected geographic distribution of refuge lakes and non-refuge lakes in Minnesota based on results in Fig. 20 and Table 9 is shown in Fig. 21. A division of the 620 Minnesota cisco lakes into 29 tier 1 refuge lakes (large green squares), 131 tier 2 refuge lakes (medium-size red triangles), and 460 non-refuge cisco lakes (small dark circles) is projected for the MIROC 3.2 future climate scenario when 11 °C and 17 °C contour lines of $AvgATDO3_{VB}$ were used as boundary limits (Fig. 20), and refuge lakes were selected separately from the three groups divided by latitude.

The statistics of four physical lake parameters that appear important for tier 1, 2, and 3 cisco lakes were developed (Jiang et al. 2012). For 29 tier 1 refuge lakes, the mean Secchi depths are from 4.72 to 9.46 m (oligotrophic lakes), lake geometry ratios from 0.69 to 1.64 $m^{-0.5}$ (strongly stratified lakes), maximum depths from 18.0

to 63.4 m, and surface areas from 0.19 to 21.27 km^2. The 50 % of the 460 non-refuge lakes have a mean summer Secchi depth less than 3.0 m (eutrophic to mesotrophic lakes), a maximum depth less than 14.3 m (relatively shallow lakes), and a geometry ratio greater than 2.52 $m^{-0.5}$. Tier 1 plus tier 2 refuge lakes selected under the MIROC 3.2 climate scenario have a Secchi depth greater than 2.3 m, a lake geometry ratio less than 2.6 m, and a maximum depth greater than 13.1 m (Jiang et al. 2012).

Discussion of Refuge Lake Selections

The fish habitat model simulated cisco oxythermal habitat similar to Jacobson et al. (2010), who developed an empirical model to predict TDO3 as a function of lake productivity, climate, and lake geometry ratio. Summer total phosphorus concentration was selected to represent primary productivity of each lake (Jacobson et al. 2010). In our study, phosphorus was not used to characterize any of the cisco lakes. Instead, Secchi depth, a measure of lake transparency, was used to represent trophic state. The trophic state expresses primary productivity and is directly related to DO production by photosynthesis in the MINLAKE2010 model. Chlorophyll-*a* concentration in cisco lake was calculated from Secchi depth using the Carlson trophic index (Carlson 1977) and generic seasonal growth patterns (Marshall and Peters 1989). Therefore, SD and GR are representative parameters to characterize each of the 620 cisco lakes in the database. Contour plots using GR and SD as axes were previously and successfully used to present characteristics of water temperature, DO, and fish habitat parameters in lakes (Fang and Stefan 1997, 1999, 2009; Fang et al. 2004a, b).

The effects of dissolved organic carbon (DOC), e.g., in the form of humic acids, were not modeled explicitly in MINLAKE2010, although DOC can contribute to water color and light attenuation in Minnesota lakes; this effect is captured by Secchi depth, but it also weakens the relationship between SD and primary productivity, chlorophyll-*a* concentrations, and DO production by photosynthesis. MINLAKE2010 did not directly include nutrient input from the surrounding watershed into a lake or groundwater inflow. Simulation results obtained with MINLAKE2010 are, nevertheless, representative of the nutrient input from the watershed which is reflected in the trophic state and therefore the Secchi depth (SD) of the lake; but groundwater inflow and its effect on stratification are not accounted for in SD or GR.

$AvgATDO3_{VB}$ values derived from 30 virtual lakes are presented as isolines on a coordinate system of lake geometry ratio GR versus Secchi depth (SD) (Figs. 14 and 19). GR and SD appear to be sufficient to represent essential features of different lake types, GR characterizes the potential for stratification and mixing dynamics, and SD characterizes transparency, but also trophic state as a surrogate, at least in most Minnesota lakes. Lake turbidity from suspended inorganic sediment is relatively rare in Minnesota, and total phosphorus or chlorophyll-*a* in most Minnesota lakes are well correlated with SD. Monthly variations in these parameters follow well-established generic patterns in Minnesota lakes.

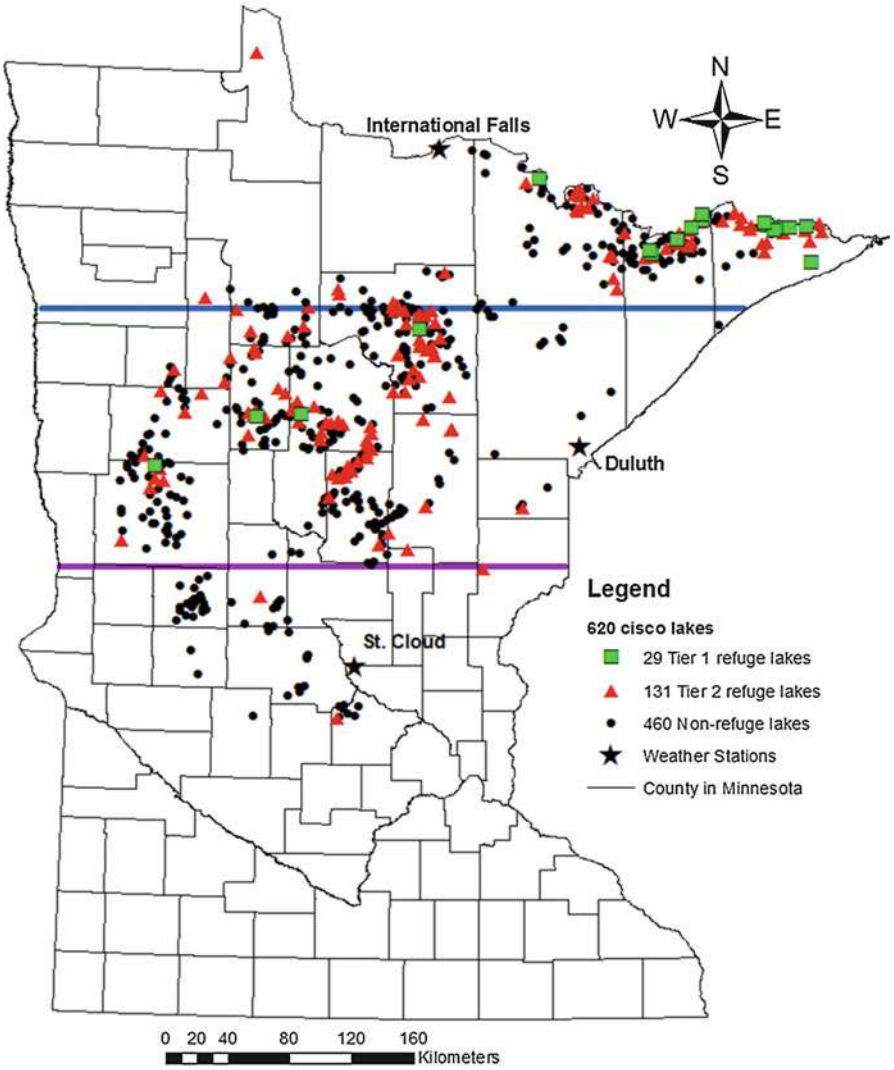

Fig. 21 Geographic distribution of tier 1 and tier 2 cisco refuge lakes and tier 3 non-refuge cisco lakes simulated for the future climate scenario MIROC 3.2. Lakes are grouped by latitude into 166 northern, 399 mid-latitude, and 55 southern cisco lakes. The boundary limits for tier 1 and tier 2 refuge lakes were contour lines of $\text{AvgATDO3}_{\text{VB}} = 11\ ^{\circ}\text{C}$ and 17 °C, respectively. Variable benchmark periods were used, and principal weather stations (International Falls, Duluth, and St. Cloud) were associated by latitude with each lake group (modified from Jiang et al. 2012)

The partitioning of cisco lakes into tiers was useful for distinguishing potential refuge value for cisco and possibly other species after climate warming. Because the TDO3 limit of 11 °C corresponds to the upper central niche border for lake whitefish (Jacobson et al. 2010), the tier 1 refuge lakes selected from the study are useful for

the management of lake whitefish. The partitioning of the cisco lakes into tiers 1, 2, and 3 was guided by TDO3 temperatures of 11 °C and 17 °C. These boundary lines are considered fairly stringent because the upper ultimate lethal temperature of young ciscoes was determined in a laboratory study by Edsall and Colby (1970) to be 26 °C, and mortality of adults begins at 22 °C at 3 mg/l of oxygen based on the analysis of observed temperature and DO profiles in 23 Minnesota lakes (Jacobson et al. 2008). Median values of $\max T_{DO3}$ were 18.2 °C for lakes with cisco populations (Jacobson et al. 2010).

Tier 1 and tier 2 cisco lakes identified for past climate conditions (1961–2008) may be called viable cisco lakes where cisco is capable of living, growing, and reproducing under favorable conditions. Using fixed and variable benchmark methods, 137 (22 %, Table 8) and 114 (18 %, Table 9), respectively, of the current 620 lakes with known cisco populations were identified by the simulations as non-refuge lakes under past climate conditions (1962–2008) and represent marginal cisco habitat. This does not mean that these 137 or 114 cisco lakes cannot support cisco habitat at all. Cisco can still persist in lakes with TDO3 values greater than 17 °C but at a reduced probability of occurrence in this marginal habitat (Jacobson et al. 2010). Frey (1955) postulated that young ciscoes are more tolerant of high temperatures and low DO concentrations than the larger and older ciscoes; they can survive through hot summers in a thin stratum above the thermocline in stratified deep lakes. Therefore, summer mortality events primarily affect adult cisco (see Fig. 2). Cisco populations can persist in lakes with multiple years of mortality as long as some juveniles remain in the lakes. Recruitment of juveniles is therefore as important to cisco's survival as the duration of exposure to lethal conditions, but recruitment is not included in current simulations and projections. At the same time, the shallow lakes that are projected to have cisco kill every year with continuous lethal conditions up to 94 days (Fig. 11) under the future climate scenario are most likely not able to sustain cisco habitat at any life stage.

For the selection of refuge lakes, lakes were divided into three categories (tiers) using only two TDO3 isotherms (11 °C and 17 °C) as contour lines (Figs. 16 and 20). Another approach would be to use more isotherms at finer increments to rank each lake according to where it is located between TDO3 contour lines. To do this, 620 cisco lakes in Minnesota were assembled in narrow (2 °C and 1 °C) bands of TDO3 values (Fang et al. 2010b). Names and locations of lakes in each band were tabulated, and lakes with the lowest TDO3 values were placed on top of the list and were presumed to be the best candidates for cisco refuge lakes, because low TDO3 values are presumed to reflect the least stress on adult cisco.

Projected changes in the multiyear average TDO3 (i.e., AvgATDO3_{FB}) between future (CGCM 3.1 and MIRCO 3.2) and past climate conditions have mean values ranging from 2.58 °C to 2.93 °C with model input from three weather stations in Minnesota (maximum differences up to 6.51 °C). The potential impact of climate change on fish habitat is inevitable. Using fixed and variable benchmark period methods (Fang et al. 2012b; Jiang et al. 2012), 67 % and 74 % of cisco lakes projected to be non-refuge lakes are similar to those of a study (using a different methodology) of about 170 cisco lakes in Wisconsin (Sharma et al. 2011) which was

summarized as "By 2100, 30–70 % of Cisco populations could be extirpated in Wisconsin due to climate change, Cisco are much more at risk due to climate change rather than interactions with exotic species."

The fixed benchmark (FB) period is a very good average for many lakes, but may not fit some individual lakes. In a given year, ATDO3 in the FB period can be different from the highest ATDO3 over the VB period. There were moderate differences in the number of refuge lakes obtained using FB and VB periods with identical TDO3 isotherms (11 °C and 17 °C) as boundary lines. When VB periods were used, 34 (past), 64 (CGCM 3.1), and 74 (MIROC 3.2) fewer refuge lakes were identified than with an FB period by comparing results between Tables 8 and 9.

Management Strategies of Cisco Refuge Lakes

The identification of cisco refuge lakes (Fang et al. 2010b) has formed the basis of a significant conservation effort in Minnesota directed at protecting these important lakes (Jacobson et al. 2013). Specifically, the good water quality that is critical for the ability of these lakes to provide cold, oxygenated water in the future will need to be protected. Threats to water quality include urban development and conversion of forest lands to agriculture in the watersheds of these lakes. Jacobson et al. (2013) identified catchments most at risk to some of these land-use changes and developed a prioritization system for targeting protection efforts toward those catchments. Since these lakes lie primarily in the forested region of Minnesota, the primary goal of these lake protection efforts is to keep forested lands in the watersheds of these lakes forested. Conservation tools such as private forest conservation easements, forest land acquisition, and zoning regulations are being used or considered in those targeted watersheds. These efforts will use watershed protection goals suggested by Cross and Jacobson (2013) of maintaining at least 75 % of a lake's watershed in a forested state. Protection of these watersheds will be critical for the lakes to operate as refuges in climate-warmed Minnesota.

Future Directions

Distributions of total number of years with cisco lethal days and average cisco kill days for the years with lethal conditions under MIROC 3.2 (Figs. 7 and 8) were not used to divide 385 medium-depth and 221 deep cisco lakes into tier 1 to tier 3 refuge lakes as it was done using TDO3 (Fang et al. 2012b; Jiang et al. 2012). Several good-growth parameters, e.g., the good-growth period, good-growth habitat area (GGHA), and good-growth habitat volume fraction (GGHVF), were derived when the fish model was run for these lakes but have not been analyzed. These good-growth habitat parameters used in previous studies (Stefan et al. 1996, 2001; Fang et al. 2004a, b) may be used to classify cisco lakes into tiered refuge lakes in a future study.

Jacobson et al. (2010) developed central species response borders of TDO3 derived from measured T and DO profiles for lake trout, lake whitefish, and burbot. The method developed to rank the quality of fish habitat for cisco in Minnesota lakes was presented as a flowchart in Fig. 3 and can be applied for other cold-water fish species and at other geographic locations. The next future study could be to use the same methodology developed in this study to identify refuge lakes for lake trout in Minnesota. Lake trout was present in lakes with the lowest values of $maxT_{DO3}$ and represented by central species response borders of $maxT_{DO3}$ from 4.0 °C to 5.1 °C (Jacobson et al. 2010). It will be interesting and valuable to use the method to identify cisco refuge lakes in Wisconsin, which can be directly compared with results by Sharma et al. (2011). Requirements for the study include a database of cisco lakes in Wisconsin, observed T and DO profiles in several cisco lakes for further model validation, and historical weather data at representative locations in Wisconsin.

Although variable benchmarks perform better to quantify the maximum oxythermal stress to a fish species, fixed benchmarks are still valuable because the niche model developed by Jacobson et al. (2010), which was used to identify refuge lakes, was based on them (including the 11 and 17° tier thresholds). To fully use a variable benchmark model, it is necessary to redo the niche model with variable benchmark periods in the future research.

The increase in the number of annual lethal days in different lake types is projected under one future climate scenario (MIROC 3.2), and the selection of refuge lakes was performed under two future climate scenarios (CGCM 3.1 and MIROC 3.2). Many hydrologic studies conducted on the impacts of climate warming or climate change on watersheds and aquatic systems used an assemblage of GCMs. Future studies on cisco habitat projections should include more GCM future climate scenarios from most recent IPCC studies. Overall, the projection of fish kill and fish growth in lakes is still a challenging and growing research area and needs further model validation with more field observations of fish species in different lakes.

Abstract

Changes in the atmospheric composition due to anthropogenic increase in greenhouse gases lead to changes in the radiative balance of the earth and consequent alterations in temperature, general wind circulation pattern, and weather patterns. The aftereffects of these changes are likely to manifest as major climate changes over the surface of the earth. Numerical models of the atmosphere have proved to be a very good tool in the assessment of the effect of increasing greenhouse gases on the earth's climate. These models predicted an increase in the earth's surface temperature during this century because of accumulation of greenhouse gases in the atmosphere. The effect of buildup of the sulfate aerosols in the atmosphere and its ability to increase the albedo of the atmospheric system, thereby cooling the atmosphere, has been recognized recently by the Intergovernmental Panel on Climate Change.

Agricultural activities are very sensitive to climate conditions. Agricultural decision-makers either are at the mercy of these natural factors or try to be benefit from them. The following decisions should not be made without knowing the elements of climate change.

Through the Decision Support System for Agrotechnology Transfer (DSSAT), the study for rice crop was carried out in order to define the impact of climate change on yield production in addition to flowering date, physiological maturity, and biomass at harvest.

The current work contains detailed analysis and investigation of possible changes up to 2017 (Egyptian strategy planning year). The results imply quiet remarkable changes in all agriculture parameters for this period, and sensitivity to climate variations was fairly detected.

Introduction

The Earth has warmed by 0.7 °C on average since 1900 (Jones and Moberg 2003). Most of the warming since 1950 is due to human activities that have increased greenhouse gases (IPCC 2001). There has been an increase in heat waves, fewer frosts, warming of the lower atmosphere and upper ocean, retreat of glaciers and sea ice, an average rise in global sea level of approximately 17 cm, and increased heavy rainfall in many regions (IPCC 2001; Alexander et al. 2006). Many species of plants and animals have changed their location or behavior in ways that provide further evidence of global warming (Hughes et al. 2003). To estimate future climate change, scientists have developed greenhouse gas and aerosol emission scenarios for the twenty-first century. These are not predictions of what will actually happen. They allow analysis of "what if?" questions based on various assumptions about human behavior, economic growth, and technological change (Church and White 2006). Computer models of the climate system are the best tools available for

simulating climate variability and change. These models include representations of the atmosphere, oceans, biosphere, and polar regions (Vinnikov et al. 2006). Confidence in the reliability of these models for climate projections has also improved (IPCC 2001), based on tests of the ability to simulate the present average climate, including the annual cycle of seasonal changes, year-to-year variability, extreme events such as storms and heat waves, climates from thousands of years ago, and observed climate trends in the recent past. The Intergovernmental Panel on Climate Change (IPCC) attributes most of the global warming observed over the last 50 years to greenhouse gases released by human activities. To estimate future climate change, the IPCC prepared 40 greenhouse gas and sulfate aerosol emission scenarios for the twenty- first century that combine a variety of assumptions about demographic, economic, and technological driving forces likely to influence such emissions in the future.

Crop simulation models can be used to assess the likely impact of climate change on grain yield and yield variability. These crop models must accurately predict several key characteristics over a wide range of climatic conditions, such as timing of flowering and physiological maturity, through correct descriptions of phenological responses to temperature and day length. Furthermore, accumulation of yield needs to be predicted by accurately predicting the development and loss of leaf area and, therefore, a crop's ability to intercept radiation, accumulate biomass, and partition it to harvestable parts such as grain.

Climate change urgently needs to be assessed at the level of the farm so that poor and vulnerable farmers dependent on agriculture can be appropriately targeted in research and development activities to alleviate poverty (Jones and Throntonb 2003). Assessing the possible impact of climate change on production risks is therefore necessary to help decision-makers and stakeholders to identify and implement suitable measures of adaptation (Torriani et al. 2007).

Climate Change Scenarios

In this work, the HadCM3 which is a coupled Atmosphere-Ocean General Circulation Model (AOGCM) developed at the Hadley Centre for Climate Prediction and Research (United Kingdom) was used (Gordon et al. 2000; Pope et al. 2000) and considered as significant and more sophisticated than earlier versions (Hulme and Jenkins 1998). This model has a spatial resolution of 2.50 × 3.75 (latitude by longitude). HadCM3 provides information about climate change over the entire world during the twenty-first century and presents information about three times slices: 2020s, 2050s, and 2080s. In order to provide information on possible changes in the world climate, the climate change models are forced to consider future scenarios. The IPCC (Nakicenovic et al. 2000) has developed emission scenarios known as Special Report on Emission Scenarios (SRES). The four

SRES scenarios combined two sets of divergent tendencies: one set varying between strong economic values and strong environmental values and the other set between increasing globalization and increasing regionalization (IPCC-TGCIA 1999). Two climate change scenarios were considered in this study: A2 and B2. These selected two scenarios consider a rise in global mean temperature by 3.09 °C and 2.16 °C, respectively; CO_2 concentration will be 834 and 601 ppm, respectively; and global mean sea level will rise by 62 and 52 cm, respectively. As the resolution of the model is too big, simple interpolation techniques of these percentages have been applied to fit the station site. Data were downloaded in GRIB format (GRIdded Binary is an international, public, binary format for the efficient storage of meteorological/oceanographic variables) from the Intergovernmental Panel on Climate Change (IPCC) Data Distribution Centre Web site. The GRBCONV program was used to convert the data files from GRIB format to the more conventional ASCII (American Standard Code for Information Interchange). The download site does not offer the option to subset the data based on an area of interest, so a custom program was used to extract the data for the region of interest. HadCM3 model (Hadley Centre for Climate Prediction and Research, UK) variables were monthly precipitation, solar radiation, and minimum and maximum temperatures. A2 and B2 climate change scenarios were used to run the CropSyst model to predict wheat yield for the chosen climate period. The simplest method of downscaling is to interpolate the change fields to the site or region of interest by using Cartesian geometry and geostatistics.

Crop Environment Resource Synthesis (CERES-RICE) Model

The CERES-RICE is one of the family members of the Decision Support System for Agrotechnology Transfer (DSSAT) system. The DSSAT system is a set of crop models, utility programs, and data sets for facilitating technology testing through simulation. The CERES-RICE simulates the growth, development, and yield of a component crop growing on a uniform area of land under prescribed or simulated management as well as the changes in soil water, carbon (C), and nitrate (N) that take place under the cropping system over time. The model considers the effects of weather, genetics, soil water, soil C and N, and management in single or multiple seasons and in crop rotations at any location where minimum inputs are provided. Hunt and Boote (1994) provided the minimum data sets for operation, calibration, and validation either of rice model, grown singly or in sequence.

Rice Production in Egypt

Rice production occurs mostly in the lower valley of the Nile River in about 10 % of the agricultural area of Egypt. Egypt is the largest rice producer in the Near East region (Sabaa and Sharaf 2000).

According to the Egyptian agriculture calendar, rice is a summer crop that is mainly grown in the Nile Delta. Rice areas have gradually increased since the construction of the countrywide irrigation network in the nineteenth century. Almost 50 % of the amount of water diverted to rice fields is consumed in terms of evapotranspiration, and the rest is lost via percolation (EWUP 1983).

Farmers like planting rice because it brings high profits. Since rice cannot be grown in all areas of Egypt, some areas have a rice surplus and others have a rice deficit. Today Egypt is a rice exporter too (FAO 2004).

Effect of Climate Change on Rice Production

The impact of climate change on rice yields differs from scientist to scientist because of the model and the scenario used. Leemans and Solomon (1993) predicted an 11 % increase using simple crop models. On the other hand, Rosenzweig and Parry (1994) found that rice yields would reduce by 2–4 %.

Boote et al. (1994), Horie et al. (1996, 1997), and Matthews et al. (1995) have assessed the impacts of high temperature and carbon dioxide on both growth and rice production. They have found that adoption of high-temperature-tolerant cultivars is considered as one of the most effective way to counteract a danger or threat of climate change to keep high productivity and stability of rice under the anticipated climate in temperate regions.

Conroy et al. (1994) proved that crop responses to a change in temperature depend on the temperature optima of photosynthesis, growth, and yield, all of which may differ. Baker and Allen (1993) found that small increase in temperature can dramatically reduce grain yield of rice. Increasing temperature reduced photosynthetic water use efficiency of rice canopy by increasing water loss (Jones et al. 1985; Baker and Allen 1993).

Kimball et al. (2002) found that rice (*Oryza sativa* L.) is generally less responsive to elevated CO_2 compared to other crop species, while variation exists in the degree of enhancement by elevated CO_2 among previous studies of rice, ranging from 4 % up to 44 % (Baker and Allen 1993; Nakagawa and Horie 2000; Kim et al. 2003).

Baker (2004) reported that at the 28 °C temperature treatment, CO_2 enrichment increased grain yield by 46–71 % among the three cultivars. Yamakawa et al. (2004) found that the dry matter of rice has increased by an elevated CO_2.

Data and Methodology

This experiment has been carried out at Sakha, latitude 31.12° and longitude 30.95°, Kafr el-Sheikh Governorate, Egypt, during two growing seasons of 1998 and 1999 and published by Sedeek (2001). Eleven rice cultivars (Giza 171, Giza 172, Giza 176, Giza 177, Giza 178, Giza 181, Sakha 101, Sakha 102, Sakha 103, Sakha 104, and Egyptian Yasmin) have been used in this experiment.

Table 1 Pedigree of the different cultivars of rice used in this study (Field Crops Research Institute, ARC, Giza, Egypt)

Cultivars	Pedigree
Giza 171	Nahda/Calady40
