there is not adequate information regarding other selection criteria. Impregnated mesoporous silica sorbents showed improved capacity in the presence of water vapor, whereas grafted silica showed good thermal stability at high temperature (<473 K). However, a considerable amount of time is required to regenerate these sorbents via thermal swing cycling, and it is found that SO_2 has an adverse effect on CO_2 removal, and its removal is required prior to CO_2 adsorption. Moreover, all of the identified sorbents are in the early development stage and require further investigation.

Technical Challenges and Pilot Plant Developments

Technical Challenges

Compared to conventional aqueous amine absorption/regeneration processes, an efficient and cost-effective sorption technique using a solid sorbent could produce certain technical and economic advantages. It appears that there are some potentially attractive solid sorbents that exhibit better CO_2 adsorption capacities and lower regeneration energy than conventional aqueous amine-based absorbents on the basis of the ongoing both experimental and theoretical studies. However, the efficient use of the solid sorbent in a particular contactor type is a key point and will ultimately determine whether the sorbent-based technology can actually be economical for CO_2 capture. The knowledge of key engineering data such as equilibrium CO_2 adsorption capacity under given conditions of pressure, temperature, and concentration, kinetic data for adsorption and desorption, mass transfer and diffusional effects, effects of moisture, effects of flue gas contaminants, the heat of adsorption and desorption, particle/bed characteristics of solid sorbents, etc. are essential for candidate sorbents being developed and for the design of CO_2 capture system. All of these characteristics are not available up to now. Process design and economic analysis are limited because of the lack of sufficient data on solid sorbent performance in various contactor configurations.

The process technologies frequently explored for a continuous CO_2 capture process are the cyclic processes, such as PSA, VSA, and TSA. Ho et al. (2008a) investigated the economic feasibility of PSA for CO_2 capture from power plant flue gas, using zeolite 13X with a working capacity of 2.2 mmol/g and a CO_2/N_2 selectivity of 54. They reported that the use of vacuum regeneration reduces the capture cost from US$57 to US$51 per ton of CO_2 captured. This cost is comparable to the cost of MEA absorption (Ho et al. 2008b). On the basis of experimental data and economic analysis on VSA process for CO_2 capture from flue gas, Zhang et al. (2008b) found that the operating capture costs vary significantly with process configuration and operating parameters, such as feed gas temperature, feed concentration, and evacuation pressure, which have significant influence on power consumption and CO_2 capture cost. For example, for CO_2 capture from a 500 MW coal-fired power plant flue gas stream using zeolite 13X sorbents, the estimated operating capture costs for a six-step VSA cycle without purge is

US$12–$35 per ton CO_2 captured, and the costs for a nine-step VSA cycle with purge are US$18–$32 per ton CO_2 captured.

The bed configuration for sorbent system also has strongly influence on techno-economic analysis. The possible configurations for contacting CO_2 streams with solid sorbents are fixed bed, fluidized bed, and moving bed. Fluidized-bed contactors is likely to be superior to the fixed-bed adsorber, due to some inherent advantages, such as (i) excellent gas–solid contact due to vigorous agitation of sorbent particles, (ii) minimum diffusional resistance, (iii) uniformity of temperature, and (iv) faster overall kinetics over fixed-bed contactors. For the sorbents that withstand fluidized-bed conditions, their operation shortcomings in fixed beds introduce can be overcome. Circulating-bed and fast-fluidized-bed, transport-bed, and other innovative contactor configurations will be the subject of future search for an optimal contactor configuration to meet the design constraints of CO_2 capture. Moreover, there is considerable scope for process optimization, because of the variety of cycle configurations, process conditions, and adsorbent types available (Zhang et al. 2008b).

Pilot Plant Developments

A few pilot-scale demonstrations are investigating the effectiveness of low-temperature adsorbents for CO_2 adsorption. One of the first pilot plant projects was the CO2CRC H3 project (Qader et al. 2011) lignite-fired power plant based at International Power's Hazelwood Power Station, which was commissioned in 2009 at Latrobe Valley, Victoria, Australia, and completed in 2011. The performance of CO_2 adsorbents was investigated with a three-bed multilayered VSA process at high humidity levels in the presence of SO_x and NO_x. Multilayered adsorbents were used to remove the water firstly and subsequently SO_x/NO_x from the flue gas. A layer of CO_2-selective sorbents was then added. A purity of ~71 % and a recovery of ~60 % were achieved after continuous running of the process with a simple six-step cycle (without purge) for a week.

The capture and concentration of CO_2 from a dry flue gas by VSA process has been experimentally demonstrated in a pilot plant by Krishnamurthy (Krishnamurthy et al. 2014). The pilot plant has the provision for using two coupled columns that are each packed with approximately 41 kg of Zeochem zeolite 13X (Fig. 13). With the cycle configuration, CO_2 was concentrated to 95.9 $\pm$ 1 % with a recovery of 86.4 $\pm$ 5.6 %. To enhance the process performance, a four-step cycle with light product pressurization (LPP) using two beds was investigated. This cycle was able to achieve 94.8 $\pm$ 1 % purity and 89.7 $\pm$ 5.6 % recovery. The energy consumptions in the pilot plant experiments were 339–583 $\pm$ 636.7 kWh ton^{-1} CO_2 captured, and they were significantly different from the theoretical power consumptions obtained from isentropic compression calculations. The productivities were 0.87 ~1.4 $\pm$ 0.07 ton CO_2 m^{-3} adsorbent day^{-1}.

CO_2 capture from the real flue gas was performed in an existing coal-fired power plant by Li's group (Fig. 14) (Liu et al. 2012; Wang et al. 2013a, b). The pilot-scale

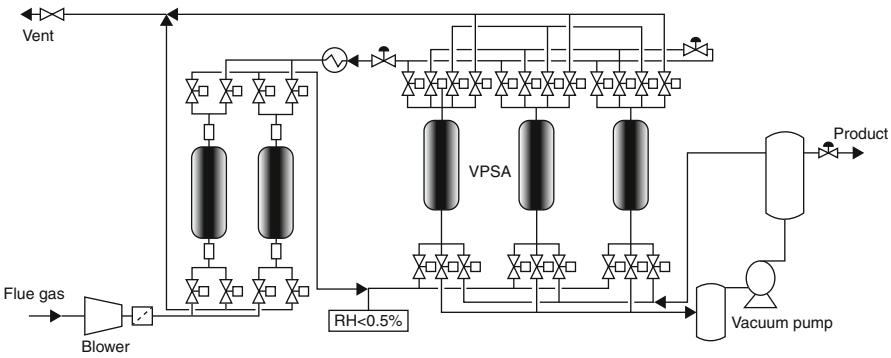

Fig. 14 Schematic diagram of pilot-scale carbon capture plant consisting of a dehumidifying unit and a CO_2 capture unit

CO_2 capture plant consisted of a CO_2 capture unit and a dehumidifying unit. The dehumidifying unit received the desulfurized flue gas from the power plant at a controlled flow rate and supplied the dehumidified flue gas (15.5–16.5 % CO_2, less than 0.5 % relative humidity) for the CO_2 capture unit. The three-bed eight-step vacuum pressure swing adsorption (VPSA) process was employed in the CO_2 capture unit, where two types of adsorbent materials were tested, zeolite 5A and 13XAPG done. 85–95 % CO_2 is recovered from the flue gas with 73–82 % purity in product gas. With the three-bed eight-step VPSA process CO_2 adsorption, the power consumption of a blower and a vacuum pump is measured onsite as 1.79–2.14 MJ/kg CO_2. However, the actual power consumption of vacuum pump accounts for two third of the total power consumption and is greater than the theoretically predicted value by the conventional adiabatic pump-down calculation.

Inventys claims that their VeloxoTherm^{TM} process can capture CO_2 for US$15/t. The technology involves an intensified TSA process with structured adsorbent and steam regeneration in a rotating adsorbent wheel. ETI announced the award of £20 million funding for a 5 MW project that can be used for a new-build CCGT or retrofitted onto one. The initial stage of the project is lab-scale studies, while the final aim is to have a commercial technology by 2020.

The ATMI/SRI BrightBlack microporous carbon was tested at a coal-fired steam production facility carried out by the University of Toledo in Ohio, USA. The material exceeded the DOE targets of >90 % CO_2 capture with >90 % CO_2 purity during tests with 200 standard l min^{-1} of flue gas. In addition, the column operated for approximately 7000 adsorption/regeneration cycles with no signs of adsorbent degradation and no loss in process or adsorbent performance. The project partners are now looking at scaling up to pilot-scale testing.

Due to the early stages of development, not much information is available currently on the pilot plants; the availability of data on these projects in the future will represent a crucial step toward the deployment of adsorption processes at commercial scale.

Future Directions

Compared to conventional liquid amine processes, solid sorbents for capture CO_2 are advantageous in regeneration energy cutback, corrosion prevention, and cost reduction. However, as discussed previously, solid sorbents also have limitations and challenges to be addressed before they can be applied commercially. The following are three recommendations for further research:

- Synthesis and modification of the potential solid sorbents to enhance the adsorption performance, such as working capacity, selectivity, and multicycle durability
- Comparison of some of the most promising solid sorbents, based on techno-economic assessment of the system including thermal integration
- Performance study of the potential solid sorbents under actual gas conditions using various bed configurations, such as fixed bed, fluidized bed, moving bed, and circulating bed

CO_2 Capture by Membrane

Teruhiko Kai and Shuhong Duan

Contents

Abstract

Among various CO_2-capture technologies, membrane separation is considered as one of the promising solutions because of its energy efficiency and operation simplicity. Many research and development are conducted for the (1) CO_2/N_2 (CO_2 separation from flue gas), (2) CO_2/CH_4 (CO_2 separation from natural gas), and (3) CO_2/H_2 (CO_2 separation from integrated gasification combined cycle (IGCC) processes). In this section, recent research and development of various types of membranes (polymeric membranes, inorganic membranes, ionic liquid membranes, facilitated transport membranes) for these applications are reviewed, as well as future prospects of membrane separation technologies.

Introduction

Carbon dioxide (CO_2) capture and storage (CCS) is generally considered as an option for climate change mitigation. There are three principal pathways to capture CO_2 from large emission sources: (1) CO_2/N_2 (CO_2 separation from flue gas), (2) CO_2/CH_4 (CO_2 separation from natural gas), and (3) CO_2/H_2 (CO_2 separation from integrated gasification combined cycle (IGCC) processes).

For practical application of the CCS technology, cost-effective methods for CO_2 capture are required. Many studies have focused on the development of effective CO_2-capture and CO_2-separation technologies. Among them, membrane separation is one of the promising solutions because of its energy efficiency and operation simplicity.

In the case of CO_2 separation from flue gas, more than half of the cost of membrane separation goes toward powering the vacuum pump to evacuate the permeate side of the membrane. In addition, the costs of the membrane module and piping are high because the pressure ratio between the feed and the permeate side is low, and a large membrane area is needed. Therefore, high CO_2 permeability is more important than high selectivity to reduce the cost of the membrane modules.

On the other hand, in the case of CO_2 separation in IGCC processes, a significant reduction in the CO_2-capture cost is expected via the use of membrane technology, because a vacuum pump is not needed for high-pressure gas separations. In this case, both CO_2 permeability and CO_2/H_2 selectivity are important to separate CO_2 effectively.

A schematic diagram of the IGCC process with membrane separation is shown in Fig. 1. Coal is gasified into synthesis gas and is then converted into H_2 and CO_2 via the water-gas shift reaction. Here, the gas composition is roughly 60 % H_2 and 40 % CO_2 at pressure of 2–4 MPa. Therefore, it is expected that membrane separation can reduce the cost of CO_2 capture from IGCC. However, it is very difficult to separate CO_2 from H_2, which has a smaller molecular size. Therefore, it is very important to develop CO_2-selective membranes with high CO_2/H_2 selectivity. In this section, research and development on CO_2-selective membranes using various types of materials is reviewed.

CO_2-Separation Membrane

Principle of Membrane Gas Separation

The early membrane separations were osmosis described by Nollet in 1748, electroosmosis described by Reuss in 1803, and dialysis described by Graham in 1861. These observations laid the scientific milestone of the beginning of membrane separation (Mulder 1996). Research on membrane gas separation using O_2, N_2, CO_2, CH_4, SO_2, etc. started around 170 years ago. However, the application of membrane gas separation started relatively recently. In 1979, Monsanto Company in the United States developed membrane modules for O_2/N_2 separation

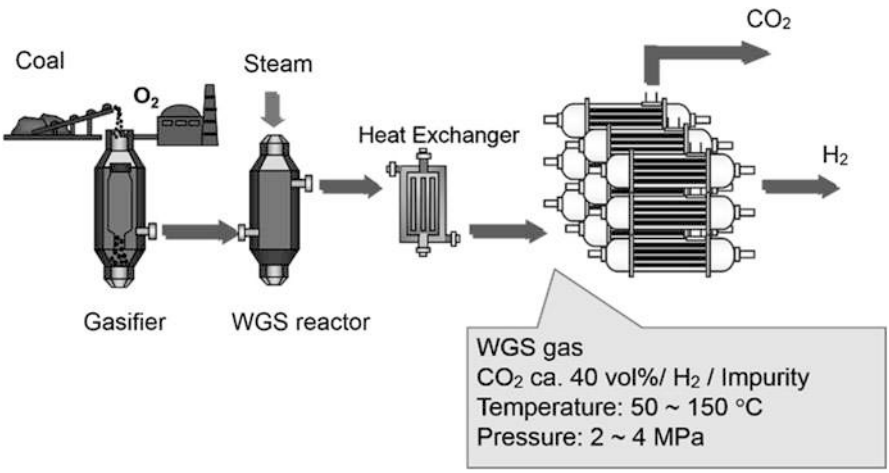

Fig. 1 Schematic diagram of IGCC with CO_2 capture

(Nakagama 1989). Membranes were known to have the potential to separate gas mixtures long before 1960, but the technology to fabricate high-performance membranes and modules economically was lacking. The development of high-flux asymmetric membranes and large-surface-area membrane modules for reverse osmosis applications occurred in the late 1960s and early 1970s. The innovative concept of high-flux asymmetric membranes was reported and prepared by Loeb and Sourirajan in 1961 initially for reverse osmosis and then adapted to gas separation, as shown in Fig. 2 (So et al. 1973). An acetone solution of 20 % (w/v) cellulose acetate was cast on a glass plate and dried for about 2 min for forming the surface dense layer and then immersed in water. Phase separation of water and acetone resulted in pore formation in the inner membrane. Hence, asymmetric membrane with porous layer and skin dense layer was prepared, and high flux was obtained.

Milestones in the development of membrane gas separation are shown in Fig. 3 (Adapted from (Baker 2002; Li et al. 2006; Ismail and David 2001)). It is considered that the first plant with polysulfone hollow fiber membranes for gas separation was performed by Permea PRISM® membranes in 1980 for H_2/N_2 separation. The first plant for CO_2/CH_4 separation with cellulose triacetate membranes was produced by Separex in 1982. The first commercial vapor separation plants were installed by MTR, GKSS, and Nitto Denko in 1988. The largest membrane plant for natural gas processing (CO_2/CH_4 separation) was installed in Pakistan in 1994 with spiral wound modules, which was a clear example of the easy scale-up of membrane technology. LTA zeolite membranes were commercialized by MES for dehydration in 1997. The development of membrane materials was investigated from conventional polymers to nanoporous materials (zeolite, carbon, silica, MOF, TR polymer, etc.).

With the development of industry, separation of carbon dioxide from gas mixture has become very important. CO_2 gas separation can be used for many industrial

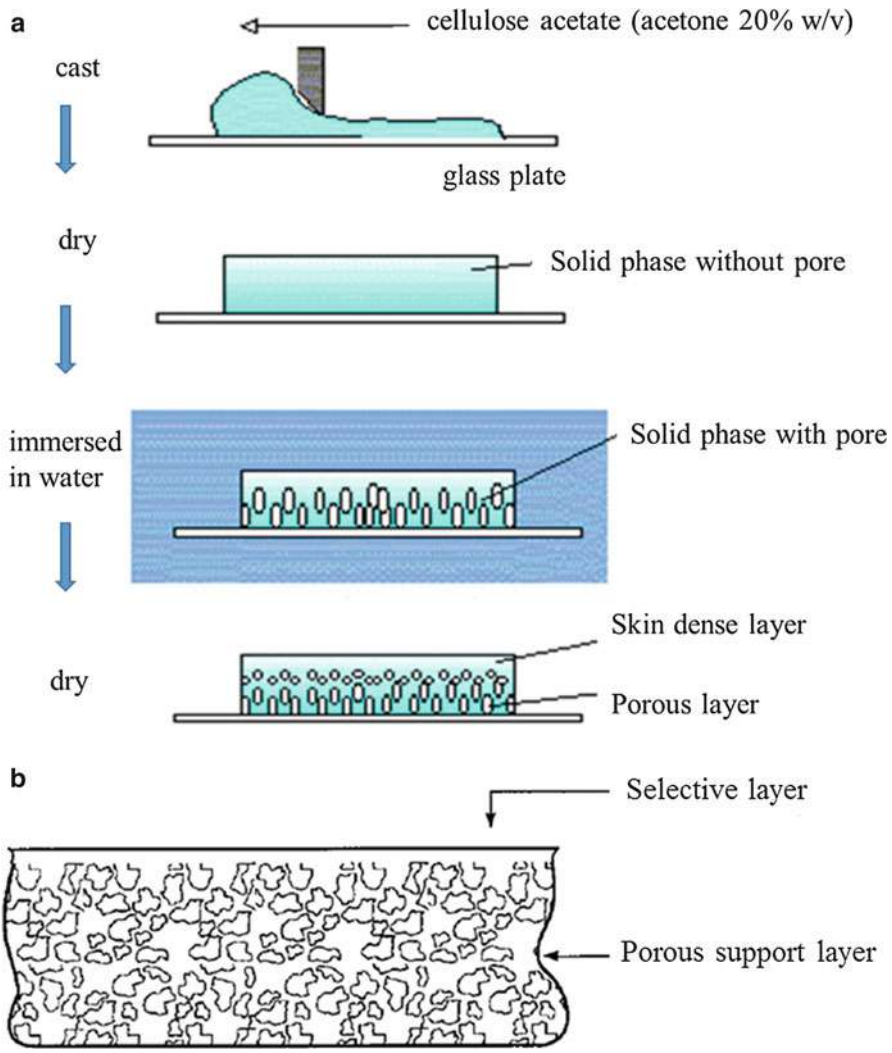

Fig. 2 Diagram of high-flux asymmetric membranes prepared by Loeb and Sourirajan (Preparation of asymmetric 1973). (**a**) Diagram of membrane preparation. (**b**) Loeb and Sourirajan anisotropic phase separation membrane

fields, such as natural gas or land fill gas recovery process, enhanced oil recovery (EOR), upgrading of methane (CO_2/CH_4 separation) generated by the decomposition of biological wastes, and integrated gasification combined cycle (IGCC) processes (CO_2/H_2). And, CO_2 membrane separation will play an important role in CCS.

The membrane can be considered as a permselective barrier or interface between two phases as shown in Fig. 4a. Phase 1 is usually considered as the feed or upstream side phase while phase 2 is considered as the permeate side or downstream side phase. The membrane has the ability to transport one component from

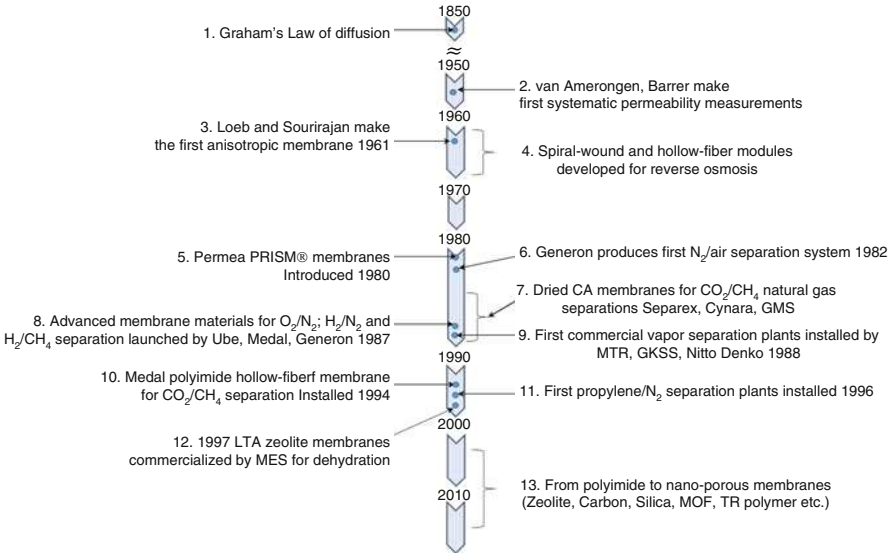

Fig. 3 Milestones in the development of membrane gas separation (Baker 2002; Li et al. 2006; Ismail and David 2001)

the feed mixture more readily than any other component or components because of differences in physical or chemical properties between the membrane and the permeating components. Transport through the membrane takes place as a result of a driving force acting on the components in the feed. In many cases, the permeation rate through the membrane is proportional to the driving force.

The two phases divided by a membrane are different for various membrane separation processes as depicted in Fig. 4b. Driving force can be gradients in the pressure, concentration, and temperature. Membrane separation processes can be classified according to their driving force as in Table 1.

Most of membranes used for gas separation have been nonporous polymer membranes, such as cellulose acetate (Yan 1996), silicone rubber polysulfone (Hao Jihao and Wang Shichang 1998; Ismail and Shilton 1998; Borisov et al. 1997), and polyimide (Li and Teo 1998; Thundyil et al. 1999; Staudt-Bickel and Koros 1999). Recently, microporous inorganic membranes, such as zeolite membranes (Wang et al. 1998; Poshusta et al. 1999; Aoki et al. 1998), nanoporous carbon membranes (Hernandez-Huesca et al. 1999), and ceramic membranes (Paranjape et al. 1998), have also been developed.

Mechanism of membrane gas separation has been proposed depending on the properties of both the permeant and the membranes, as shown in Fig. 5. Different mechanisms may be involved in the transport of gases across a porous membrane included Poiseuille flow, Knudsen diffusion, and the molecular sieve effect as shown in Fig. 5(1). When membrane has pore sizes much larger than the dimension of gas molecules, Poiseuille flow takes place. Knudsen diffusion is the predominant transport mechanism in small pores at low pressures and high

temperatures. When membrane has pore sizes close to the dimension of gas molecules, the molecular sieve will be effective. In some cases, affinity between gas molecules (e.g., CO_2) and membrane materials can play an important role in high separation performance.

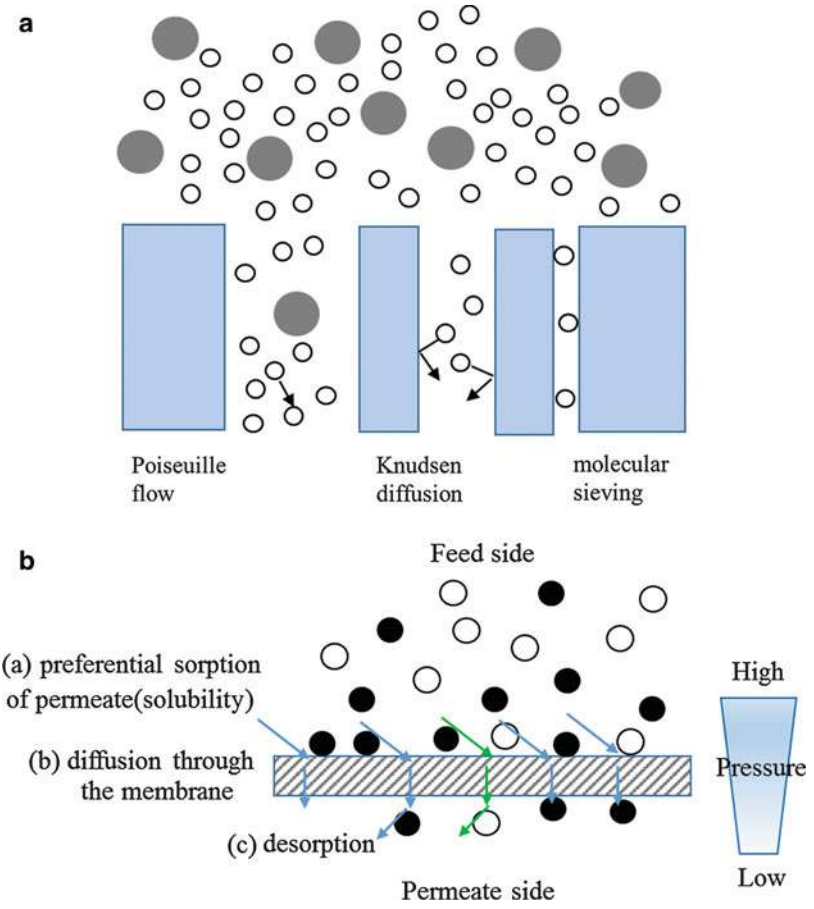

Fig. 5 Mechanism of membrane gas separation. (*1*) Mechanisms for gas flow though a microporous membrane. (2) Mechanisms for gas flow though a nonporous polymeric membrane

The solution–diffusion model is used for transport mechanism for the permeation of gases through nonporous polymeric membranes, as shown in Fig. 5(2). The solution—diffusion model describes the transport of gases through a membrane as a three-step process: (a) preferential sorption of the gas into the membrane at the feed side, (b) diffusion through the membrane due to an applied concentration gradient (e.g., partial pressure), and (c) desorption of the gas from the permeate side of the membrane.

Gas Transport Through Porous Membrane

Up to now a lot of work has been done in modeling the gas transport through membranes including porous and nonporous membranes.

The models of gas permeation through porous membrane began with a comparison of the mean free path of the gas molecules and the mean membrane pore size. If the mean free path of the gas molecules is very small relative to the pore

diameter, gas transport takes place by viscous or Poiseuille flow, and no separation is achieved. The volume flux through these pores may be described by the Hagen–Poiseuille equation (Mulder 1996):

$$J = \frac{\varepsilon r^2 \Delta P}{8\eta\tau l} \tag{1}$$

where J is the volume flux through the pores, ε is the porosity, r is pore radius, ΔP is pressure difference across a membrane of thickness l, η is viscosity, and τ is pore tortuosity.

If the mean free path of the gas molecules is much greater than the pore diameter, gas transport takes place by Knudsen flow, and separation is achieved. Mass transfer may be expressed by the following equation (Mulder 1996):

$$J = \frac{\pi n r^2 D_K \Delta P}{RT\tau l} \tag{2}$$

where n is the number of pores and r is the pore radius. D_k, the Knudsen diffusion coefficient, is given by

$$D_K = 0.66 r \sqrt{\frac{8RT}{\pi M_W}} \tag{3}$$

T and M_w are the temperature and molecular weight, respectively. Equations 2 and 3 show that the flux is proportional to the driving force, i.e., the pressure difference (ΔP), across the membrane and inversely proportional to the ratio of the square root of the molecular weights of the gases.

If the pore size of membrane used in separation is close to the mean free path of the gas molecules, the transport of gases and vapors falls in the transition between Knudsen and Poiseuille flow. Schofield et al. (1990) developed the transport model of gas and vapor for the transition region between Knudsen and Poiseuille flow in a simple and effective semiempirical relationship. The flux was expressed as follows:

$$J = aP^b \Delta P \tag{4}$$

where a is membrane permeation constant and b is 0 for Knudsen diffusion and 1 for Poiseuille flow.

Gas Transport Through Nonporous Polymeric Membrane

The transport of gases through a dense, nonporous membrane is expressed in terms of a solution–diffusion model, as described above (Fig. 5b). The relationship between permeability, solubility, and diffusivity is expressed as follows:

$$\text{Permeability}(P) = \text{Solubility}(S) \times \text{Diffusivity}(D) \tag{5}$$

The ability of a membrane to separate two molecules, A and B, is expressed as the ratio of their permeability (the selectivity, α):

$$\alpha = P_A/P_B \tag{6}$$

For a binary gas mixture, the selectivity can also be determined from a molar concentration of the two gases in feed and permeate:

$$\alpha = y(1-x)/x(1-y) \tag{7}$$

where y is the permeate concentration of the fast permeating gas and x is its feed concentration.

The simplest way to describe the transport of gases and vapors through nonporous membrane is by Fick's first law (Mulder 1996):

$$J = -D\frac{dc}{dx} \tag{8}$$

The flux J of a component through a plane perpendicular to the direction of diffusion is proportional to the concentration gradient dc/dx. The proportionality constant D is called the diffusion coefficient.

If it is assumed that the diffusion coefficient is constant, the change in concentration as a function of distance and time is given by Fick's second law (Mulder 1996):

$$\frac{\partial c}{\partial t} = -D\frac{\partial^2 c}{\partial x^2} \tag{9}$$

Gas Transport Through Facilitated Transport Membrane

Facilitated transport membranes, a type of liquid membranes, were developed for gas separation with high selectivity, especially at low gas partial pressure. Facilitated transport membranes selectively permeate specific gases (e.g., CO_2) by means of a reversible reaction between the gases and the membrane. Other gases such as H_2, N_2, and CH_4 do not react with the membrane and can only permeate by a solution–diffusion mechanism.

The model of gas transport through a carrier membrane is described as follows.

First, component A molecules form a complex AC with the carrier, and AC diffuses through the membrane. Second, dissolved gas A diffuses across the membrane with normal Fickian diffusion (shown in Fig. 6). The total flux of component A will then be the sum of the two contributions, i.e.,

$$J_A = \frac{D_A}{l}\left(C_{A,o} - C_{A,l}\right) + \frac{D_{AC}}{l}\left(C_{AC,o} - C_{AC,l}\right) \tag{10}$$

The first term on the right-hand side of Eq. 10 represents permeant diffusion according to Fick's law, where D_A is the diffusion coefficient of the uncomplexed

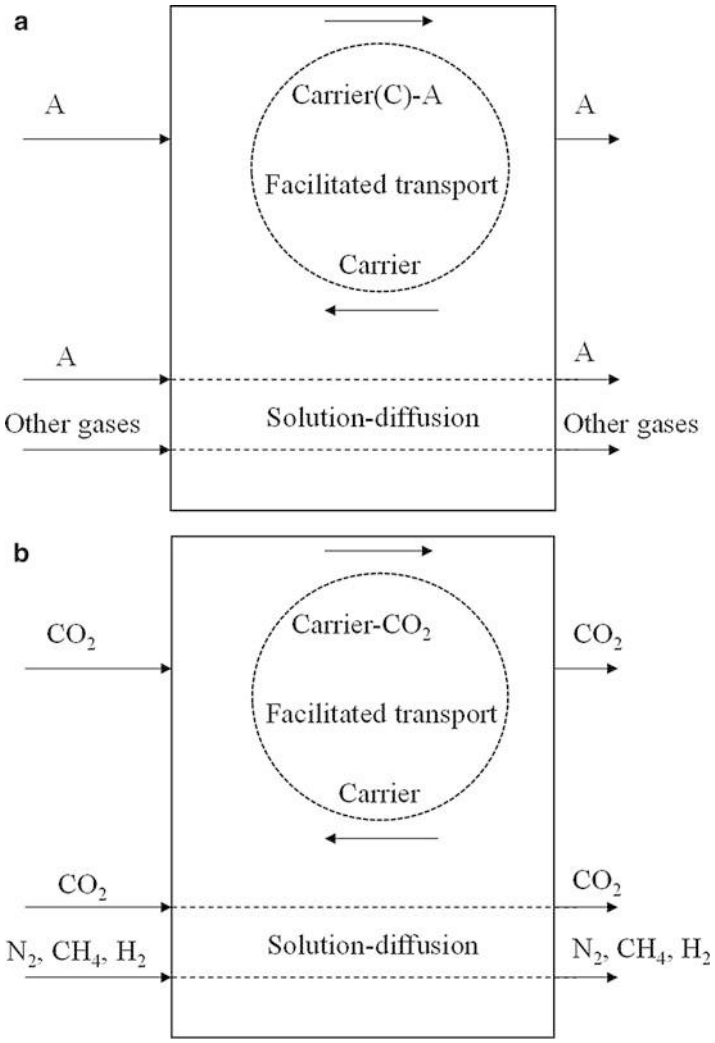

Fig. 6 The mechanism of a facilitated transport membrane. (**a**) The scheme of a facilitated transport membrane. (**b**) The scheme of a facilitated transport membrane for CO_2

component inside the liquid membrane, while $C_{A,o}$ is the concentration of component A just inside the liquid membrane at the feed side and is equal to the solubility of the liquid of A when thermodynamic equilibrium occurs at the interface. The second term represents carrier-mediated diffusion with the flux being proportional to the driving force, which in this case is the concentration difference of complex across the liquid membrane. D_{AC} is the diffusion coefficient of the complex, and $C_{AC,o}$ is the concentration of the complex at the feed side. The following limiting cases can be observed:

1. $C_{A,o} \gg C_{AC,o}$
   When the concentration of the complex *AC* is much lower than the concentration of *A*, the first term, i.e., Fickian diffusion, is rate determining.
2. $C_{A,o} \ll C_{AC,o}$
   When the concentration of the complex *AC* is much greater than the concentration of *A*, the second term, i.e., diffusion of the complex, is rate determining.
3. $C_{A,o} \approx C_{AC,o}$
   When the concentration of the complex *AC* is close to the concentration of *A*, both Fickian diffusion and the diffusion of the complex are rate determining.

Facilitated transport membranes for CO_2 separation were originally prepared by impregnating pores of microporous support membranes or polymer matrices with carrier solutions such as amines and alkali metal carbonates, which have chemical affinity to CO_2. Figure 6b shows the conceptual diagram of CO_2-facilitated transport membranes (Matsuyama et al. 1996). As shown in Fig. 6b, CO_2 carrier incorporated membrane can react selectively and reversibly with CO_2. The CO_2 permeation rate can be facilitated because CO_2 carrier of the reaction product can transport through the membrane, in addition to CO_2 transport membrane of physical solution–diffusion mechanism. On the other hand, other gases, such as N_2, CH_4, and H_2, transport through the membrane only by solution–diffusion mechanism. As a result, the CO_2 selectivity of facilitated transport membranes can be extremely high at low CO_2 partial pressures.

If amine is used as CO_2 carrier, the reaction of carrier and CO_2 is expressed as follows:

$$2CO_2 + 2RNH_2 + H_2O \rightleftharpoons RHNCOOH + RNH_3^+ + HCO_3^- \tag{11}$$

The weak basic amino group will initiate the reaction. However, considering that amino groups are not consumed during the reversible reactions, they are taking the role of catalysts for the reversible CO_2 hydration reactions; the final reactions can therefore be demonstrated with Eq. 12:

$$H_2O + CO_2 \overset{+NH_2}{\rightleftharpoons} H^+ + HCO_3^- \tag{12}$$

It is suggested that the high CO_2 selectivity and permeability can be obtained by the reversible reaction above.

An Overview in the Development of CO_2 Membrane Separation Material

Polymeric Membranes

Many studies have reported CO_2-selective polymer membranes for the separation of CO_2/CH_4 and CO_2/N_2 gas mixtures. On the other hand, there are comparatively few polymeric membranes that can be utilized for the selective recovery of CO_2

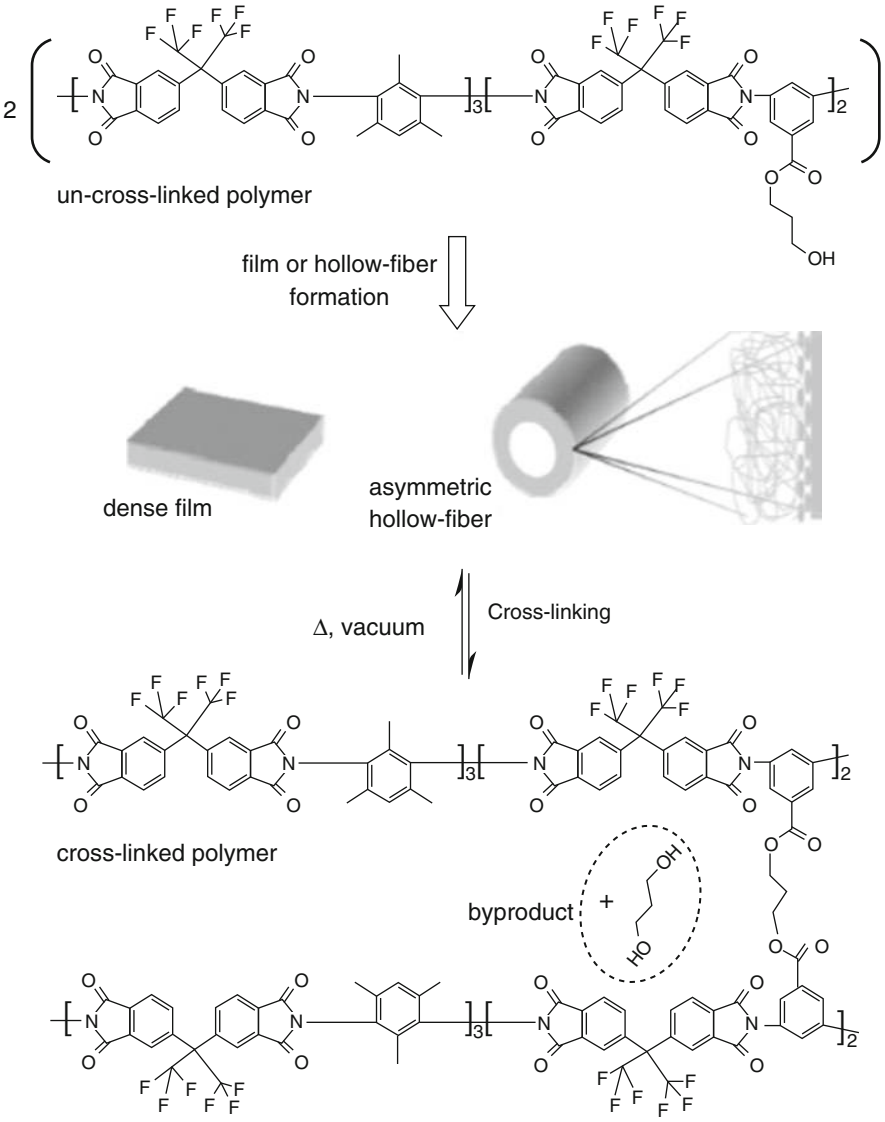

Fig. 7 Illustration showing the cross-linked polyimide (propane-diol monoesterified) membrane formation (Omole et al. 2010)

over H_2. Polymeric membranes made from glassy polymers such as cellulose acetate and polyimide have exhibited practical use in selective CO_2 separation from CO_2/CH_4 gas mixtures. However, CO_2/CH4 separation greatly decreases under high CO_2 partial pressures due to CO_2-induced plasticization. Koros et al. reported that cross-linked polyimide membranes exhibited enhanced resistance to CO_2 plasticization, as shown in Figs. 7 and 8 (Omole et al. 2010).

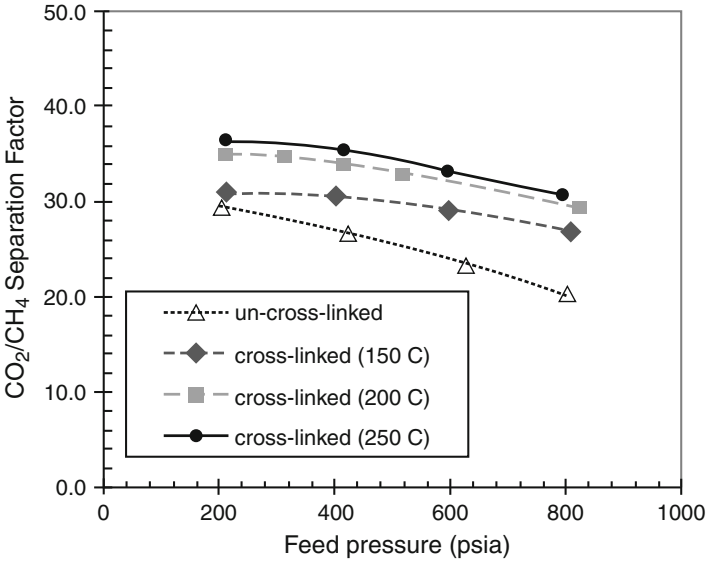

Fig. 8 Effect of cross-linking temperature on CO_2/CH_4 separation factor (Omole et al. 2010)

The structure of polyimide consisted of the following three monomer units: (1) 4, 4′-(hexafluoroisopropylidene) diphthalic anhydride (6FDA), (2) 2,4,6-trimethyl-1,3-diaminobenzene (DAM), and (3) 3,5-diaminobenzoic acid (DABA), in the ratio 5:3:2. The DABA groups were used as sites for cross-linking at 150, 200, and 250 °C for 2 h under vacuum, as shown in Fig. 2. The effect of cross-linking temperature on CO_2/CH_4 separation factor using a mixed-gas feed with 50 % CO_2 was shown in Fig. 3. 200 and 250 °C cross-linked fibers showed higher selectivities than the un-cross-linked and 150 °C cross-linked counterparts. Due to scale-up considerations for using lower cost conventional ovens, lower temperatures are referred commercially. Considering these aspects, 200 °C cross-linking temperature would be useful to pursue.

Robeson reported that there was a trade-off relationship between separation factor and the gas permeability for polymeric membranes. This upper-bound relationship for CO_2/CH_4 is shown in Fig. 9 (Robeson 2008). In recent years, the development of new membrane materials has been studied to produce both high permeability and high selectivity. Among of them, thermally rearranged polymers (TR polymers) are a novel polymer material in which the molecular sizes of the interchains are controlled by heat treatment. The outstanding performance of TR polymer membrane results from largely unique cavity formation with the size of angstrom order during thermal molecular rearrangement (Park et al. 2007). In the case of TR polymer, free-volume structure and distribution are suitable for gas transport (formation of cavity with size, distribution, and shape for a preferred CO_2 transport) in contrast with conventional polymers. For comparative investigation, mixed-gas separation of CO_2/CH_4 by TR polymer and carbon molecular sieve

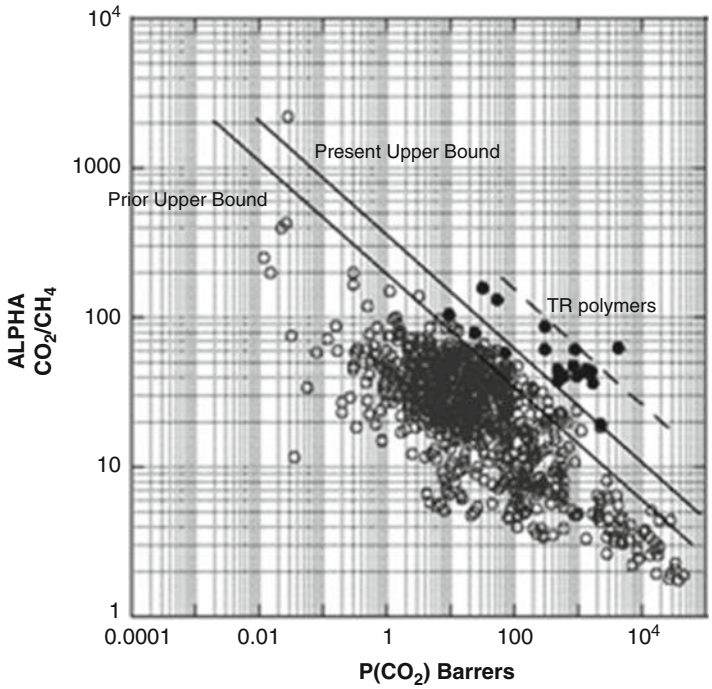

Fig. 9 Upper-bound correlation for CO_2/CH_4 separation (Robeson 2008)

membranes derived from a polyimide of intrinsic micro porosity was reported. High CO_2/CH_4 separations by TR polymer membranes were maintained under high pressures because of its high free volume and enhanced resistance to plasticization (Swaidan et al. 2013). Chung et al. reported that thickness, durability, and plasticization of membrane with TR polymer from ortho-functional polyimide based on 2,2′-bis-(3,4-dicarboxyphenyl) hexafluoropropane dianhydride (6FDA) and 3,3-dihydroxy-4,4-diamino-biphenyl (HAB) for CO_2 permeability was studied. Long-term exposure of the TR films to CO_2 showed that the CO_2 permeability of the thick TR films (15–20 μm) did not show significant decline at 32 atm for over 500 h (Wang et al. 2014). Lee et al. reported on physical properties, cavity size, and transport behavior of TR-PBO membranes by precursor hydroxypolyimide (Calle et al. 2013). Freeman et al. investigated on TR poly(benzoxazole)/polyimide-blended membranes for CO_2/CH_4 separation and showed that blending a-hydroxy-polyimides with non-TR polyimides was a feasible strategy to produce films with improved mechanical strength that retain the high gas separation performance of the TR polymer alone (Scholes et al. 2014a, b). It was also reported that MOP (microporous organic polymer) membranes with high affinity to CO_2 displayed excellent CO_2 separation, the same as TR polymer (Du et al. 2011; Xu and Hedin 2014). In addition, the directions for new membrane material design have been investigated to obtain high CO_2 gas selectivity and permeability. And more

research and investigation are carried out actively to introduce the molecular sieve ability with angstrom order size (Gin and Noble 2011; Hudiono et al. 2011).

Poly(ethylene glycol) (PEG) has a high physical affinity toward CO_2 and was expected to be a viable CO_2-separation membrane material. However, pure PEG exhibited very low CO_2 permeability, owing to its crystallization. Freeman et al. developed cross-linked PEG membranes in order to prevent this crystallization. The cross-linked PEG membranes exhibited favorable interactions with CO_2, which enhanced the solubility of CO_2 over that of H_2 and showed a CO_2/H_2 selectivity of about 10 at 35 °C and 25 at −20 °C (Lin et al. 2006). Wessling et al. developed a PEG block copolymer membrane and obtained a CO_2/H_2 selectivity of 10 at 35 °C (Husken et al. 2010). Peinemann et al. also developed a PEG block copolymer with CO_2 affinity and obtained a CO_2/H_2 selectivity of 10.8 at 30 °C (Car et al. 2008).

As stated in introduction, CO_2 separation from flue gas using membranes is performed under low pressure ratio between the feed and the permeate side, and the improvement in CO_2 permeability is important in terms of flowering the system cost and membrane area. It is also important to improve the separation process. Merkel et al. proposed a new system to obtain a CO_2 partial pressure difference between the feed and the permeate side using air as a sweep gas to reduce the energy cost. In addition, a membrane module with high CO_2 permeability (Polaris TM membrane) was developed (Merkel et al. 2010). Huang et al. investigated on pressure ratio between feed side and permeate side and its impact on membrane gas separation processes. They reported that the optimum membrane processes may not correlate with the highest selectivity because of limited pressure ratio (Huang et al. 2014). Hägg et al. reported similarly that the optimization of the operating conditions is important for membrane gas separation process, by investigating the influences of the operating parameters such as temperature, pressure, and stage-cut using the carbon membrane (He and Hagg 2011).

Inorganic Membranes

As for inorganic membranes, zeolite membranes and carbon membranes, among others, have been reported for CO_2 separation. Inorganic membranes have appropriate-sized pores that can act as molecular sieves to separate gas molecules by their effective size. In addition, inorganic membranes with strong CO_2 affinities show high CO_2 selectivity over N_2 and CH_4.

Noble et al. reported that zeolite SAPO-34 membrane showed a high CO_2/CH_4 separation performance (Zhang et al. 2010). Zhou et al. reported preparation for silica MFI membranes with a thickness of 0.5 μm on analumina support membrane. The membrane showed a separation selectivity of 109 for CO_2/H_2 mixtures and a CO_2 permeance of 51×10^{-7} mol m^{-2} s^{-1} Pa^{-1} at −35 °C (Zhou et al. 2014).

Sub-nanoporous carbon membranes are prepared through precursor polymer thermolysis and carbonization in several hundred degrees or more by heat treating. Polyimide, polyacrylonitrile, cellulose, phenolic resin, etc. are used as precursors. Carbon membranes prepared from a precursor polyimide based on 6FDA-mPDA/DABA (3:2) by thermolysis under 550 °C showed CO_2 permeability as high as

14750 Barrer with CO_2/CH_4 selectivity of approximately 52. Even 800 °C pyrolyzed carbon membranes still showed high CO_2 permeability of 2610 Barrer with high CO_2/CH_4 selectivity of approximately 118 (Qiu et al. 2014).

Inorganic membranes show high gas separation performance and high stability and durability at high temperature. On the other hand, they have the disadvantages of high membrane cost, compared with polymeric ones. To combine the benefits of both polymeric and inorganic materials, mixed-matrix membranes (MMMs), a type of organic/inorganic composite membranes, have also been studied. Many studies have been reported on gas separation membranes using ZIF (zeolitic imidazolate frameworks), a type of MOF (metal-organic framework), as inorganic nanoparticles. Bae et al. reported that MMMs prepared by incorporating MOF (ZIF-90) into a polymeric matrix showed a high CO_2/CH_4 separation performance (Bae et al. 2010). MMMs prepared by incorporating ZIF-108 nanoparticles into polysulfone (PSf) matrix showed CO_2/N_2 selectivity of 227 (Ban et al. 2014). Hägg et al. developed ZIF-8/PEBAX-2533 MMMs for CO_2 capture. MMMs from PEBAX-2533/ZIF-8 with 25 % ZIF-8 loading showed CO_2 permeability of 1129 Barrer with CO_2/N_2 selectivity of 31 (Nafisi and Hagg 2014). Because CO_2 separation by inorganic membranes is mainly carried out via molecular sieving, a high selectivity is obtained for CO_2/CH_4 and CO_2/N_2 separation but generally not for CO_2/H_2 separation.

Ionic Liquid Membranes

Ionic liquid (IL) membranes have received increasing interest and have been studied in recent years because of their low vapor pressures and stability at high temperatures. Polymerized IL membranes were prepared for the separation of CO_2/N2, CO_2/CH_4, etc. by Noble et al. (Bara et al. 2007). Amino-containing ILs were investigated for the separation of CO_2/H_2 by Myers et al. (2008), and a CO_2/H_2 selectivity of 15 was obtained at 85 °C. Matsuyama et al. reported amino-containing IL membranes for the separation of CO_2/CH_4, and the membrane showed constant separation abilities for 260 days ($\alpha_{CO2/CH4}$ = ca. 60) (Hanioka et al. 2008). Nagai et al. reported impregnating IL and ZSM-5 into PI matrix for improvement of IL composite membrane stability. The resulting membrane exhibited CO_2/CH_4 selectivity of 31 with CO_2 permeability of 4509 Barrer (Shindo et al. 2014). IL monomer was polymerized to improve pressure durability of IL membranes by Wessling et al. The resulting membrane showed CO_2/CH_4 selectivity of 22 with CO_2 permeability of 18 Barrer at 40 °C, CO_2 (50 vol.%)/CH_4 (50 vol.%) of feed mixed gas under 40 atm total pressure (Simons et al. 2010).

Facilitated Transport Membranes

Facilitated transport membranes for CO_2 separation were originally prepared by impregnating pores of microporous support membranes or polymer matrices with carrier solutions such as amines and alkali metal carbonates, which have chemical affinity to CO_2. Figure 10 shows the conceptual diagram of CO_2-facilitated transport membranes (Zou and Ho 2006). As shown in Fig. 5, CO_2 carrier incorporated membrane can react selectively and reversibly with CO_2. The CO_2 transport membrane rate can be facilitated because CO_2 carrier of the reaction product can transport through the

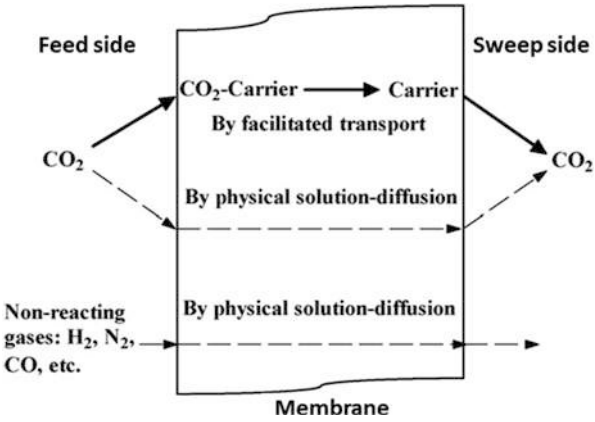

Fig. 10 The conceptual diagram of CO_2-facilitated transport membrane (Zou and Ho 2006)

membrane, in addition to CO_2 transport membrane of physical solution–diffusion mechanism. On the other hand, other gases, such as N_2, H_2, and CO, transport membrane only by solution–diffusion mechanism. As a result, the CO_2 selectivity of facilitated transport membranes can be extremely high at low CO_2 partial pressures.

Facilitated transport membranes for CO_2 separation have been studied since the 1960s. Ward and Robb immobilized an aqueous bicarbonate–carbonate solution into a porous support and obtained a CO_2/O_2 separation factor of 1500 (Ward and Robb 1967). Immobilized liquid membranes impregnated with carbonate and bicarbonate solutions were studied by Jung and Ihm (1984), Bhave and Sirkar (1986) and Yamaguchi et al. (1996). Apart from carbonate or bicarbonate ions as the reactive carrier, amines were other chemicals that can facilitate CO_2 transport. Aqueous solution of diethanolamine (DEA) was used for facilitating CO_2 transport (Guha et al. 1990) (Matsuyama et al. 1996). The transport of acid gases through an ion-exchange membrane was facilitated with a diamine carrier (Quinn et al. 1997). The membrane which acted as a fixed carrier membrane for CO_2-facilitated transport was prepared by plasma grafting 2-(N, N-dimethyl) aminoethyl methacrylate (Matsuyama et al., 1996) (Neplembroek et al. 1992). The membranes based on the polyelectrolyte, poly(vinylbenzyl trimethyl ammonium fluoride), exhibited high permselective properties for CO_2/CH_4 (Quinn et al. 1997; Kemperman et al. 1997).

Although the immobilized liquid membranes have quite high permselectivity, they have a shortcoming of instability. Some methods were proposed to improve membrane stability under a pressurized condition or in a vacuum. For example, polymer gel was used to retain CO_2 carriers in membrane (Neplembroek et al. 1992; Kemperman et al. 1997; Matsumiya et al. 2004, 2005) or the surface of support membrane was treated by chemical method and liquid membrane layer was formed on the pretreated support membrane (Ito et al. 1997), etc.

Ho et al. developed facilitated transport membranes by blending amines with poly(vinyl alcohol) (PVA) (Zou and Ho 2006). These membranes showed a CO_2/H_2 selectivity of 300 at 110 °C and 100 at 150 °C, as shown in Fig. 11. Matsuyama et al. reported facilitated transport membranes prepared by the immobilization of

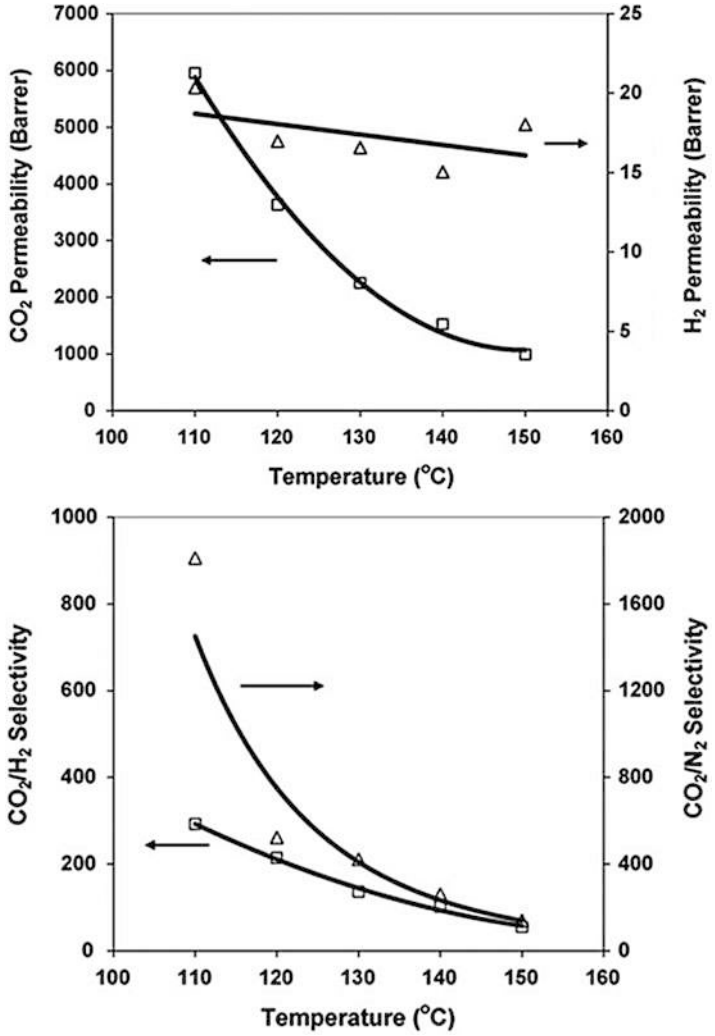

Fig. 11 CO_2/H_2-separation properties of facilitated transport membranes prepared by blending amines with poly(vinyl alcohol) (PVA) (Zou and Ho 2006)

2,3-diaminopropionic acid and cesium carbonate in a PVA/poly(acrylic acid) copolymer matrix, and the resulting membrane showed a CO_2/H_2 selectivity of 432 at 160 °C, as shown in Fig. 12 (Yegani et al. 2007). Hägg et al. developed a CO_2/N_2-separation membrane by blending PVA and poly(vinyl amine) (PVAm). The composite membrane with a selective layer thickness of 0.3 μm was prepared by casting a solution of PVA/PVAm on a polysulfone (PSf) support membrane (Sandru et al. 2010). A model of CO_2-facilitated transport membrane mechanism was shown in Fig. 13. In this model, the bicarbonate ion is considered as CO_2 carrier and plays an important role for CO_2 permeation.

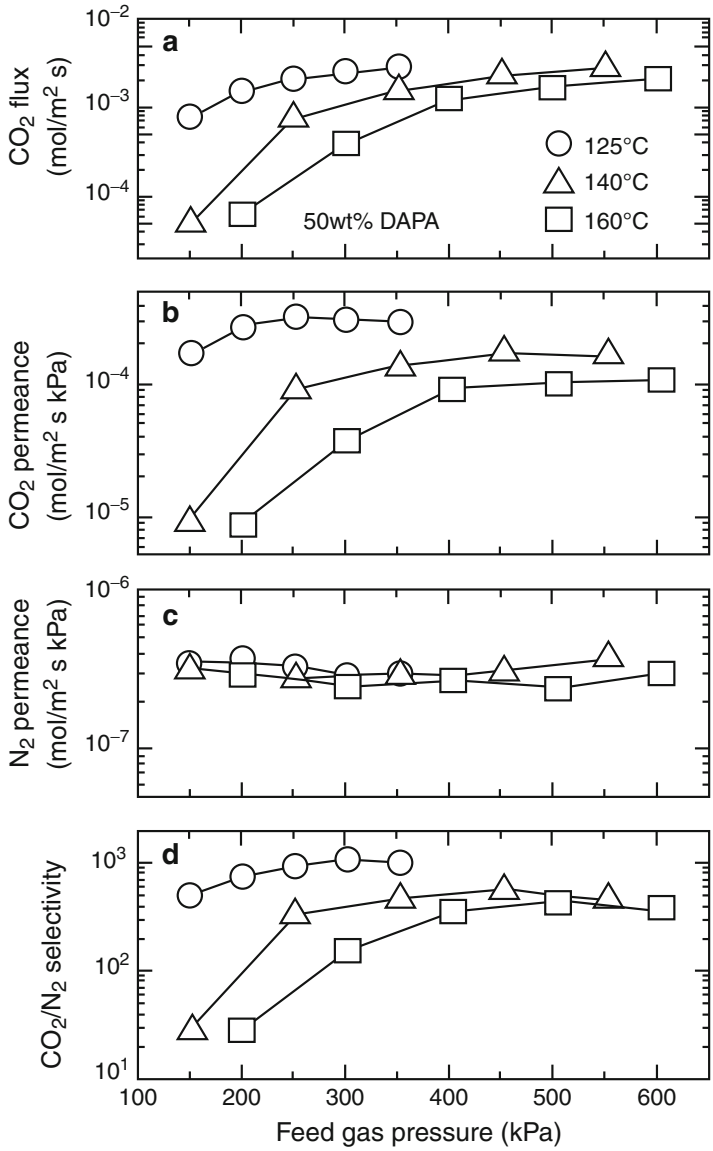

Fig. 12 CO_2/N_2-separation properties of facilitated transport membranes prepared by the immobilization of 2,3-diaminopropionic acid and cesium carbonate in a PVA/poly(acrylic acid) copolymer matrix (Yegani et al. 2007)

Myers et al. reported that amino-containing IL membrane showed CO_2-facilitated transport for dry CO_2/H_2 mixed-gas separation (Myers et al. 2008). Matsuyama et al. developed amino acid IL-based facilitated transport membranes for CO_2 separation. A tetrabutylphosphonium proline as amino acid IL membrane showed

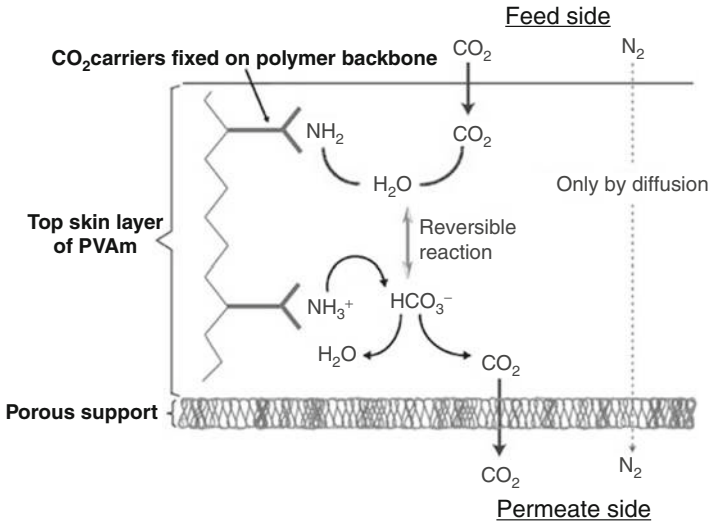

Fig. 13 CO_2-facilitated transport membrane mechanism by bicarbonate (Sandru et al. 2010)

an excellent CO_2 permeability of 14,000 Barrer with CO_2/N_2 selectivity of 100 at 373 K under dry conditions and 10 kPa CO_2 partial pressure (Kasahara et al. 2012). CO_2 partial pressure and temperature significantly influenced CO_2 permeability and CO_2/N_2 selectivity (Kasahara et al. 2014a, b).

Svec et al. developed polymer hybrid CO_2-facilitated transport membrane by photopolymerization based on polyaniline and 2-hydroxyethylmethacrylate. The resulting hybrid membranes showed a CO_2 permeability of 3460 Barrer with CO_2/CH_4 selectivity of 540 under 8.3 kPa CO_2 partial pressure (Blinova and Svec 2012). Sirkar et al. reported excellent CO_2/N_2 selectivity using a viscous and nonvolatile poly(amidoamine) (PAMAM) dendrimer as an immobilized liquid membrane under isobaric and saturated water vapor test conditions (Kovvali et al. 2000). In the integrated coal gasification combined cycles with CO_2 capture and storage (IGCC-CCS), CO_2-separation membranes will play an important role for reducing CO_2-capture costs. In Japan, PAMAM dendrimer/polymer hybrid membranes were developed for CO_2 separation from flue gas (CO_2/N_2) (Duan et al. 2006; Kai et al. 2008) and from IGCC process (CO_2/H_2) (Taniguchi et al. 2008; Duan et al. 2012; RITE today (annual report 2015).

Membrane Module Design and Manufacturing for CO_2 Membrane Separation

Industrial membrane plants for gas separation often require hundreds to thousands of square meters of membrane to perform the separation. It is very important to provide a large surface area to deal with large quantity of flue gas or fuel gas.

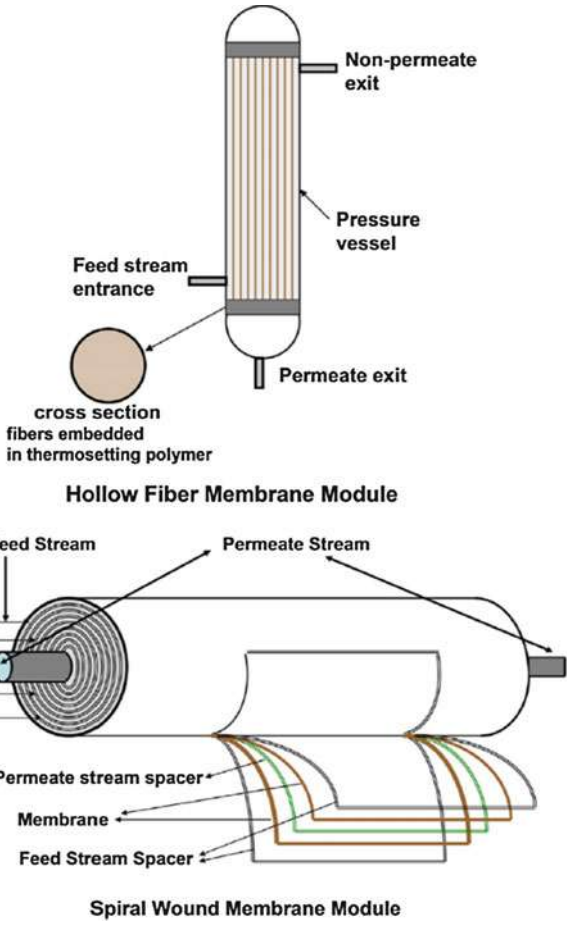

Fig. 14 Modular constructions employed for gas separation processes (Sanders et al. 2013)

Hence, it is very important to design and produce membrane modules. There are several ways to economically and efficiently package membranes for high surface area and economical module for gas separation. These packages are called membrane modules. The examples of membrane modules are shown in Fig. 14 (Sanders et al. 2013).

1. Hollow Fiber Membrane Modules
   A typical hollow fiber bundle contains on the order of 10^5 hollow fibers which are tightly packed (packing fractions on the order of 50 % are common) with both ends embedded in a thermosetting epoxy polymer (Coker et al. 1998). A hollow fiber bundle would then be housed in a polymeric or metal pressure vessel, depending on the pressure that the system was expected to encounter during operation. Feed gas can be introduced into the bore side or the shell side of a hollow fiber module, depending on the application.

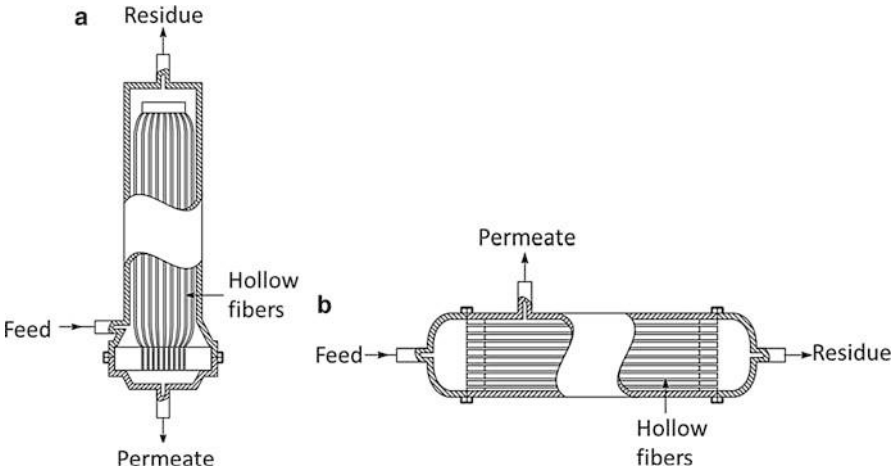

Fig. 15 Hollow fiber membrane module. (**a**) Countercurrent flow. (**b**) Cocurrent flow

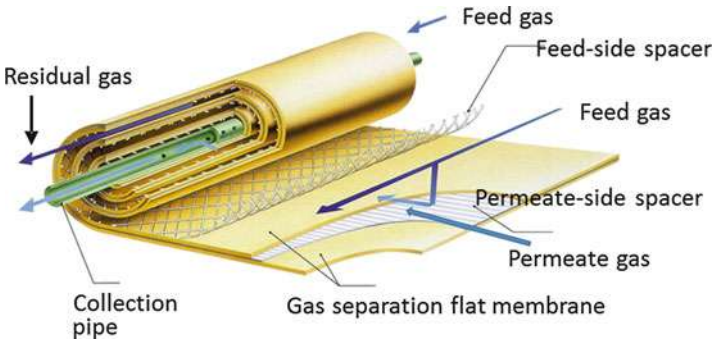

Fig. 16 Cross section constructions of spiral wound membrane module for gas separation

Two basic shapes of hollow fiber membrane module are shown in Fig. 15: (a) countercurrent flow and (b) cocurrent flow. Countercurrent shape module has the shell-side feed design with a loop of fibers contained in a pressure vessel. The system is pressurized from the shell side, and the permeate passes through the fiber wall and exits through the open fiber ends. It is easy to make very large membrane areas, thick wall, and small diameter to stand the pressure for used in-gas separation.

In cocurrent shape module, fibers are open at both ends, and the feed fluid is circulated through the bore of the fibers. Large diameter is needed to minimize pressure drop (Δp) for in-gas separation at $p < 10$ bar.

2. Spiral Wound Membrane Modules

The spiral wound membrane module configuration as shown in Fig. 16 includes some layers of flat sheet asymmetric membranes with porous spacers between

the membrane sheets. The feed gas passes axially down the module across the membrane envelope. The permeate gas spirals toward the center and exits through the collection pipe.

Demonstration (Field Test)

In the United States, the US Department of Energy (DOE) sponsored CO_2-capture technology projects of three primary technology areas (post-combustion, precombustion, and advanced combustion systems), and various stages of development (lab scale, bench scale, and pilot scale) are conducted. CO_2-capture technologies include absorption, adsorption (solid sorbent), and membrane separations Achievement of the projects is reported in the annual NETL CO_2 Capture Technology meeting. In the NETL CO_2 Capture Technology meeting in 2015, latest results of more than 50 projects were reported (http://www.netl.doe.gov/events/conference-proceedings/2015/2015-co2-capture-technology-meeting).

In some of the projects above, field test has been conducted in the National Carbon Capture Center (NCCC) (2014–2019). Realistic syngas and flue gas for performance verification are used for membranes supplied by various membrane companies, universities, and research institute (http://www.nationalcarboncapturecenter.com/).

For post-combustion, CO_2-selective membranes, such as polymeric membranes by MTR and Air Liquide and polymeric/inorganic hybrid membranes by the Ohio State University are tested.

For MTR CO_2 membrane process, primary CO_2 removal with cross-flow module and selective recycle of CO_2 with countercurrent/air sweep module to increase overall capture are combined. Combustion air sweep provides driving force that lowers the capture energy. In addition, pre-concentrated CO_2 decreases membrane area and power required. So far, 0.05 MW bench-scale unit was operated successfully.

In MTR, bench-scale hybrid membrane-absorption CO_2-capture processes (series and parallel systems) are also developed.

Ho et al. (Ohio State University) reported membranes composed of selective amine polymer layer/zeolite nanoparticle layer/polymer support.

For pre-combustion, H_2 selective membranes, such as Pd–alloy membranes by WPI, carbon molecular sieve (CMS) membranes by MPT, and polymeric membranes by MTR, are tested. CO_2-selective membranes by MTR are also tested.

Summary and Future Prospects

As described above, over the past three decades, membrane gas separation in industry application has become widely used for a variety of industrial application. From a commercial point of view, three steps of membrane material, membrane module design, and manufacturing, system design, and engineering are very important for the application of CO_2 capture by membrane (Fig. 17; Bernardo and Clarizia 2013).

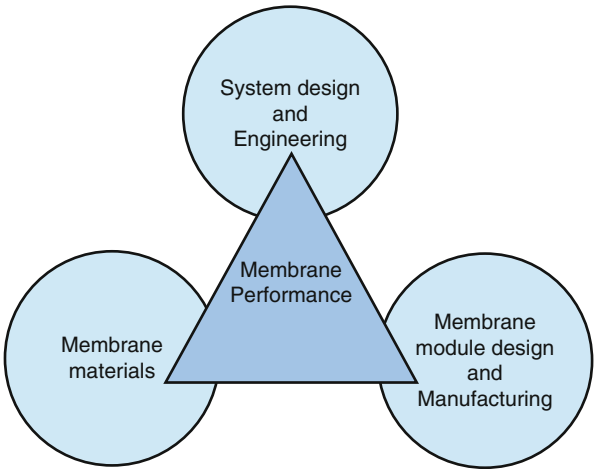

Fig. 17 Main points in membrane performance development (Bernardo and Clarizia 2013)

So far, various types of CO_2-selective membranes have been developed using both organic and inorganic materials. As for polymeric membranes, research using PEG-based materials and microporous polymer membranes using TR polymer, MOP, etc. are reported. As for IL membranes, novel IL-containing amino group and their fabrication into polymeric membranes are reported. As for inorganic membranes, zeolite membranes and carbon membranes among others have been reported in the selective separation of CO_2. Mixed-matrix membranes (MMMs), a type of organic/inorganic composite membranes, combining the benefits of both polymeric and inorganic materials have also been studied extensively. As for facilitated transport membranes, novel membranes using ILs, amines, etc. are reported.

In the case of CO_2 separation from flue gas (post-combustion), it is pointed out that the CO_2 permeability is more important than CO_2/N_2 selectivity because pressure ratio between feed side and permeate side is small. On the other hand, in the case of CO_2 separation from IGCC process (precombustion), both CO_2 permeability and CO_2/H_2 selectivity are important to separate CO_2 effectively. It is also important to consider the difference of properties of membrane materials. System analysis as well as field test using membrane modules using real flue gas or real syngas would be also very important to make membrane module and membrane system more reliable and feasible.

Abstract

Carbon dioxide (CO_2) geological storage is the last process in carbon dioxide capture and storage (CCS). Technical issues to conduct it safely are firstly introduced. Geophysical and geochemical trapping mechanisms to store CO_2 within the reservoir, geophysical monitoring and modeling, and geomechanical modeling are then described as key issues. Finally, future directions are discussed.

Introduction

Carbon dioxide capture and storage (CCS) is a key technology for reducing the amount of carbon dioxide (CO_2) emitted into the atmosphere to mitigate climate change. It consists of several processes: separating and capturing CO_2 from large-scale emission sources, such as thermal electric power plants and steel mills, transportation, and then storing and isolating it underground or under-seabed geological formations for long periods of time. CO_2 geological storage (CGS) can be conducted using deep saline aquifers, depleted oil, and gas reservoirs as well as coal seam fixing. CO_2 injection has been also utilized for enhanced oil recovery (EOR) and enhanced gas recovery (EGR).

Since the Intergovernmental Panel on Climate Change (IPCC) published their special report on CCS in 2005 (IPCC 2005), CCS has received attention as an option in the portfolio of mitigation actions for stabilization of atmospheric greenhouse gas concentrations. Each process of CCS, however, has been developed individually, and CCS can be recognized as a combination to be practical these existing techniques as a climate change countermeasure. Drilling technologies similar to those used for the exploration and production of petroleum and gas can be applied to CGS, and CO_2 injections have been performed for enhanced oil recovery (EOR) since the 1970s (Blunt et al. 1993). Furthermore, storage in saline aquifers (Koide et al. 1992) and coal seams (Gunter et al. 1997) has been proposed.

Technical Issues

Let us consider technical challenges regarding CGS into a deep saline aquifer along the lines of life cycle of a large-scale demonstration or commercial-scale storage project. First, we need to select candidate reservoirs that seem to be suitable for the storage project. It might be onshore or offshore sites. The technical suitability criteria, such as sufficient storage capacity of reservoirs, injectivity, seal integrity, and other geological

features, should be carefully examined using wide variety of site-specific geological, geophysical, and geochemical data and numerical modeling techniques. Further studies should be necessary regarding economics, risk, and environmental aspects. How to estimate the reservoir capacity for CO_2 storage is also one of the important issues.

After the site screening process, the project proceeds to further assessment using investigation well drilling, baseline survey of geophysical monitoring, and reservoir simulation to check whether the site meets the required criteria; then an overall plan for CO_2 injection will be developed.

Once full-scale CO_2 injection is started, monitoring techniques play key roles whether stored CO_2 remains within the reservoir as expected quantitatively, which is also very important in putting CCS into practical use. Available monitoring tools are well logging using injection and observation wells, seismic reflection, gravity method, and so forth. In order to measure and verify the amount of injected CO_2 quantitatively and predict the further reservoir performance, construction of precise reservoir model, history matching using the monitoring data, and revise of the reservoir model are inevitable. Numerical simulation of subsurface changes and geophysical observables can be used to find an appropriate combination and layout of geophysical measurements for the CCS project and to detect discrepancies between actual and simulated subsurface changes, which provide a clue to find unexpected CO_2 leakage or to improve reservoir model. Monitoring, not only in operation phase, yet after operation ends should be sometimes carried out, so that cost reduction of monitoring methods is the issue to be considered. It is also an important task to quantitatively investigate how injected CO_2 is physically and chemically trapped (retained) in the structure, strata, and formation water.

By any chance, a small amount of CO_2 leakage might be occurred in the vicinity of the seafloor or shallow tapped water aquifer. To this end, evaluation of environmental impact is also indispensable. Underground stress change due to CO_2 injection is also a concern to induce micro-earthquakes. To avoid them, the appropriate injection rates and the characteristics of the reservoir are sufficiently assessed in advance and during injections. Real-time seismicity monitoring is important with high-accuracy seismic network. For earthquake-prone countries like Japan, there is a possibility that a natural earthquake occurs around. In preparation for such a situation, it is also necessary to evaluate the robustness of the reservoir in advance.

We will first discuss sealing mechanisms of CGSs and then proceed to describe state of the art of geophysical and geomechanical reservoir modeling and geophysical monitoring tools.

Evaluation of the Sealing Performance of Caprocks

Introduction

To implement the CGS technology, it is necessary to verify that the reservoir layer such as deep saline aquifer can safely store CO_2 for a long time. For this, evaluating the sealing performance of potential CO_2 leakage pathways (e.g., abandoned wells,

faults, and caprocks) is needed (e.g., IPCC 2005). In particular, the sealing performance of a caprock itself is important in terms of the: (1) leakage of CO_2, (2) CO_2 storage potential, and (3) upper pressure limit at the time of CO_2 injection.

In this paper, the author first discusses capillary pressure theory and measurement methods that describe the sealing performance of rocks. Following this, current research dealing with the evaluation of the safety of CGS is reviewed. It is important to estimate the range of variations in capillary pressures, especially in rocks. Thus, the author introduces new approaches for evaluating the sealing performance of rocks in which artificial samples, with controlled internal structures, are used to design empirical models.

Capillary Pressure Theory

Sealing Mechanisms of Porous Medium

When an immiscible non-wetting phase (mainly gas and nonaqueous liquid) permeates a porous medium (rocks such as caprocks) that has pore space filled with water, the capillary pressure P_c acting on a curved interface (meniscus) between two fluids is defined as the following Laplace equation (Washburn 1921):

$$P_c = \frac{2\sigma\cos\theta}{r} \tag{1}$$

Therein, σ is the interfacial tension between the wetting phase and non-wetting phase, θ is the contact angle of the wetting phase on the solid surface, and r is the pore throat radius within a solid.

The sealing performance of a porous medium against a non-wetting phase is determined by the magnitude relationship of P_c and the difference in the pressures of non-wetting phase and wetting phase (P_{nw} and P_w). In other words, when $P_{nw}-P_w < P_c$, the porous medium functions as a seal and prevents penetration of the non-wetting phase; however, when $P_{nw}-P_w > P_c$, penetration of the non-wetting phase occurs. In fact, there are pores (i.e., pore spaces with relatively large diameter forming between particles) and pore throats (i.e., the narrowest point of a tube connecting pores) of various sizes within the target porous medium. Therefore, even if $P_{nw}-P_w > P_c$ for a certain pore or pore throat diameter, penetration of CO_2 (breakthrough) does not occur immediately, and the non-wetting phase is blocked by the next throat of the flow path with a smaller diameter. The first breakthrough occurs when the continuous flow path for the non-wetting phase is formed between both ends of the porous medium. The flow path of the non-wetting phase at this point occupies an insignificant fraction of total pore space (i.e., the water saturation S_w is high). A further increase in the difference of P_{nw} and P_w enables the penetration through pore throats with a smaller diameter, which results in the expansion of the flow path volume of the non-wetting phase.

In contrast, a reduction of the difference between P_{nw} and P_w after the breakthrough of the non-wetting phase leads to re-imbibition of the wetting phase,

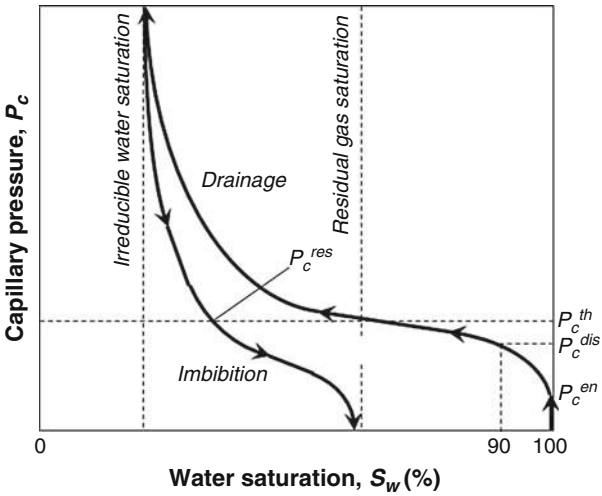

Fig. 1 Relationship of each P_c term characterizing the sealing performance (P_c^{en}, P_c^{dis}, P_c^{th}, and P_c^{res}) with the P_c–S_w curve

starting with the smallest pores and proceeding successively to larger pores (Hildenbrand et al. 2002). As a result, the connected flow path becomes blocked; the permeability k of the non-wetting phase decreases. Ultimately, the flow path in the largest pore throats is shut off, and the penetration of the non-wetting phase stops.

The drainage and imbibition process of the wetting phase within the porous medium presents a P_c-S_w curve (Fig. 1). Generally, the P_c in the imbibition process is smaller than that of the drainage process on the equal S_w. Therefore, the P_c-S_w curve between the two produces large hysteresis.

Definition of P_c

On the P_c-S_w curve, the P_c value changes with penetration of the non-wetting phase into the porous medium. However, depending on its processes, various terms are defined to characterize the sealing performance. These terms include the entry pressure P_c^{en}, displacement pressure P_c^{dis}, threshold pressure P_c^{th}, and residual capillary pressure P_c^{res}. Here, Fig. 1 presents their general definitions and relationships with P_c-S_w curve.

The P_c^{en} is the pressure when the non-wetting phase first comes in contact with the target porous medium. It is an index of the diameter of pores or maximum pore throat exposed at the porous medium surface. In this case, however, the throat does not need to be connected to the opposite end of the porous medium. The P_c^{en} is easy to identify experimentally, but the structures of pores and pore throats exposed on the surface are dependent on the effects of sample size and heterogeneity. Thus, the physical meaning of measured P_c^{en} is not necessarily clear (Pittman 1992).

Based on a breakthrough experiment of mercury in sandstone, limestone, and silty shale rocks, Schowalter (1979) defined the P_c at a mercury saturation of 10 % as the P_c^{dis}. Although these samples had a wide pore throat diameter distribution,

the non-wetting phase saturation necessary to build connected flow paths was limited to a narrow range of 4.5–17 %. Thus, it is concluded that breakthrough of non-wetting phase occurs in many rocks when S_w is approximately 90 %.

The P_c^{th} is a particularly ambiguous measure of sealing performance, and its definition has varied in past research. Generally, it refers to the difference of P_{nw} and P_w at both ends of porous medium, when building a connected flow path for the non-wetting phase in the porous medium. Experimentally, it is measured as the differential pressure when the non-wetting phase initially penetrates the porous sample. The magnitude of P_c^{th} is defined by the P_c at the maximum pore throat diameter. Katz and Thompson (1986, 1987) considered that the pressure at which mercury forms a connected pathway within the sample is equivalent to the inflection point at which the $P_c{-}S_w$ curve becomes convex upward and defined this pressure as P_c^{th}. In connection with this, Thomeer (1960) and Swanson (1981) both showed by numerical analysis and experiments, respectively, that a pore system with a good connectivity forms within rocks at the vertex of a hyperbola (i.e., a point where the slope of the tangent is 45°) obtained when the $P_c{-}S_w$ curve is expressed in a double logarithmic diagram.

Along with P_c in these drainage processes, the P_c in imbibition process is also defined. If the flow path of the non-wetting phase is completely blocked in the imbibition process of the wetting phase, residual pressure difference is generated at both ends of the porous medium and defined as the P_c^{res} (Hildenbrand et al. 2002).

Measurement Methods for P_c

Commonly, P_c is measured by mercury intrusion or gas sorption (mainly using nitrogen). The results are then converted to the P_c in the target system. In the former method, a throat diameter of several nm to several hundred μm is the target, while the throat diameter of approximately 0.1–100 nm is the target for the latter method. In either method, the principle of analysis is the same. For example, conversion to the CO_2–water system using the mercury intrusion method is conducted as follows (Purcell 1949):

$$(P_c)_{c-w} = \frac{\sigma_{c-w} \cdot \cos\theta_{c-w}}{\sigma_{m-a} \cdot \cos\theta_{m-a}} \cdot (P_c)_{m-a} \tag{2}$$

where subscripts $c{-}w$ represents the CO_2–water system and $m{-}a$ represents the mercury–air system. Specifically, the relationship between the volume of injected mercury and pressure is measured, and $(P_c)_{m-a}$ is obtained from the shape of the $P_c{-}S_w$ curve. At this point, σ_{m-a} (480 dynes/cm) and θ_{m-a} (40°) are both known; thus by using σ_{c-w} and θ_{c-w} under the target condition as the input parameters, $(P_c)_{c-w}$ is determined.

There are several methods that use the actual target fluid to determine P_c. The most common is the step-by-step approach, where the pressure of the non-wetting phase is slowly increased in steps and the P_c is obtained based on the flow rate

changes of the injected non-wetting phase and effluent wetting phase. The step-by-step approach corresponds to the measurement under static conditions in conformity with the definition of the seal; thus, it is considered to be the optimum method. However, to eliminate the dynamic effect, injection of the non-wetting phase at an extremely slow flow rate is required. As a result, it takes a few days to up to several weeks or more to measure the breakthrough of non-wetting phase (e.g., Liu et al. 1998).

In contrast with these drainage processes, the P_c^{res} is measured for imbibition processes (Hildenbrand et al. 2002). In this method, under the condition of constant volume for the whole system, the non-wetting phase is injected instantaneously at the same or higher pressure than the predicted P_c^{th}. Following this, the upstream pressure in the sample decreases, while the downstream pressure increases. By measuring pressure changes in the non-wetting phase at both ends of the sample, P_c^{res} is obtained from the difference in the final residual pressure. However, the P_c^{res} measured in experiments possibly becomes lower when re-imbibition of the wetting phase is prevented because the flow path volume is different between at drainage and imbibition process. In fact, Hildenbrand et al. (2002) confirmed that in samples with $k > 100$ nD, P_c^{res} becomes smaller than the P_c^{th} in drainage process.

To replace above static or quasi-static measurement methods, Egermann et al. (2006) proposed a dynamic measurement method, in which the non-wetting phase is injected applying a constant overall pressure drop, above P_c^{th}, across the sample. This method stands on the following mechanism. Before the non-wetting phase reaches to the sample surface, the drainage rate of the wetting phase depends on the pressure drop over the whole sample. However, once the non-wetting phase starts to penetrate within the sample, the generation of P_c^{th} at its front decreases the drainage rate of the wetting phase. From the experiments with a brine–nitrogen system, they showed that for fine-grained sandstone, carbonates, and chalk rocks with $k \geq 1$ μD, the dynamic measurement method has a similar accuracy as the step-by-step approach, and measurements can be conducted in the same time as the P_c^{res} method (Egermann et al. 2006). However, it is noteworthy that the P_c^{th} measured in this method is influenced by the flow. In other words, under dynamic conditions, the interface between the wetting and non-wetting phase takes a shape defined by the receding contact angle against the wetting phase; thus, for rocks with poor wettability (i.e., θ of the wetting phase $> 0°$), there is a possibility that θ becomes different from the equilibrium contact angle corresponding to static conditions. In such a case, P_c^{th} may be overestimated (Egermann et al. 2006).

Evaluation of Sealing Performance Under CGS Conditions

Previous Works

The sealing performance of systems for CGS is evaluated with two types of methods: a method that converts from mercury's P_c (e.g., Dewhurst et al. 2002; Bachu and Bennion 2008) and the direct measurement using CO_2 (Hildenbrand et al. 2004; Li et al. 2005; Plug and Bruining 2007; Wollenweber et al. 2010). As shown clearly in

Eq. 1, P_c depends on the type of fluid; thus, the latter method is more desirable in order to reduce uncertainties. However, the number of studies is currently limited.

As one example, Li et al. (2005) measured the P_c^{th} of N_2, CH_4, and supercritical CO_2 in anhydrite ($CaSO_4$) (a simulated sample of the caprock) using the step-by-step approach. It was shown that the P_c^{th} of CO_2 is lower than those of CH_4 and N_2, which reflects the fact that P_c^{th} is proportional to σ between gas and brine. In contrast, after injecting CO_2 with a constant flow in unconsolidated sand samples under the condition of various temperatures and pressures, Plug and Bruining (2007) kept the CO_2 pressure constant to cause the imbibition of water with a constant flow. As a result, they indicated that an increase of CO_2 pressure, which causes a decrease of σ, decreases the P_c in both drainage and imbibition processes. Hildenbrand et al. (2004) measured the P_c^{res} of N_2, CH_4, and CO_2 in argillaceous rocks from changes in the differential pressure for imbibition. In addition to the derivation of the relational expression of k and P_c^{res}, they also analyzed the pore size distribution based on P_c. In a similar manner, Wollenweber et al. (2010) conducted an experiment with limestone and marl as the target. By repeatedly injecting CO_2, a decrease in P_c^{res} was observed, which was attributed to the dissolution and re-precipitation of carbonates.

Modeling of the Correlation Between P_c^{th} and k

Generally, rocks in nature can differ greatly from their P_c^{th} because penetration depends on the flow path structure in individual samples. Therefore, from the perspective of stable CO_2 containment, it is necessary to ascertain the range of variation of caprock's P_c^{th} by measuring numerous samples instead of a single one. Moreover, the sealing performance over a widespread area must be evaluated especially for grand-scale CGS. However, the core samples that one can realistically obtain from a storage site are numerically restricted. Moreover, samples are not necessarily available over the whole site.

Because of these problems, the authors have proposed a method to represent P_c^{th}'s variation using artificial samples of which the internal structure is intergraded from a simple to a more complicated one (Sorai et al. 2014a). This methodology enables the prediction of the range of variation of rocks' P_c^{th} without repeated measurements of numerous rock samples. As a first step, the authors prepared sintered compacts of uniform spherical silica particles with diameters of 0.1–10 μm. Manufactured sintered compacts were made available for measurements of k and P_c^{th}. Specifically, P_c^{th} was measured in supercritical CO_2–water system under conditions of 1,000 m depth (10 MPa and 40 °C). The CO_2 in this condition corresponds to the supercritical phase. The CO_2 pressure at the sample bottom was increased to higher than 10 MPa in steps of 10 kPa, but the water pressure at the upper side of the sample was maintained 10 MPa. The authors determined P_c^{th} of a sample based on differential pressure at the instant when the CO_2 breakthrough was observed through a sample cell observation window.

Figure 2 shows a breakthrough image of supercritical CO_2 from the upper surface of the sample, taking the 0.1 μm particle sample, for example (Sorai et al. 2014a). Initially the CO_2 was not able to penetrate into the sample because

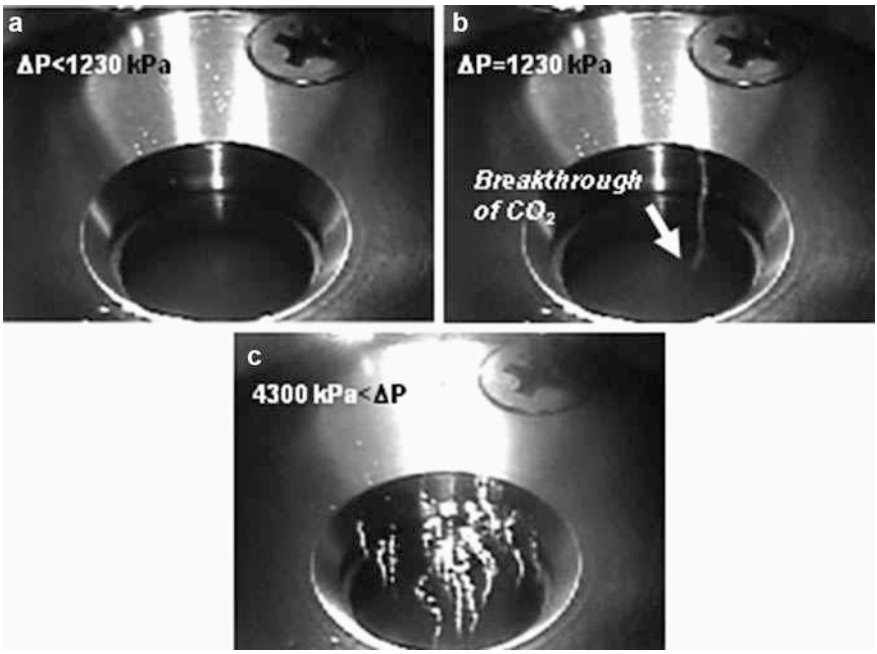

Fig. 2 Breakthrough image of supercritical CO_2 from an upper surface of a sample (Modified after Sorai et al. 2014a): (**a**) immediately before breakthrough; (**b**) breakthrough started from a specific point; and (**c**) finally the entire surface was covered with numerous breakthrough points

of a capillary effect (Fig. 2a), but a further increase of differential pressure caused CO_2 seepage from the upper surface. The breakthrough started from a specific point even though particles were packed homogeneously in the interior of a sample. The CO_2 flow passing through this point increased with increasing differential pressure (Fig. 2b). An additional rise of the differential pressure gradually increased the number of breakthrough points. Finally, the entire surface was covered with numerous breakthrough points (Fig. 2c).

Figure 3 presents the correlation between P_c^{th} and k for sintered compacts. The closest-packing structure of uniform spherical particles is defined theoretically as a line on a double logarithmic plot. Here, it is noteworthy that sintered compacts scatter around the closest-packing line because of their random packing (Sorai et al. 2014a). This variation is enhanced on lower k. Moreover, results suggest that samples with inhomogeneous particle packing are above the line, but samples in which particles are packed homogeneously overall, with inhomogeneous structures such as cracks included locally, are below the line. Figure 3 also shows experimentally obtained results for various sedimentary rocks. The P_c^{th} of rock samples, which is shifted downward further distant from the closest-packing line, seems to be lower than that of sintered compacts. This is due to the diverse sizes, shapes, and mineral compositions of the particles contained in rocks. In other words, the rock's P_c^{th} can vary greatly due to such factors.

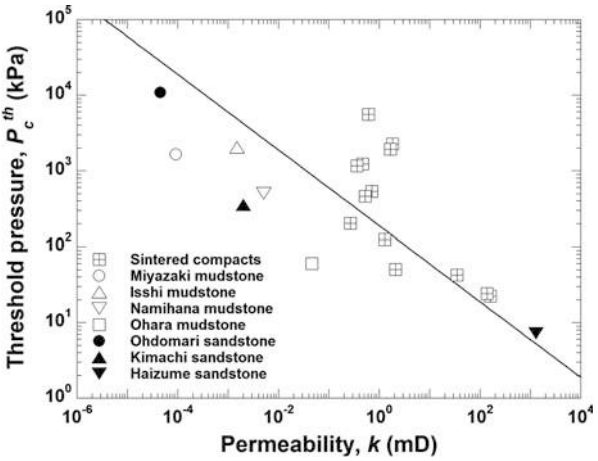

Fig. 3 Correlation between P_c^{th} and k of sintered compacts and various sedimentary rocks. The *straight line* represents calculated values for a case in which the closest packing of spherical particles is assumed

To what extent does such variation of P_c^{th} affect the predictions of the spread of CO_2 plumes after injection? For this problem, the migration of a CO_2 plume was numerically simulated for a case, where a 100 m thick alternating sandstone and mudstone layer was set as the site, and one million ton of CO_2 was injected annually into a sandstone stratum at 950–1,050 m depth for 50 years (Sorai et al. 2014b). The simulation compared the experimentally obtained upper (1.2 MPa) and lower limit (150 kPa) for the P_c^{th} of mudstone stratum, assuming the k of each stratum in the vertical direction to be 10 mD (millidarcy) and 0.1 mD respectively. The result revealed a significant impact on the spread of the CO_2 plume, particularly during the period following the completion of the injection. When P_c^{th} was increased, almost all of the CO_2 remained within the injection stratum over a longer period of time (Fig. 4a). However, when P_c^{th} decreased, CO_2 moved upward through the mudstone stratum due to its buoyancy, even after the injection had completed and reached the sandstone stratum located one layer above after 1,000 years (Fig. 4b). The magnitude of P_c^{th}, therefore, has a significant impact on the predictions of CO_2 behavior after storage. Determining the variation range of rock's P_c^{th} will be an issue tackled in the future. As the next step, the authors are investigating the impact of particle configuration and mineral composition on P_c^{th}, in addition to the effect of particle size distribution arising from mixtures of particles with various sizes.

Conclusion of This Section

With respect to the sealing performance of rocks, fundamental theory, measurement and analytical methods, and the application of obtained data have been well studied, particularly in the field of petroleum exploration. The acquired knowledge is directly useful in evaluating the safety of CGS. However, some questions remain regarding CGS, which were not necessary for consideration in petroleum exploration, such as the interaction of the non-wetting phase (CO_2) and wetting phase

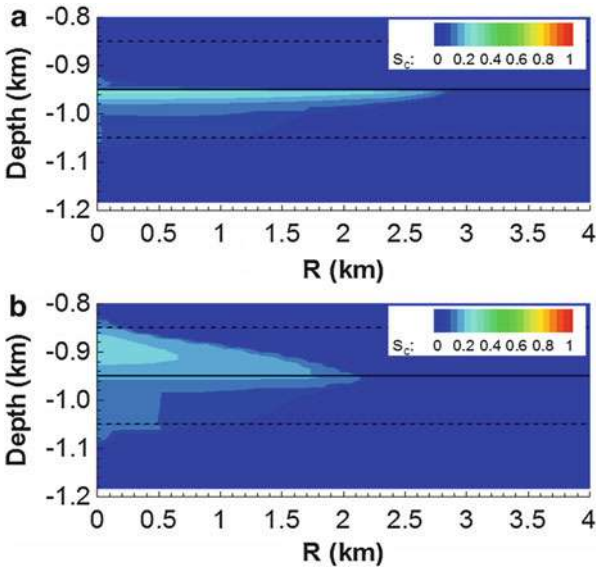

Fig. 4 Impact of difference in P_c^{th} of mudstone stratum on CO_2 plumes (After Sorai et al., 2014b). The *solid line* represents the upper edge of the sandstone stratum, while the *dotted lines* represent the *upper* edge of the mudstone stratum. The P_c^{th} of the mudstone stratum corresponds to (**a**) 1.2 MPa and (**b**) 150 kPa, respectively

(formation water) and the phase change of non-wetting phase itself. Moreover, even for existing evaluation methods, many issues remain such as the development of an accurate and efficient measurement method and the establishment of a theory that can be applied to rocks with complex internal structures. Future work should hopefully involve new approaches, such as modeling of P_c^{th} using artificial samples with controlled internal structures, which can further develop the methods for the evaluation of sealing performance for CGS.

Evaluation of Geochemical Processes

Introduction

Implementing the CGS requires the quantitative evaluation of the behavior and effects of the injected CO_2. Regarding this, the focus is generally on physical processes, such as CO_2 migration, starting immediately after CO_2 injection. This leaves many unknowns in the long term ($\geq$1,000 years) (IPCC 2005) such as the effect of geochemical interactions. For instance, in storage aquifers in which the highest storage potential is expected, active geochemical processes are expected to occur due to the acidification of formation water caused by dissolution of CO_2. The time scale for this process is expected to be long term, e.g., ranging from several hundred years to several tens of thousands of years. However, some processes may start immediately after CO_2 injection in areas near injection wells and in rocks containing highly reactive carbonate minerals.

In this paper, the author presents the target processes and the methods for understanding geochemical processes related to CGS in aquifers. The author focuses on numerical simulations as the essential approach for the evaluation of long-term geochemical processes. To improve model reliability, the author examined conditions and issues to improve the accuracy of input parameters. The paper also includes an example of reaction rate measurements for carbonates at hot springs.

Approach to Evaluation of Geochemical Processes

On CGS in aquifers, geochemical processes on various temporal and spatial scales are predicted to occur in components of the storage system, such as reservoirs, sealing layers, cracks, faults, wellbores, and upper aquifers. These processes include the dissolution of CO_2 in formation water, reactions of acidified water with surrounding rocks, pore-filling materials, and cement, carbonation of CO_2 through reaction with mafic or ultramafic rocks, evaporation of formation water (dry-out), formation of CO_2 hydrate, groundwater pollution, etc. These processes are directly related to the evaluation of important issues associated with implementing CGS. These issues include: the storage potential (geochemical trapping) based on long-term mechanisms; CO_2 injectivity in reservoirs; leakage risks from caprock, cracks, faults, and wellbores; and environmental effects on shallow groundwater.

Four types of approaches are applied for the evaluation of the abovementioned issues: field tests, laboratory experiments, natural analogue studies, and simulation studies. Each method targets a different temporal and spatial scale. Laboratory experiments have significant constraints on the temporal and spatial scales, yet conditions can be strictly controlled. Thus, laboratory experiments are suitable for elucidating mechanisms and the acquisition of parameters for each fundamental process. In contrast, natural analogue studies make it possible to understand phenomena occurring on the geological time scale. However, the transitional history of the environmental conditions is not always clear; thus, these are not suitable for acquisition of quantitative data related to reaction kinetics. On the other hand, simulation studies can deal with phenomena of all scale and play a crucial role in complementing other approaches. Especially in recent years, a three-dimensional reactive transport simulation is becoming mainstream with drastic advances in computing power (e.g., Xu et al. 2003; Johnson et al. 2004; White et al. 2005). However, as will be later discussed, there are many issues regarding the reliability of calculation results.

Field tests are quite efficient for conducting quantitative analysis of CO_2 behavior in underground conditions. Starting with the Norwegian Sleipner Project in 1996 for the study of CGS in aquifers, demonstration projects of various scales are currently in progress around the world. However, geochemical approach mainly bases on ex situ analyses of brine and rock samples. In other words, there is no effective tool for in situ monitoring of geochemical processes.

The Role and Directionality of Simulation Studies

Geochemical processes are phenomena that occur on an extremely long time scale. Thus, the ultimate evaluation of these processes must rely on numerical simulations. However, as previous studies have indicated, current simulations are based on many assumptions with various uncertainties and unknown parameters. Thus, for the long-term evaluation of CGS, these uncertainties must be reduced in order to increase the accuracy of simulation results. Here, to improve the prediction accuracy of geochemical processes, the author examined the parameters that are especially important for simulation studies including contributions from each of the abovementioned approaches.

Equilibrium Parameters

Equilibrium parameters include the density, solubility, and enthalpy in the CO_2–water system and so forth (Gaus et al. 2008). For these parameters, it is necessary to formulate as a function not only of temperature, pressure, and salinity but also of the effect of impurities and acidic gases other than CO_2.

Interfacial tension and wettability that regulate capillary pressure of CO_2 in rocks are also important parameters to which geochemical processes indirectly contribute. As for interfacial tension, a relatively large number of measurements have already been made for the CO_2–water system (e.g., Bachu and Bennion 2009), and in part, expansion into multicomponent systems such as a mixed gas of CO_2 and H_2S is underway (Shah et al. 2008). Wettability is difficult to evaluate due to its complex behavior depending on the surface conditions; thus, subsurface minerals are often assumed as a condition of the surface being completely saturated with water (i.e., contact angle of 0°). However, some of the recent studies showed that contact angles of mica and quartz change in the presence of CO_2 (e.g., Chiquet et al. 2007). Therefore, additional data from laboratory experiments are desired.

Kinetic Parameters

Generally, the rate formula for the mineral reaction is expressed as the following Eq. 3 (e.g., Lasaga 1998):

$$\text{Rate} = kA\exp(-E/RT)\,\Pi a_i^{n_i} f(\Delta G_r), \tag{3}$$

where k is the rate constant, A signifies the reactive surface area, E is the activation energy, R denotes the gas constant, T is the absolute temperature, a_i is the activity of chemical species i, and n_i stands for the reaction order for a_i. The last term $f(\Delta G_r)$ corresponds to a function related to the Gibbs free energy change, which is expressed as a function of the degree of saturation:

$$\Delta G_r = RT\ln\left(Q/K_{eq}\right), \tag{4}$$

where Q signifies the activity product and K_{eq} is the equilibrium constant. As shown clearly in Eq. 3, the reaction rate is calculated as the product of each parameter;

thus, just one inaccurate parameter can reduce the overall reliability of the calculated results.

The US Geological Survey (USGS) compiled the value of k, E, and n for H^+, in acidic, neutral, and alkaline ranges, based on the dissolution rate data for all the important minerals (Palandri and Kharaka 2004). This is currently one of the most useful reaction rate database, but these values are not always measured under conditions consistent with those in CGS. As a result, reaction rates may change due to differences in reaction mechanisms.

The A has long been discussed as the parameter with the highest uncertainty (e.g., Lasaga 1998). Especially when obtaining A, there is no agreement on whether the commonly used BET method – based on the amount of adsorbed inert gas – expresses the actual reactive surface areas. In addition, natural mineral surfaces are different from fresh cleavage planes often used in laboratory experiments and may be influenced by adhesion of clay minerals, coating of secondary products precipitated from leaching components, etc. (Blum and Stillings 1995; White and Brantley 2003). These effects of surface conditions also should be investigated further.

The $f(\Delta G_r)$ have mostly been overlooked in numerical simulations until now, as the knowledge of dissolution mechanism is especially limited. As a result, it was often approximated as a linear function of Q/K_{eq} based on the transition state theory (e.g., Xu et al. 2005). However, based on dissolution experiments of feldspars in recent years, it has been shown that $f(\Delta G_r)$ follows a sigmoidal curve, or an irregular shape is produced in response to the difference in dissolution mechanisms (Burch et al. 1993; Lüttge 2006; Hellmann and Tisserand 2006; Sorai and Sasaki 2010). On the other hand, the function form of the ΔG_r in the precipitation should incorporate the nucleation process prior to the growth. Most simulations assume that secondary minerals precipitate immediately after the solution becomes supersaturated (i.e., $Q/K_{eq} > 1$). In fact, however, nucleation first occurs when a certain critical supersaturation is achieved. In addition, rates differ in homogeneous nucleation in free space and heterogeneous nucleation on the wall. Especially the heterogeneous nucleation rate is predicted to change significantly depending on the property of the wall surface.

A factor that has not been considered much in previous numerical simulations is the activity of various impurities other than H^+, i.e., promotion and inhibition effects of the reaction. It is unrealistic to examine the effects of all chemical species dissolved in the formation water for each mineral in this regard. However, for example, in the precipitation of calcite – the most important CO_2 fixing mineral – it has been known for a long time that divalent cations such as Mg^{2+} function as inhibitory factors (e.g., Morse et al. 2007). Therefore, given the fact that the formation water generally includes these ions, effects of impurities should be taken into account at least in such reactions that relate to the nature of geochemical processes.

Setting Conditions

Simulation results are strongly influenced by the setting of primary and secondary minerals. Primary minerals can reflect the analysis of the rock samples from the site, but generated secondary minerals cannot be determined based on thermodynamically stable relationships only. In other words, when conducting an analysis from a kinetics perspective, in addition to the setting of a metastable phase as an intermediate product, the deviation from the thermodynamically stable region caused by changes in environmental conditions must also be considered (Gaus et al. 2008).

The simulation of CGS into sandstone aquifers often assumes that the CO_2 is mineralized into dawsonite. However, both thermodynamic and kinetic properties of dawsonite are not fully understood yet, except for some thermodynamic parameters (Bénézeth et al. 2007). Regarding this, the dawsonite dissolution rate measured at 80 °C and pH range of 3–10 indicates that dawsonite is in a stable phase only under high CO_2 pressure conditions; it dissolves rapidly as the CO_2 pressure decreases and mainly precipitates as kaolinite (Hellevang et al. 2005). Therefore, to avoid the overestimation of mineral trapping, care should be taken when assuming dawsonite. Similar issues exist for dolomite and magnesite, for which the precipitation mechanism is still unknown.

Measurement of Reaction Rates of Carbonates at Hot Springs

The CO_2 stored in aquifers dissolves in formation water to become carbonic acid, which in turn dissolves mineral components in rocks over a long period of time. Reaction rates of minerals are ordinarily extremely slow, but carbonates such as calcite or aragonite (calcium carbonate in both cases) are exceptions as they have high reactivity. When carbonates dissolve within alternating sandstone and mudstone layers, particularly in cases where the thicknesses of respective strata are thin, it can potentially lead to the formation of a leakage path to upper strata. In contrast, precipitation of carbonates can also occur when cations reaching from minerals in a sandstone stratum combine with bicarbonate or carbonate ions. In such cases, sealing performance would be enhanced due to the clogging of the sandstone stratum. The reaction of carbonates is, therefore, one of the most important geochemical processes associated with CGS, and knowing its rate is essential for geochemical simulations of CGS.

It has been pointed out that mineral reaction rates measured in laboratories are completely different from those in nature because of the effects of various factors, such as reaction time, surface area, surface conditions (defects and coatings), pore water compositions, mass transfers, and biological activities (Blum and Stillings 1995; White and Brantley 2003). For this problem, the authors attempt to obtain carbonate reaction rates at carbonated and bicarbonated springs in various regions of Japan, regarding these sites as the natural analogue field of CGS. Selected sites

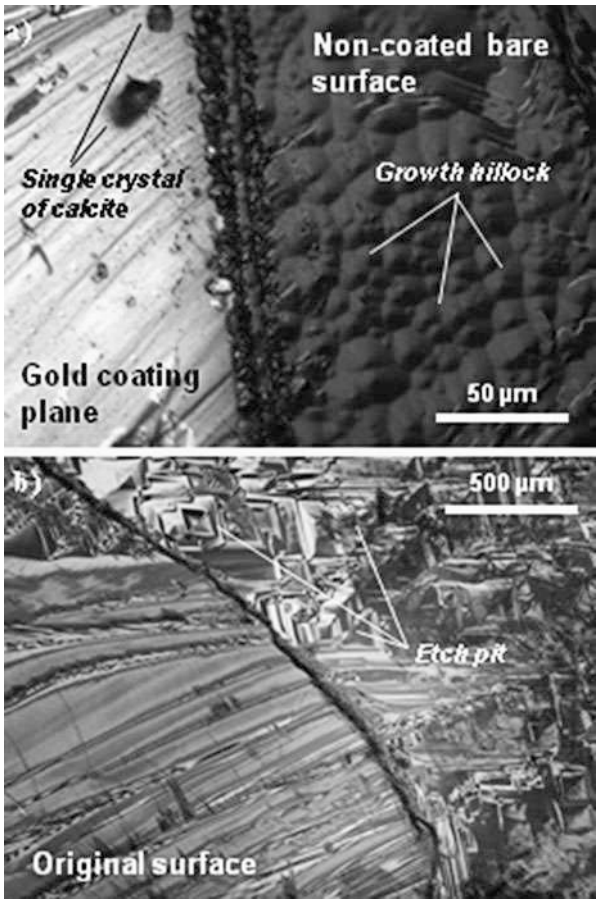

Fig. 5 Differential interference microscope images for reacted calcite surface: (**a**) growth experiment at Masutomi Hot Springs (30 min after the start of the reaction) and (**b**) dissolution experiment at Shichirida Hot Springs (336 h after the start of the reaction)

contain either undersaturated or supersaturated waters with respect to carbonates. At each site, cleaved single crystals of various carbonate species were immersed in the spring water for up to 1 month. Each sample was taken out at prescribed times for surface observations. A part of the sample surface was covered with a sputtered gold thin film or a silicon rubber for an inert reference area.

Figure 5a shows the calcite cleavage plane reacted in the supersaturated water at Masutomi Hot Springs in Yamanashi, Japan, as viewed with a differential interference microscope. Numerous pyramidal-shaped pattern, referred to as growth hillocks, formed immediately after the start of experiment. These growth hillocks grew in size and repeatedly combined with the progress of reaction. It is noteworthy that calcite single crystals in the shape of rhombohedron formed on a gold coating plane. This signifies that the solute flux applied uniformly on the sample was directly incorporated on a non-coated bare calcite surface to form growth hillocks, but the heterogeneous nucleation of calcite occurred on a gold coating plane, since solutes were not incorporated into gold. In contrast, Fig. 5b corresponds to the sample

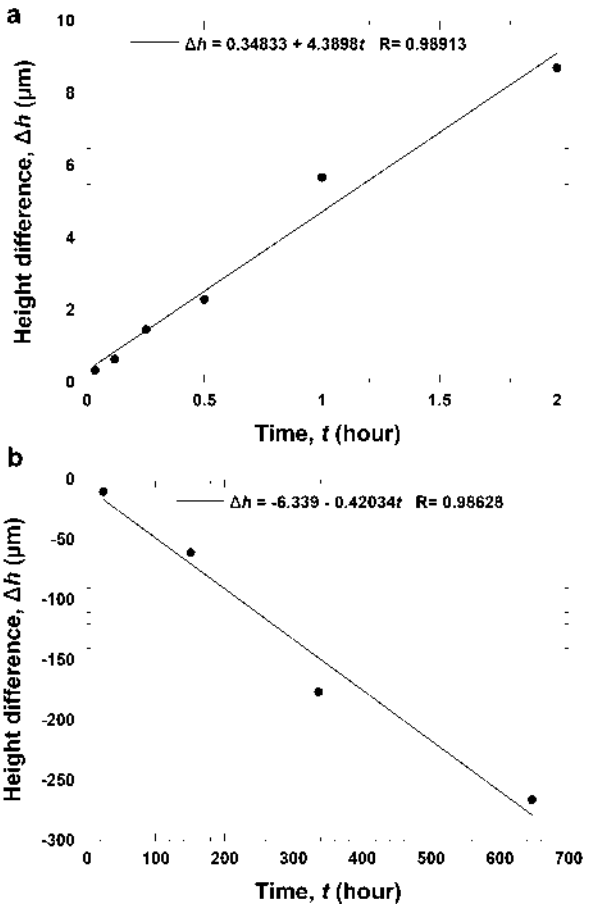

Fig. 6 The temporal profile of the height difference between the reacted and reference surface (gold coating or original surface): (**a**) growth experiment at Masutomi Hot Springs and (**b**) dissolution experiment at Shichirida Hot Springs

reacted in the undersaturated water at Shichirida Hot Springs in Oita Prefecture. The length scale of the image is different from that of Fig. 5a, since the change of surface configuration was greater due to the long duration of the experiment. The undersaturated water produced numerous etch pits in the shape of inverted pyramids, a pattern of dissolution. These etch pits were expanded and combined with the progress of reaction.

A phase shift interferometer with a nanoscale vertical resolution and a laser microscope were used to take measurements of the height difference Δh between coated and non-coated areas of these calcite cleavage planes (Sorai and Sasaki 2010). Figure 6 presents the time-course change of the Δh, corresponding to the experiments shown in Fig. 5 (Sorai et al. 2014b). The Δh for the former was expressed as a positive value, being growth from the reference plane, while the latter was expressed as a negative value, being regression from the reference plane. The growth and dissolution rates were estimated to be 3.3×10^{-5} and

3.2×10^{-6} mol m^{-2} s^{-1}, respectively, from the slope of a fitting line to the temporal profile. However, the growth and dissolution rates derived based on the USGS database described above were 4.5×10^{-5} mol m^{-2} s^{-1} and 2.9×10^{-6} mol m^{-2} s^{-1}, respectively, under identical temperature and pH conditions (Palandri and Kharaka 2004), showing that the experimentally obtained values, particularly with regard to the growth rate, were smaller by almost 30 %. Regarding this, the USGS database defines the reaction rate as a function of temperature, pH, and the degree of saturation, with no consideration given to the effects of impurities contained in the solution. Therefore, it is possible that the growth rate was reduced by trace dissolved components, primarily magnesium ions, in the field experiment. On the other hand, the effect of impurities on the dissolution process of calcite is presumably small because the actually measured and calculated values are practically identical for the dissolution rate.

Conclusion of This Section

Geochemical processes improve the safety of a reservoir by stabilizing and changing the form of CO_2 on geological time scales; however, geochemical processes can also result in negative effects such as increased leakage risks near injection wells and lowered injectivity. Evaluation of these geochemical processes tends to rely on numerical simulations owing to the long time scales involved. However, the author highlights that many previous studies point out the lack of sufficient knowledge on reaction kinetics, especially compared to the equilibrium theory. Therefore, to improve the reliability of simulation studies, data with high uncertainties and assumptions should be examined on a case-specific basis while referencing appropriate monitoring results of demonstration tests, laboratory experiments, natural analogue studies, etc.

Geophysical Monitoring and Modeling

Introduction

In CO_2 geological storage projects, monitoring is indispensable for verification of CO_2 storage. Various techniques are used to monitor the location of CO_2 injection and volumetric extent of CO_2 migration and detect possible leaks of CO_2 at faults and seals. Monitoring is required to implement for long time, beginning with the survey and development of a site, continuing throughout the CO_2 injection period, and even after the site is closed. Therefore, it is essential to develop monitoring technology that is cost-effective. In order to make CO_2 geological storage (CGS) projects acceptable to society, consideration of long-term cost is also very important.

Monitoring technologies for CGS are divided into four main categories: (1) atmospheric monitoring tools, (2) near-surface monitoring tools, (3) subsurface

monitoring tools, and (4) data integration and analysis technologies (Litynski et al. 2012). Here we describe geophysical monitoring and modeling technologies concerning the latter two categories.

Seismic Monitoring

Geophysical exploration methods that detect the two- or three-dimensional distribution of physical properties from the ground surface/sea surface are used as effective monitoring methods that can supplement well data (which provide direct information of the deep underground, but consist only of linear or point measurements). Among them representative one is seismic monitoring using active seismic methods such as seismic reflection, vertical seismic profiling (VSP), and cross-hole seismic tomography. Seismic monitoring is considered to be the standard monitoring method in CGS worldwide (e.g., Eiken et al. 2011). In these methods, an elastic wave emitted from multiple source points by a moving artificial hypocenter is received by a multichannel seismometer array spread across the wellbores or on the ground surface/seabed and then analyzed to estimate the elastic properties of the medium (e.g., elastic wave velocity and attenuation) through which the elastic wave propagates. The underground structure and physical state are estimated based on the results. Since it is believed that the outline of the underground area where injected CO_2 has spread (a CO_2 plume) can be detected through this process, active seismic exploration method, especially seismic reflection, is considered to be an extremely useful method for CO_2 monitoring.

In active seismic exploration, a "snapshot" that captures the underground CO_2 plume at a given time is obtained. This process of taking a snapshot is repeated over appropriate time intervals to detect temporal variations of the snapshots. In the seismic reflection, a method that obtains a "three-dimensional snapshot" using sources and geophones distributed on the ground surface is called three-dimensional (3D) reflection method. It is also called 4D reflection method since a time axis is added in monitoring. However, such seismic reflection surveys are expensive, in particularly expensive to conduct surveys in the ocean, where a ship is used for the deployment of sources and geophones. Since sources and geophones are spread over a wide area, negotiations with local people and officials in the survey area are also required, which can influence social receptivity to CGS. Therefore, it is desirable to decrease the number of 3D seismic reflection survey when monitoring needs to be conducted regularly. There are also the following fundamental limits: seismic waves can only detect elastic properties, and the detectable structures and resolution can change depending on the frequency, energy, and source location of the elastic wave. Considering these limitations, it is worthwhile to take into account the use of other geophysical methods, in particular passive exploration methods, which can supplement seismic methods and reduce overall monitoring cost.

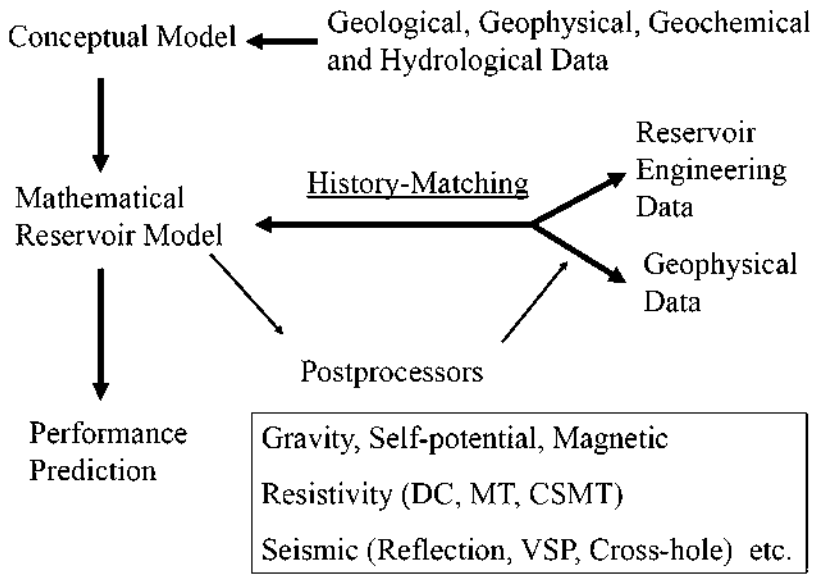

Fig. 7 Geophysical postprocessors. Various computational postprocessors permit the user to calculate temporal changes that are likely to be observed if geophysical surveys of an operating and/or closed CO_2 injection site are repeated from time to time. Results may be used to supplement conventional reservoir engineering measurements in history-matching studies undertaken during reservoir model development

Geophysical Modeling

To appraise the utility of geophysical techniques in monitoring of CO_2 injected into deep aquifers, Ishido et al. (2011) carried out numerical simulations using the so-called geophysical postprocessors. The geophysical postprocessors calculate temporal changes in geophysical observables that result from changing underground conditions computed by reservoir simulations (e.g., Pritchett et al. 2000; Ishido et al. 2011, 2015). The purpose of the development is to enable us to use monitoring data from repeat and/or continuous geophysical measurements in history-matching studies (Fig. 7). The name, postprocessor, comes from the fact that there is no need to couple and solve governing equations for geophysical phenomena with governing equations for reservoir simulations to calculate changes in geophysical observables; rather, they can be solved using the results of a reservoir simulation (snapshots) "afterwards." For example, electrokinetic phenomena handled by the self-potential postprocessor (Ishido and Pritchett 1999) are current flows coupled with fluid flow within the pores of rocks. It handles a phenomenon in which the potential difference (streaming potential) is created proportional to the pore pressure difference. The streaming potential leads to secondary pressure difference due to an electroosmotic effect at the same time, but the secondary pressure difference is extremely small and can be neglected.

Thus, governing equations for electrokinetic phenomena do not need to be solved at the same time as the governing equations for reservoir simulations. A simulation that couples "G" (geophysical observables) to a reservoir simulation, which is a TH coupled simulation in which governing equations for the transport of T (heat) and H (fluid/chemical species) are coupled and solved simultaneously, is generally not required. However, when calculating underground stress changes and/or ground surface deformation due to pressure or temperature changes, a THM coupled simulation that includes M (mechanics) should be performed if changes in porosity and permeability due to stress changes are important.

In the applications to CGS, the geophysical postprocessors can be used for the following purposes:

1. Planning of an appropriate monitoring system: Effective methods and way of monitoring can be chosen based upon prediction of changes in geophysical observables, which are calculated from underground flow models and potential risks associated with vertical faults, openings in the caprock, etc.
2. Quick understanding of the underground conditions: Whether or not injected CO_2 is stored as predicted can be judged by comparing the monitoring data obtained from actual geophysical measurements with predicted changes. If the behavior that is different from the predictions possibly arises from potential risks, the selection and deployment of effective monitoring methods can be examined.
3. Verification of the storage model: If the measured changes in geophysical observables are different from the predictions, the underground flow model is improved so as to reproduce the measured changes (history matching). The calibrated flow model provides a basis for reliable long-term predictions.

Flow Simulation Based Upon Tokyo Bay Model

Here, illustrative computations which have been carried out using various geophysical postprocessors are described, based upon the results of numerical simulations of CO_2 injection into an aquifer system underlying a portion of the Boso Peninsula/Tokyo Bay area and calculations of the temporal changes in geophysical observables caused by changing underground conditions as computed by the reservoir simulation.

The Tokyo Bay area in the southern Kanto plain is a representative industrial area in Japan. A number of large-scale CO_2 emission sources surround the Tokyo Bay. From a geological point of view, sedimentary strata underlying the Tokyo Bay area are believed to be suitable for open aquifer CO_2 storage (e.g., Okuyama et al. 2009). Late Pliocene to Middle Pleistocene Kazusa Group sediments are found below several hundred meters depth, comprising an alternation of turbidite sandstone and pelagic to hemipelagic mudstone. The sandstone is poorly consolidated with high porosity and permeability. The mudstone, on the other hand, is well consolidated, having fairly high porosity but very low permeability. Below the Boso Peninsula, the Kazusa Group sediments are more than 2,000 m thick, almost undeformed, and dip to the west toward Tokyo Bay at very low angles (less than 10°).

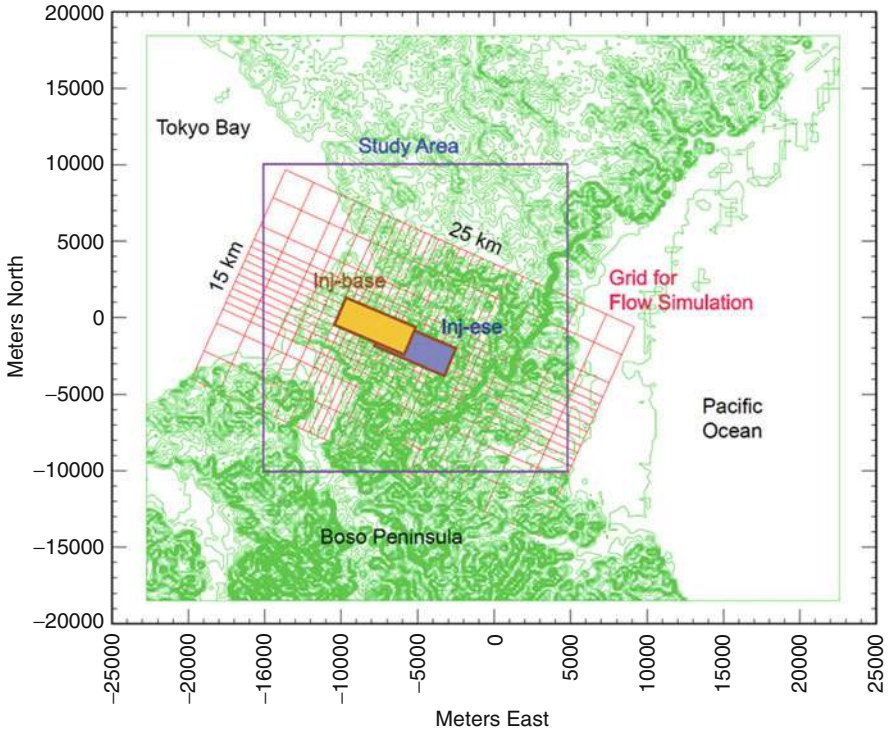

Fig. 8 Study area (in the Boso Peninsula, Japan) considered in the numerical simulation. Also shown is a top view of the computational grid blocks used for flow simulations. "Inj-base" and "Inj-ese" indicate the location of CO_2 injection site for the base and the ESE injection scenarios, respectively

A three-dimensional model is covering a 25 × 15 km^2 area (Fig. 8) and representing 2,500 m of alternating sandstone- and mudstone-dominated formations based broadly upon the geological structure underlying the Tokyo Bay area (Fig. 9). In the base-case model, the horizontal and vertical permeabilities are simply assumed as 50 and 10 mD (1 mD = 10^{-15} m^2), respectively, for the sandstone-dominated (aquifer) formations, and 10 and 1 mD, respectively, for the mudstone-dominated (seal) formations. In view of the relative thinness of individual mudstone layers compared to the vertical size of the computational grid blocks (=100 m), they assumed a relatively high average permeability for the mudstone-dominated seal formations. The porosity is assumed to be 0.2 for all formations. Relative permeability models for CO_2 gas and liquid water are represented by Corey-type curves (with 0.1 residual saturation) and van Genuchten-type curves (with 0.2 residual saturation), respectively (Fig. 10). Capillary pressure (gas or liquid CO_2 phase vs. aqueous phase) is represented by a van Genuchten-type model, and the capillary pressure magnitude is 3.58 kPa when the water saturation is ∼0.8 in the base model (Fig. 11).

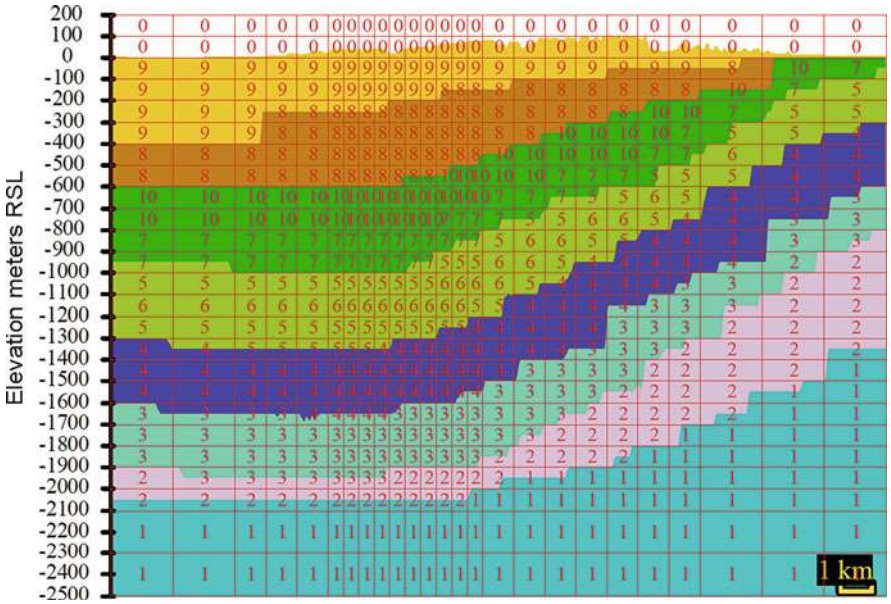

Fig. 9 Distribution of rock formations in the WNW-ESE section (x-z plane) at j = 8. The Umegase formation is indicated by the *dark blue* color.

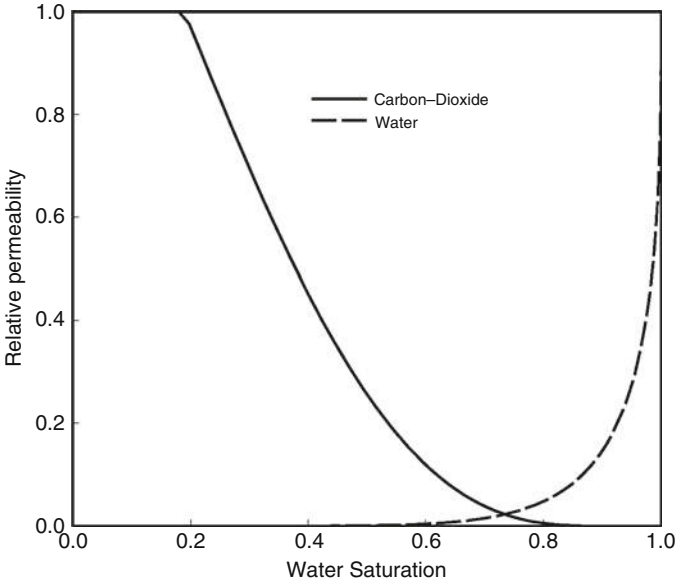

Fig. 10 Relative permeabilities for the non-wetting (carbon-dioxide gas, liquid carbonate) and wetting (water) phases. Residual saturation for the wetting (non-wetting) phase is 0.2 (0.1)

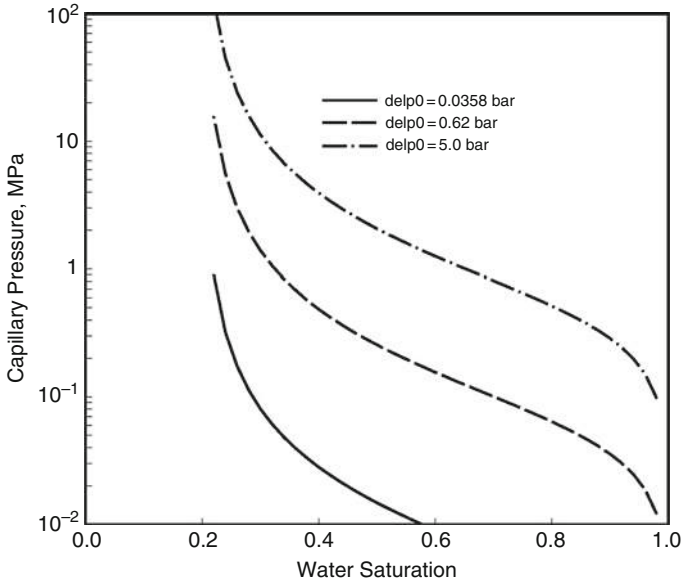

Fig. 11 Van Genuchten capillary pressure curves parameterized by delp0 (capillary pressure magnitude when the water saturation is ~0.8)

In the initial state, all of the pore space within the computational grid is full of motionless liquid H_2O (with small amount of dissolved CO_2). At the outer lateral boundaries, the fluid pressure distribution is maintained at the initial (hydrostatic) value. At the top boundary, the pressure and temperature are maintained at 1 bar and 15 °C, respectively. The bottom boundary is impermeable, and its temperature varies between 40 °C at x = 0 km and 60 °C at x = 25 km.

In the numerical simulations, the "STAR" reservoir simulation code (Pritchett 1995, 2002) was used with the "SQSCO2" fluid constitutive module (Pritchett 2008) which represents the thermodynamics and thermophysical properties of H_2O–NaCl–CO_2 mixtures over the range from liquid-CO_2 to supercritical-CO_2 conditions including the three-phase region. (For test problem #3 in a code intercomparison project (Pruess et al. 2002), the STAR/SQSCO2 gave almost the same results (dry-out region development, disolved CO_2 mass fraction, etc.) as those given by the TOUGH2/ECO2N simulation (Pruess 2005). See Fig. 12) Similar to the TOUGH2/ECO2M (Pruess 2011), the STAR/SQSCO2 can describe all possible phase conditions for brine–CO_2 mixtures, including transitions between super- and subcritical conditions and phase change between liquid and gaseous CO_2.

Simulations were carried out for 50 years of injection (at a rate of ten million tons of CO_2 per year) into a sandstone-dominated layer at 1,400 m depth (the Umegase formation) at the grid blocks (i = 10, 11; j = 8, 9; k = 9; "Inj-base" shown in Fig. 8) followed by 1,000 years of shut-in. The internal energy of the injected

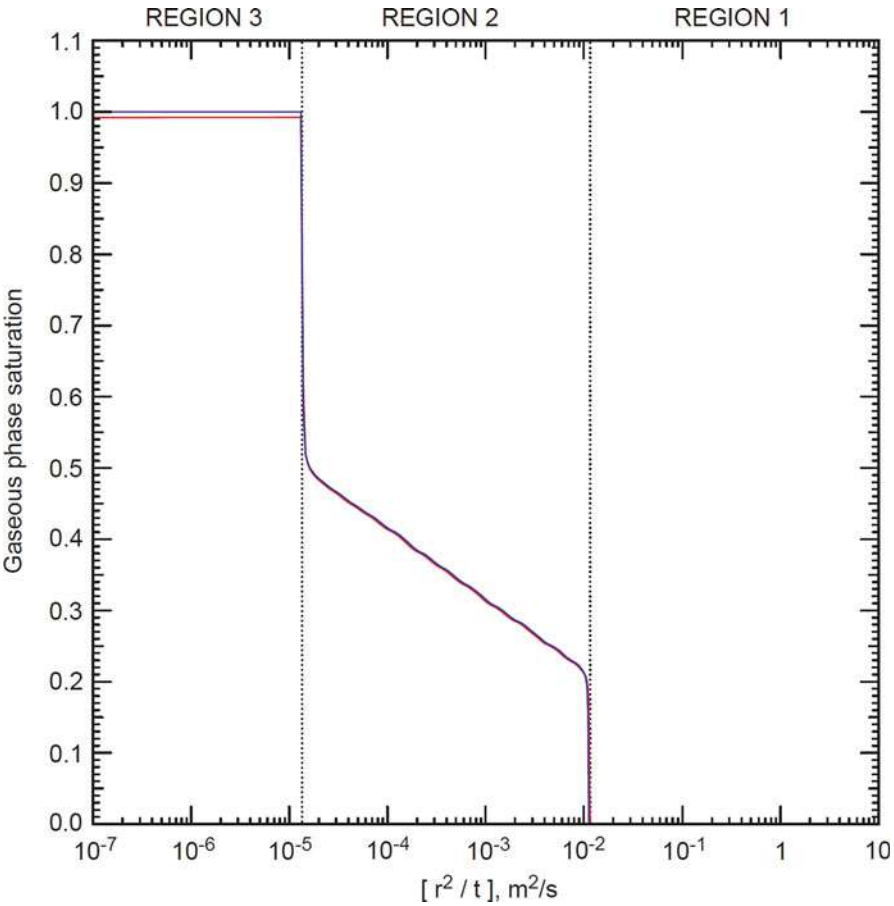

Fig. 12 A result of the "STAR/SQSCO2" application to test problem #3 in a code intercomparison project (Pruess et al. 2002). Computed distribution of gaseous-phase saturation as a function of the similarity variable ξ ($= r^2/t$) for freshwater (blue) and seawater (red) cases (after Pritchett 2008)

CO_2 corresponds to a temperature and pressure of ~34 °C and ~144 bars (same as in situ conditions prior to injection). Here the results for two variants of the base case model: "*L-k*" and "*H-k*" models are presented, in which the horizontal/vertical permeabilities of the Umegase formation are 50 mD/ 10 mD and 500 mD/ 100 mD, respectively. Figure 13 shows the distribution of pressure, temperature, and phase saturations at t = 50 years (when injection ceases) and 1,050 years (after 1,000 years of shut-in) for the "H-h" model. At t = 50 years, the injected CO_2 remains as a supercritical free phase with the saturation 0.2 or more within the sandstone-dominated layers (the Umegase and underlying Otadai formations). After injection ceases, the CO_2 density decreases (and its volume increases) due to pressure release. The supercritical CO_2 then gradually migrates upward for hundreds of

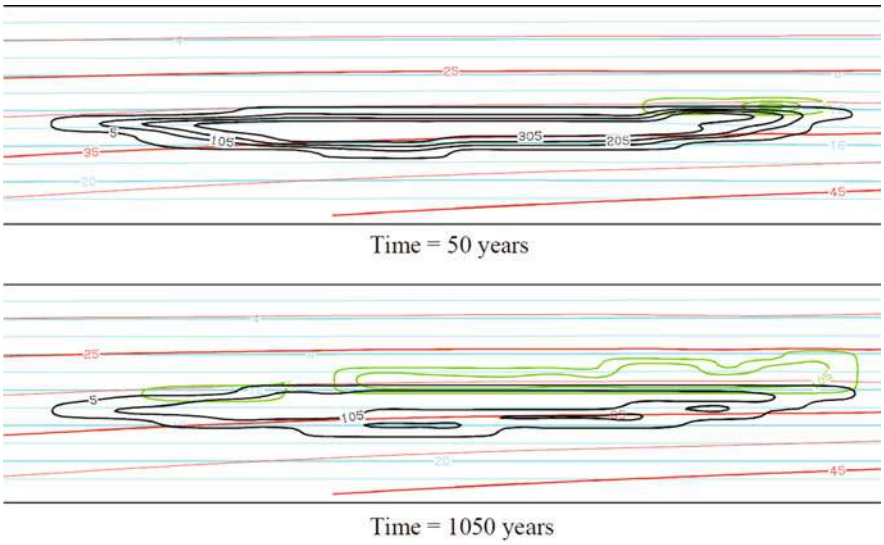

Fig. 13 "*H-k*" model: pressure (*cyan*), temperature (*red*), liquid CO_2 (*green*) and gas (*black)* saturation contours in x-z plane at j = 8 at t = 50 and 1050 years. Contour interval is 2 MPa for pressure and 5 °C for temperature. Liquid CO_2 and gas saturation contour labels are 0.005, 0.105, 0.205 and 0.305. The region shown in the figure extends 2500 m in the vertical (z) direction and 10,000 m (i = 3, . . ., 19) in the x-direction

years due to buoyancy and penetrates into the overlying seal layer (the Kokumoto formation). However, the rising gaseous CO_2 is then densified at shallower levels as the temperature decreases below the critical temperature at sufficiently deep levels and becomes relatively immobile liquid CO_2 condensate. As shown in Fig. 14, at t =1,050 years about 17 % of the CO_2 is trapped as immobile CO_2 condensate at near residual saturation, and the remaining CO_2 is trapped as dissolved CO_2 in the aqueous phase (41 %) and supercritical residual gas below the seal layer (42 %). Other similar calculations have shown that if a much lower permeability (i.e., 0.1 mD) or a larger capillary pressure is assumed for the seal layer than in the base-case model, CO_2 intrusion into the seal layer in the postinjection period will become negligible.

Prediction of Changes in Geophysical Observables

Next, various "geophysical postprocessors" were used to calculate time-dependent earth-surface distributions of seismic observables (from reflection, VSP, or tomography surveys), microgravity, electrical self-potential (SP), and apparent resistivity (from either DC or MT surveys). The temporal changes are caused by changing underground conditions (pressure, temperature, gas saturation, concentrations of dissolved species, flow rate, etc.), as computed by the reservoir simulations.

Figures 15 and 16 show seismic sections calculated by applying the seismic (reflection survey) postprocessor (Stevens et al. 2003) to the reservoir simulation

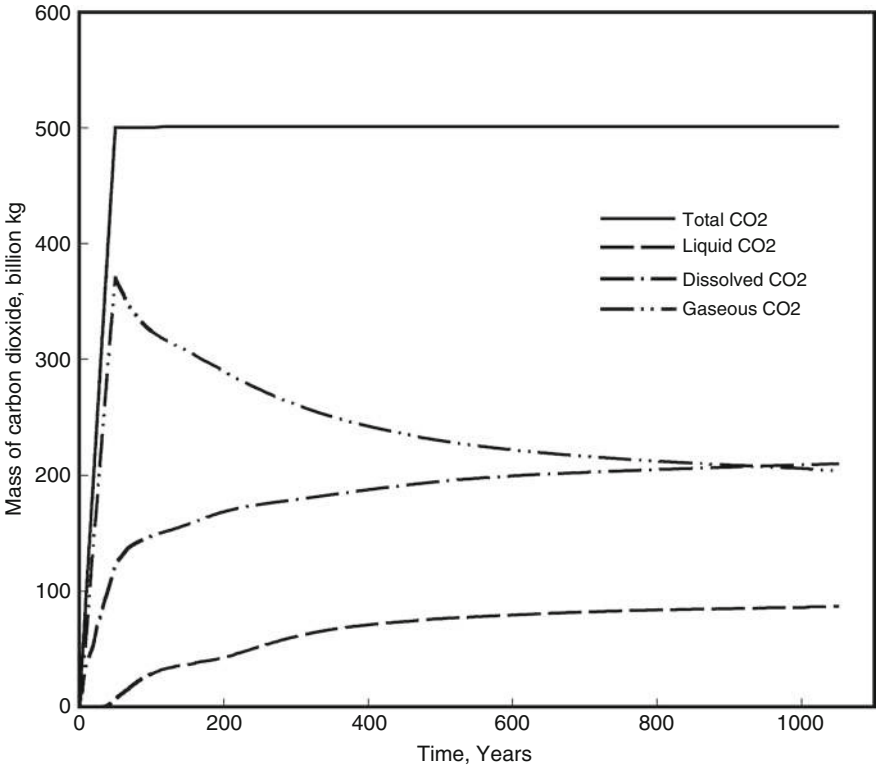

Fig. 14 "*H-k*" model: total mass of carbon-dioxide, mass of liquid CO_2, mass of CO_2 dissolved in water, and mass of gaseous (and supercritical) CO_2 in the computational grid

results. The reflected waves correspond to the upper and lower boundaries of regions containing CO_2 gas around the injection wells. In this case, the seismic postprocessor calculated the seismic velocity and Q factor in the water/gas two-phase regions using a "patchy saturation" model (e.g., Mavko et al. 2009). In this model, the low-frequency and high-frequency limiting bulk moduli are given by Gassmann's relation and by Hill's relation, respectively. The "standard linear solid" is applied to predict the velocity dispersion and attenuation with the characteristic frequency, which is inversely proportional to the square of liquid cluster size which depends on the liquid-phase saturation. The reflection events for the "*H-k*" model (Fig. 15) corresponds to the CO_2 gas region at t=50 year shown in Fig. 13. Compared with this, the seismic events for the "*L-k*" model (Fig. 16) remains in a narrower region, which corresponds to a less horizontal expansion of CO_2 gas region due to lower permeabilities of the injection aquifer (the Umegase formation) assumed for the "*L-k*" model.

Figure 17 shows "sounding results" calculated by using the magnetotelluric (MT) postprocessor for the "*L-k*" model. In this calculation the postprocessor assumes that the pore fluid salinity is homogeneous at 0.01 below the upper surface

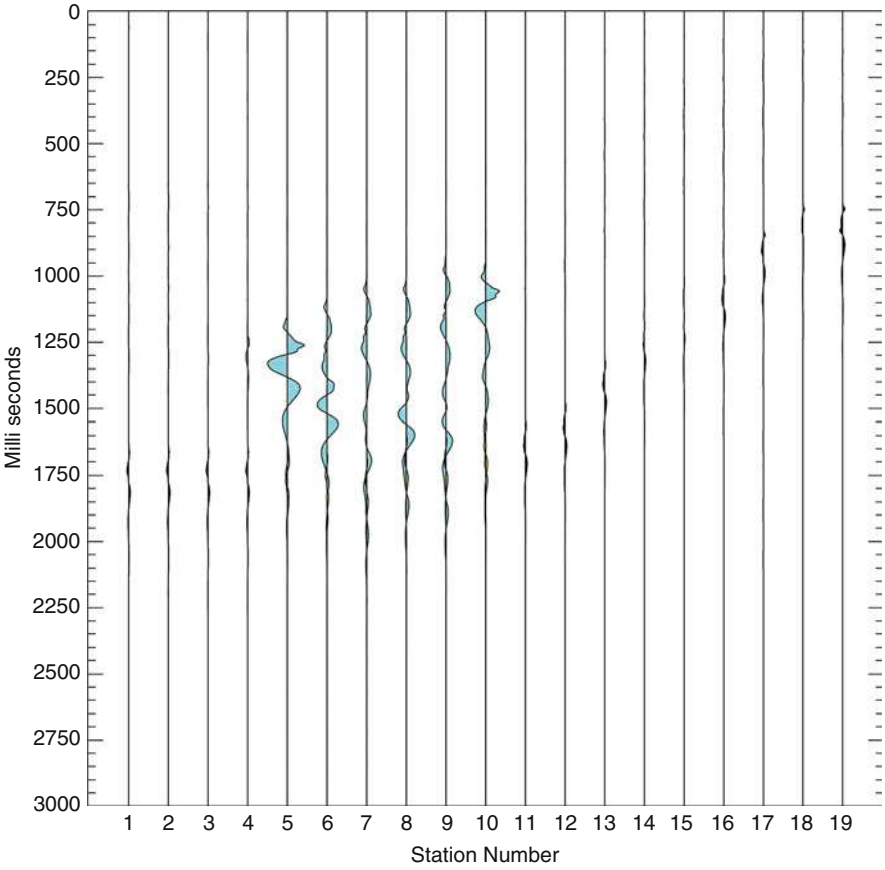

Fig. 15 "*H-k*" model: comparison of time-series results (*blue*) calculated for a seismic reflection survey after 50 years of CO_2 injection with those for an initial survey (*yellow*) across the center of the study area (along 24 km-long A–A′ line shown in Fig. 18). The results overlapped with each other are shown by *black color*

of the seal layer (the Kokumoto formation), which gives ~2.5 S/m pore fluid conductivity around the injection level. Change in the pore fluid conductivity (σ) due to CO_2 injection is given so as that σ is proportional to the square of the aqueous-phase saturation. In shallower levels than the seal layer, the bulk conductivity of rock–fluid mixture is fixed at 0.01 S/m to represent freshwater regions. As seen in Fig. 17, although the apparent resistivity of the CO_2-saturated region does not change very rapidly, it has increased by 15 % or more after 50 years.

Figure 18 shows changes in earth-surface gravity at t = 50 years for the "*H-k*" model. The maximum decrease, which appears just above the injection zone, is about 75 μGal. The gravity disturbance grows almost linearly with time during the 50 year of injection interval (Fig. 19). After shut-in, further gravity decrease takes place up to about t = 55 years arising from the upward buoyant migration of the

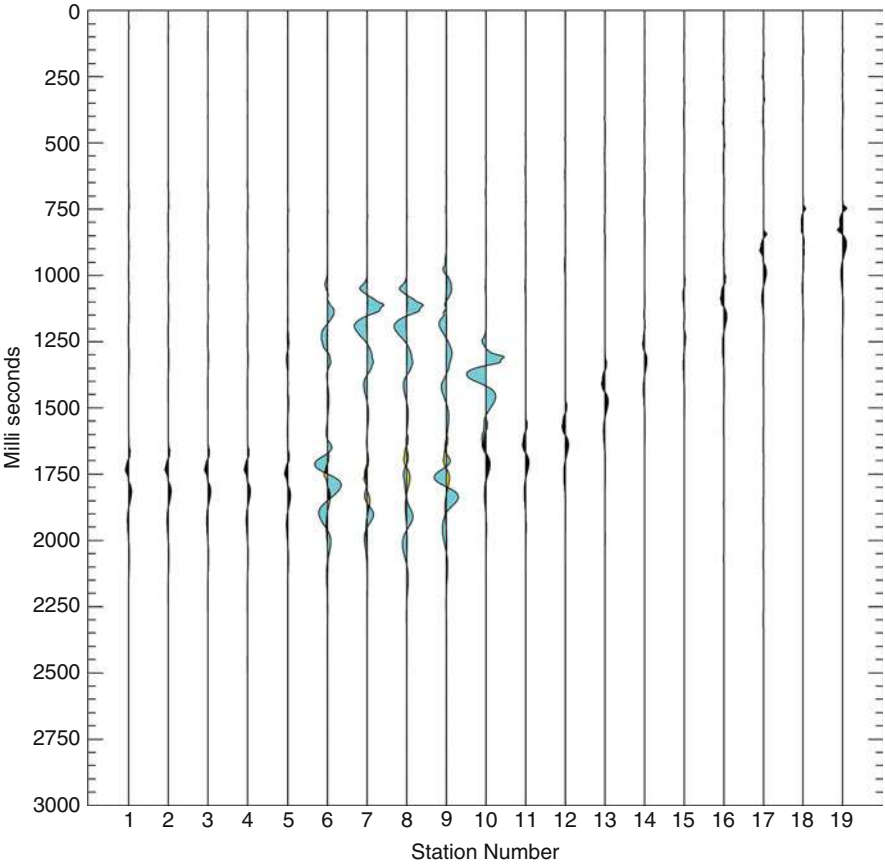

Fig. 16 "*L-k*" model: comparison of time-series results (*blue*) calculated for a seismic reflection survey after 50 years of CO_2 injection with those for an initial survey (*yellow*) across the center of the study area (along 24 km-long A–A′ line shown in Fig. 18). The results overlapped with each other are shown by *black color*

CO_2 (Fig. 19). However, the rate of further gravity change becomes very small after $t = 60$ years although the upward migration continues for hundreds of years after shut-in. This is because the supercritical CO_2 entering the Kokumoto seal layer is densified by condensation as the temperature decreases below the critical temperature at sufficiently deep levels and the upward movement slows down. As for the "*H-k*" model, gravity increase and decrease continue at stations 1 and 2 respectively after $t = 55$ years. This slight change reflects CO_2 gas movement from the injection location to peripheral regions.

Figure 20 shows downhole borehole-gravity response at stations 1 and 2 (see Fig. 18 for the locations) for the "*H-k*" model. At the injection location (station 1), pronounced gravity changes appear even as early as $t = 5$ years, corresponding to the thickness of the CO_2 plume. At station 2, the change in earth-surface gravity is

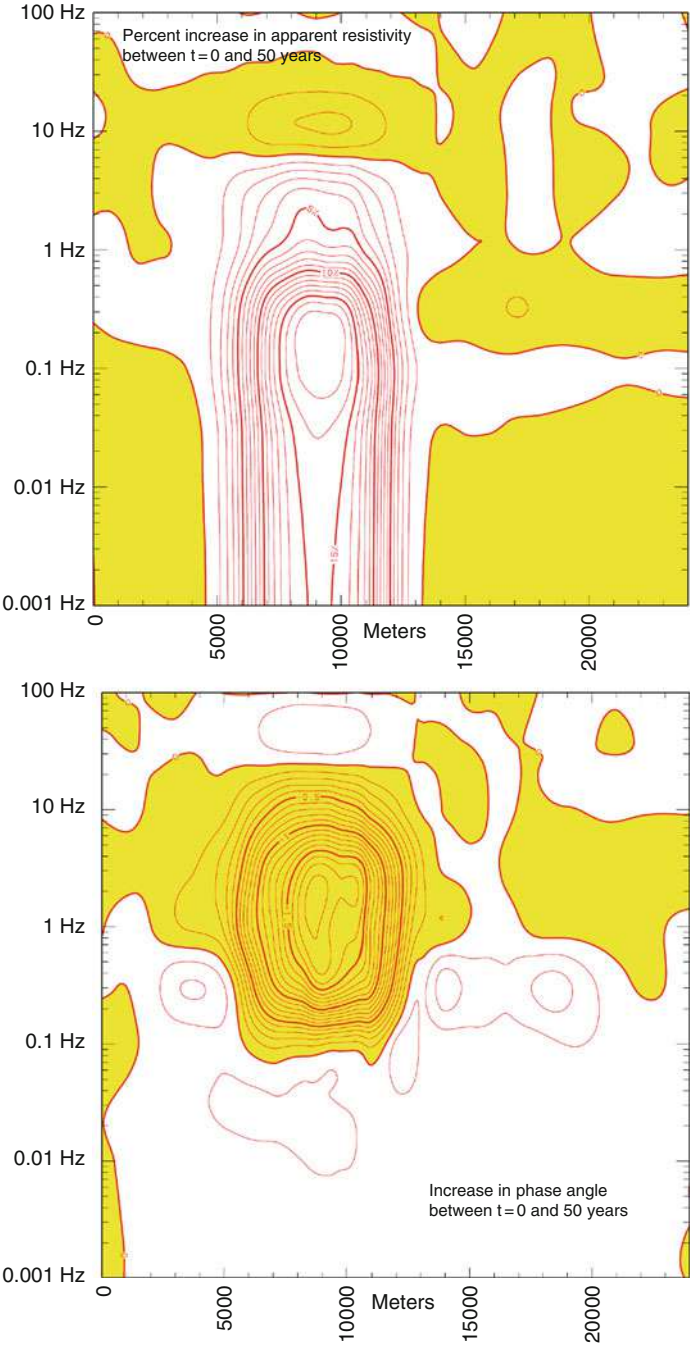

Fig. 17 Percentage apparent resistivity increase (*upper*) and phase angle increase (*lower*) as a function of frequency between t=0 and 50 years along 24 km long A–A0 line shown in Fig. 18

small even at t = 50 years (Fig. 19), but the borehole response is very apparent particularly after 25 years or so when the expanding CO_2 plume engulfs the borehole location.

Figure 21 shows change in self-potential (SP) at t = 5 years for the "*H-k*" model; the maximum increase, which appears just above the injection zone, is more than 40 mV. The self-potential postprocessor calculates changes in subsurface electrical potential induced by pressure disturbances through electrokinetic coupling (Ishido and Pritchett 1999). Since the permeability of the seal layer (the Kokumoto formation) is relatively large in the present model, a pressure disturbance propagates to shallower levels where a transition zone between the shallower fresh and deeper saline water is assumed to be present as in the MT calculations. This transition zone acts as an interface between regions of different streaming potential coefficient. Pressure increases about 2 bars around this interface, which is located at a depth of ~1,000 m at the injection location, bringing about a positive change of 40 mV at the earth surface (see the vertical section in Fig. 21). This obvious SP change develops rapidly with pressure increase for the first several years and persists until shut-in at t = 50 years. After shut-in, SP disturbance gradually declines as pressures return to their original levels. As seen in Fig. 22, more pronounced SP disturbance appears for the "*L-k*" model, which corresponds to larger pressure buildup (about 5 bars) due to CO_2 injection into the lower permeability formation.

Summary

Of course, the applicability of any particular method is likely to be highly site specific, but the calculations described here indicate that none of these techniques should be ruled out altogether. In addition to seismic methods (especially reflection surveys, e.g., Chadwick et al. 2009), microgravity surveys appear to be suitable for characterizing long-term changes, and SP measurements are quite responsive to short-term disturbances.

The computed gravity changes suggest that microgravity monitoring can be used to characterize the subsurface flow of CO_2 injected into underground aquifers. Gravity monitoring results are sensitive to the lateral migration of the CO_2-rich phases (both liquid condensate and particularly gaseous CO_2). Gravity monitoring may also be useful for assessing the suitability of particular disposal aquifers for CO_2 sequestration. If the geothermal gradient is low as is observed in a portion of the Tokyo Bay area, the predicted decrease in gravity is quite small considering the relatively large injection rate. Even if the (supercritical) gaseous CO_2 gradually migrates upward for hundreds of years after injection, the gaseous CO_2 will be densified as the temperature decreases below the critical temperature at sufficiently deep levels and become relatively immobile liquid condensate, which is much less likely to escape the aquifer than highly buoyant, low-viscosity CO_2 gas. When this occurs, the gravity change is very slight during the 1,000-year postinjection period. Considering the current advanced technology for field measurements (e.g., Nooner et al. 2007; Alnes et al. 2008; Sugihara and Ishido 2008; Sugihara et al. 2013), microgravity monitoring is thought to be a very promising technique for evaluating CO_2 geological storage.

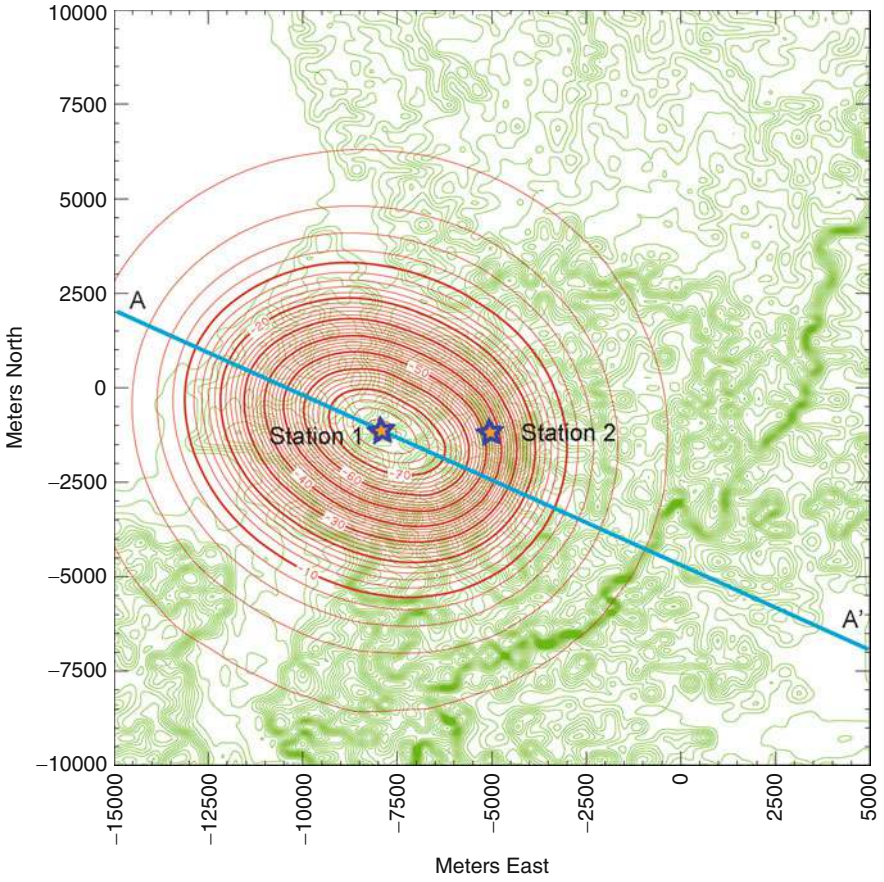

Fig. 18 Distribution of gravity change between t = 0 and 50 years in the study area shown in Figure 8 (extending from −15 km to 5 km in the east-west direction and from −10 km to 10 km in the northsouth direction). Maximum decrease is ∼75 μGal near the injection site centered at −8 km east and −1 km north

The self-potential postprocessor calculates changes in subsurface electrical potential induced by pressure disturbances through electrokinetic coupling. If the permeability of the seal layer overlying the injection zone is not too small, substantial SP changes will appear at the earth surface during the first few years of injection. At least in coastal and estuarine environments, this large change is produced by a pressure increase of several bars at the interface between the shallower fresh and deeper saline water layers, which acts as an interface between regions of different streaming potential coefficient. If a discontinuity of streaming potential coefficient is present, SP monitoring can be an effective technique for monitoring pressure changes near the interface at depth.

Geomechanical Modeling

Introduction

When any kind of fluid like CO_2 is pressure injected into an underground reservoir as is done for geological CO_2 storage, the pressure (pore pressure) of the fluids underground increases, and the stress distribution underground may change. Stress redistribution within and surrounding the reservoir and caprock system may lead to geophysical changes, microseismicity, and fault reactivation and may even trigger

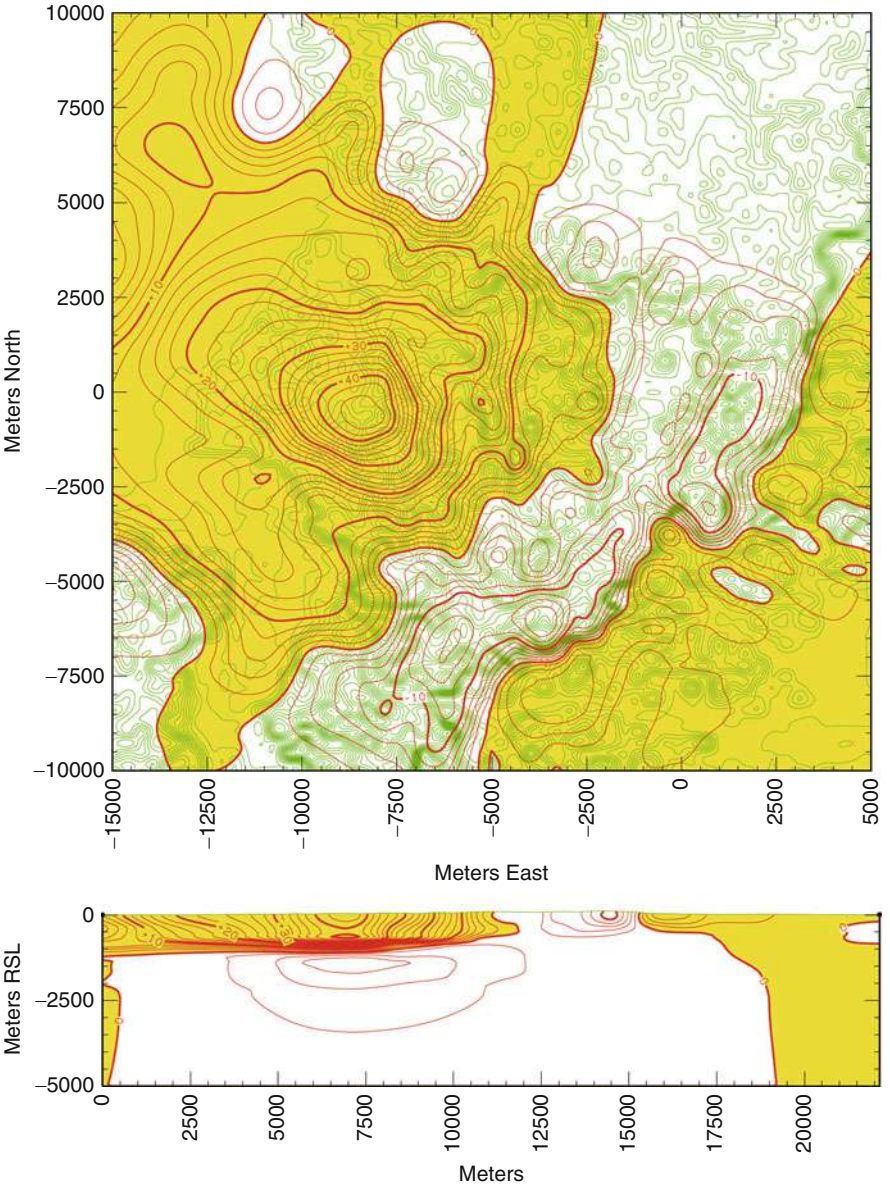

Fig. 21 Distribution of self-potential at the earth's surface (*upper*) and a vertical section (*lower*) for the "*H-k*" model at t = 5 years. The area represented is the same as that of Fig. 18. Contour interval is 5 mV, and the *yellow color* denotes positive SP

large earthquakes (Giammanco et al. 2008; Lei et al. 2008; Miller et al. 2004; Yamashita and Suzuki 2009). For example, at a gas field in In Salah, Algeria, where CO_2 is pressure injected to enhance natural gas production, synthetic aperture radar observations from a satellite have indicated a ground uplift rate of about 1 cm/year around the CO_2 pressure injection wells, along with a similar amount of subsidence around the gas production wells (Onuma and Ohkawa 2009). In some gas fields in the Sichuan Basin, China, following injection of unwanted water into depleted gas reservoirs, a number of seismic sequences have been observed with sizable earthquakes ranging up to M4 $\sim$ 5 (Lei et al. 2008, 2013). In recent years, following the rapid increase of applications in which fluids are intensively pressed into the deep formations of the Earth's crust, such as the enhanced geothermal system (EGS), fracking of shale gas, and geological sequestering of CO_2, injection-induced earthquakes and other risks related to injection-induced rock deformation and failure have attracted growing attention (Ellsworth 2013; Lei et al. 2013; Zoback et al. 2013; Zoback and Gorelick 2012).

Indeed, geophysical changes and microseismicity are useful in the monitoring and management required during and after a large-scale injection project. However, the risks related to fluid leakage and earthquakes that can be felt may give rise to strong social impacts. The issue of noticeable or damage-causing earthquakes induced by artificial operations is controversial and has been the cause of delays and threatened cancelation of some projections such as the EGS (enhanced geothermal system) project at Basel (Deichmann and Giardini 2009). To carry out geological CO_2 storage safely and for this technology to be accepted not only by the

inhabitants around the storage sites but also by the society as a whole, technological developments that address such public concerns are essential. In addition, there is a strong desire to be able to control or predict the occurrence of damaging earthquakes. In this regard, geophysical/geomechanical modeling is key in site selection, injection operation, and postinjection management.

The purpose of the following subsections is to provide a general framework for geophysical/geomechanical modeling and microseismicity analysis. Section "A General Framework of Geophysical/Geomechanical Modeling" introduces a general framework for modeling. Then, section "Numerical Simulation for THM Coupling Analysis" introduces the numerical simulation technology used in the coupled THM (heat transferring, fluid flow, rock mechanics) analysis. Postprocessing for history matching and fault stability analysis is presented in section "Fault Stability Analysis: Coulomb Failure and Slip Tendency." A case study of a natural analogue is introduced in section "An Example of a Natural Analogue: The Matsushiro Seismic Swarm Driven by CO_2-Quality Fluid Activity." Finally, section "Data Processing and Analysis of Injection-Induced Seismicity" introduces some key technologies for data processing and analyzing of injection-induced seismicity.

A General Framework of Geophysical/Geomechanical Modeling

Figure 23 shows a schematic flowchart of modeling with coupled THM simulation and history matching using a geophysical postprocessor (see section "Geophysical Monitoring and Modeling" for details). Firstly, existing geological and geophysical data should be integrated to build a conceptual geological model of a reservoir system. Then the mechanical and petrological properties of the major rocks in the geological model must be sufficiently investigated to create a numerical model. Additional laboratory experiments might be required to collect data on specified rocks to improve the reliability of the numerical analysis. Finally, history matching is applied to refine the numerical model of a reservoir to reproduce observed data. All data obtained through geophysical exploration methods, such as microgravity measurements, seismic exploration, electrical or electromagnetic exploration, etc., can be used in history matching to improve the accuracy of future forecasts. Geophysical postprocesses are used to convert changes in pressure, temperature, salinity, CO_2 saturation, etc., calculated by reservoir simulation into changes in geophysical observables (Ishido et al. 2011, section 5). Since there are uncertainties in many aspects of the numerical model, such as small-scale inhomogeneity and upscaling, uncertainty analysis is necessary for a probability-based prediction.

In geomechanical modeling, discontinuous structures including joints, fractures, and faults have a governing role in fluid flow and rock stability. Studies on water injection-induced seismicity in depleted gas/oil reservoirs show that earthquakes of relatively greater magnitude (M3 or greater) are mostly related to the reactivation of preexisting faults, favorably or unfavorably oriented, within or

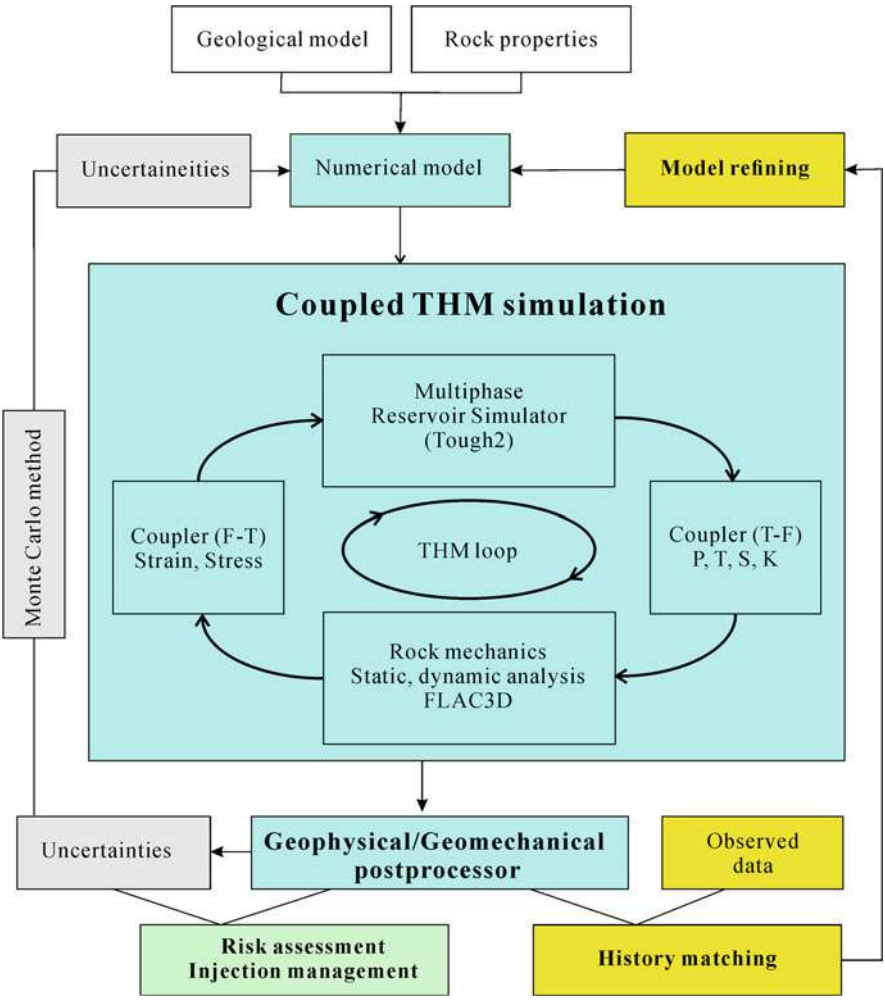

Fig. 23 Flowchart of modeling with coupled THM simulation and history matching using a geophysical postprocessor

surrounding the reservoir (Lei et al. 2008, 2013). Therefore, estimating fault stability and sustainable fluid pressures for underground storage of CO_2 is an important issue in geomechanical modeling (Rutqvist et al. 2008; Streit and Hillis 2004). Known major faults in or near target aquifers can be avoided during site screening. Since a fault of a dimension of a few hundreds/thousands of meters is sufficient to produce $\sim$ M3/M5 earthquakes as indicated by the empirical relationship between source dimension and earthquake magnitude (Utsu 2002), faults that are not resolvable by geophysical surveys must also be properly addressed (Mazzoldi et al. 2012).

Numerical Simulation for THM Coupling Analysis

There is a current focus on coupled THM analysis as a budding technology. This technology is used to predict injection-induced changes in rock properties, formation deformation, stress redistribution, and fracture/fault stability. Although the simulation technology is still in development, there are a number of choices of research-oriented or commercial software for reservoir simulation and/or stress analysis, such as TOUGH2 and FLAC3D. TOUGH2 is a multiphase reservoir simulation program developed by the Lawrence Berkeley National Laboratory (LBNL) in the US FLAC-3D (Itasca 2000) and is a commercial software for stress analysis. As a promising combination, the "TOUGH-FLAC" approach with couplers developed by Rutqvist et al. (2002) has proven useful in the analysis of deformation accompanied with fluid flow within hard and soft rocks in geothermal studies (Todesco et al. 2004), in CCS studies (Funatsu et al. 2013; Rinaldi and Rutqvist 2013; Rutqvist et al. 2008), and in natural analogues (Cappa et al. 2009).

A schematic of the couplers and physical quantities handled by the TOUGH-FLAC approach is shown in the center of Fig. 23. A reservoir is presumably a porous medium filled with formation water. If a fluid (CO_2 in CGS) is pressure injected into this reservoir, the pore fluid pressure increases, and there is flow between the formation water and the pressure-injected fluid. Changes in pore fluid pressure lead to small changes in the reservoir rock. In addition, if there is a temperature difference between the reservoir and the pressure-injected fluid, as the fluid flows and spreads, heat is transported, and the temperature change causes rock deformation. The fluid flow simulator TOUGH2 calculates changes in the pore fluid pressure, temperature, degree of saturation, etc., and sends the results to the rock mechanics simulator in FLAC3D. The rock mechanics simulator then calculates the solid deformation and sends the changes in porosity, permeability, and capillary pressure back to the fluid flow simulator. The couplers are some built-in functions in TOUGH2 and FISH codes in FLAC3D (Rutqvist et al. 2002). Such coupling approaches, termed sequential coupling, work well for problems in which coupling is relatively weak.

In the THM coupling simulation, the following parameters and models are required and should be investigated through laboratory experiments: (1) parameters governing the deformation and fracturing behaviors of a given rock; (2) petrophysical models linking porosity, intrinsic permeability, relative permeability, and effective confining pressure; and (3) permeability of fracture as a function of effective confining pressure. Rock properties and mechanical behaviors strongly depend on individual rock types and structures within the rock. Thus, individual rocks of a target reservoir system should be fully investigated to obtain reliable parameters. If a typical rock of the reservoir system has not been investigated by earlier studies, additional experimental study is required. Further, laboratory experimentation has a twofold role in geomechanical modeling. On one hand, it is the only way to get the physical/mechanical/hydraulic properties of a given rock and the constitutive laws required for conducting numerical models (Lei and Xue 2009; Lei et al. 2011a). On the other hand, a well-designed experiment is

useful for verifying and improving a related numerical model by matching the numerical results with the experimental results (Lei et al. 2015).

Permeability might change greatly due to deformation and fracturing (Zhang et al. 2007). In brittle rocks, fault rupturing can lead to a 2-order-of-magnitude permeability increase as estimated by in situ testing (Ohtake 1976) and laboratory experiments (Alam et al. 2014). Thus, permeability as function of deformation should be properly considered. In the TOUGH-FLAC approach, permeability is revised within Tough2 in every time step by built-in functions. In some previous works, permeability has been expressed as a function of volumetric strain (ε_v) or shear strain (ε_s) (Cappa et al. 2009; Cappa and Rutqvist 2011; Chin et al. 2000):

$$k = k_0(1 + \beta\Delta\varepsilon_s) \tag{5}$$

$$k = k_0\left(\frac{\phi}{\phi_i}\right)^n, \varphi = 1 - (1 - \varphi_i)e^{-\varepsilon_v} \tag{6}$$

where ϕ and k are porosity and permeability, respectively, with ϕ_i and k_i being the initial values. A β on the order 10^4 or n of ~30 results in a 2-order-of-magnitude permeability increase for a fully reactivated fault (Fig. 24). As seen from Fig. 24, Eqs. 5 and 6 result in quite different behaviors. This should be examined in future studies.

Fault Stability Analysis: Coulomb Failure and Slip Tendency

In most cases, the stress tensor is not fully defined or is badly defined, so rock failure analysis based on absolute stress tensors may lead to incorrect results. The earth's crust is considered to be critically stressed; thus, a small change in stress may trigger earthquakes. The amplitude thresholds of the Coulomb failure stress change (ΔCFS) required to trigger earthquakes has been estimated to range from 0.01 to 0.03 MPa (Brodsky and Prejean 2005; Cochran et al. 2004; King et al. 1994; Lockner and Beeler 1999; Stein 1999). Based on Coulomb failure law, the critical condition for rupturing on a preexisting fault is

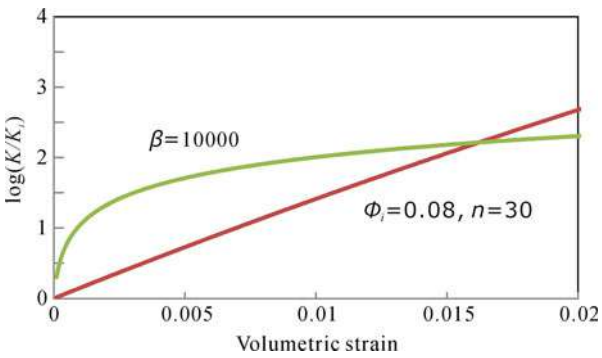

Fig. 24 Rock permeability as a function of volumetric strain for two different models

$$\tau = \mu\sigma_e = \mu\left(\sigma - P_f\right) \tag{7}$$

where τ and σ are shear and normal stresses acting on the fault plane, respectively, σ_e is effective normal stress, P_f is pore pressure, and μ represents the sliding friction of the fault plane. A change in Coulomb failure stress (ΔCFS) is defined as

$$\Delta CFS = \Delta\tau - \mu\Delta\sigma_e \tag{8}$$

The tendency of a planar discontinuous structure such as a fault to undergo slip under a given stress pattern depends on the frictional coefficient of the surface and the ratio of shear to normal stress acting on the plane. The slip tendency of the fault is defined as the ratio of the shear stress and normal stress (Morris et al. 1996) and thus equals the friction coefficient:

$$Ts = \tau/\sigma_e \tag{9}$$

Slip-tendency analysis is a technique that visualizes the stress tensor in terms of its associated slip-tendency distribution and the relative likelihood and direction of slip on interfaces at all orientations (Morris et al. 1996). It can be used in assessing the risks of geological CO_2 storage (Kano et al. 2014).

Under a uniform regional stress field, the most optimally oriented fault has the maximum slip tendency, as faults with greater slip tendency values are easier to rupture.

Under the principal stress coordinate system (s1, s2, s3), the shear and normal stresses on a surface of given direction cosines (l, m, n) can be calculated from the three principal stress magnitudes (σ_1, σ_2, σ_3) as:

$$\begin{aligned} \tau^2 &= (\sigma_1 - \sigma_2)^2 l^2 m^2 + (\sigma_2 - \sigma_3)^2 m^2 n^2 + (\sigma_3 - \sigma_1)^2 n^2 l^2 \\ \sigma^2 &= {\sigma_1}^2 l^2 + {\sigma_2}^2 m^2 + {\sigma_3}^2 n^2 \end{aligned} \tag{10}$$

In some cases, only the direction of the principal stresses and the stress difference ratio (R), or equivalently the shape ratio (ϕ), are given (Etchecopar et al. 1981; Gephart and Forsyth 1984):

$$R = \frac{(\sigma_1 - \sigma_2)}{(\sigma_1 - \sigma_3)} \tag{11}$$

$$\phi = 1 - R = \frac{(\sigma_2 - \sigma_3)}{(\sigma_1 - \sigma_3)} \tag{12}$$

In addition, $\sigma_1 - \sigma_3$ is not well constrained and can be expressed as an unknown parameter k. By further assuming that the frictional sliding envelope is tangential to the (σ_1, σ_3) Mohr circle, then the principal stresses are given by

$$\begin{aligned}\sigma_1 &= k(1/\sin(\phi)+1)/2\\ \sigma_2 &= \sigma_1 - kR\\ \sigma_3 &= \sigma_1 - k\end{aligned} \tag{13}$$

where $\tan\varphi = 1/\tan(2\theta) = \mu$. Inserting Eq. 13 into Eq. 10 leads to the following equations for shear stress and normal stress:

$$\begin{aligned}\tau &= k\left[(1-\phi)^2 l^2 m^2 + \phi^2 m^2 n^2 + n^2 l^2\right]^{1/2}\\ \sigma &= k\left(\frac{\csc(\varphi)+1}{2} - (1-\phi)m^2 - n^2\right)\end{aligned} \tag{14}$$

Thus, the slip tendency is independent of the choice of the unknown parameter k, and we can get a slip tendency normalized by the maximum. For such a partially defined stress field, we can draw the 3-D Mohr circles for shear and normal stresses normalized by k or the maximum shear stress.

It is convenient to define an overpressure coefficient λ for fluid pressure (Terakawa et al. 2013):

$$\lambda = \frac{(P_f - P_0)}{(P_{\max} - P_0)} \tag{15}$$

where P_0 is the critical pore pressure required to initiate rupture on the optimally oriented fault for a given friction coefficient, $P_{\max}$ ($=\sigma_3$), which is the maximum pore pressure above which hydrofracture occurs.

In the geophysical/geomechanical modeling approach, one can develop a postprocessor to calculate ΔCFS and slip tendency. It can be done within Flac3D by writing a simple FISH program. ΔCFS and slip tendency are especially useful for analyzing the effect of injection to preexisting nearby faults that have not been involved in the numerical model. Figure 25 shows an example of slip tendency analysis for a location where only the direction of the principal stresses and the stress difference ratio R ($=0.6$) are given. Faults having a strike and dip in the red zones have relatively greater probability of being reactivated.

An Example of a Natural Analogue: The Matsushiro Seismic Swarm Driven by CO_2-Quality Fluid Activity

In geological CO_2 storage, it is important to clarify the mechanisms and geomechanical conditions of worst-case events, such as damaging earthquakes and reservoir leakage, so that they can either be avoided or mitigated. It is most desirable to use an actual CGS site in which such events have actually occurred and have been well monitored. However, many pilot projects are sited in places with

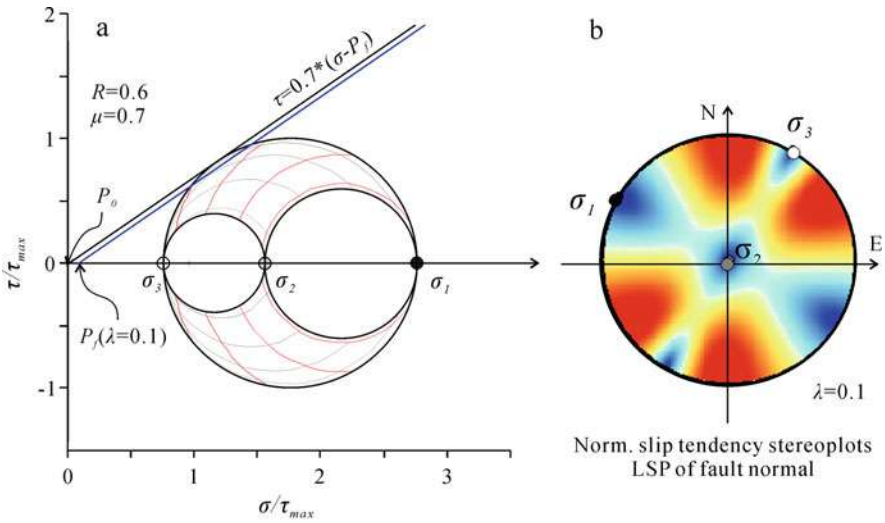

Fig. 25 (**a**) 3D Mohr circles and (**b**) normalized slip tendency stereoplots (*LSP* lower sphere projection) under an over pore pressure constant of 0.1 and a local stress field in which only the direction of the principal stresses and the stress difference ratio *R* are given

good conditions for safely pressing CO_2 into the reservoir. Thus, it is valuable to carry out "natural analogue research," analyzing similar phenomena caused by the activity of a natural CO_2-quality fluid to examining the modeling technology. Here, we make a brief review of studies on the fluid-driven earthquake swarm in Matsushiro, central Japan, as a natural analogue of seismicity induced by fluid injection.

In the Matsushiro area, which is located in the central and northern part of Nagano Prefecture, a series of more than 700,000 earthquakes occurred over a 2-year period (1965–1967). This swarm, termed the Matsushiro swarm, resulted in ground surface deformations (uplifts as large as 75 cm), cracking of the topsoil, enhanced spring outflows with changes in chemical compositions, and CO_2 degassing. Ten million tons of CO_2-rich saltwater was estimated to have seeped out from underground along the cracks (Ohtake 1976). Thus, the Matsushiro swarm is believed to have been triggered and driven by high-pressure CO_2-rich fluid from deep sources. Data observed during the Matsushiro swarm can therefore be used as a natural analogue for examining THM coupling analysis (Cappa et al. 2009; Funatsu et al. 2013). In Matsushiro and surrounding areas, subsurface geophysical surveys have been frequently conducted since the occurrence of earthquake swarms, and underground data, such as seismic wave velocity structure data, are abundant. In addition, the surface geology is relatively well understood. The geological model was developed based on these existing data. Here, a new Matsushiro model is used, which is basically an improved model modified from earlier studies (Cappa et al. 2009; Funatsu et al. 2013). In the new model, the

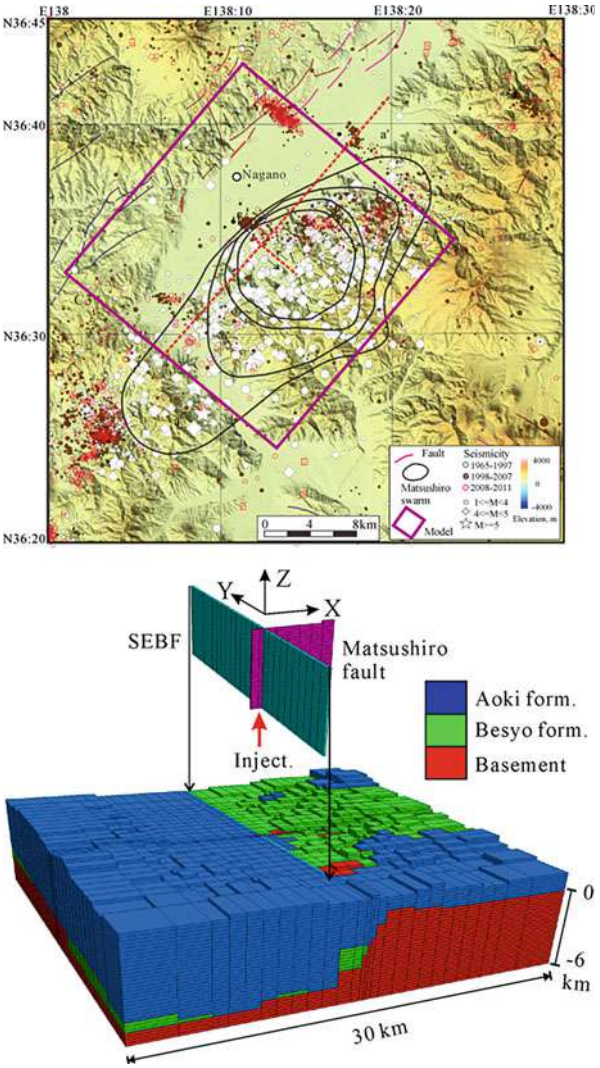

Fig. 26 Map showing basic features around the Matsushiro earthquake swarm. The model area is shown on the topographic map. *Red dotted lines* indicate the Matsushiro fault and the Southeast Boundary Fault (SEBF) of the Nagano basin. Contours show earthquake swarm migration (Modified from Hagiwara and Iwata 1968). The *right plot* shows a 3D model for numerical analysis viewed from the southwest

boundaries along all four sides are enlarged to limit the effect of boundary conditions. It covers a $50 \times 50 \times \sim 6$ km area with a focus dimension of $24 \times 24 \times 6$ km centered at the intersection of the Matsushiro fault and SEBF (Fig. 26). In addition, the topography is also involved in the new model to simulate subsurface ground water flow. In order to better represent the deep structure in the area, a geological model of three lithology groups was constructed, considering the seismic profiles obtained so far. Two vertical faults that intersect at the center of the model are assumed. The faults are modeled as narrow zones of a new group termed "fault." The regional stress field has its maximum compression axis in the east–west direction, and its minimum compression axis in the north–south direction. This

Table 1 Mechanical properties

Property	Aoki	Besyo	Basement	Fault/fault inters.

	$k = k_0(1 + \beta\Delta\varepsilon_s), \beta = 30,000$			
Porosity	0.05	0.01	0.01	0.05

model is divided into grids by steps so that the fault zone is split in small parts, while the surrounding matrix becomes coarser as the distance from the fault increases (depth, however, is equally split at 500 m intervals). The total number of elements is 9,248. Mechanical properties, which are set similar to those in Cappa et al. (2009), are listed in Table 1, and the geometry of the model is shown in Fig. 26. After failure, in order to incorporate strain softening behavior into the model, we decreased the cohesion and tensile strength with strain following two linear paths to given values. After failure, the friction angle and dilation angle also change with the shear strain. The associated parameters are listed in Table 1.

Note that some parameters used this, and former studies differ significantly from laboratory-derived data for intact rocks. For instance, the values of Young's modulus used in the numerical model appear too low. As we know, the real crust contains fractures and faults at all scales. It is impossible to represent all individual fractures and small faults in a model, so we have to adjust some properties, such as the bulk and shear moduli, as an upscaling technique. Similar techniques are used in core-scale simulation to account for preexisting microcracks in rock samples (Lei et al. 2015).

The calculated horizontal displacements and uplifts at the ground surface are shown in Fig. 27. The maximum uplift, 66 cm, is obtained at the point where the faults cross 1 year after from the beginning of fluid injection. This value is close to the observed maximum value of 75 cm. The uplift pattern becomes asymmetric to the SEBF, which concurs with observations. Left-lateral slip along the two faults is also identified. Results of the new model match observed values better than previous studies. The uplift gradually stretches away from the intersection of the two faults along their extensions in a skewed rhombic pattern, indicating a fault-controlled pore pressure diffusion process.

Figure 28 compares the Matsushiro earthquake swarm migration and a calculated distribution of ruptured zones along the Matsushiro and east Nagano earthquake faults 180 and 720 days after injection began. Except for fractures at the surface, all fractures demonstrate shear mechanisms. Surface fractures show tensile modes. Calculated surface uplift is plotted in Fig. 29. For comparison, some data

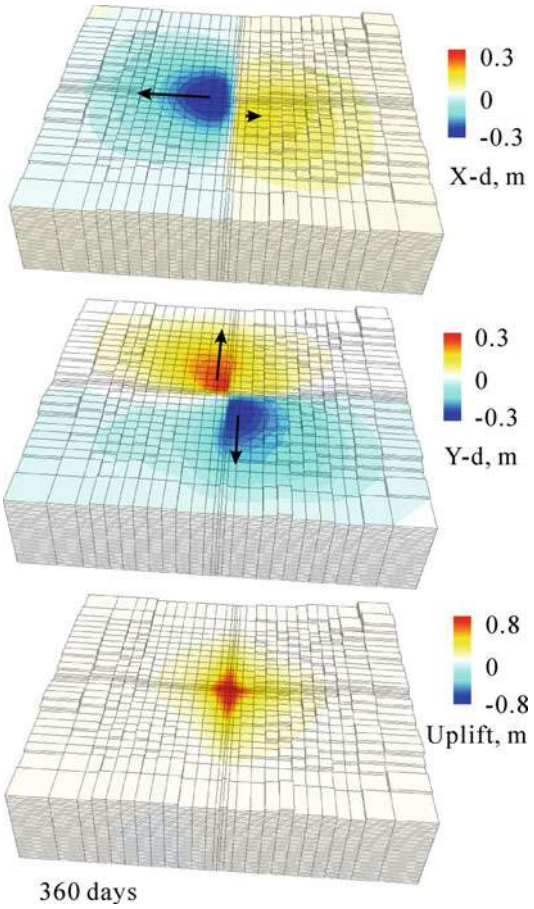

Fig. 27 Calculated distributions of X- and Y-displacement and uplift of the ground surface 360 days after injection began

estimated from field observations (Kasahara 1970; Tsukahara and Yoshida 2005) are also plotted.

In conclusion, the numerical model and coupled THM analysis using the TOUGH-FLAC3D approach successfully represent major characteristics of observed phenomena associated with the CO_2-rich fluid-driven Matsushiro earthquake swarm.

Data Processing and Analysis of Injection-Induced Seismicity

Statistical Properties of Injection-Induced Seismicity Based on ETAS Modeling

It is well known that an earthquake triggers aftershocks following modified Omori's law. In the case of injection-induced seismicity, it is important to be able to discriminate induced activity from background seismicity and statistically

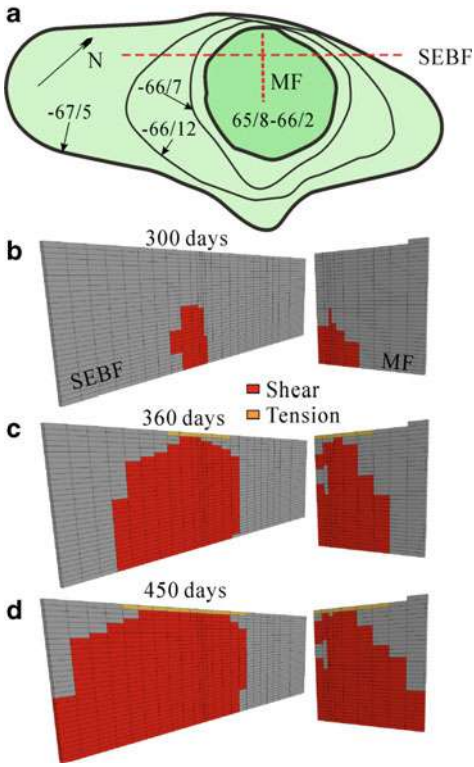

Fig. 28 A comparison of the Matsushiro earthquake swarm's migration and calculated distribution of ruptured zones at 300, 360, and 450 days after injection began along the Matsushiro and east Nagano earthquake faults

separate fluid-induced and Omori-law-type aftershock triggering. The epidemic-type aftershock sequence (ETAS) model (Ogata 1992), which incorporates Omori's law by assuming that each earthquake has a magnitude-dependent ability to trigger its own Omori-law-type aftershocks. The ETAS model is an appropriate tool for testing the significance of changes in seismic patterns (Ogata 1992, 2001), detecting minor stress changes (Helmstetter et al. 2003), and extracting a fluid signal from seismicity data (Hainzl and Ogata 2005). Thus, it is particularly useful for analyzing injection-induced seismicity (Lei et al. 2008, 2013). In the ETAS model, the total occurrence rate is described as the sum of the rate triggered by all preceding earthquakes and a forcing rate λ_0(t) that represents the background activity:

$$\lambda(t) = \lambda_0(t) + \nu(t), \nu(t) = \sum_{\{i:t_i<t\}} K_0 e^{\alpha(M_i - M_c)} (t - t_i + c)^{-p} \tag{16}$$

where M_c is the low cut-off magnitude of the catalogue and α is a constant that specifies the degree of magnitude dependence. For injection-induced seismicity, the background activity consists of tectonic background and injection-induced activities. The injection-induced activity forcing rate is somewhat dependent on injection

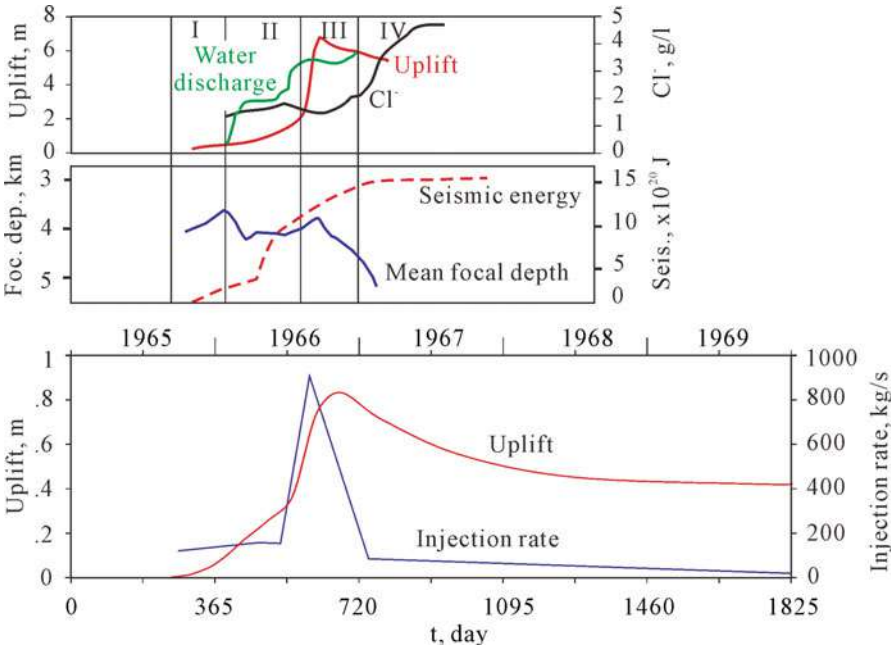

Fig. 29 Calculated maximum surface uplift with given injection rate against time. As a comparison, some data, including uplift, water discharge, concentration of Cl^-, accumulated seismic energy, and mean focal depth, estimated from observations (Kasahara 1970; Tsukahara and Yoshida 2005) are also plotted

parameters such as injection rate, total volume so far injected, well head pressure, fluid temperature, and so on. The sophisticated algorithm inspired by Zhuang et al. (Marsan et al. 2013; Zhuang et al. 2002) is very powerful for use in estimating the time-dependent forcing rate and other parameters of injection-induced seismicity (Lei et al. 2013).

It is well-documented that injection-induced seismicity demonstrates (1) smaller α values ($<\sim 1.5$), (2) varying forcing rates correlated with injection pressure or other factors, and (3) forced seismicity takes on a major component and shows strong correlation with injection factors such as injection rate and volume injected so far (Lei et al. 2008, 2013). These characteristics are similar to seismic swarms observed in geothermally active areas (Lei et al. 2011) but significantly different from tectonic background seismicity, which has greater a values ($> \sim 2$) and a minor component of forced activity.

Lessons from Some Significant Cases of Injection-Induced Seismicity

In many cases, fluid injection induces only small earthquakes ($M < 3$). But there are increasing cases in which damaging earthquakes of a magnitude greater than $4 \sim 5$ are observed. Although the injected fluid, in most cases, is not CO_2 but

water, the major mechanism of inducing earthquakes is similar. Therefore, insights gained from such worst cases may also provide a better understanding of why damaging events occur so that they can be avoided or mitigated. The injection-induced seismic activity in the Sichuan Basin in southwest China has proven to be a significant example. During the past decades, a number of seismic sequences have been observed with sizable earthquakes ranging up to M4 $\sim$ 5 (Lei et al. 2008, 2013; Lei and Ma 2013). Statistical models of their timing, location, and occurrence patterns convincingly suggest that these sequences were induced by water injected into deep wells in the gas fields in this region. Event rates fluctuated following changes of injection rates and tapered after injection was shut down. Most events show shear fracturing mechanisms, which, together with hypocenter location data, demonstrate that preexisting faults, known or unknown, in the formations have a governing role in controlling the hypocenter distribution of the induced earthquakes (Lei et al. 2013). In some cases of long-term injection, there are clear phases of deeper events that mirror the reactivation of underlying faults. Faults of a relative larger scale have a twofold role: working as a bounding interface for horizontal fluid flow and a leakage path for vertical fluid flow.

In agreement with other cases, the injection-induced seismic sequences in the Sichuan Basin demonstrate following general features. (1) Injection-induced seismicity is more swarm-like, characterized by smaller α values (normally $1 \sim 1.5$ or less) in the ETAS model. (2) Most events occurred due to reactivation of preexisting planar structures including faults, fractures, joints, and bedding surfaces. (3) During the earlier stages of injection, the total fraction of Omori-law-type aftershocks is also important, indicating that the stress in the formations is critical or subcritical and seismic triggering and injection forcing are both important for earthquake occurrence. (4) As a natural implication of (2), the maximum magnitude of potential earthquakes is determined primarily by the size of preexisting faults in which the pore pressure may be raised during injection. (5) It is commonly observed that the forced earthquake rate increases with injection time. (6) A uniform regional stress field is insufficient to interpret all focal mechanism solutions, indicating the local stress field on the scale of the reservoir is inhomogeneous.

Results of rock fracture experiments on rock samples collected from the Sichuan Basin shed some light on the question of why injection-induced seismicity is so significant there (Lei et al. 2014). Major Pre-Triassic sedimentary rocks in this region, including dolomite, shale, and dolomitic limestone, are strong and demonstrate brittle deformation/fracturing behaviors. Such properties are necessary conditions for maintaining high-level reservoir stress and lead to seismic fracturing. In general, critically or subcritically stressed faults of a dimension of a few kilometers are sufficient to allow M $\sim$ 5 class earthquakes. Such faults are distributed widely in the reservoir system in this region. Lessons from the Sichuan Basin tell us that it is important to investigate the basic rock properties and the size and location of preexisting faults in assessing the risks of a candidate CO_2 storage site.

Future Directions

There are 13 large-scale CCS-related projects in operation as of October 2014, and the same number of projects is scheduled to begin operations by 2015 (Global CCS Institute 2014). The first offshore commercial-scale project that is not an EOR is the Sleipner gas field operated by STATOIL in the North Sea since 1996. Approximately 1 $MtCO_2$ is separated annually from the produced natural gas and injected into the deep saline aquifer located approximately 800 m to 1,000 m depth formations below the seabed. Monitoring by seismic reflection method, to gain an understanding of the behavior of the stored CO_2, as well as gravity monitoring using seafloor gravity meters, is being performed (Arts et al. 2004).

Other than the 13 sites currently in operation, about 42 sites are being planned for CCS-related projects, and they are not limited to EOR- and EGR-related projects. These include projects that use aquifers as the storage site (Global CCS Institute 2014). However, there is an emerging shift to EOR-related projects, in which economic incentives are in effect, mainly in the United States and other countries. On the other hand, a technical committee known as the TC265 was established at the ISO (International Standardization Organization) in October 2011, and examination for the international standardization of CCS begins.

Abovementioned technical issues regarding CGS should be examined by applying the techniques to the individual site-specific geological storage site, and then the techniques will be expected to brush up, supporting practical realization of CGS over the world.

Abstract

The world is likely to emit almost 40 Gt/year of CO_2 into the atmosphere. Even if only a small fraction of the globally emitted CO_2 is captured, there will be a large quantity of CO_2 available to society for use in a variety of ways. Thus, CO_2 should not be regarded as a waste product, but as an asset that, with human ingenuity, could be used in a sustainable way. Since sustainability is at the intersection of environmental, economic, and intergenerational stewardship, the selection of a CO_2 utilization process must offer net CO_2 and waste reductions compared to conventional methods of producing the same end product, must be economical, and must not leave any additional problems for future society to solve. The criteria for selection may involve a variety of local considerations, such as government incentives, the availability of suitable renewable energy source, availability of water and other chemicals, land use, local demand for a specific product, etc. Therefore, CO_2 utilization is a locally sustainable solution, rather than a one-size-fits-all approach. Utilization of CO_2 may involve mostly physical processes, such as in enhanced oil recovery (EOR), solvent use, and beverage industry, where the CO_2 is essentially retained in its original valence state, or chemical processes, where its valence state undergoes a change (Fig. 1). We will focus in this chapter on chemical conversion, which broadly includes thermochemical and electrochemical processes. The critical technology development parameters as well as the barriers for adoption of utilization technologies are also discussed.

Introduction

The utilization of CO_2 to make a variety of end products can be potentially transformational because it enables the valorization of CO_2 using thermochemical, biochemical, and electrochemical processes (Fig. 1). The utilization technologies will vary in the volume of CO_2 utilized, the economic value of the end product (i.e., value added), and the time of fixation of CO_2 (Fig. 2). Carbon capture and storage (CCS) can potentially store and theoretically fix large volumes of CO_2 in geological media for hundreds of years but without any monetary value (unless

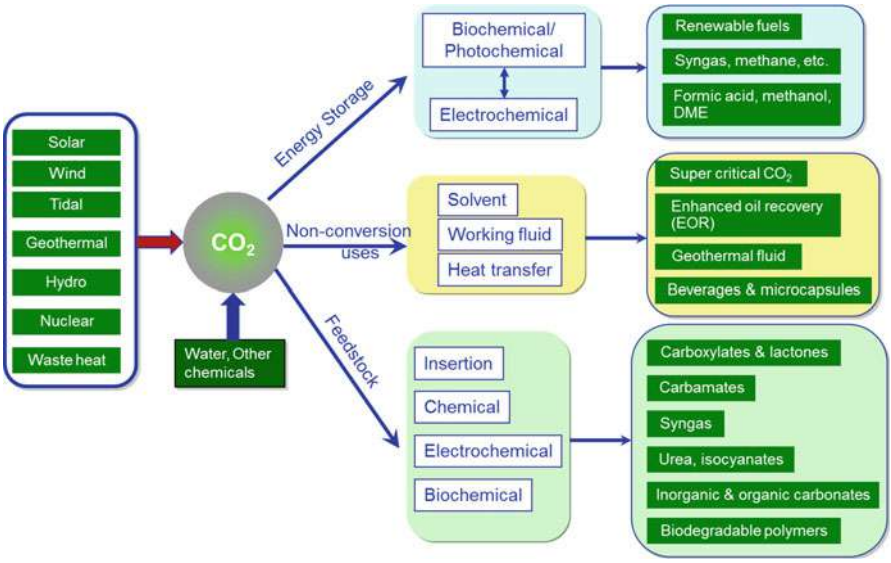

Fig. 1 Different ways in which CO_2 can be used to create value and the energy sources needed for sustainable use (Peters et al. 2011; Wu et al. 2007; Tao 2008; Zaelke et al. 2011; Pew Charitable Trusts 2012; Global CCS Institute 2012; Al-Musabbeh et al. 2006; Moats et al. 2008)

enhanced oil recovery (EOR) is done). Cements and minerals made from CO_2 can provide some value, while being able to convert relatively large volumes of CO_2. On the other hand, specialty chemicals can have attractive economic value, but are in limited quantities, and fix CO_2 over a limited period of time. Plastics, in principle, can be stable for many decades, but will eventually biodegrade. Fuels have a very short fixation time, emitting CO_2 as soon as they are burned. However, they add significant value because they contribute to energy storage from renewable power and provide energy security to those countries that are dependent on foreign sources of fuel. It is already recognized that biofuels from photosynthetic plants and organisms have the potential to substantially reduce net life cycle CO_2 emissions. However, photosynthetic biofuels, including sugar cane, cellulosic, and algae-based biofuels, require significant land use.

An example of a novel pathway is the conversion of formic acid and methanol into ethanol. The traditional corn-based ethanol process emits about 2.6 mol of CO_2 per mole of ethanol (or about 70 g of CO_2 equivalent/MJ). This does not include the CO_2 emitted upon use in the internal combustion engine. In contrast, the electro-biochemical route of ethanol from CO_2 and methane could involve a net consumption of CO_2 of the order of three million ton per year even using fossil-based power. The net reductions can be increased if greater percentage of renewable power is used.

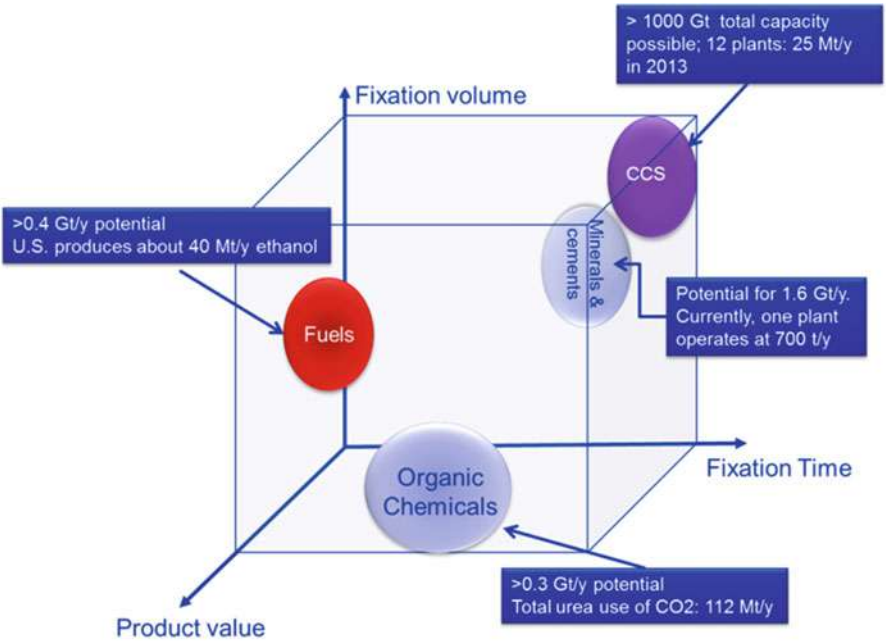

Fig. 2 CO_2 utilization value for different products (Peters et al. 2011; Wu et al. 2007; Tao 2008; Zaelke et al. 2011; Pew Charitable Trusts 2012; Global CCS Institute 2012; Al-Musabbeh et al. 2006; Moats et al. 2008; Hu et al. 2013)

Thermochemical Methods

Chemical fixation of CO_2 to useful products might represent an attractive way of reducing emissions of CO_2 to air. Using CO_2 as a feedstock also has the potential of replacing fossil feedstock such as natural gas, carbon monoxide, syngas, methanol, and even higher hydrocarbons (Fig. 3). The main challenge in utilizing CO_2 as a chemical feedstock is its unfavorable thermodynamics.

Figure 3 summarizes the major CO_2 to chemical routes which will be discussed. This is by no means an all-inclusive representation. These routes were chosen from the many options based on the relative maturity of the technologies as well the sizeable market volumes the chemical can support. For some chemicals, such as formic acid, the direct market is relatively small (<1 MM tpy), but the market can be expanded by employing it as a base chemical to manufacture other large volume chemicals.

There are numerous reviews and books which provide descriptions of reactions, products, and markets derived from CO_2 chemistry (Peters et al. 2011; Quadrelli et al. (2011); Wu et al. 2007; Hu et al. 2013; Quadreilli et al. 2011; Centi and Perathoner 2009; Ratnasamy and Wagner 2009).

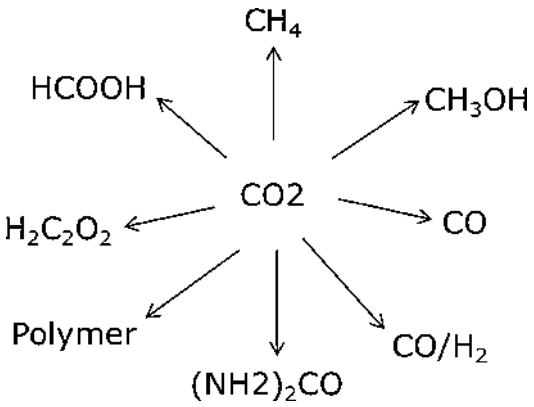

Fig. 3 CO_2 conversion to chemicals

Hydrogen Supply

The interesting observation about the various paths in Fig. 3 is the hydrogen requirement for all products except carbon monoxide. So while the main problem being addressed for the CO_2 utilization is obviously the CO_2 itself, the problem can in large part be restated to be a "hydrogen problem." The next section discusses the requirements to supply the hydrogen as dihydrogen (H_2).

Steam methane reforming (SMR) is the most common method of producing commercial bulk hydrogen. Other hydrocarbons may be used, such as propane or naphtha. Hydrogen is used in the industrial synthesis of ammonia and other chemicals. At high temperatures (800–1000 °C) and 20–30 atm in the presence of nickel-based catalyst, steam reacts with methane to yield carbon monoxide and hydrogen (Olah 2005):

$$CH_4 + H_2O \rightleftharpoons CO + 3H_2 \quad (1)$$

Additional hydrogen can be recovered by a lower-temperature water-gas shift (WGS) reaction with the carbon monoxide produced. The reaction is summarized by

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad (2)$$

Carbon dioxide is a substantial waste product from these processes. SMR emits a mole of CO_2 per mole of methane (2.75 kg CO_2 per kg of methane) reacted in the scheme above. The gas is then fed to a gas separation system, such as pressure swing adsorption, which can provide hydrogen at a range of purities, such as 99.5–99.995 % H_2. Impurities such as CO, which acts as a poison for most precious metal catalysts, can be minimized to less than 10 ppm.

Because of the concurrent emission of CO_2 from SMR, lower CO_2-emitting processes need to be used for H_2 supply. The predominant renewable method for H_2 production is via electrolytic water splitting. The electrical energy for this process needs to be from renewable sources, or a non-carbon-emitting source, such as wind, solar, nuclear, or hydroelectric. These methods are described elsewhere (Utgikar 2006).

Table 1 LCA-based CO_2 emissions for various production methods

Hydrogen production method	Kg CO_2/kg H_2	Mole CO_2/mol H_2
Biomass	2.9	0.23
Hydroelectric/elect.	2	0.09
Solar photovoltaic	6	0.27
Wind/elect.	1.5	0.045
Steam reforming	12	0.55
High-temp electrolysis	4	0.18

Utgikar and Thiesen report the life cycle assessment of the various hydrogen production methods (Utgikar 2006). They reported the mass of CO_2 emitted per mass of H_2 produced by various means. Hydrogen from SMR emits roughly 0.55 mol CO_2/mol H_2 produced. Wind-generated electricity supplying a water electrolysis unit is the lowest in the study, at ~0.045 mol CO_2/mol H_2. Table 1 provides a summary of various H_2 generation technologies along with the respective carbon balances.

The key message from the life cycle assessment (LCA) results is that CO_2 emissions are generated from even the "clean" sources of H_2. But there is a wide range – fossil fuel systems being the worst emitter.

Carbon Monoxide and Synthesis Gas Production

Catalytic Hydrogenation

By reversing the water-gas shift reaction (2), one can produce carbon monoxide from carbon dioxide and hydrogen (Ratnasamy and Wagner 2009; Whitlow and Parish 2003; Edwards and Maitra 1995):

$$CO_2 + H_2 \rightarrow CO + H_2O \tag{3}$$

Depending on the reaction conditions, the equilibrium for the water-gas shift can be pushed in either the forward or reverse direction with temperature and pressure adjustments. The reversibility of the WGSR is important in the production of ammonia, methanol, and Fischer–Tropsch synthesis, where the ratio of H_2/CO is critical. Many industrial processes exploit the reverse water-gas shift (RWGS) reaction as a source of the synthetically valuable CO from cheap CO_2. Typically, it is done using a copper on alumina catalyst.

Reforming with CO_2

Dry reforming refers to the production of synthesis gas ($CO + H_2$) from natural gas, petroleum or coal, and CO_2. By contrast to SMR above, there is no water introduced in this process. CO_2 is the soft oxidant (Logan 1997; Song and Pan 2004; Ted Oyama et al. 2012). For natural gas, the reaction is

$$CO_2 + CH_4 \rightarrow 2CO + 2H_2 \tag{4}$$

The syngas can then be converted to chemical products and hydrocarbons. However, Oyama points out that this reaction has limited utility due to the consumption

of the hydrogen generated by the reverse water-gas shift reaction (Ted Oyama et al. 2012). This point is missed in many studies due to operation at low pressures. At pressures above 5 atm, the RWGS takes over. That is, H_2 is further converted to H_2O according to reaction (3). This reduces the H_2/CO ratio to less than one, an unfavorable composition if the desire is to upgrade the CO/H_2 to higher hydrocarbons. The system is also plagued by rapid catalyst deactivation as a result of coke formation. So while attractive on paper, the system has yet to be successfully commercialized.

A second option for syngas production is a combination of the steam methane reforming reaction (1) and dry reforming reaction. The net reaction in this case is

$$CH_4 + H_2O \rightarrow CO + 3H_2 \tag{5}$$

$$CO_2 + CH_4 \rightarrow 2CO + 2H_2O \tag{6}$$

$$\text{Net} : 3CH_4 + \ + CO_2 \rightarrow 4CO + 6H_2 \tag{7}$$

This bi-reforming gives a molar CO:H_2 ratio of 1:1.5, the stoichiometry required for methanol synthesis (Goeppert et al. 2014). The presence of steam reduces the tendency to form coke, and the system has shown good stability at low pressures and, with different catalysts, at elevated pressures (Wittcoff et al. 2013).

Yet another option is tri-reforming of methane, a novel concept for catalytic production of industrially useful synthesis gas with desired H_2/CO ratio (Ted Oyama et al. 2012). The proposed tri-reforming process is a synergetic combination of CO_2 reforming, steam reforming, and partial oxidation of methane in a single reactor for effective production of industrially useful synthesis gas (syngas). Power plant emissions flue gas typically contains a small amount of oxygen. The oxygen is typically a poison for water-gas shift catalysts and needs to be removed if RWGS is to be used. However, the tri-forming does not need this removal and allows for effectively an autothermal oxidation of methane. Another key feature is the ability to adjust feed composition to CO:H_2 ratio in the product, preferably into the 1:2–3 range needed for conversion to methanol or hydrocarbons via Fischer–Tropsch. These options are discussed extensively in recent reviews (Quadreilli et al. 2011; Logan 1997; Song and Pan 2004).

Methanol Synthesis

Renewably produced methanol has been actively promoted as an alternative fuel and chemical to the traditional energy and petrochemicals markets based on oil and natural gas. The methanol market is well established with a global consumption of 58 million tons in 2008 and 83 % of the product going to chemicals production (Olah et al. 2011).

Catalytic hydrogenation of mixture of CO_2 and CO is at the basis of syngas processes. These syngas processes make it possible to produce a variety of chemical

products, including methanol. Chemical reactions involved for methanol production are

$$CO + 2H_2 \rightarrow CH_3OH \tag{8}$$

$$CO_2 + 3H_2 \rightarrow CH_3OH + H_2O \tag{9}$$

Methanol production can hence be enhanced by injecting CO_2 (Wittcoff et al. 2013; Olah et al. 2009; http://www.carbonrecycling.is/). Both reactions (8) and (9) are exothermic and favored by high pressures. The standard operating conditions (for low-pressure synthesis) are 50–80 bar pressure and 210–290 °C temperature (reactor inlet/outlet).

Methanol production has trended toward very large plants with daily capacity at 3000–5000 t. This trend has been largely due to the economies of scale and the lower production costs. The Middle East, Latin America, and Asia produce 80 % of the market. With recent increases of shale gas in the USA, some methanol production is returning to the USA (http://www.carbonrecycling.is/).

In order to capitalize on renewable energy and point sources of CO_2, carbon-neutral synthesis of methanol plants will need to be significantly smaller than the megaplants. Carbon Recycling Inc (CRI) is one of the first companies to demonstrate industrial solutions in power-to-methanol production, by capturing carbon dioxide (CO_2) from flue gas, large-scale conversion of renewable energy to hydrogen, and reacting hydrogen and carbon dioxide to produce methanol. CRI's power-to-methanol production plant in Iceland, which has been operating since 2012, produces ultra-low carbon intensity methanol that is used for biodiesel manufacturing and gasoline blending. The plant has recently been expanded to 4000-t/year production capacity (Pontzen et al. 2011).

Methanol can be used in various sectors, and if CO_2 comes from the atmosphere in the beginning, the methanol is then considered CO_2 neutral when burned in an internal combustion engine or when used in a direct methanol fuel cell (DMFC), for instance. This is the basis for the so-called "methanol" economy where methanol replaces fossil fuels and is used as an energy carrier (Olah 2005).

Production of higher hydrocarbons from methanol is a well-established technology as well. For example, methanol to olefins and methanol to gasoline technology is well known. Another possibility is the formation of dimethyl ether (DME) from methanol (Tao 2008). This reaction is also exothermic (Utgikar 2006; http://etogas.com/fileadmin/documents/datasheets/ETOGAS_Hydrogen-to-SNG_Datasheet_EN_Rev1.pdf):

$$2CH_3OH \rightarrow CH_3OCH_3 + H_2O \quad \Delta H = -21.25\ \text{kJ/mol} \tag{10}$$

DME has many advantages: its fuel characteristics are similar to LPG, it is relatively environmentally friendly, and it is nontoxic and noncarcinogenic.

Methanation

The methanation of carbon dioxide, also known as the Sabatier reaction, allows producing methane from carbon dioxide and hydrogen and is a strongly exothermic reaction:

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O \quad \Delta H = -165\ \text{kJ/mol} \tag{11}$$

The methane produced can then be used for many purposes, and again if the CO_2 comes from the atmosphere and if the hydrogen is produced from renewable sources, the methane is also considered CO_2 neutral.

The methanation reaction is also referred to as "power to gas" in some instances. This is attractive in some geographies which do not have natural gas readily available. Domestically produced renewable gas successively permits the displacement of fossil gas, thus reducing dependence on gas imports (Quadreilli et al. 2011).

While this synthetic natural gas is equivalent to natural gas and can be fed into the gas grid without limitations, the produced gas will be limited by the amount of unreacted hydrogen remaining.

As a CO_2 mitigation strategy, this should be pursued only when the CO_2 storage capacity is completely utilized. Natural gas itself can store CO_2; however, it is typically consumed via combustion for heat and power purposes.

The German company ETOGAS designs and builds multi-megawatt power-to-gas (PtG) turn-key systems based on its proprietary technology portfolio, comprising high-pressure alkaline electrolyzers and methanation systems as well as balance of plant components. ETOGAS has designed and installed and operates the world's largest commercial 6.3 MW power-to-SNG system in Werlte, Germany, for customer Audi AG (Ledgard et al. 2011).

Urea

The production of urea is a large consumer of CO_2. The process consists of two main equilibrium reactions, with incomplete conversion of the reactants. The first is carbamate formation: the fast exothermic reaction of liquid ammonia with gaseous carbon dioxide (CO_2) at high temperature and pressure to form ammonium carbamate ($H_2N\text{-}COONH_4$):

$$2NH_3 + CO_2 \rightleftharpoons H_2N\text{-}COONH_4 \tag{12}$$

The second is urea conversion: the slower dehydration is an endothermic decomposition of ammonium carbamate into urea and water:

$$H_2N\text{-}COONH_4 \rightleftharpoons (NH_2)_2CO + H_2O \tag{13}$$

The overall conversion of NH_3 and CO_2 to urea is exothermic, the reaction heat from the first reaction driving the second (Quadreilli et al. 2011). The overall enthalpy of reaction of urea formation from CO_2 and NH_3 is −133.6 kJ/mol.

Table 2 Net CO_2 mol emitted for various H_2 sources (negative is CO_2 reducing)

	SMR	Biomass	Solar	Wind
Emissions (mol CO_2/mol H_2)	0.55	0.23	0.27	0.045
$CO_2 + H_2 \leftrightarrow CO + H_2O$	−0.45	−0.77	−0.73	−0.96
$CO_2 + 3H_2 = CH_3OH + H_2O$	0.65	−0.31	−0.19	−0.87
$CO_2 + 4H_2 = CH_4 + 2H_2O$	1.2	−0.08	0.08	−0.82

Ammonia is typically produced by the reaction of H_2 and N_2, where the H_2 is supplied by the SMR-WGS-PSA route. Legard et al. reported an LCA on urea production and delivery to New Zealand. They show the production of urea can vary from 0.73 kg CO_2/kg urea in the case of Middle East from natural gas for H_2 source to 2.14 kg CO_2/kg urea for material produced in China where the H_2 is derived from 80 % coal/20 % natural gas (Halmann and Steinberg 1999).

Net CO_2 Reduction

Table 2 shows the net CO_2 emissions for some of the reactions discussed accounting for various H_2 production methods. The table values are derived by using the reaction stoichiometry for H_2 required and the amount of CO_2 emitted per hydrogen consumed. Positive values are a net increase in CO_2 emissions. The results show that with biomass, solar photovoltaic, and wind-generated H_2, there is a net CO_2 reduction. Admittedly this is not a completely rigorous CO_2 accounting since the complete LCA is not performed on the conversion process. But it does provide some scale of the differences.

Electrochemical Conversion of CO_2 to Value-Added Chemicals

The electrochemical method of utilizing carbon dioxide (CO_2) includes two generic categories (Sanchez-Sanchez et al. 2001): (1) electrocarboxylation, which involves the coupling of CO_2 to electrochemically reduced organic molecules, and (2) direct electrochemical reduction of CO_2 to hydrocarbons, alcohols, or other fuels. CO_2 cannot be used widely by category 1 because electrocarboxylation is mostly used to synthesize chemicals that are of pharmaceutical interests whose amount needed is limited. Therefore, we only focus on the second category in this section because the wider applications of the products from the direct electrochemical reduction of CO_2 may significantly reduce net CO_2 emissions.

The investigation of electrochemical conversion of CO_2 in gaseous and liquid phases has been carried out with a variety of catalysts, electrolytes, electrode potential, pressure, and temperature ranges. Different reduction products can be formed via different reaction pathways including carbon monoxide (CO), formaldehyde (CH_2O), formic acid (HCOOH) or formate ($HCOO^-$) in basic solution, oxalic acid ($H_2C_2O_4$) or oxalate ($C_2O_4^{2-}$) depending on the pH of the solution, methane

(CH_4), ethylene (CH_2CH_2), and many others. Solid oxide fuel cells (SOFCs) were employed for CO_2 conversions at high temperatures usually permitting a higher selectivity (Spinner et al. 2012). Transition metal-based electrodes in conventional electrochemical cells constitute the low-temperature systems (Spinner et al. 2012) which provide a broader range of products. Low-temperature CO_2 conversions in liquids require large overpotentials leading to large energy and power demands.

Electrochemical conversion of CO_2 is a very promising method for reversing CO_2 to a reduced form such as fuels or other useful chemicals. Compared with other CO_2 conversion/reduction methods, electrochemical methods have the following advantages:

1. Extensive studies on electrochemical CO_2 conversion have been conducted for more than 50 years, with greater focus in the last 25 years. Heterogeneous catalysts with high activity and selectivity for various useful products such as CO, formic acid, methane, ethylene, and methanol have been found for aqueous reaction systems. Heterogeneous catalyst can be easily separated from the products, unlike in the homogeneous catalytic chemical CO_2 conversion in either aqueous or nonaqueous solutions.
2. Most electrochemical conversion processes can be performed at room temperature and ambient pressure, while most chemical conversion processes require high temperature and high pressures which could lead to corrosion, material failure, and accidental release.
3. Unlike chemical or combustion type reactions, electrochemical processes are not limited by traditional thermochemical cycles, thereby being capable of providing significantly higher energy efficiencies.
4. In electrochemical processes, the electrode potential can be manipulated to a desired value to obtain the optimal reaction rate and catalyst selectivity, with such precise adjustments being difficult in other processes.
5. Electrons flowing as current may be regarded as one of the reagents thereby simplifies requirements for commercial production. In fact, by careful selection of the proper reaction schemes, most electrochemical CO_2 conversion processes will not generate any environmentally harmful "by-products" or waste solutions. Also, if the supporting electrolytes are fully recycled, the overall chemical consumption can be minimized to just water or waste water.
6. Any source of electricity can be used to drive electrochemical CO_2 conversion processes, including solar, wind, hydro, geothermal, tidal, and atomic power. Therefore this method can also be used as an off-peak electricity or renewable energy storage vehicle; it converts the electrical energy to chemical energy by producing fuels from CO_2, and the stored energy can be released later for end use by oxidization of the fuels through fuel cells or normal fuel-burning engines.
7. Electrochemical reaction system is modular and easy for scale-up application. At the same time, the benefits of economy of scale are less for electrochemical processes than other processes.
8. Electrochemical processes require relatively small spatial footprint. There is significant experience base in industrial scale electrochemistry through chlor-alkali production.

Table 3 Half-cell reactions for the electroreduction of carbon dioxide. E^0 versus normal hydrogen electrode (NHE) at 298 °K in aqueous solutions and pH = 0

(a)	$2CO_2 + 2H^+ + 2e^- \rightarrow H_2C_2O_4$	$E^0 = -0.500$ V
(b)	$CO_2 + 2H^+ + 2e^- \rightarrow HCOOH$	$E^0 = -0.250$ V
(c)	$CO_2 + 2H^+ + 2e^- \rightarrow CO + H_2O$	$E^0 = -0.106$ V
(d)	$CO_2 + 4H^+ + 4e^- \rightarrow HCHO + H_2O$	$E^0 = -0.070$ V
(e)	$CO_2 + 6H^+ + 6e^- \rightarrow CH_3OH + H_2O$	$E^0 = +0.016$ V
(f)	$CO_2 + 8H^+ + 8e^- \rightarrow CH_4 + 2H_2O$	$E^0 = +0.169$ V

Low-Temperature Direct Electrochemical Pathways

Electrochemical reduction of CO_2 generates a wide variety of products through various reaction pathways or combinations of several pathways. These pathways critically depend on experimental conditions, such as the nature of the catalyst, electrode potential, electrolyte chemistry, pH, temperature, and CO_2 concentration. The details of the proposed pathways can be obtained elsewhere (Spinner et al. 2012; Saeki et al. 1995; Magdesieva et al. 2002; Ikeda et al. 1987; Li and Prentice 1997). In this chapter, the discussion is framed around the end products of the CO_2 conversion.

In Table 3, the standard equilibrium potentials, E^0 (the standard equilibrium potentials are related to free energy change associated with the reaction by $\Delta G = -nFE$ where "n" is the number of electrons involved in the reaction and F is the Faraday's constant = 96,485 C/mol. equivalent) indicate only the thermodynamic propensity and do not indicate the knowledge of the mechanism which are much more complicated. The kinetics of these reactions are sluggish even with presence of catalysts and require significant overpotential (i.e., potential more negative than the equilibrium potentials) to obtain useful product for detection and could be more to achieve sufficient production rates.

There are relatively few effective electrocatalysts for electrochemical conversion of CO_2, although a number of other catalysts may produce some products (Fig. 4).

Major Products

Carbon Monoxide (CO)

Carbon monoxide is the major product from CO_2 electrochemical conversion on Au, Ag, Zn, Pd, and Ga electrode; the selectivity on these metals can reach as high as 90–100 %. CO can also be generated in smaller amount on other metals such as Cu and Ni under optimized operation conditions. CO is considered a more versatile starting material than CO_2 as chemical feedstock. Carbon monoxide can be used in a host of organic syntheses, but it is best known as a component of synthesis gas (syngas), which is an important feedstock in the chemical industry for making hydrocarbons via Fischer–Tropsch (FT) reactions. Some research efforts have been pursued on the electrochemical reduction of CO_2 to syngas with certain ratio of

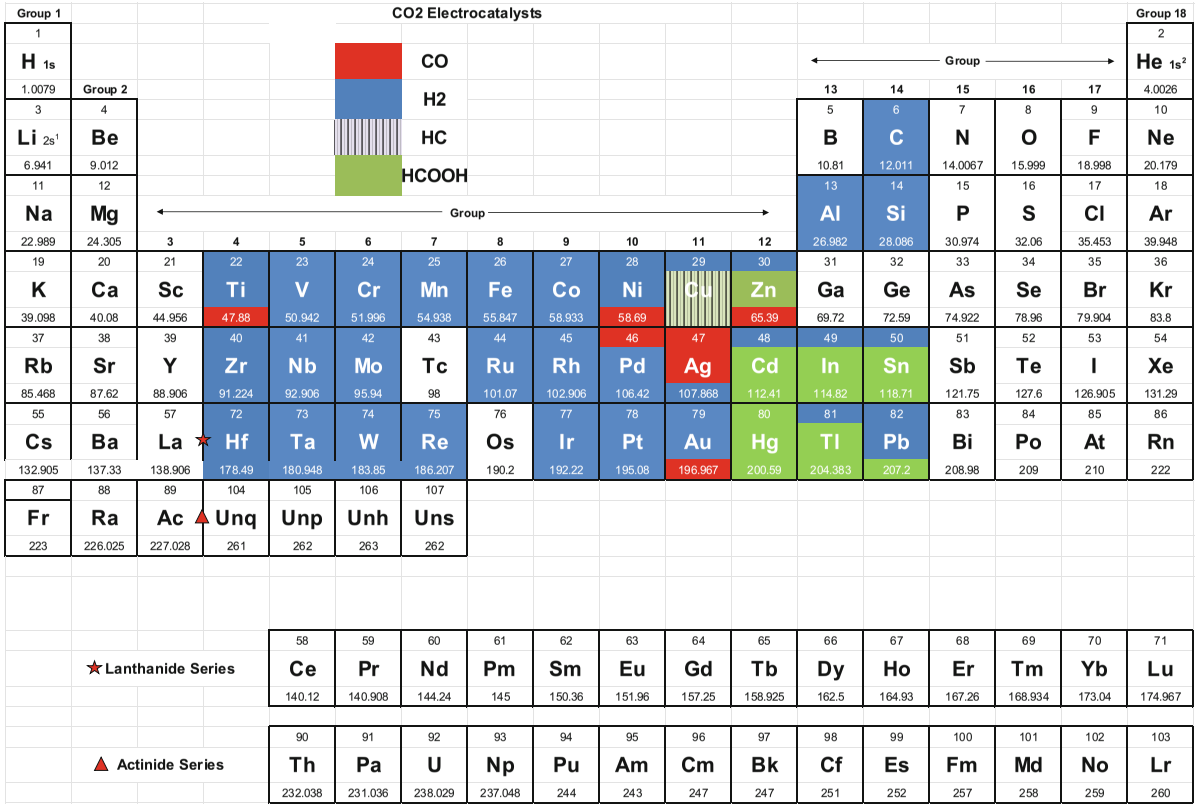

Fig. 4 Periodic table indicating metals for electrochemical CO_2 to specific products

CO/H_2 on metal electrodes such as Ag which favors both CO and H_2 evolution kinetically (Hori et al. 2003; Yamamoto et al. 2002; Delacourt et al. 2008).

Formic Acid

Formic acid appears as an energy storage medium that is being considered both as a fuel for direct formic acid (DFA) fuel cells and as a source of H_2 for hydrogen fuel cells. Formic acid is now manufactured by thermochemical processes based on the carbonylation of methanol in sodium hydroxide and by the oxidation of hydrocarbons, all of which have negative environmental consequences. High selectivity of formic acid from electrochemical reduction of CO_2 is found on metals with high hydrogen overpotential such as indium (In), lead (Pb), mercury (Hg), and tin (Sn) (selectivity ranges from 65 % to 100 % depending on the metals, CO_2 pressure, and electrolytes (Jitaru et al. 1997a)). Tin may be the most practical candidate for production of formic acid as it has been studied extensively in the literature, as well as its availability, cost, and low toxicity to humans. A number of studies using Sn as a catalyst have been conducted (Udupa et al. 1971; Mahmood et al. 1987; Todoroki et al. 1995; Akahori et al. 2004; Agarwal et al. 2011; Chen and Kanan 2012; Furuya et al. 1997; Hinogami et al. 2012).

Hydrocarbons and Alcohols

Copper electrode uniquely reduces CO_2 to methane, ethylene, and alcohols at high current densities (0.05–0.1 kA/m^2) in aqueous electrolytes (Gattrell et al. 2006; Hori et al. 1997; Tang et al. (2012); Li and Kannan 2012; Schouten et al. 2012). These products are particularly of interest in transportation applications as a way to convert renewable or nuclear power to carbon-based energy. Besides the mass transfer limitation as that for CO and formate/formic acid products, high overpotentials and low selectivity are two additional issues for these products. Some work has been done to address the selectivity problem. For example, it is found that selectivity is affected by CO_2 pressure, stirring conditions, and current density (Hara et al. 1994). Particularly, on a gas–liquid–solid (GLS) three-phase Cu electrode, the main product is ethylene (Yano et al. 2002a; Ogura 2003; Ogura et al. 2003), while on flat electrodes, it is methane. The selectivity issue has to be addressed in the practical applications as selectivity may change with position in a larger electrolysis reactor due to pressure drop, intermediates product (CO) accumulation and conversion, nonuniform potential distributions, etc.

Critical Technology Development Factors for Electrochemical Methods

Economic viability is the key for any technology to be accepted commercially even if there is a significant environmental benefit. The economic feasibility is a trade-off between operating and capital expenditure along with the market factors affecting product salability, as depicted in Fig. 5. The cost of operation is mostly dependent on energy cost and consumption, consumable chemicals, long-term stability, and also the replacement and/or recycling of reactor components. The process infrastructure would decide the capital expenditure. Product pricing, demand/availability, and its ease of utility in broader applications are the major factors affecting the

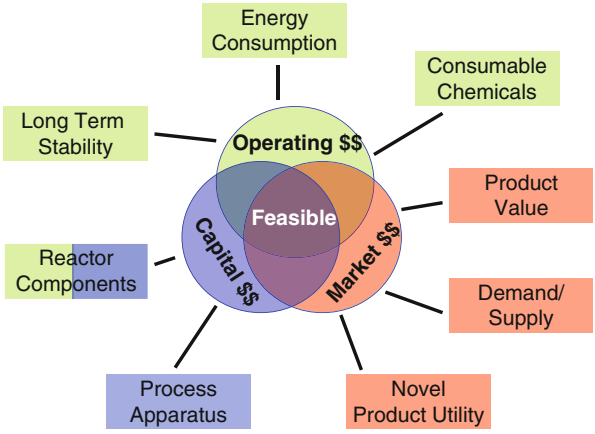

Fig. 5 Critical factors that together determine economic feasibility

market value. Only when sufficient knowledge of all these components is available can a comprehensive economic and value chain analysis be performed and the commercial feasibility of the process assessed with high confidence.

Typical requirements for a commercial electrochemical process are continuous (or on demand) operation, high product selectivity and rate of generation, long-term stable operation, and preferably operating close to ambient temperature and pressure. Catalysts should be able to favorably convert CO_2 to the desired product, i.e., display high selectivity. To reduce the size of the electrochemical reactor, it is also required to have high reactivity or product generation rate, which depends on the current density. Degradation of catalyst with time, limiting use of consumable chemicals, and decrease of electrical energy requirement by proper catalyst selection are critical for stable long-term operation. Continuous processing is essential for large-scale CO_2 utilization. Hence, optimal processing conditions for stable long-term operation need to be evaluated. Although considerable development has occurred in these different areas, as will be discussed in this section, gaps still exist. There are also limited efforts in developing and operating near commercial size reactors to solve issues related to long-term stable continuous operation.

Catalysts Activity and Selectivity

Specific energy indicates how much energy is consumed for each unit amount of CO_2 that is reduced. It is proportional to cell voltage and inversely proportional to the Faradic efficiency or selectivity. Therefore by decreasing the overall cell voltage and improving the selectivity, lower specific energy can be achieved. Both cell voltage and FE depend on current density or reaction rate; typically at larger current density (which is preferred for faster CO_2 reduction rate), higher cell voltage and worse selectivity will be observed.

Cell voltage is the summation of the difference of equilibrium electrode potential between anode and cathode, overpotential of anode, overpotential of cathode, and solution potential drop through membrane and electrolyte. Not many reports have been found giving specific energy except Oloman's work on electrochemical

reduction of CO_2 to formate on Sn electrode where 340 kWh/kmol was obtained at 3.1 kA/m^2 (probably when cell voltage is 4.3 V). High overpotential of cathode can be mitigated by the use of transition metal complex or photoelectrochemical process but stability of the electrodes is a big issue for these electrodes. Choosing anode materials with low overpotential and finding a membrane with high conductivity can also help lower the overall cell voltage. Relatively lower energy consumption is expected for CO and formic acid products from electrochemical reduction of CO_2.

One currently studied application involving the electrochemical reduction of CO_2 on Cu electrode is to adjust the selectivity of the gaseous products mix (hydrogen, methane, ethylene, and CO) such that it has close fuel properties to "hythane," a clean burning hydrogen/natural gas blend that has been promoted as an alternative fuel for existing vehicles (Gattrell et al. 2006, 2007; Gupta et al. 2006). Gattrell's group (Gattrell et al. 2007) specifically studied using this electrolysis process to upgrade biogases to a fuel mix that can be directly used by existing engines with minimal modifications. Assuming a total cell voltage of 3 V (−1.5 V for cathode, 1.2 V for anode-IrO_2, and IR drop of 0.3 V at 0.5–1 kA/m^2), the energy efficiency would be around 40 %.

As shown in Table 3, electrochemical reduction of CO_2 to hydrocarbons and alcohols is a multielectron transfer reaction which requires catalysts with high electron density. Noble metal nanoclusters are expected to be suitable as such catalysts because large percentage of metal atoms lying on the surface can provide high electron density. Moreover, the electrons in nanoclusters are confined to spaces that can be as small as a few atom widths across, giving rise to quantum size effects. Some preliminary research result is reported on utilizing Pd and Pt nanoclusters deposited on carbon nanotubes (CNT) or carbon nanofibers (CNF) to electrochemically reduce CO_2 to hydrocarbons and alcohols at room temperature (Perathoner et al. 2007). With Nafion membrane, after 30 min electrolysis at applied potential of −1.99 V, the main products are C1−C3 hydrocarbons (CH_4, C_2H_6, C_3H_6) and alcohols (CH_3OH, CH_3CH_2OH). However, selectivity and current density are not analyzed in their report. Also adsorptions of heavier products on the gas diffusion cathode (GDE) after longer time of electrolysis (30 min) deactivate the electrodes.

Work by Jaramillo et al. identified and explained the mechanism of hydrocarbon product formation using a flow cell with a Cu-based cathode (Kuhl et al. 2012). Numerous other studies showed that modifying copper surfaces lowers the overpotential and increases the selectivity for hydrocarbon formation (Tang et al. 2012; Li and Kanan 2012; Schouten et al. 2012). Tang et al. showed that by covering a Cu electrode with Cu nanoparticles, a higher selectivity toward hydrocarbons was achieved due to a greater abundance of under-coordinated sites (Tang et al. 2012). Li et al. annealed Cu foil in air and employed these modified Cu electrodes which provided a stable electrode that lowered the overpotential by 0.5 V compared to polycrystalline Cu (Li and Kanan 2012). Schouten et al. observed two different mechanisms for ethylene formation on the two single crystal copper electrodes (Schouten et al. 2012).

Ag catalysts have been extensively pursued for CO production, with reported current densities as high as 91 mA/cm^2 (Jhong et al. 2013a). Use of ionic liquids in the aqueous electrolyte has been shown to decrease the overpotential for CO generation on Ag. The work by Rosen et al. decreased the overpotential for CO production to 0.17 V by using an aqueous ionic liquid solution, in which the 1-ethyl-3-methylimidazolium ($EMIM^+$) cation serves as a cocatalyst, in combination with Ag nanoparticles immobilized on the electrode (Rosen et al. 2011). The current densities were less than 5 mA/cm^2. Tornow et al. showed that the use of diaminotriazole-based organometallic silver catalysts decreased Ag loading by a factor of 20, while keeping similar performance (Tornow et al. 2012). They also suggested a cocatalyst role of the ionic liquid species. Salehi-Khojin et al. observed that the optimal activity of Ag particles on CO_2 reduction is at an average size of 5 nm (Salehi-Khojin et al. 2012). Chen et al. reported highly selective reduction of CO_2 to CO at overpotentials of about 0.14 V with Au nanoparticles synthesized by reduction of Au oxide films (Chen et al. 2012).

Metal oxides (Chen and Kanan 2012), alloys (Agarwal et al. 2011; Furuya et al. 1997), and MOF catalysts (Hinogami et al. 2012) have been employed as active electrocatalysts for HCOOH production. Work by Chen et al. showed that a Sn/SnOx catalyst displays higher current density and faradaic efficiency for HCOOH unlike SnO that seems to mostly produce H_2 (Chen and Kanan 2012), suggesting the role of SnOx in CO_2 conversion mechanism. Agarwal et al. employed Sn alloy catalysts that provided higher faradaic efficiencies than pure Sn at lower polarization (Agarwal et al. 2011). Copper rubeanate metal organic framework catalysts (CR-MOF) developed by Hinogami et al. decreased the potential for onset of CO_2 reduction by 0.2 V compared to a plain Cu electrode (Hinogami et al. 2012).

Cathode Current Density

Any practical electrochemical reactor for CO_2 reduction must also deal with the issue of mass transfer of CO_2 to the cathode surface. Relatively low solubility of CO_2 in aqueous solutions (ca. 70 mM at STP) creates a mass transfer constraint on reaction rate to a maximum current density of 0.1 kA/m^2 under 1 atm and 25 °C for formic acid production, while a superficial current density greater than 1 kA/m^2 is desired for practical operations. Current density may be increased by using a gas diffusion cathode (GDE) or using a fixed-bed cathode while providing a "three-phase interface" for the reaction by sparging the cathode chamber with CO_2 gas or high CO_2 pressure or activated carbon fibers simulating high pressure by "nanospace effect" (Yamamoto et al. 1998, 2000). For example, Hara and Skata (Hara and Sakata 1997) reported a total current efficiency of 50 % (five products) at 6 kA/m^2 on a Pt GDE under 2000 kPa(abs) CO_2 pressure. Nanostructured electrode (Perathoner et al. 2007) is claimed to be able to "simulate" the high-pressure effects to obtain large current density with the confinement effects inside the nanopores. However, two issues with the use of GDE and/or nanostructured electrodes are the temporal stability and the potential for accumulation of liquid phase reaction products in the pores of the electrode.

The use of organic solvent instead of water is also considered because higher solubility of CO_2 in organic solvents may increase the current density. Furthermore,

the competition from hydrogen evolution can be suppressed in organic electrolytes. Methanol is especially actively explored because CO_2-saturated methanol from industrial absorbers (the Rectisol process) is readily available (Kaneco et al. 2002, 2007). (However, methanol used in Rectisol process absorbs not only CO_2 but also H_2S.)

Li and Oloman (Oloman and Li 2008) developed a scaled-up, continuous reactor using tin as the cathode catalyst to generate formic acid/formate as the reduction product of CO_2. They demonstrated that a reactor can operate for relatively extended periods of time (up to 200 min) and produce significant current efficiency ranging from 91 % to 67 %. Under a reactor current of 3.1 kA/m^2 ($\sim CO_2$ reduction rate of 0.025 t/m^2.h), a formate product concentration of 1 M was obtained in a single pass resulting in a specific energy of 340 kWh/kmol of formate. A trickle-bed cathode consisting of a 3-mm thick sandwich of approximately 0.3 mm tin granules was used to obtain a high CO_2 mass transfer capacity in two-phase flow with adequate gas space velocity. The work also pointed to three problems that could prevent commercial development of electrochemical reduction of CO_2 to formate/formic acid, specifically, (1) temporal stability of the cathode; (2) crossover of formate, through the cation membrane, from cathode to anode; and (3) two-phase fluid distribution in the cathode. Commercialization of this technique is sought by Mantra Venture Group (www.mantraenergy.com).

Electrode Structure Affecting Current Density

The performance and durability of electrodes is critical for all heterogeneous electrochemical reactions. These are dependent on the processes occurring at the electrode–electrolyte interface and within the electrode of the electrochemical reactor. The electrodes usually consist of a complex structure with a catalyst layer on top of a backing or substrate layer. The backing layer delivers reactant gas, CO_2, from flow-field channels to the catalyst layer, and transports product from the catalyst layer into flow channels or to the electrolyte/membrane. It also acts as the current distributor for the catalyst layer and should possess a low resistance to avoid large potential variations to be applied to the catalyst layer (Hori et al. 2003; Hara et al. 1994). All these transport processes require optimization for maximizing the electrode and, consequently, the reactor performance.

There have been limited efforts to understand electrode geometrical effects (Delacourt et al. 2008; Yano et al. 2002a; Jhong et al. 2013a; Hori et al. 1994, 2005). CO_2 reduction reaction on planar metal electrodes (Cu, Au, Ag, Zn, Pd, Ga, Pb, Hg, In, Sn, Cd, Tl, Ni, Fe, Pt, Ti) used by Hori et al. in the early work resulted in low current densities of about 5 mA/cm^2 (Hori et al. 1994). Apart from the low surface area of planar electrodes, the low CO_2 concentrations in due to the limited CO_2 solubility in the aqueous electrolytes are responsible for low current density. Metal (Ag, Cu) mesh cathodes were employed by Yano et al. in a modified H-type cell where CO_2 reduction takes place at a three-phase gas–liquid–solid interface by delivery of gaseous CO_2 from a gas chamber (Hori et al. 1997; Yano et al. 2002a). However, current density data was not reported, probably owing to difficult in determining the geometric electrode area in the multiphase system.

Delacourt et al. developed electrodes by spray-painting Ag catalyst ink on gas diffusion layers (GDLs), similar to those prepared for polymer electrolyte membrane fuel cells, cathodes with a Ag loading of 8–10 mg/cm^2, and Ag particle sizes of about 1 μm (Delacourt et al. 2008). Current densities as high as 20 mA/cm^2 were obtained with product selectivities comparable to the findings by Hori et al. (1994) and Yano et al. (2002a). Kenis et al. developed gas diffusion electrodes (GDE) covered with a catalyst layer of Ag nanoparticles (particle size of 70 nm) (Jhong et al. 2013a) and obtained a current density as high as 91 mA/cm^2 in combination with 94 % faradaic efficiency for CO and 46 % energetic efficiency. Deposition of a very thin, crack-free catalyst layer (Ag loading of only 0.75 mg/cm^2) using a fully automated airbrushing method was critical for the high current density achieved. Salehi-Khojin et al. observed that the optimal activity of Ag particles on CO_2 reduction is at an average size of 5 nm (Salehi-Khojin et al. 2012).

Electrolyte

Electrolyte composition is another parameter that has a significant effect on current density and product selectivity of electrochemical CO_2 reduction (Hori et al. 1989; Murata and Hori 1991; Wu et al. 2012). Supporting electrolytes in varying concentrations, such as salts comprising of alkali cations (e.g., Na^+, K^+), halide anions (e.g., Cl^-), bicarbonate (HCO_3^-), or hydroxide (OH-) (Hori et al. 1989, 1994; Murata and Hori 1991; Wu et al. 2012), are employed generally to minimize the ohmic potential loss by keeping the electrolyte conductivity high. Protons in the electrochemical CO_2 reduction process are provided by water (Hori et al. 1994; Peterson et al. 2010). For example, Hori et al. showed that the choice of cation for bicarbonate (HCO_3^-) electrolytes affects the distribution of product formed on copper (Cu) electrodes (Murata and Hori 1991). Another study by Hori et al. showed that anions (i.e., Cl^-, ClO_4^-, SO_4^{2-}, HCO_3^-, $H_2PO_4^-$) affected product distribution by changing local pH at Cu electrodes, which in turn affects the reaction kinetics (Hori et al. 1989). Wu et al. observed similar electrolyte effects on activity and selectivity of tin (Sn) electrodes (Wu et al. 2012). Thorson et al. reported that larger cations in electrolyte salts favor CO production and suppress H_2 evolution (Thorson et al. 2013). Use of ionic liquids, in combination of aqueous solutions, can increase the solubility of CO_2 and reduce mass transfer limitations (Rosen et al. 2011; Tornow et al. 2012). Jingjie Wu et al. (2012) evaluated electrolyte effects on the selectivity and activity for the electrochemical reduction of CO_2 on the Sn electrode. They found that SO_4^{2-} anion and Na^+ cation favor higher faradaic and energy efficiencies while HCO_3^- and K^+ produce formate at a faster rate. Cs^+ containing electrolytes showed the lowest faradaic efficiency. As the electrolyte is diluted, faradaic efficiency was seen to increase, while the current density decreased. Na_2SO_4 and $KHCO_3$ were found to be most optimal.

Cathode Catalyst Stability and Life

For commercial viability, it is imperative that electrodes in an electrochemical reactor can be used for up to several thousands of hours without significant loss in activity or selectivity. Currently, for most applications reviewed above, there exists a big gap between the reported lifetime of the electrodes/catalysts and the desired ones.

Production of formate/formic acid can be highly selective at the beginning of an electrochemically CO_2 reduction process; however, the longest tested operation time before substantial deactivation of the electrodes is for a few days, far less than the required several thousands of hours lifetime for the electrodes.

Deactivation of the Cu electrode (Jitaru et al. 1997b; Chaplin and Wragg 2003) (for hydrocarbons and alcohols), of Pb and Sn (Koleli et al. 2003) (for formate/formic acid), and of Ag electrode (Yano et al. 2002b) (for CO) have been reported. Several "poisoning" mechanisms are proposed:

1. Poisoning of the electrodes occurs due to graphitic carbon deposition at the electrode formed by further reduction of CO (Yano et al. 2002b; Ishimaru et al. 2000; Lee and Tak 2001)
2. Organic adsorbates, such as formaldehyde HCHO (Kostecki and Augustynski 1994) and formic acid which form complexes (Li and Oloman 2007)
3. Presence of Fe and Zn impurities in the electrolyte, which deposit at the electrode surface and progressively induce a change in product selectivity (Hori et al. 2005)

In order to suppress this poisoning effect, some authors have proposed the use of pulse techniques, aimed at desorbing the intermediates before they can further be reduced into a "poison" by shifting periodically the potential to a less negative value (Ishimaru et al. 2000; Yano and Yamasaki 2008) or reverse the polarity of applied current (Li and Oloman 2007). As to the last possible poisoning mechanism, a pre-electrolysis of the electrolyte is performed to reduce the concentration of metallic impurities (Hori et al. 2005).

Jingjie Wu et al. studied the stability of the Sn electrode for CO_2 reduction as a function of electrolytes such as $KHCO_3$ and Na_2SO_4 (Wu et al. 2012). Deposition of Zn on Sn cathode from the impurities present in the catholyte leads to obstruction of the CO_2 reduction with Sn, and rapid loss in faradaic efficiency was observed during the initial 10-h operation in both Na_2SO_4 and $KHCO_3$ electrolytes. L. Chiacchiarelli et al. (2012) studied the cathodic degradation mechanisms of pure Sn in a nitrogen atmosphere as a function of rotation rate, time, current density, electrolyte concentration, grain size, and orientation. Anawati et al. (2014) studied the degradation of Sn catalyst used for CO_2 reduction to formate in 2 M KCl solution using a rotating disk electrode. Optimum faradaic efficiencies were obtained at −1.8 VSCE. Two types of degradation were observed after cathodic polarization using SEM/EDS and XPS. Cathodic corrosion of Sn at higher cathodic potentials leads to a crystallographic type of etching morphology near and at the grain boundaries. Intermetallic colloidal deposits of KSn were observed on the Sn cathode causing an increase in total current due to excessive hydrogen evolution. It is imperative to develop a technique to avoid or remove the alkali metal deposit for sustained stable performance.

The pulse techniques proved to be useful to counteract the poisoning. However, in most research work, the pulse techniques were applied to a rather small size of electrode (0.28 or 1.0 cm^2), and it is unknown whether these methods are applicable

on a practical scale. Evaluation on how the electric charge consumed during the anodic polarization is lacking in the estimation of energy efficiency. Furthermore, in the repeated anodic polarization techniques, anodic dissolution of the electrode may occur and shorten the life of the electrode. Hence, poisoning of the electrodes should be prevented by means of some chemical methods without using any anodic treatment. In situ deposition of catalyst to the electrode by adding salts like $AgNO_3$ was shown to improve the lifetime of Ag electrode (Yano et al. 2002b). Sn catalyst can be regenerated by washing used catalysts with dilute hydrochloric acid and potassium hydroxide (Li and Oloman 2007). It is found that the GLS (gas–liquid–solid) interface (Yano et al. 2002a) and lower pH of the electrolyte (Yano et al. 2002b) would suppress the deposition of poisoning species.

Electrolyzer

Majority of the work on CO_2 conversion involves the setup of a half cell for the study of cathodic electrode behavior. However, the evaluation of the performance of an electrochemical reactor requires a full-cell setup which consists of cathode, anode, cathodic and anodic chambers for holding and distributing electrolytes, membranes for ionic transport, electrolyte conductivities, and corrosivity (Jhong et al. 2013b). The selection of materials for anodes, electrolytes, and membranes plays a significant role in terms of improving the energy efficiency (by decreasing the overall cell voltage) and maintaining long-time stable operation. Compatibility of materials needs to be considered. In the case of low one-pass conversion rate, recirculation of the reactants (both CO_2 gas and electrolytes) may be needed to improve the overall efficiency of the process. A microfluidic flow cell design has been employed by researchers to study the performance of a full cell, where the geometric surface area of the electrode surface is of the order of 10 cm^2 (Delacourt et al. 2008; Agarwal et al. 2011; Wu et al. 2013). Chlor-alkali industry, an established manufacturing technology, employs electrochemical reactors with single cells spanning an electrode area of about 2 m^2. Few groups are looking to advance the full cell design of reactors to such sizes (http://llchemical.com/technology; http://www.dioxidematerials.com/co2.html; Zhai et al. 2015). The scaling-up of reactors brings in new challenges such as fluid flow distribution both within and between the cells of a multicell stack, distribution of concentration, electrode potential, pressure drop, etc. that needs to be optimized. Reactor modeling may speed up the analysis on the effects of process variables (concentrations and flow rates, cell potential, current, pressure, pH, temperature, materials) and their optimization.

Anode Performance

In the methods for CO_2 electroreduction discussed above, very little attention is given to the anodic process. The overall energy efficiency can be significantly improved by optimizing the anodic process specifically complementing the electroreduction of CO_2.

Anodes used in cases where formic acid/formate ion is the primary product, such as carbon (Mahmood et al. 1987) and stainless steel (Oloman and Li 2008), do not exhibit the optimum catalytic behavior for oxygen evolution reaction, while

platinum-coated mesh (Li and Oloman 2007) might be expensive or prone to rapid poisoning. Ni foam anodes employed for (CO + H_2) synthesis (Yamamoto et al. 2002) showed variable behavior depending on the type of the cathode catalysts.

Significantly improved anode catalysts for oxygen evolution reaction have been proposed for the generation of pure hydrogen by water electrolysis, few of which are discussed in Table 4. Although the development of these catalysts is not specifically aimed at ERC of CO_2, these systems can be applied for optimizing the electroreduction process.

The advantages of employing anode catalysts developed for PEM and alkaline water electrolyzers are:

- Oxygen evolution at the anode using nickel catalyst (fairly inexpensive, good corrosion resistance in alkaline medium) or mixed oxide noble metal (similar to dimensionally stable anodes (DSAs) in acidic media) is well characterized.
- Cationic exchange membrane to separate the anodic and cathodic chambers, similar to the ERC of CO_2.
- Industrial scale reactors have been developed and employed over long times, indicating excellent durability and low likelihood of poisoning.

Other Electrochemical Methods

Photoelectrochemical Reduction of CO_2

The photoelectrochemical method for the conversion and reduction of CO_2 is of interest because it employs direct solar energy conversion to fuels/chemicals and can be regarded as an artificial photosynthesis. Many investigations have been conducted on the photoelectrochemical reduction of CO_2 on p-type semiconductor electrodes including p-GaP, p-CdTe, p-GaAs, p-InP, p-SiC, and p-Si and its diamond coats. Most recent reports on the progress of photoelectrochemical reduction of CO_2 involves the use of methanol as the solvent in electrolyte because the solubility of CO_2 in methanol is approximately five times higher than in water at room temperature. Kaneco et al. (2006a, b) studied the photoelectrochemical reduction of CO_2 at p-type semiconductor electrodes, p-GaAs and p-InP, in the methanol-based electrolyte. The main products from CO_2 were carbon monoxide and formic acid. The onset potentials of the photocathodic current in the methanol-based electrolyte were around -1.2 and -0.8 V versus Ag/AgCl with p-GaAs and p-InP electrodes, respectively. Compared to potentials with normal metallic electrodes (in the same methanol-based electrolyte), the photo-aided electrolysis can reduce the total voltage by about $0.3 - 1.0$ V. The maximum current efficiency for CO ($FE = 41.5$ %) was obtained at -2.4 V for the p-InP photocathode. Another research group at Princeton University (Barton et al. 2008) showed a high selectivity of methanol as the product (nearly 100 %) from photoelectrochemical

Table 4 Characteristics of anode catalysts for oxygen evolution employed in hydrogen generators

	Catalyst/electrolyte and temperature/reference	Salient features			Physical characteristics/ electrode construction
Polymer electrolyte membrane (PEM) electrolyzers for hydrogen generation					
1.	Ru, RuO_2, Ir, IrO_2/ acidic (0.5 M H_2SO_4) at RT/(Shidong et al. 2008)	IrO_2 – high stability, 20 h at 0.3 A/cm^2 for cell potential ~1.55 V for 500 nm thick layer 0.2 mg/cm^2 loading			BET sp. area 10–200 m^2/g/catalyst coated on cation exchange membranes
2.	IrO_2 on Ti/C/acidic Nafion type at 90 °C/(Labou et al. 2008)	High uniform surface area with low metal deposit negligible C substrate oxidation			Magnetron-assisted Ir sputtering on Ti-coated carbon/ catalyst-coated Nafion membrane
		1 A/cm^2 at 1.51 V for 0.2 mg/cm^2 loading			
3.	Mixed oxide, noble metals/acidic Nafion type at 90 °C/(Grigoriev et al. 2006)	**Catalyst composition**	**Loading mg/cm^2**	**Cell potential (V) at 1 A/cm^2**	Commercial/catalyst-coated Nafion membrane
		Ir	2.4	1.75	
		RuO_2 (30 %) – IrO_2 (32 %) – SnO_2 (38 %)	2.0	1.7	
		RuO_2(50 %) – IrO_2(50 %)	2.0	1.65	
		Cathode – Pt30/C, 2 mg/cm^2			
	Alkaline water electrolyzers for hydrogen generation				
4.	Sintered Ni/30 % KOH at 25 °C/ (Dyer 1985)	Reduction in overpotential by 200 mV as compared to unactivated Ni (measured at 250 mA/cm^2)			Sintered Ni avg. porosity 77.5 %, mean pore size 12.7 μm with activation by AC cycling (125 mA at 0.25 Hz in 1 M KCl) to form uniform Ni $(OH)_2$/Ni mesh
		<1 mV change in overpotential per hr in 6 h test			
5.	Raney Ni + Co_3O_4 on Ni substrate/30% KOH, 40–80 °C/ (Schiller et al. 1998)	300 mA/cm^2 at cell voltage ~1.6 V			Vacuum plasma spraying of NiAl (50 %) and Co_3O_4 (50 %) on porous Ni substrate, heat 700 °C, cold roll, activation/Al leaching at 80 °C in 30 % KOH+ K–Na tartrate tetrahydrate/Ni mesh
		Intermittent operation 1500 h			
		Negligible degradation of 600 cm^2 area electrodes			

(*continued*)

Table 4 (continued)

Catalyst/electrolyte and temperature/reference	Salient features	Physical characteristics/ electrode construction
6. Composite Ni + Mo, Ni + Mo + Si/5 M KOH, 25 °C (Kubisztal and Budniok 2008)	High surface area of deposited catalysts lead to high current densities at low overpotentials	Co-deposition of Ni with Si and Mo powders suspended in Ni bath, modified by leaching out Si/carbon steel substrate
	Overpotentials for a current density of 10 mA/cm^2: Ni = 354 mV, Ni + Mo = 273 mV, Ni + Mo + Si = 254 mV	

reduction of CO_2 on p-GaP electrode at low potentials of −0.2 V to −0.7 V (SCE). However, the current density was very low, less than 0.01 kA/m^2.

Another type of direct solar energy electrochemical conversion of CO_2 is the use of n-type semiconductor such as TiO_2 as anode in the electrolysis cell to act as an electron donor for the reduction of CO_2. The photoelectrocatalytic (PEC) reactor concept was originally proposed by "Hitachi Green Center" researchers (Doi et al. 1995; Ichikawa and Doi 1996). Photosensitizers such as complexes containing 2,20-bipyridine (bipy) are used with transition metals for the reduction of CO_2 under irradiation in both aqueous and nonaqueous electrolytes (Kitamura and Tazuke 1983; Lehn and Ziessel 1982, 1990).

On the anode side a photocatalyst (nanostructured titania (TiO_2)) photodissociates water to produce protons and electrons which are used on the cathode side of a membrane to reduce CO_2 to hydrocarbons. The membrane is a proton-conductive membrane such as Nafion 117. Development of efficient photocatalysts for anode, electrocatalysts for cathode, and integration in the PEC device are required for practical application. The development of the anode side may benefit from the improvement on the photocatalysts for water splitting. The construction, characteristics, and materials (apart the photocatalytic side) of the PEC reactor are those of PEM fuel cells. There is no solvent on the cathode side and therefore there is no need to recover the products from a liquid phase (a main problem in the conventional CO_2 photo- and electroreduction), and there are no problems of solubility of CO_2. Electrodes based on nanostructured carbon is suggested for the cathode in order to use the confinement effect inside the nanopores to create a virtual higher pressure of the reactant (CO_2) at the electrocatalyst surface and thus favor the chain growth. The use of nanostructured carbon would also favor a high mobility of hydrogen radicals that are important in the reaction mechanism.

General problems of photoelectrochemical reduction of CO_2 are low current density due to high resistances of the semiconductor electrodes, long-term stability of the electrodes, the requirement of high purity semiconductor electrodes, and low energy efficiency when sunlight is used as light source.

High-Temperature Electrochemical Conversion Using Solid Oxide Electrolyzers

Electrochemical syngas (CO and H_2) production using solid oxide fuel cell-based electrolyzers (SOFCs) is developing into a potentially viable method due to high

current densities and its potential to co-generate power, as compared to low-temperature electrochemical processes that are generally highly power intensive. Solid oxide electrolyzers (SOEs) are essentially solid oxide fuel cells (SOFCs) operated in reverse and are capable of higher efficiencies for water electrolysis and CO_2 reduction to CO compared to solution-based electrolysis cells. This is because of the higher operating temperatures (>925 K) that significantly lower the electrode potential by lowering the thermodynamic (Nernst) potential (Parkinson 2006). In SOEs the electrolyte membrane conducts oxygen anions, rather than protons in low-temperature, solution-based electrolyzers. Yttria-stabilized zirconia, YSZ, with its oxygen-anion conduction and electronic insulation properties is most commonly used as the electrolyte.

The cathodic or the fuel-side reaction is the electrochemical reduction of water to produce H_2 and O^{2-} anions and (Eq. 2) CO_2 reduction to CO and O^{2-} anions:

$$H_2O + 2e^- \rightarrow O^{2-} + H_2 \tag{14}$$

$$CO_2 + 2e^- \rightarrow O^{2-} + CO \tag{15}$$

The anodic or the air-side reaction is the recombination of the oxygen ions to O_2:

$$O^{2-} \rightarrow 2e^- + 1/2O_2 \tag{16}$$

Nernst potentials for the electrolysis of H_2O and CO_2 are similar (Sanchez-Sanchez et al. 2001). There are a few reports for the electrochemical reduction of CO_2 to CO in SOEs (Yamamoto et al. 2002; Sridhar and Vaniman 1997; Tao et al. 2004). Idaho National Laboratory developed a syngas generation electrolyzer (called "Syntrolysis") from CO_2 and H_2O by using solid oxide electrolyzer which operates at high temperature of 830 °C (http://www.inl.gov/factsheets/docs/syntrolysis.pdf). The cell design is based on solid oxide fuel cell (SOFC). This novel technique is claimed to be very promising in recycling CO_2 to fuels (through Fischer–Tropsch processes of the syngas) if it is integrated into carbon-free nuclear energy production facilities where process heat and electricity from an advanced nuclear reactor can be used for the electrolysis. Some research focused on O_2 production for space missions employ CO_2 to CO reaction at the cathode (Yamamoto et al. 2002; Sridhar and Vaniman 1997; Tao et al. 2004). The use of expensive bulk Pt electrodes make these SOEs less practical for large-scale CO_2 electrolysis where the intent is sustainable chemical and fuel (CO) production. Furthermore, Pt electrodes displayed higher overpotentials leading to low overall efficiency for CO_2 reduction. Dry reforming (CH_4 reforming with CO_2 rather than steam) is less energy intensive and could produce syngas with more favorable H_2/CO ratios (Belyaev et al. 1998; Kim et al. 2002). An yttria-stabilized zirconia (YSZ)-based electrolyte or tube with various metal and/or mixed metal catalysts at the anode and cathode is typically employed in such cells (Belyaev et al. 1998; Choudhary et al. 1995). SOFCs using nickel-based catalysts, such as ceria-doped nickel-YSZ or nickel oxide–calcium oxide-mixed metal electrodes have been employed for CH_4 reforming (Kim et al. 2002; Choudhary et al. 1995). Bidrawn et al. demonstrated direct CO_2

electrolysis to CO without utilizing CH_4 (Eq. 15) with high current densities of the order of 1 A/cm^2 (Bidrawn et al. 2008). Furukawa et al. utilized H_2 fuel with CO_2 at lower temperatures (500 °C) with nickel/zeolite and silver electrodes to generate CH_4 at yields as high as 80 % (Furukawa et al. 1999):

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O \tag{17}$$

Electrode degradation due to prolonged usage at high temperature and deactivation due to coke formation and deposition (via CH_4 decomposition and CO disproportion) are major impediments to the long-term usage of SOFCs. Inclusion of small fractions of metal or metal oxide phases such as CeO_2, gadolinia-doped ceria (GDC), copper, palladium, and $Ce_{0.48}$ $Zr_{0.48}$ $Y_{0.04}$ (CZY) to SOFC electrodes could lead to reduced electrode coking and better overall cell performance and stability (Kim et al. 2002; Bidrawn et al. 2008; Huang and Chou 2009).

Metal-Free Catalysts

There is an upcoming trend for CO_2 conversion processes using metal-free electrocatalysts that can be obtained by relatively inexpensive means, do not use noble metals, and show comparable catalytic activities relative to the metal-containing electrocatalysts described above. These consist of conducting polymers, pyridinium derivatives, radical anions, and heteroatom-doped carbon materials (Mao and Alan Hatton 2015).

In the case of homogeneous catalysts (i.e., pyridinium derivatives and radical ions), the electrode type is critical due to its direct contact with the electrolyte solution, thus affecting the faradaic efficiencies and product selectivity. Seshadri et al. (1994) employed pyridium in a Pd-catalyzed scheme to reduce CO_2 to methanol at a faradaic efficiency of 30 % in an aqueous solution with a pH value of 5.4, 200 mV overpotential, 40 mA/cm^2 current density, and stable life of 19 h, with the rest of the product being hydrogen. The Bocarsly group developed important mechanistic understanding of pyridinium ion-based systems (Cole et al. 2010; Morris et al. 2011). They showed that the electrochemical reduction of carbon dioxide did not occur in presence of an inert electrode that does not catalyze hydrogen evolution. Also, carbon dioxide rather than bicarbonate was reduced during electrolysis with a pyridinium/Pt system, suggesting that carbon dioxide reduction proceeds by a first-order surface-active rate-limiting step with respect to both pyridinium and carbon dioxide. Selectivity was seen to increase significantly with a semiconducting electrode, combined with the pyridinium-based homogeneous catalytic system (Barton et al. 2008). A faradaic efficiency of almost 100 % was achieved by Barton et al. for CH_3OH from CO_2 reduction using the pyridinium/p-GaP system under illumination. However, the low solar-to-fuel quantum efficiencies obtained in this case is not feasible for commercialization. Nonetheless, this photoelectrochemical process is of great interest due to its very low overpotentials and extremely high faradaic efficiency for methanol production from CO_2.

Heterogeneous conducting polymer catalysts are usually prepared from monomers (e.g., aniline and pyrrole) that are electrochemically polymerized onto conductive

substrates (i.e., electrodes). Since the electrode is usually covered completely by the resulting polymer film avoiding its contact with the electrolyte solution, the nature of the electrode has negligible effects on the catalytic performance. Lack of stability due to degradation and reduced catalysis efficiencies because of morphological changes in the polymer structure during long-term electrolysis, however, is an issue. Stability can be improved by hybridization of conducting polymers with other materials such as graphene and carbon nanotubes. Heteroatom-doped carbons appear to be quite stable during electrocatalysis. Another advantage is the ability of being employed in nonaqueous solutions such as ionic liquids which eliminates the hydrogen evolution side reaction and thereby significantly improves faradaic efficiencies of desired products. Along with these materials, established strategies for modulating the electronic properties of carbon materials could be employed for improving the catalytic performance. A potential issue could be the overall carbon footprint of these electrodes if they are made in large scale since most of these materials are derived from fossil fuel sources. Aydin et al. (Aydin and Koleli 2004) employed a polypyrrole electrode in a methanol/$LiClO_4$/H_2O/H^+ (pH = 1) electrolyte at a potential of −0.4 V versus Ag/AgCl to obtain a mixture with the majority products being HCOOH, HCHO, and CH_3COOH, with a decrease in FE with time. Electrolysis under high CO_2 pressures, ranging from 5 to 20 bar, improved the faradaic efficiencies for HCOOH and HCHO, while that of CH_3COOH remained unchanged. A polyaniline-based electrode was developed by Koleli et al. (2004) for electrocatalytic reduction of carbon dioxide under ambient conditions, using methanol as the solvent. In this case the maximum faradaic efficiencies observed were for the formic acid (12 %) and acetic acid (78 %). Kumar et al. (2013) developed polyacrylonitrile (PAN)-based heteroatomic carbon nanofiber (CNFs) for reducing carbon dioxide to carbon monoxide in 1-ethyl-3-methylimidazolium tetrafluoroborate (EMIN-BF4) with a high FE of 98 %.

Novel CO_2 Electro-biochemical Pathways

One of the challenges for CO_2 utilization revolves around balancing the energy required (or costs) to produce a chemical with a large market volume and high value. The conversion of CO_2 to chemicals such as formic acid that are less energy intensive to make and have a high selling price are more likely to reach commercialization. However, such chemicals have a smaller worldwide market demand (1–10 million t/year). It would be desirable to convert CO_2 to chemicals that can be directly employed as fuels since they have a much larger demand and hence can make a bigger impact on reducing CO_2 emissions. However, the energy-intensive nature of such direct CO_2 conversion processes (e.g., electrochemical synthesis of methane; the primary component of natural gas requires four times the electrical energy per mole as compared to formic acid) makes them significantly less economical.

A combination of electrochemical and biochemical pathways has been proposed that addresses these issues. Photosynthesis converts solar energy into stored chemical energy in plants, which is the biomass that is converted into biofuels. However, current biomass processing methods for biofuel production require large areas of land and sunlight, conditions that are not widely available. Developing microorganisms that can circumvent the low efficiency photosynthesis and directly utilize

energy and nutrients from chemicals produced from CO or CO_2 have been receiving greater attention recently. The use of bacteria for large-scale chemical production is not new and has been successfully employed in processes such as bioethanol production via fermentation. Bulk of the cutting-edge research in this field is focused on genetically modifying these microorganisms for greater efficiency and liquid fuel choice. The advantages include:

- Much greater energy efficiencies than photosynthetic routes
- Ability to operate in the dark
- Independent of geographic limitations
- Reduced land usage
- No competition to food
- The process can use any renewable energy source
- The processes can be scaled to different needs

The Advanced Research Projects Agency-Energy (ARPA-E), which is a part of the US Department of Energy, has funded several projects based on this concept under the "electrofuels" initiative (http://arpa-e.energy.gov/?q=arpa-e-programs/electrofuels). Researchers at EASEL, one of the recipients, have been engineering bacteria to convert CO_2 with electricity to higher carbon chain compounds that can be directly used as fuel. It is a two-step process, where CO_2, with the aid of electricity, is first converted to formate ion and then the bacteria in the vicinity of the electrode, where formate is generated, converts formate into biofuels (http://www.easelbio.com/technology/). Another recipient of the ARPA-E award, Ginkgo Bioworks, worked on incorporating the genes responsible for CO_2 metabolism in *E. coli* for production of liquid fuels (http://arpa-e.energy.gov/?q=arpa-e-programs/electrofuels). They found that mass transfer limitations owing to low solubility of the reactants CO_2 and H_2 that need to be fed to the microorganisms in aqueous solution could be bypassed by providing formate salts/formic acid directly as a source of carbon and hydrogen. This new hybrid process consisted of production of formic acid via electrochemical reduction of CO_2 based on the technology developed by DNVGL which is then further processed by genetically engineered autotrophic bacteria by Ginkgo Bioworks yielding liquid fuels, such as ethanol, butanol, and isoprenol (http://www.dnv.com/press_area/press_releases/2012/dnv_and_gingko_bioworks_with_potentially_game_changing_technology_for_utilizing_co2.asp) (Fig. 6).

Technical Barriers to Adoption of CO_2 Utilization

Energy Reduction

The first technical challenge is to reduce the energy required for activation of CO_2 molecule so that it reacts with protons or other molecules. CO_2 is a relatively stable molecule, although it is not the most stable product of carbon – carbonates and

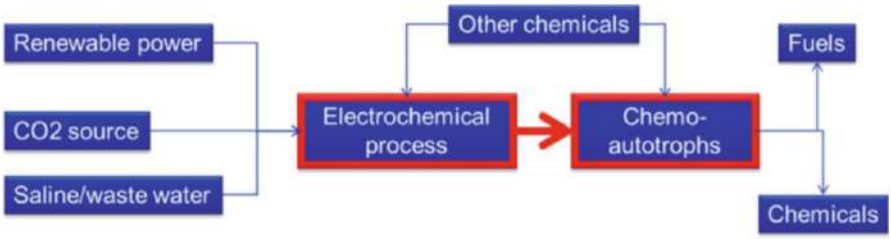

Fig. 6 Combination of electrochemical and biochemical pathways for fuels from CO_2

oxalic acid are even more stable. The Gibbs free energy for formation is an indicator of the energy hill we have to climb to make a product from CO_2. It requires far less energy in theory (0.24 MWh/t) to convert CO_2 to formic acid compared to other products we experience in daily life, but practical considerations require us to expend more energy to speed up the process. For example, at the current state of technology, the energy required to convert CO_2 to formic acid at a reasonable production rate is about 6 MWh/t. In comparison, polysilicon for a solar panel is produced from quartz at an energy penalty of about 60 MWh/t of Si (Tao 2008). Single crystal silicon for semiconductors requires a much greater energy penalty of about 350 MWh/t (Fig. 7).

Renewable Energy

Renewable energy is needed because the use of fossil energy would negate the benefit of CO_2 utilization. Because renewable energy, with the exception of hydro-electric energy, is variable in nature, CO_2 utilization processes must operate intermittently, which will make it expensive due to idling capital equipment during the time renewable power is not available. Additionally, when the process is not operating, provisions to mitigate equipment/catalyst damage due to corrosion must be made. In places where geothermal energy is readily available, such as Iceland, CO_2 conversion processes using renewable energy are being demonstrated. In addition to well-known renewable energy sources, energy harvesting from heat (a relatively low efficiency process using current thermoelectric technologies), ocean currents, or salinity differences at estuarine areas may be used in selected places.

Consumable Chemicals

As the energy usage is optimized, the cost of consumable chemicals can affect the overall profitability of the process and must be minimized. The lack of ready availability of some consumables may also render a process unattractive. For

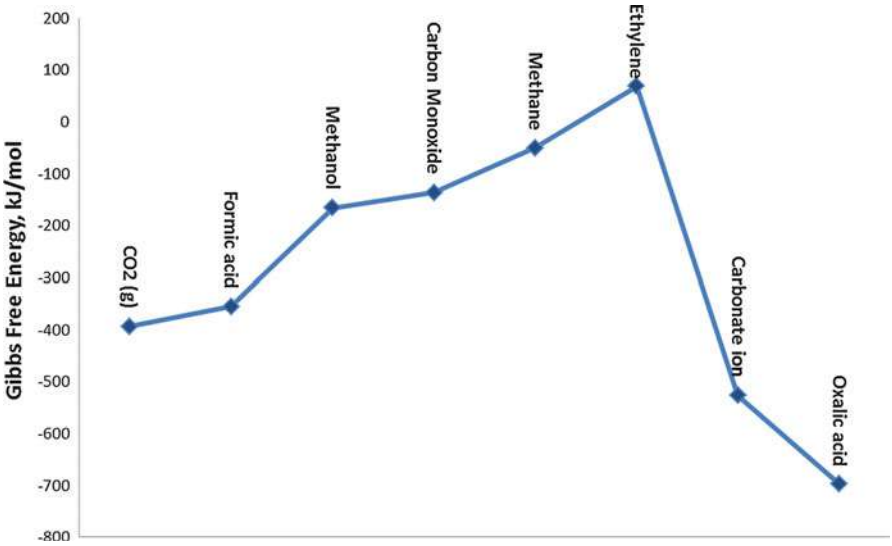

Fig. 7 Gibbs free energy for various products of interest from CO_2 conversion

example, Calera's cement manufacturing from CO_2 pilot plant in Latrobe Valley power plant in Australia had to be canceled partly due to the lack of proper brine chemistry available at the site and partly due to inadequate carbon pricing. In this regard, CO_2 utilization processes should be regarded as an integrated synthesis operation, where the products from one process can be used as inputs in another process.

CO_2 Purity

Conventional capture processes using absorption technologies are highly energy and capital intensive. Some CO_2 utilization processes, such as cement manufacturing, may be able to use low concentration exhausts directly from the stack, but most CO_2 utilization processes require a high concentration CO_2 source to be economical. Therefore, significant improvements in capture technologies are necessary for the overall system to be economical. Capture technologies involving adsorbents impregnated on porous solids may be economical and less energy intensive, but they have not been sufficiently tested at scale. Issues related to long-term (50,000 cycles or longer) degradation of adsorbents and substrates need to be addressed. Initial results from more limited duration testing appear to be promising. Alternatively, relatively pure CO_2 streams can be obtained from biofuel fermentation processes. Avoiding the need for compression reduces the energy consumption in capture processes significantly.

Material Degradation

Material degradation can contribute both to Capex (e.g., need to design more expensive alloys) and Opex (e.g., more frequent replacement of catalysts). Many CO_2 utilization processes have not been operated sufficiently long to understand material degradation issues.

Integration into Existing Systems

Integrating the rate of utilization with the rate of production is a significant challenge, even for EOR which uses significant amounts of CO_2. For example, EOR typically requires large quantities of CO_2 at the beginning of oil production and then tapers off its use, whereas a power plant expects CO_2 to be used at a relatively steady rate. Similarly, integrating renewable power with a CO_2 utilization process and a fossil plant producing CO_2 can be a challenge. Significant process engineering is required to ensure that mismatches in the production rates, thermal loads, and impurities do not adversely affect both the power production and CO_2 utilization processes. Furthermore, power plants are culturally attuned to producing electricity, not chemicals.

As mentioned before, a single CO_2 conversion process may not be economically viable. Therefore, CO_2 utilization should be considered as an integrated synthesis plant making a number of products. Integrating a number of processes is a technical challenge that can be met using a variety of simulation tools.

Product Quality Acceptance

Although product acceptance is generally a market issue, the production method may affect product acceptability. This was an issue for cement material produced from CO_2 and could be an issue for other materials, such as polymers and fuels. Significant time and process evolution may be required to meet current product specifications or change these specifications.

Life Cycle Analysis

LCA is necessary for CO_2 utilization processes to be accepted. LCA requires significant input on process parameters which may be lacking for new processes. However, LCA can also help modify process chemistry and improve CO_2 footprint.

Economic/Social/Environmental Barriers

Unlike CCS, CO_2 utilization does not face adverse public opinion. This is because recycling waste has become a cultural norm in most societies and CO_2 is regarded

as another example of waste recycling. This is evident in the interviews of public perception regarding CCS, where many participants suggested CO_2 utilization as an alternative to be explored. However, products from CO_2 utilization have to compete in the market place with products from fossil sources.

The large volume of CO_2 that can be converted to various products will saturate the local and global market. This is especially true for specialty chemicals and materials that can bring higher profitability at current market prices. For example, formic acid currently sells at approximately $1200 per ton. This provides a reasonable profit margin under current electrochemical production routes of this chemical from CO_2. However, the global annual market for formic acid is approximately 0.5 M tons. Lowering the cost can expand its market, but it is unlikely to expand it to levels that can meet the production volumes from reasonable use of CO_2. In terms of fuels, the volumes can be large, but the prices are relatively low. For example, isoprene produced from CO_2 through the formic acid has to compete with current gasoline prices of about $4 per gallon ($1300 per ton). The current biochemical process using genetically modified organisms yields 0.11 t of isoprene per ton of formic acid, thus requiring extremely low cost of production of formic acid.

Distributed Production of Fuels and Chemicals

If local sources of renewable energy and captured CO_2 (e.g., from air capture technologies or locally available CO_2 sources) are used to produce fuels and chemicals for local markets, the distribution costs can be lowered. On the other hand the advantages of centralized production in terms of scale and the use of resources available in one location can be lost. There may be greater difficulty in enforcing safety and environmental practices in a distributed manufacturing infrastructure. Electrochemical processes have a near linear cost with scale. Thus a large centralized plant brings no big cost advantage over several smaller-scale plants. The distributed production of chemicals and fuels may be useful for remote communities or in developing nations.

Policy Barriers

Green technologies, as a whole, require consistent policies to help them grow and become established. A recent research by Pew Research Center showed that in the USA, where periodic policy shifts occurred, wind energy market suffered 76–94 % drop whenever production tax credits expired. At present, CO_2 utilization is not as well recognized as CCS as a way of GHG mitigation. This has resulted in significant underfunding of efforts to develop utilization methods, other than EOR. The total government funding of large-scale CCS demonstration projects globally was approximately $9 billion in 2014. In contrast, the level of government funding for CO_2 utilization projects (other than EOR) amounted to about $50 million. Increased visibility of CO_2 utilization through government or international policies will encourage innovation and help bridge the funding gaps.

Subsidizing emerging CO_2 utilization processes or products will be necessary to help establish these technologies. At present traditional energy production (oil and gas, nuclear, etc.) receive significant government subsidies. Traditional biofuels from agricultural products also receive subsidies, although these are being phased out. Unlike these industries, the CO_2 utilization technologies lack an industry voice that can help educate policymakers and the public and promote the common goals of various technologies.

The market price of CO_2 is extremely low or nonexistent. Many of the analyses of CO_2 utilization processes assume that there will be no price for carbon. However, there is a gap in understanding between those who emit CO_2 and those who would like to utilize CO_2 regarding the price of carbon.

Future Directions

The barriers for adoption of CO_2 utilization technologies discussed above can be reduced with the following strategies:

Improved Electrochemical Reaction Kinetics Technology

As mentioned previously, for long-term viability of CO_2 utilization technologies using the electrochemical approach, improved catalyst performance is essential. This included significantly increased catalyst life, increased current densities, and increased impurity tolerance. Although significant progress has been made in the first two of these issues, the last issue has not been adequately addressed. Novel high surface area catalysts can further increased current densities, but they have to be balanced by increased life. The reactor design is another area that can be significantly improved. High-pressure operations could benefit the overall economics. Improved hydrodynamics is another area that needs further development.

Improved Biochemical Processes

The current biochemical technologies have relatively low yields requiring large land area. Furthermore, the requirements for CO_2 are somewhat low and the purity issues need further improvement.

Value Chain Analysis

An important aspect of reducing technical barriers is to set metrics for success in selected technologies. These metrics should be based on a full techno-economic (value chain) analysis, considering the uncertainties involved in many of the parameters. The characterization of uncertainties and their effects on the resultant

delivery of results is an important first step in managing the risk from these technologies. The value chain analysis enables setting technology development targets shown in the figure above on the right. In order to conduct value chain analysis, process modeling tools need to be developed in a modular fashion so that different processes can be combined in various ways to determine outputs. The value chain analysis can also be used for comparing different options and their energy, environmental, and economic consequences. Value chain analyses require significant process data that is often not available due to proprietary considerations or the early stage development of processes.

Formation of Networks: Improved Communication and Influence

Many CO_2 utilization networks have now been formed to provide venues for exchange of knowledge and capabilities. Sites, such as CO_2 Chem Network (http://co2chem.co.uk), provide a forum for technical information exchange. Focused conferences and workshops are also taking place to highlight the developments in this area and develop roadmaps for the future.

Ways to Bring Technologies to Market

Many different funding models are being tried to bring forward CO_2 utilization technologies. Venture capital has been provided in a number of cases. It has been seen that the timeline for process development is typically much too long for VC firms, who like to see a substantial return on investment within 2–3 years. Furthermore, the risk in green technologies is high as many of these technologies depend on government subsidies. When these technologies hit the valley of death, VC firms often seem to lose interest.

Governments can provide long-term support to high-risk technologies and can potentially carry these technologies through the valley of death. But, the funding is often subject to the vagaries of politics, especially in the Western countries.

Open innovation model is championed in some areas. However, proprietary technologies are barriers to open innovation because the intellectual property behind many component technologies is often unknown and the effort required to cross-license various technologies become a significant barrier. A patent pooling model, wherein all the participants in a technology with complementary patents can pool technologies that are required to work together, has been successful in consumer electronics area.

Another mechanism for bringing technologies to market is through a prize. Historically, prizes have helped spur innovation. For example, method to determine longitude was discovered through a prize scheme as were soda manufacturing and transatlantic flight. More recently private space flight was realized through the X Prize Foundation.

Oxy-Fuel Firing Technology for Power Generation

Edward John (Ben) Anthony

Contents

Abstract

In order to generate pure streams of CO_2 suitable for sequestration/storage, various routes are possible, involving either precombustion strategies such as the use of gasification technology combined with shift reactors to produce H_2 or alternatively post-combustion strategies such as CO_2 scrubbing with, for example, amine-based carriers. One of the more direct approaches is to carry out the

combustion in pure or nearly pure oxygen-oxy-fuel combustion to produce primarily CO_2 and H_2O in the combustion gases, resulting in almost complete CO_2 capture. Until recently, the primary avenue for deploying this technology was with conventional pulverized fuel-fired boilers, and there is already one large demonstration plant operating in Europe with more being planned in the future. However, more recently oxy-fired fluidized bed combustion (FBC) has also become increasingly important as a potential technology, offering as it does fuel flexibility and the possibility of firing local or indigenous fuels, including biomass in a CO_2-neutral manner. Both oxy-fuel combustion technologies have been examined here, considering factors such as their economics and potential for improvement, as well as challenges to the technology, including the need to generate CO_2 streams of suitable purity for pipeline transport to available sequestration sites. Finally, the emission issues for both classes of the technology are discussed.

Introduction

The idea that anthropogenic CO_2 could cause significant global warming was first presented over 114 years ago by Svante Arrhenius (1896); by 1907, the use of fossil fuels as a potent cause of CO_2 emissions had also been clearly spelled out: "The enormous combustion of coal by industrial establishments suffices to increase the percentage of carbon dioxide in the air to an appreciable amount" (Arrhenius 1907), albeit that Arrhenius saw global warming as a potential benefit. Unfortunately, it has taken a further 60 or more years for the potential for damage due to these phenomena to be universally recognized (Houghton 2004; Edwards 2010). Against this background, world populations have been burgeoning, and the use of fossil fuels to meet mankind's energy needs has increased and shows no signs of stopping in the near future. To further complicate the picture, many countries have aging thermal power plants, most of which will have to be replaced in the next couple of decades.

At this point the major hope for continuing to use fossil fuels for widespread power generation in an environmentally benign manner lies in the technology known as carbon capture and sequestration (CCS), as renewable and nuclear technologies would not be able to quickly fill the gap if fossil fuels were simply abandoned. In practice, this means that the norm may well be to build thermal power plants to incorporate back-end technologies for CO_2 capture following a carbon-capture-ready philosophy (Irons et al. 2007). Thus, if "new" technologies are to be introduced on a wide scale, they had best either be already commercialized, such as gasification, or in a near-market-ready state. Fortunately, for oxy-fuel combustion technology, in which the fuel is converted in a stream of nearly pure oxygen (90–95 % plus) using pulverized fuel (PF) or pulverized coal (PC), research is now well underway with various larger pilot-scale demonstrations either completed or under construction, as will be seen later in this chapter. The oxy-fuel technology, in its currently typical configuration, is presented in a

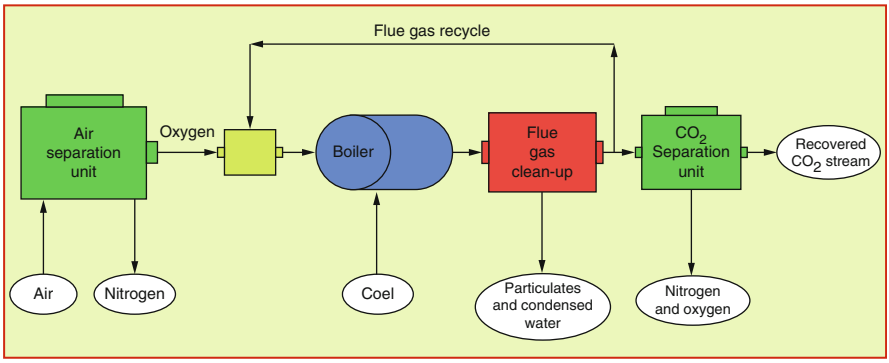

Fig. 1 Schematic of generic oxy-fired boiler configuration

schematic in Fig. 1. As an alternative there is also the possibility of retrofitting existing boilers, and here too oxy-fuel technology can potentially meet this challenge in an economically attractive fashion when compared with other CO_2-neutral options (Farley 2006). Finally, it should also be added that there are side benefits of oxy-fuel combustion, the most obvious being that thermal NO_x levels are expected to be significantly reduced, since N_2 in air is largely absent from the oxidant.

This chapter focuses on oxy-fuel PF and circulating fluidized bed (CFB), and it will not discuss oxy-fuel technology in which water is used instead of CO_2 to moderate flame temperatures, as any such technology is much further from commercialization than oxy-fuel technology with flue gas recycle (FGR) and/or may pose excessive technical challenges at the present time (Zheng et al. 2009). Nor will this chapter consider hybrid systems combining, for instance, amine scrubbing and oxy-fuel, although they have been proposed (Doukelis et al. 2008), for the same reason, namely, that such concepts are probably significantly further removed from commercialization than "conventional" oxy-fuel technology.

Oxy-Fuel Pulverized Fuel Technology

Oxy-fuel work in PF systems traces its origins to pioneering research carried out by Argonne National Laboratory in the 1980s (Weller et al. 1985). Subsequently, in the 1990s, significant oxy-fuel research and development (R&D) work was initiated elsewhere, with a number of small pilot plant programs, including CanmetENERGY (Canada), Air Liquide (USA), and the International Flame Research Foundation (IFRF) R&D program in Ijmuiden (The Netherlands) looking initially at natural gas firing (Buhre et al. 2005). In addition to the early small-scale pilot plant work, there were various economic evaluations of the technology versus back-end scrubbing, primarily for natural gas-fired systems, and there are now at least three major reviews in the open literature available to describe such developments (Buhre et al. 2005;

Toftegaard et al. 2010; Davidson and Stanley 2010). The economic studies often suggested that oxy-firing was not a preferred technology or, if so, only slightly better, with efficiencies in the mid-40 % range and costs somewhat higher than back-end capture of CO_2 for natural gas, and there has been vigorous debate about the results of such evaluations. The paper of Kvamsdal et al. (2007) is typical of such studies, looking at nine potential concepts and ranking oxy-firing of natural gas as only of moderate performance, while noting the significant energy losses associated with the cryogenic separation of air (6.6 % in that study with a further loss of 2.4 % for compression, when expressed in percent of the net plant efficiency, based on the fuel's lower heating value).

More recent studies also confirm efficiency losses of 8–10 % (on the same basis) for both natural gas- and coal-fired systems (Liszka and Ziębik 2010). Studies, which tend to focus more on coal, seem to show a fairly similar picture in terms of overall economics, that is, that oxy-fuel PC looks comparable to PC technology with back-end CO_2 capture. Thus, Bouillon et al. (2009) came to the conclusion that the penalties for both post-combustion and oxy-fuel combustion-integrated processes were around 44 €/t CO_2. In a later study, Hadjipaschalis et al. (2009) carried out an analysis for a 500 MW steam plant, with assumed efficiency of 33.5 %, a generation capacity factor of 85 %, and 90 % CO_2 capture rate. The results of their study indicate that the oxy-fuel combustion plant represents a competitive technology, which currently seems to be the most economical having the lowest electricity costs and lower CO_2 avoidance costs. Similarly, a major Canadian study done for the Canadian Clean Power Coalition (CCPC) in 2007 (Xu et al. 2007) came to the following conclusions:

- The oxy-fuel combustion technology was found to have technical and environmental benefits comparable to post-combustion capture, and it was the most economic option in one of the cases studied, which was based on a greenfield site in Alberta utilizing low-S coal, where flue gas desulfurization (FGD) was not required for oxy-fuel but was for post-combustion capture. The assumption in this case was that most SO_2 emissions would be captured in the CO_2 compression phase. In the two other sites studied (Saskatchewan and Nova Scotia), the amine-based post-combustion options were found to be more economic, but the difference was marginal.
- It was also found that parasitic energy losses directly related to CO_2 capture were the largest single cost item, closely followed in most cases by capital charges. These costs were similar for both oxy-fuel and amine-based capture if FGDs were present in both cases. The capital and operating costs of the air separation unit (ASU) represent a major problem for oxy-fuel economics, and improvements in this area will have major benefits.
- Operating and maintenance (O&M) costs were found to make up a relatively minor portion of the total charges.
- The CCPC study also found that oxy-fuel combustion was expected to capture slightly more CO_2 than post-combustion technology, which tended to help its cost-per-tonne-captured figures.

- Retrofits based on oxy-fuel were found to be significantly more expensive compared to back-end retrofits that left the existing boiler plant intact.

Finally, Farley (2006) also quotes costs which suggest that post-combustion capture and oxy-fuel technologies are comparable, but in apparent contrast to the 2007 CCPC (Xu et al. 2007) study, suggesting that a significant advantage lies in the fact that oxy-fuel technology can be retrofitted to existing plants (Farley 2006).

From the above citations, it is clear that the oxy-fuel combustion concept is comparable with post-combustion capture in terms of cost, and it represents a midterm solution with considerable potential for commercialization, as opposed to many of the schemes evaluated where scale-up presented significant uncertainties. It is also clear that very significant economic gains can be made if oxygen could be produced more cheaply.

Buhre et al. (2005) summarized some key conclusions about oxy-firing as follows:

- Typically 31 % oxygen, rather than 21 % for air-fired boilers, must be used to achieve a similar adiabatic flame temperature, and to achieve this level, it requires recycle of about 60 % of the flue gas.
- The much higher CO_2 and H_2O proportions in the flue gases result in increased emissivity, so a retrofitted boiler will have similar radiative heat transfer to an air-fired boiler for an O_2 proportion of 30 %.
- Gas flows will be reduced to about 80 % of those in the air case.
- Emissions of minor species such as SO_2 and NO will be higher in the recycled gases, unless they are removed in the recycle process.

Such conclusions are useful but are dependent on case-specific factors such as how much air leakage there is into the boiler (1 % or less is desired) and details concerning auxiliary systems. The choice of whether flue gas recycle should be wet or dry is also important. Zheng et al. (2009) suggest that, as an approximate guideline, coals with less than 1 % sulfur content are suitable for wet flue gas recycle, while coals with higher sulfur levels are not, because of concerns over corrosion associated with high SO_x levels. Zhou and Moyeda (2010) suggest that typical wet flue gas recycle should be in the range of 70–75 %. Wet flue gas recycle lowers the adiabatic flame temperature of the gas, while dry recycle allows higher flame temperatures but reduces the overall gas velocity. Table 1 gives an expected comparison for air-fired and oxy-fuel combustion with wet flue gas recycle taken from Zhou and Moyeda (2010).

These authors also note that the efficiency of such a plant is less than that of a conventional plant without carbon capture but greater than that of an air-fired plant fitted with an amine system, and this is a conclusion on which there is considerable debate, as noted above.

Finally, a last comment to be made on such plants is that since the oxygen used has to be produced cryogenically, and hence is expensive, excess oxygen levels should ideally be kept as low as possible.

Table 1 Comparison of burner gas compositions (wt%) (From Zhou and Moyeda 2010)

Composition	Conventional air fired	Oxy-fuel with wet FGR
O_2	3.2	3.1
CO_2	14.7	69
H_2O	5.85	27.5
NO_x (ppm)	154	82

Emissions: SO_x, NO_x, and Other Micro-pollutants

As PC firing is the ranking coal combustion technology, dating back to at least the 1940s when early attempts were made to use pulverized coal in fire-tube boilers, it is not surprising that an enormous amount is known about the emissions from such systems (Gunn and Horton 1989). The obvious differences between air firing and oxy-firing (with FGR) using pulverized coal are the high levels of CO_2 (of the order of five times or more) and water (of the order of two to three times more) and the somewhat smaller flue gas volumes that will tend to concentrate the emissions of micro-pollutants in the flue gas stream. Other differences would include the effect of somewhat higher oxygen levels in the burner of around 30 %, which together with the lower flue gas levels allows a similar exit oxygen content to the air-fired case (Table 1), and possible effects on fuel devolatilization and char combustion due to the differences in the gaseous environment.

Also, absolute emissions might well vary if the flame length and its temperature and/or the gas concentrations change, and it has been shown, for instance, that at high flue gas recycle ratios, flame temperatures may fall by as much as 100 °C or more (Smart et al. 2010). This affects the combustion process itself and reduces flame stability, although such effects are lower for high-volatile coals, in line with the results of earlier work (Buhre et al. 2005). Much of the early work was done in thermogravimetric analyzers (TGAs) and other laboratory-scale devices, with low heating rates, which are atypical of pulverized fuel firing. However, there is now more information from systems with realistic heating rates. Thus, for instance, wire mesh tests done with two coals in an oxy-fuel environment (30 % O_2/70 % CO_2) showed evidence of a small rise in ignition temperature of around 20 °C for the coals used in this study (Qiao et al. 2010).

Experiments were done in an entrained flow reactor (0.08 m diameter and 2 m length) with a bituminous coal but failed to find any evidence of char–CO_2 gasification reactions (Brix et al. 2010). In addition, unlike earlier studies this one found no significant change in volatile production between air firing and oxy-firing, but char burned faster in air than in oxy-fuel conditions, suggesting that the CO_2 is important in reducing the burning rate when external mass transfer dominates the combustion process, which is also in agreement with other earlier work (Shaddix and Molina 2008).

NO_x Production

The production of nitric oxides can occur in combustion systems by means of three mechanisms:

- Prompt NO_x – where hydrocarbon radicals in the flame front react with the nitrogen in the combustion gases
- Thermal NO_x – where oxygen reacts at temperatures above about 1,000 °C to form NO_x (the so-called Zeldovich mechanism)
- Fuel nitrogen reactions

Prompt NO_x is more important in gaseous hydrocarbon flames, while thermal NO_x would reasonably be expected to be substantially reduced by a factor of about 20 due to the effective removal of nitrogen from the oxidant, but fuel nitrogen mechanisms can still be expected to be important and give rise to significant NO_x production.

In a recent study using a quartz flow reactor, high CO_2 levels were shown to compete for H atoms (the main source of chain branching and hence radical production) and thus reduce the rate of oxidation of HCN (Giménez-López et al. 2010). Similar arguments concerning the change of OH/H radical concentrations in methane oxy-fuel flames have also been advanced from measurements and modeling done by Mendiara and Glarborg (2009). Since HCN is an important intermediate for the production of NO, this implies that the elevated CO_2 levels in oxy-fuel combustion should also decrease NO formation from fuel nitrogen. These results are interesting in that they are in contradiction to an earlier study which stated that the influence of CO_2 on NO_x was negligible (Okazi and Ando 1997). However, both measurements (Tan et al. 2006; Hjärtstam et al. 2009) and modeling (Cao et al. 2010) have shown reduced NO_x levels, even without flue gas recycle, which itself also causes a reduction in NO_x production.

Another difference between the air and oxy-fuel cases is that the CO levels can be higher for oxy-fuel systems, depending on flame temperature and the degree of recycle. However, in measurements of CO profiles when burning lignitic fuels in a small oxy-fuel combustor, Hjärstam et al. (2009) showed that this did not necessarily reflect in emissions of either CO or NO leaving the boiler.

SO_x Production

Sulfur in fossil fuel combustion is released as SO_2 and SO_3, and except in the case of, for example, ashes with very high Ca contents (e.g., the French Gardanne lignite, which has an extremely high natural Ca/S molar ratio in its ash), more than 90 % of the S in the fuel will typically be found as SO_2 in the flue gas (Smoot and Pratt 1979). Flue gas recycle will tend to concentrate micro-pollutants and Fig. 2, in a

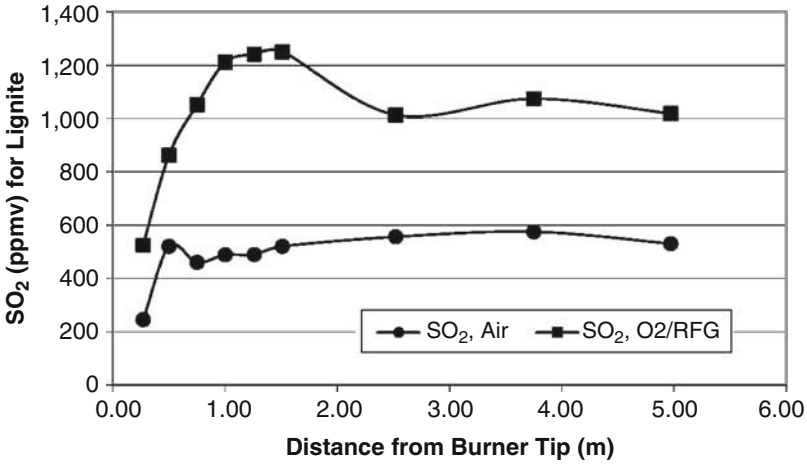

Fig. 2 SO_2 emissions from CanmetENERGY oxy-fired pilot plant (oxy-fuel case at 35 % O_2)

CanmetENERGY small-scale pilot plant study at high temperatures appropriate to suspension firing shows SO_2 levels for oxy-fuel with recycled flue gas versus the air-firing case. SO_2 is the dominant sulfur form, as even at lower temperatures oxidation of SO_2 to SO_3 tends to be very slow and dependent on the presence of catalytic reactions. However, higher SO_2 levels mean that fly ash components will tend to react more readily if they can sulfate (Sturgeon et al. 2009).

In early studies, both Hu et al. (2000), who carried out experiments in a small flow reactor burning coal (1.1 % sulfur), and Croiset and Thambimuthu (2001), operating the CanmetENERGY oxy-fuel combustor with an Eastern US bituminous coal (1 % sulfur), reported a decrease in sulfur release for oxy-fuel combustion, ranging from 75 % without flue gas recycle to 65 % with recycle. Hu et al. (2000) suggested that the reduced SO_2 levels they experienced were due to ash reactions, the possible formation of other sulfur compounds (COS and/or H_2S), or retention of sulfur in the char. The reaction of ash with sulfur in pulverized coal-fired systems is well established, especially for lignites and Western US coals (Smoot and Pratt 1979), although the ash content of the coal used in their experiments was only 2 %. The possibility that some of the sulfur is retained in the char is also reasonable for a small flow reactor, but suggestions of other sulfur compounds do not seem likely if oxidizing conditions prevail. Croiset and Thambimuthu (2001) ruled out capture in the ash and significant losses of SO_2 in condensate from the flue gas recycle for their experiments and instead postulated the production of elevated SO_3 levels.

Subsequent experiments have not, however, suggested such dramatic reductions in SO_2 releases, at least where Ca levels in the ash are not high, but elevated levels of SO_3 are indeed found. Thus, Tan et al. (2006) found that SO_3 concentrations could be up to three or four times higher for oxy-fuel with wet flue gas recycling than for the corresponding air-fired situation, with levels consistently around 5 %, whereas normal levels would vary in the range of 1–5 %, depending on the sulfur content of

Table 2 Average measured SO_2/SO_3 concentrations in ppm (From Maier et al. 2008)

Firing mode	SO_2 (ppm)	SO_3 (ppm)
Air	733	8
Oxy-fuel	1,758	85

the fuel, air/fuel mixing patterns, and excess air in the furnace. This picture for SO_3 levels has also been confirmed in later experiments. Thus, Maier et al. (2008) found an elevated level of SO_3 and indicated that the average SO_3 concentrations for their experiments were in the range of 36–121 ppm, for an average SO_2 concentration of 1,791 ppm, and flue gas moisture of 28.9 vol.%. Table 2 gives average SO_2 and SO_3 levels for their experiments (note that SO_2 levels are also elevated, as expected).

However, it is clear that an increase in SO_3 up to about 5 % may occur, which is sufficient to cause the acid dew point to be raised, leading to a real potential for enhanced corrosion, if flue gases go below that temperature. Based on their data, Maier et al. (2008) predict an increase in the acid dew point of around 30 °C for oxy-fuel conditions, from 138 °C for air to 169 °C for oxy-fuel. Ahn et al. (2010) have also noted that SO_3 levels are likely to be elevated, based on their experiments with a small pilot-scale combustor at the University of Utah, and that on average the SO_3 levels under oxy-fuel-fired conditions are about four times higher than in the air-fired situation. Both of these studies are in agreement with the work of Fleig et al. (2009), who explored the SO_3 levels to be produced for the oxy-fuel combustion of lignite for wet recycling and indicated that they should be about four times higher than in the air-fired case, with a resulting rise in the acid dew point of 20–30 °C.

As a result of these higher SO_2 and SO_3 levels, there are concerns about corrosion and deposition on boiler walls and surfaces; however, research is still in its early days. Nonetheless, the large boiler companies have initiated research programs to generate information on these potential problems, and it can be expected that significant results will be produced in the next several years (Kung and Tanzosh 2008; Bordenet et al. 2008). It should also be added that on the positive front, air pollution control (APC) devices may be reduced in size, leading to some cost reductions, and this is especially true for FGD if wet flue gas recycle is used. Concerning the use of FGD equipment, while there were questions initially on the effect of high CO_2 concentrations on limestone effectiveness in FGD, Vattenfall's experience showed that SO_2 removal rate and limestone usage are the same for air and oxy-fuel cases (Strőmberg et al. 2009). For a very detailed analysis of the issues relating to sulfation in oxy-fired PF systems, the interested reader is referred to a very recent review article by Stranger and Wall (2011).

Major Pilot Plant Developments

There are now a large number of major pilot plant and pre-commercial demonstration projects worldwide, and these include:

- Germany – 30 MW_{th} demonstration unit (Strőmberg et al. 2009, 2010; Vattenfall 2010)
- USA – Jupiter Oxygen Corporation, 15 MW_{th} burner test facility, National Energy Technology Laboratory (NETL) (Ochs et al. 2009; NETL 2010); Demonstration of a 30 MW_{th} oxy-fired unit (the Clean Environmental Development Facility in Alliance, Ohio), Babcock & Wilcox Power Generation Group, Inc. (B&W PGG) and Air Liquide (McDonald et al. 2008; Air Liquide Press 2008)
- United Kingdom – 40 MW_{th} Doosan Babcock Demonstration unit (Hesselmann et al. 2009)
- France – 30 MW_{th} Lacq Project, Total, in partnership with Air Liquide (Total 2010)
- Australia – Callide Oxy-fuel Project (30 MW unit) and various other projects (Cook 2009)

Another possibility also exists that of retrofitting older conventional power plants to operate in an oxy-fuel mode (Tigges et al. 2009). Moreover there is considerable research underway to develop cheaper methods of oxygen production, such as membrane technologies, which have the potential to make oxy-fuel technologies even more attractive, either by themselves (especially for smaller-scale applications) (Carbo et al. 2009) or possibly by first carrying out a first-stage air separation, prior to the cryogenic separation, thus reducing the size of the unit and the energy used in making oxygen at 90 % + purity (Burdyny and Struchtrup 2010). However, for now at least it is also clear that the classic approach of cryogenic air separation can, in principle, meet the needs of a new generation of oxy-fuel power plants (Allam et al. 2005), and the use of this technology is generally assumed in this chapter.

Other Issues for Oxy-Fuel Firing in Pulverized Fuel Combustion Systems

Biomass Firing in Oxy-Fuel Combustion Systems

The idea of using biomass in pulverized coal blends is well established, and there are efforts in most countries to supplement the coal fuel supply with biomass (a carbon-neutral fuel), as an approach to the reduction of carbon emissions. In Canada, for instance, trials have been undertaken with up to 100 % biomass firing in the 227 MW_e Atikokan Generating Station in Ontario (Marshall et al. 2010). Unfortunately, there are a number of issues, the first, and probably most important, being that there is usually insufficient biomass in a given area to supply a commercial-scale power plant. Second, the properties of biomass differ from coal, and so torrefaction or pelletization, before the fuel is then pulverized, is effectively essential if such fuels are to be used directly, and modifications of the fuel feed system are necessary. On this point, it is instructive that the Atikokan unit had a dust explosion in its coal feeding system during preparations for further biomass trials (Marshall et al. 2010).

One ingenious suggestion is that biomass, which typically has high moisture, might be co-fired with coal, thus providing an alternative method to flue gas recycle; however, as noted above the problem with such an approach would be the need to obtain sufficient biomass for such a concept to be applied (Haykir-Acma et al. 2010). Another issue for biomass is fouling, and depending on the nature of the coal ash (i.e., does it contain sufficient Ca in the form of CaO that it can carbonate), it is evident that the fouling and deposit behavior of an ash might be different in an oxy-fuel environment compared to that in an air-fired one. Fryda et al. (2010) carried out some experiments in a drop tube using biomass blends and a Russian and South African coal. They report some small changes in K, Na, and Ca in the deposits depending on operating conditions and speculate that the "lower char temperature" in oxy-fuel combustion may be producing such effects. At the present time, it appears that general conclusions are probably premature, but it seems likely the greatest barrier to using biomass in oxy-fuel combustion is probably simply insufficient supply, although other issues such as the inhomogeneity of biomass, potentially high alkali metal content for some types of biomass, and the cost of good quality biomass, especially if the biomass must be pelletized before pulverization, are also potential concerns.

Oxy-Fuel CFBC Combustion

Oxy-fuel combustion has been thoroughly studied for pulverized coal combustion, but to date there has been relatively little attention paid to oxy-fuel circulating fluidized bed combustion (CFBC), although the concept was examined over 30 years ago for bubbling FBC (Yaverbaum 1977). More recently the boiler companies, Alstom and Foster Wheeler, have explored the oxy-fuel CFBC concept using pilot-scale tests (Eriksson et al. 2007; Stamatelopoulos and Darling 2008). Alstom's work included tests in a unit of up to 3 MW_{th} in size but did not involve recycle of flue gas (Liljedahl et al. 2006). Foster Wheeler's work (Eriksson et al. 2007) also involved pilot-scale testing, using a small (30–100 kW) CFBC owned and operated by VTT (Technical Research Centre of Finland), and this work along with CanmetENERGY's work with its own 100 kW CFBC appears to be the first in which units were operated with oxy-fuel combustion using flue gas recycle. Foster Wheeler is currently developing its Flexi-burn™ technology, which would allow a CFBC boiler to operate either in air- or oxy-firing conditions (Eriksson et al. 2009).

The advantages of the CFBC technology are already well known in terms of its ability to burn a wide range of fuels, both individually and co-fired, to achieve relatively low NO_x emissions, because temperatures are too low for significant thermal NO_x production, and to accomplish SO_2 removal by limestone (Grace et al. 1997). Another advantage of CFBC technology, in the context of oxy-fuel firing, is the fact that hot solids are kept in the primary reaction loop by means of a hot cyclone. This solid circulation potentially provides an effective means, in conjunction with the recycle of flue gas, to control combustion and effectively extract heat during the combustion process, thus allowing either a significant

reduction of the amount of recycled flue gas or, alternatively, permitting the use of a much higher oxygen concentration in the combustor. These factors allow the economics of oxy-fired CFBC to be significantly improved over PC or stoker firing by reducing the size of the CFBC boiler island by as much as 50 % (Liljedahl et al. 2006). In considering the scale-up of CFBC units above 300 MW_e, both Foster Wheeler and Alstom are now offering much larger units, and Foster Wheeler has in operation a 460 MW_e supercritical CFBC boiler (Stamatelopoulos and Darling 2008; Hotta et al. 2008).

Advantages more difficult to quantify for the technology relate to: the possibility of co-firing biomass, so that in conjunction with CCS, the overall combustion process may potentially result in a net reduction of anthropogenic CO_2 and the potential for this technology to be used with more marginal fuels, as premium fossil fuel supplies wane. The co-firing option offers a potentially interesting advantage of CFBC technology, since it is well established that CFBC can burn biomass and fossil fuels at any given ratio ranging from 0 % to 100 %, thus offering the possibility of using local and seasonally available biomass fuels in a CO_2 "negative" manner.

The ultimate availability of premium coal for a period of hundreds of years has also recently been called into doubt with suggestions that coal production may peak well before the end of this century. Thus, Mohr and Evans (2009), for example, have developed a model which suggests that coal production will peak in 2034 on a mass basis and 2026 on an energy basis. A good general discussion of these ideas can also be found in Wikipedia (2010). In the event of such solid fuel shortages, fluidized bed combustion is ideally suited to exploit the many marginal coals and hydrocarbon-based waste streams available worldwide.

Currently R&D on oxy-fired CFBC technology is being undertaken in numerous countries, including Canada, Finland, Poland, China, and the USA among others. However, to date most test work has been done at small scale (in the $<$100 kW range) and/or using bottled gases to supply a suitable combustion gas, instead of recycling flue gas to achieve the necessary gas velocity and solid circulation rate in terms of heat transfer requirements. CFBC systems can potentially accommodate recycling of less flue gases than a PC boiler, despite the inherently low temperature of the combustion process, required to avoid ash softening or melting and to achieve better in-bed sulfur capture. This situation arises because the hot solids that are recycled in a CFBC can also be used to produce steam, thus cooling the fluidized bed, and hence less flue gases need to be recycled than for a suspension-fired boiler. However, the minimum amount of flue gas recycling is governed by the need to maintain sufficient fluid velocity in the fluidized bed while ensuring that enough water/steam-cooled surface area is available to provide adequate internal and external solid heat transfer.

Probably the most important developments in the area of oxy-fuel FBC are the construction and operation of an increasing number of pilot-scale test facilities. This section will concentrate on the CanmetENERGY work, because it appears to be the most detailed and well reported of such studies that exist. CanmetENERGY has two pilot plants which are capable of being operated in the oxy-fuel mode, with full flue gas recycle: a nominal 75 kW unit and a larger 0.8 MW_{th} unit. However, it is the

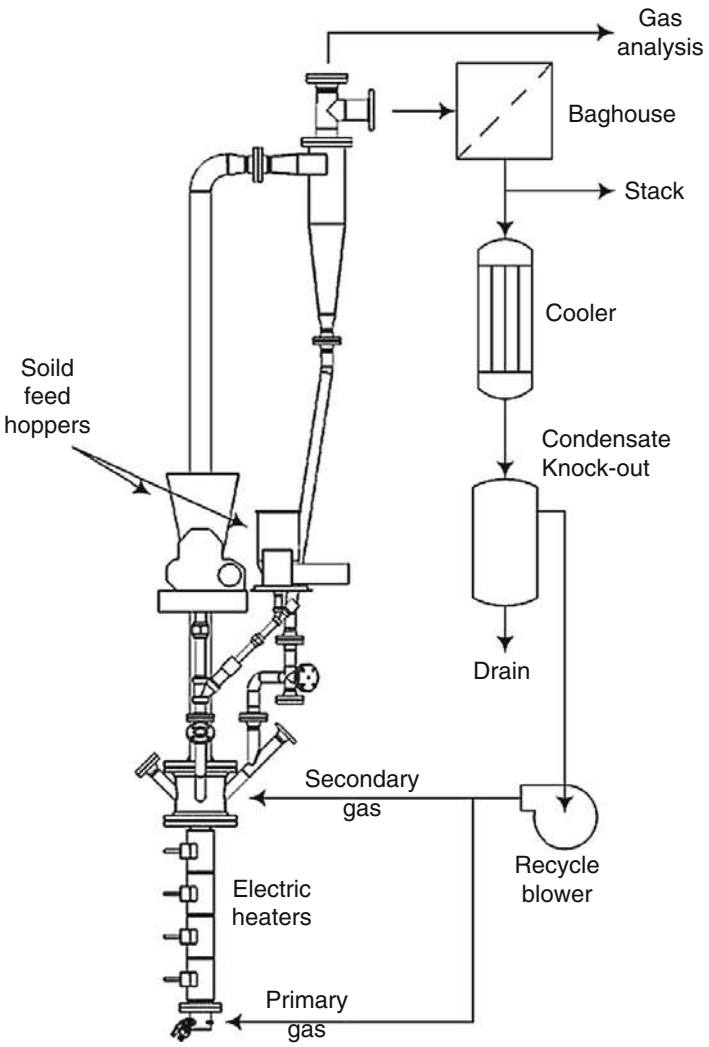

Fig. 3 CanmetENERGY's 5.5 m high, 100 mm diameter minibed oxy-fired CFBC

smaller unit which will be discussed in detail in this section. This unit (Fig. 3) was first described in 2006, for the tests carried out by Hughes et al. (2006). However, that initial work was marred by the fact that the unit still had significant air leaks, and, as a consequence, high CO_2 levels were not produced in the off-gases, which is a typical problem for this type of unit. Completely successful results from the unit were first presented in 2007 (Jia et al. 2007).

CanmetENERGY's mini-CFBC consists of a 0.1 m inside diameter stainless steel riser (Fig. 3) covered with 100 mm of insulation. Independent feed augers can supply multiple fuel types and a sorbent, with solid fuel feed rates of up to 15 kg/h. Oxygen,

CO_2, and recycled flue gas flow rates are controlled by a combination of mass flow controllers and rotameters. Bed temperature is in the range of 750–950 °C, which is the typical range for fluidized bed combustion. Superficial gas velocity can be varied up to 8 m/s, although the unit is more normally operated at around 4 m/s.

Fuels and limestones primarily tested to date are given in Tables 3 and 4, respectively.

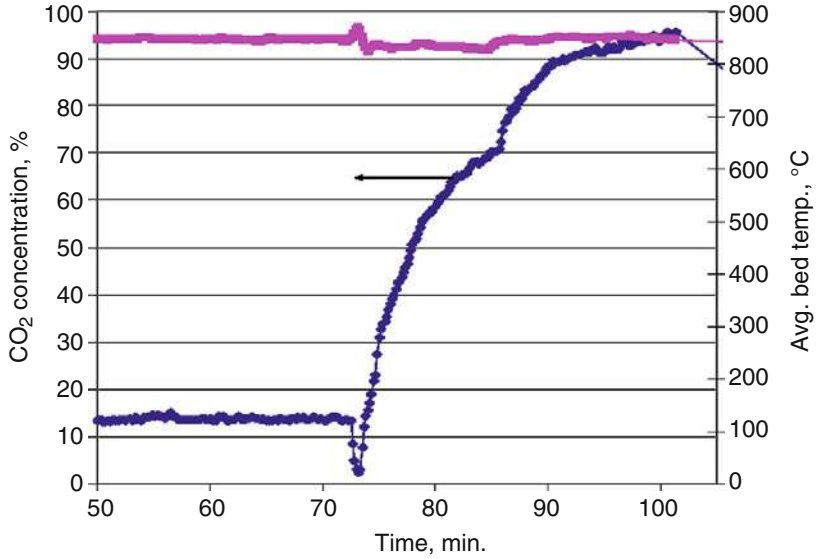

Fig. 4 Transition from air firing to oxy-fuel firing in CanmetENERGY's mini-CFBC during second Highvale coal test

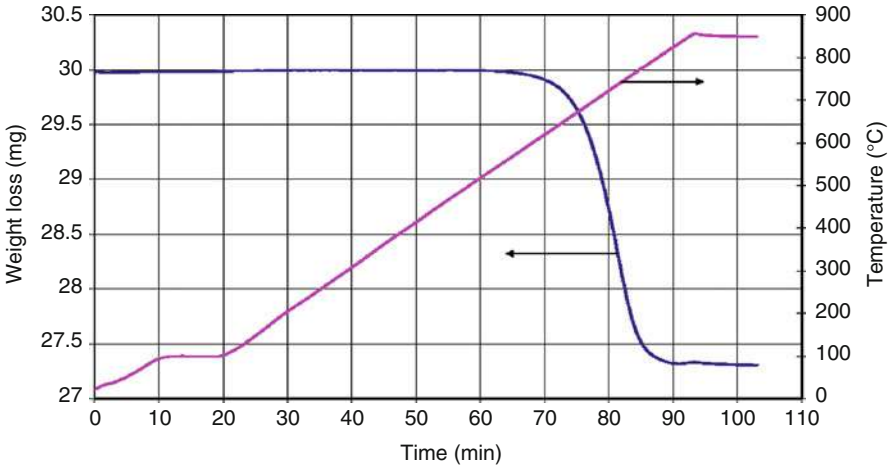

Fig. 5 TGA analysis of bed ash generated in oxy-fuel CFBC combustion with Eastern bituminous coal

Jia et al. (2007, 2010) have reported that it was easy to change from air-fired to oxy-fired mode, at least with the pilot-scale units, and Fig. 4 shows a typical result. Another important, albeit anticipated, result was that $CaCO_3$ was stable at typical bed temperatures (850 °C), as is indicated in Fig. 5, which means that sulfation can be expected to proceed via direct reaction (see section "SO_2 Emissions").

CO Emissions

In the initial work done by Hughes et al. (2006), CO was elevated with levels of up to 0.75 %, and it was speculated that this might be due to elevated CO_2 levels, based on equilibrium considerations. However, more careful work later with much higher CO_2 levels failed to establish such behavior and instead showed that CO levels were extremely sensitive to cyclone temperature (see Fig. 6) (Jia et al. 2007), which is also in good agreement with work by Knöbig et al. (1998).

NO_x Emissions

A series of oxy-fuel combustion trials (Jia et al. 2007, 2010) indicated that fuel nitrogen conversions were always lower or comparable with those in air firing, as indicated by Table 5.

Two tests done with petroleum coke at a nominal 950 °C showed, if anything, a very similar level of fuel nitrogen conversion of 3.3 % and 3.7 % with Havelock and Katowice limestone, respectively, despite the fact that this temperature meant that the limestone must have calcined and, therefore, might be expected to influence fuel nitrogen conversion via catalytic processes, as suggested early on by Lyngfelt and Leckner (1989).

SO_2 Emissions

Sulfur capture is an important issue, because one of the main reasons for using this technology under air-firing conditions is the ability to capture SO_2 in situ with limestone addition. An important difference between oxy-fuel combustion and air

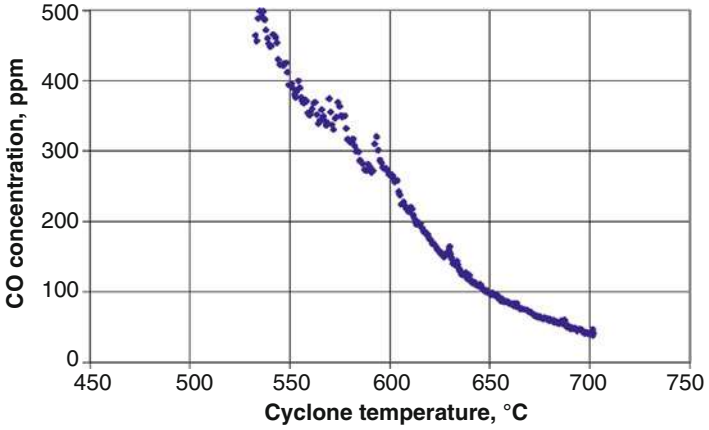

Fig. 6 Effect of cyclone temperature on CO concentration, Highvale coal

	26			43
Katowice	22 [25]	23 [27]	22	29

[a][ ] represents data for air firing

firing is that, at least until a temperature of around 900 °C (depending on the partial pressure of CO_2), sulfation can be expected to occur with $CaCO_3$ (i.e., the limestone will not calcine) (Reaction 1), instead of the indirect mechanism, which is the normal route for atmospheric pressure FBC systems (Reactions 2 and 3).

$$CaCO_3 + SO_2 + 1/2O_2 = CaSO_4 + CO_2 \quad (1)$$

$$CaCO_3 = CaO + CO_2 \quad (2)$$

$$CaO + SO_2 + 1/2O_2 = CaSO_4 \quad (3)$$

Table 6 gives Ca utilizations for various oxy-fuel tests. Unfortunately, these results do not agree with the only comparable set of studies done by VTT, which showed much higher Ca utilizations (more than double) (Eriksson et al. 2007; Hotta et al. 2008), and instead, all tests done to date at CanmetENERGY have continued to show these rather low utilizations for limestone at typical Ca/S molar ratios (2–3:1) for sulfur capture. The exception here is with petroleum coke at higher temperatures, where indirect sulfation would prevail, and the sulfur capture was somewhat better, if not exceptional; a typical result can be seen in Fig. 7. It is interesting to note that, in small-scale tests (in a 40 mm diameter, electrically heated fluidized bed reactor) directed at studying attrition under oxy-fired conditions, Scala and Salatino (2010) have also found a much lower conversion rate than would be expected in air firing.

To understand these results, there is substantial literature on direct sulfation conditions for pressurized fluidized bed (PFB) combustion, where sulfation normally occurs directly with $CaCO_3$. However, even here it is clear that the mechanisms for direct sulfation are still not completely understood (Hu et al. 2006).

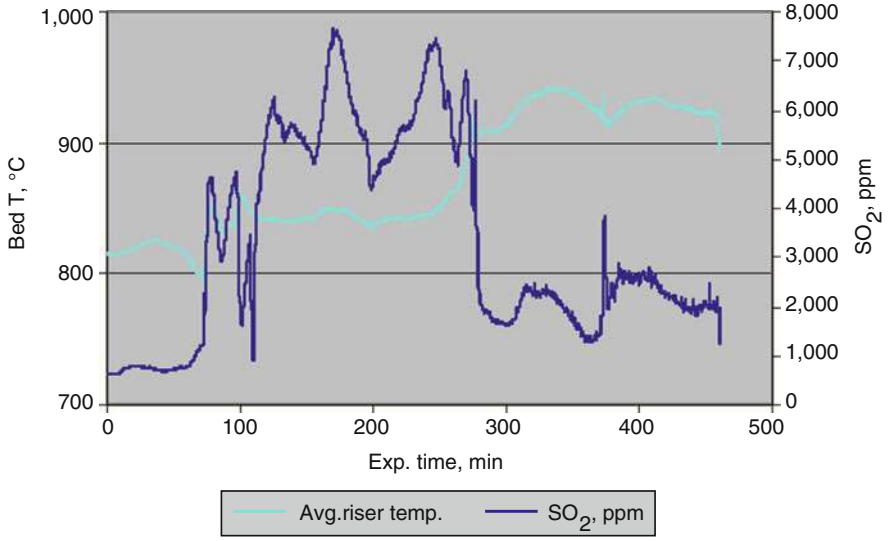

Fig. 7 Profiles of SO_2 concentration and average bed temperature for petroleum coke

Very early work by Snow et al. (1988) and Hajaligol et al. (1988) suggested that direct sulfation might be more effective than indirect sulfation, and an explanation was advanced that counter-diffusion of CO_2 allowed improved sorbent performance. Similar results were produced much later by Liu et al. (2000), who studied limestone sulfation using two limestones at atmospheric pressure with different concentrations of CO_2 in the sulfation gases in a fixed bed reactor. Interesting findings from that study are that indirect sulfation is faster at low degrees of Ca conversion (<0.3), but thereafter direct sulfation becomes faster, and that sintering was much reduced in direct sulfation, so that at higher conversions direct sulfation was faster than indirect sulfation. Very similar arguments have been put forward recently by Chen et al. (2009), who again note the earlier literature concerning almost complete conversion of $CaCO_3$ and mention the back-diffusion argument by CO_2. Like Liu and his coworkers (2000), they found that direct sulfation becomes faster at fractional conversions of 0.4, for limestone samples sulfated in a TGA. In this context, it is worth noting that while Hu and his colleagues agree with the observation that the sulfate layer is porous, they argue that this is not due to back diffusion of CO_2, but instead due to the way the product crystal grains form on the calcite surface, and local porosity (Hu et al. 2007). However, to add a note of caution, it is worth remarking that results from pilot-scale and commercial PFBC units tend to show comparable performance to air-fired FBC (Cuenca and Anthony 1995) and not the superior performance reported from fixed beds and TGA tests for which most of the studies have been done to date. This is not altogether surprising, given the various additional factors that must pertain to a real system, such as oxidizing/reducing conditions, particle loss due to attrition, etc.

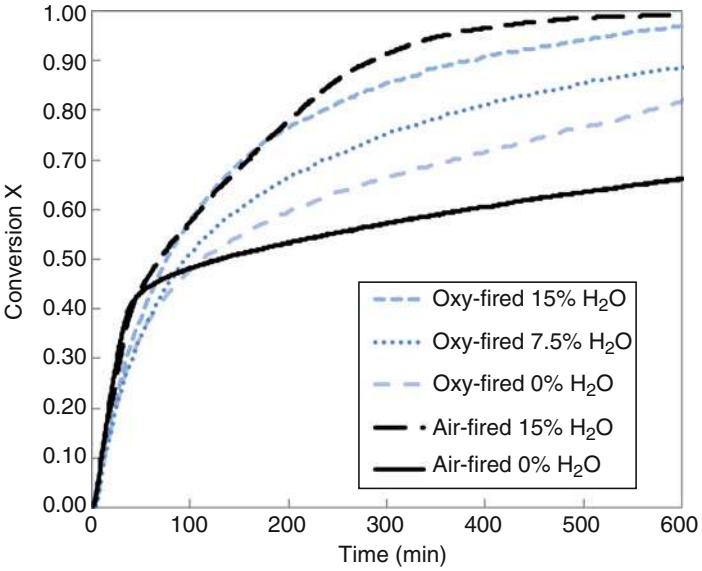

Fig. 8 Sulfation conversion profiles under oxy-fired conditions for varying concentrations of H_2O, with air-fired profiles overlaid

The studies of Hu et al. (2006, 2007, 2008) noted that high partial pressures of both CO_2 and H_2O might cause significant sintering of the $CaCO_3$, thus impairing overall sulfation performance. In a TGA study done in a fixed bed laboratory reactor at temperatures ranging from 500 °C to 700 °C, a concentration of 7.5 % H_2O produced an enhancement of sulfation behavior (Hu et al. 2007). In practice, depending on the fuel used, one would always expect H_2O to be present in a pilot-scale combustor at levels greater than that, and calculations indicate, for the CanmetENERGY work, water concentrations varying from 5.8 to almost 19 %.

In a series of sulfation tests reported by Stewart et al. (2010), Cadomin limestone samples sized 75–115 μm were sulfated in a TGA under varying concentrations of water and CO_2 over the course of 10 h to simulate CFB conditions. Figure 8 shows that the indirect sulfation reaction is greatly enhanced in the presence of water for sulfation beyond the initial regime. In 10 h, 100 % conversion is achieved, and the addition of 15 % H_2O is responsible for an increase in conversion of nearly 45 %. Figure 8 shows the conversion profiles for tests performed under both air-fired (indirect) and oxy-fired (direct) conditions (15 % and 85 % CO_2, respectively). In the tests performed without water, oxy-fuel conditions led to more rapid reaction rates for conversion levels >0.45, a level that is dependent on particle size and is thus comparable to the findings of Liu et al. (2000) and Chen et al. (2009) for direct sulfation.

Stewart et al. (2010) have also argued that it is important to note that the bench-scale studies showing the direct sulfation reaction is more rapid at conversions >0.3 do not include the effects of water in this determination. Figure 8 shows that water

greatly enhances the direct sulfation reaction; however, the effects only become apparent after initial sulfation (~0.40 conversion). Furthermore, it appears that the indirect sulfation reaction is just as rapid as the direct sulfation reaction for conversions >0.3 in the presence of 15 % water, contrary to previous findings for the reaction without water. The effects of water observed here also have an implication on increasing the sulfur capture performance of FBCs firing high-rank/low-moisture fuels such as petroleum coke. It is conceivable that the simple addition of water into the bed at or above concentrations of 15 % would result in enhanced calcium utilization.

Other Issues for Oxy-Fuel Firing in CFBC Systems

If oxy-fuel CFBC is used primarily with high-sulfur fuels, as tends to be the case for the larger air-fired atmospheric boilers, there are several possible issues relating to fouling and to ash disposal or utilization where limestone is used for sulfur capture. In the event that the boiler is operated under conditions such that direct sulfation occurs (Reaction 1), then the ash is expected to show similar characteristics to that produced by PFBC ash (Anthony et al. 1997). In particular, it can be expected to have low free lime content, and this will give it a number of advantages.

Normally, ash from air-fired CFBC boilers using limestone can have up to 20–30 % free lime content. This means that, prior to its disposal, it must first be conditioned (reacted with water), which entails significant water losses due to evaporation. When it is subsequently compacted in the landfill, it can be expected to show significant expansive behavior due to the formation of Ca alumino-sulfate compounds such as ettringite. In practice this means that a landfill that may have the permeability of a clay liner after suitable compaction will after several weeks have the permeability of sandy soil, potentially producing three or more orders of magnitude of high-pH (12–13) leachate with high total dissolved solids (mostly Ca^{2+} and SO_4^{2-} ions), which most regulators will require to be treated before discharge. The high carbon and sulfate contents, along with this expansive behavior, have also meant that such ashes have found very limited use in construction applications, while the heavy metal content from the coal ash-derived fraction means that they have also found relatively little traction for use as soil amendment agents or for agricultural use (Anthony et al. 1995). By contrast, such ashes produced from an oxy-fired CFBC operating with direct sulfation might have much lesser issues with the production of a high pH content (due to its low free lime content). Therefore, they might be expected to show fewer problems in the landfill and might even find more use in construction applications because of the absence of ettringite formation, even though the high carbon and sulfate content would continue to pose a problem. Currently, the only study on oxy-fuel CFBC ash is due to Wu et al. (2008), looking at ashes from the CanmetENERGY pilot plant, and this seems to support the analysis presented above. However, if the combustor is operated at higher temperatures and indirect sulfation prevails, then the ash disposal behavior and potential for use should be very similar to those for the air-fired case.

There is one other issue that deserves to be mentioned for the indirect sulfation case (Reaction 3). CaO, the product of calcination, can react very readily with CO_2 at appropriate conditions, and this is the basis of the so-called Ca looping technology. In early work, Nsakala et al. (2004) identified recarbonation as a potential issue for flue gas fluidized bed heat exchangers (FBHE), which are cooled to below about 650 °C, and if this recarbonation was sufficiently great, it might be enough to defluidize the FBHE. Unfortunately, such a unit cannot easily be fluidized with air, since N_2 is likely to find its way into the combustion stream, thus reducing its purity. The alternatives in this case appear to be to fluidize with steam or replace such units, and Nsakala et al. (2004) proposed the use of a moving bed heat exchanger.

Another possibility that they identified was fouling in the convective pass due to the formation of $CaCO_3$ (Nsakala et al. 2004), which could potentially be a problem. If the sulfation performance in such units is significantly worse, requiring more limestone use than for the air-fired case as suggested by Jia et al. (2007, 2010), then this situation might be exacerbated, as Anthony et al. (1998, 2000, 2001a, b) have shown that both sulfation and carbonation of lime, in situations where there is relatively little fuel-derived ash, are potential problems for CFBC boilers.

Wang et al. (2008) have suggested that such carbonation effects are likely to be enhanced by water over a wide range of temperatures from 800 down to 300 °C, with such effects becoming more pronounced at lower temperatures. This finding has also been recently reiterated in a study by Manovic and Anthony (2010) of the effect of water on carbonation for Ca looping cycles for nine different limestones at water concentrations from 10 % or more, which are typical of most hydrocarbon fuels. The implication of this work is that there is a potential for enhanced fouling due to carbonation in situations where indirect sulfation is employed, which may be problematic for oxy-fuel FBC systems firing fuels with high sulfur levels.

A possible issue is that of gas mixing in fluidized beds. Although solids mixing in FBC systems are excellent, the same is not true of the fluidizing gases, especially for larger boilers (Grace et al. 1997), and this opens the possibility of maldistribution of oxidant and fuel. This could potentially be important if the amount of recycled flue gas was reduced by applying high oxygen concentration to take advantage of the possibility of using hot solids for heat removal in external heat exchangers, thus allowing the construction of physically smaller boilers for a given thermal power capacity. According to Johnsson (2010, Department of Energy and Environment, Chalmers University of Technology, Gothenburg, personal communication) and Seddighi et al. (2010), this could result in local hot spots. This is possible because the dense bottom bed in a CFB furnace of industrial size is typically characterized by large fluctuations in gas flow with high-velocity (oxygen rich) bubbles passing the bed (Svensson et al. 1996a, b). In the case of oxy-fuel firing with high primary oxygen concentration, this may result in high-temperature flame combustion within the bubbles, and this need requires further investigation in order to determine if this is a potential problem which can lead to phenomena such as agglomeration. Another possible problem when applying high oxygen concentrations is that since a majority of the heat most likely has to be extracted from external heat particle coolers, this will require high external solid flux (Gs), which could cause erosion. Commercial

air-fired CFB boilers have rather low Gs, less than 10 kg/m^2 s, whereas an oxy-fuel-fired CFB boiler applying low recycle flue gas flows may require 30–50 kg/m^2 s in order to close the heat balance (Seddighi et al. 2010).

Flue Gas Issues and Conditioning for Oxy-Fuel Technology

Ultimately, the goal of all oxy-fuel combustions, whether pulverized fuel or fluidized bed, is to produce a stream of CO_2 suitable for transportation and sequestration. A few key factors will determine what that stream looks like, while the pressures for piping and storage will be set by practical requirements for those technologies, which are quite independent of boiler conditions or operation. Another factor that will help in the development of the technology is smaller flue gas volumes for oxy-fuel PF technology (perhaps by 20–30 %) and oxy-fuel FBC technology (perhaps by 30–50 % from the air-fired case). Ultimately, it must also be remembered that at this time there is no firm agreement on the purity requirements for the gases to be either transported or stored, whether they are used in enhanced oil recovery (EOR) or simply sequestered (Pipitone and Bolland 2009).

In particular, the oxygen purity used will help determine what the final gases to be treated and sequestered look like, regardless of whether oxy-fuel PF or FBC is employed, even if air leaks can be minimized to a low level. Almost certainly, it is simply too expensive to produce pure or nearly pure O_2, and instead oxygen with 90–95 % purity will be used, and this in turn will mean that the flue gases produced will contain 3 % or 4 % N_2 and about 1 % Ar. In a recent modeling study of oxy-fuel PF technology, the N_2/Ar ratio was predicted to vary from 1 to 3 depending on oxygen purity, and O_2 concentrations were predicted to vary from 3 % to 5 % depending on combustion stoichiometry, with water concentrations from 10 % to 40 % dependent on fuel properties and the partitioning between dry and wet flue gas recycles (Liu and Shao 2010).

The other important factor is of course the micro-pollutants, SO_2, SO_3, NO_x (mainly NO), CO, possibly HCl, and Hg. Their levels will be set by two factors, namely, what the technology itself produces and the perceived cleanup necessary for both transport and ultimate storage. Here it seems that there could be a difference between the two technologies, namely, SO_2 can be scrubbed by means of in situ limestone addition and NO_x levels are likely to be comparable or even lower from oxy-fuel FBC, although in both cases NO_x levels will be lower than in the air-fired cases. If there is a possibility of co-capture of SO_2 along with CO_2 (for co-sequestration), this could offer significant cost reductions and might preclude treatment altogether, providing it did not raise significant corrosion issues for piping, for example. In an early IEA study (Report 2004), it was estimated that the gas to be sequestered might in that case have 2–3 % SO_2 content that might produce savings of the order of $12–25/t CO_2. This point has been again discussed in a more recent paper by Pehnt and Henkel (2009), which makes a comparison between oxy-fuel and precombustion CO_2 capture and notes that co-capture would make oxy-fuel a more attractive choice than precombustion options. Alternatively, White and his

colleagues (2009) have suggested that, with suitable conditions, SO_x and NO_x can be removed with the water if sufficient pressure (around 3 MPa) is employed, and the development of such technologies might also make significant changes to the economics of oxy-fuel technology. However, at this point probably the most important developments are a firmer regulatory framework, in the jurisdictions that might employ CCS, and agreement as to the purity levels required for CCS, rather than likely emissions from oxy-fuel boilers. Pending the outcome of these regulations, low-NO_x burner design is still an important area for the oxy-fuel PF and possibly the CFBC case and/or the use of selective catalytic reduction (SCR) and selective non-catalytic reduction (SNCR). Also, depending on the APC technologies used, Hg capture may be easier in the oxy-fuel case, in part due to lower flue gas volumes as well as chemical factors, and this may lead to cost reductions.

Larger-Scale Tests and Future Industrial Plans

Oxy-Fuel CFBC

Foster Wheeler has recently commissioned 8 months of oxy-fuel combustion trials at CanmetENERGY using the larger 0.8 MW_{th} unit. Figure 9 provides an example of the CO_2 emissions over a 2½-day trial under oxy-fuel conditions, indicating that it is possible to maintain excellent control on CO_2 levels and combustion conditions; these tests are briefly described in a recent paper by Kuivalainen et al. (2010). To date performance has been excellent, which is a very positive sign for the further development of the technology.

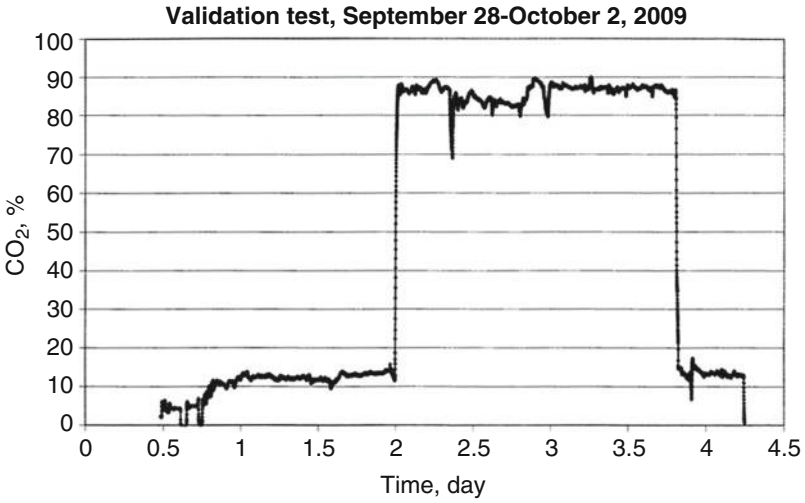

Fig. 9 Tests on oxy-fired combustion using CanmetENERGY's 0.8 MW_{th} CFBC

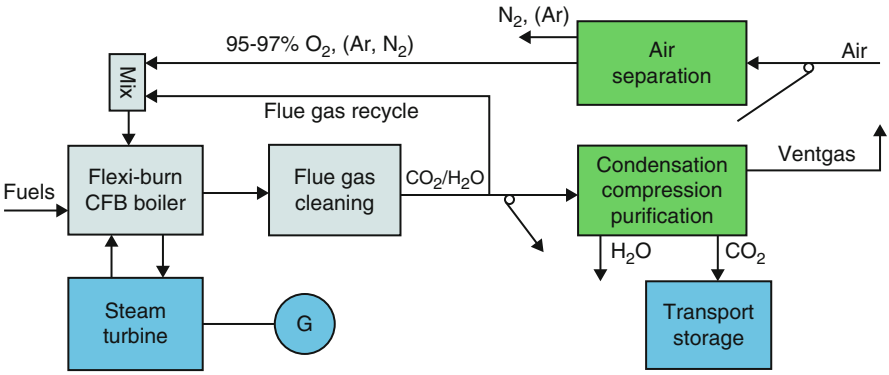

Fig. 10 Schematic of a Flexi-burn™ CFB power plant (With permission of the Foster Wheeler North America Corporation)

Foster Wheeler is also the first company to commercialize supercritical CFBC technology (Lagisza Power Plant, Poland), and with this as the basis, it is now working with the power company ENDESA on the development of a 500 MW_e supercritical Flexi-burn™ CFBC (Fig. 10 provides a general schematic of the technology). The predicted CO_2 capture for the Flexi-burn CFBC technology is 90 % of emissions, and it is anticipated that it could be available by 2020 (Eriksson et al. 2009). Ultimately, Foster Wheeler believes that it could offer such technology at the 600–800 MW_e size with 600 °C steam temperature.

Following the extensive tests at CanmetENERGY in Canada, demonstration tests are scheduled to start in 2010 at the 30 MW_{th} CIUDEN pilot CFB facility, which will provide a full experimental CCS platform for the demonstration and validation of the flexible air/oxy-fuel CFB combustion. Finally, it must be noted that Alstom has also announced its intention of carrying out a 100 MW_e oxy-fuel CFB demonstration, although at the time of writing no further information appears to be available in the open literature (Suraniti et al. 2009). At this point in time it appears that oxy-fired CFBC technology is making major strides to enter the commercial arena, and there seems little doubt that before the end of the decade it will also be available as a commercial and competitive CCS technology along with oxy-fuel PF technology.

Oxy-Fuel Retrofit Plans

The US DOE's FutureGen program, which for the first 7 years of its existence had the objective of constructing, operating, and demonstrating a gasification plant with hydrogen production and carbon capture and sequestration, was recently and somewhat surprisingly refocused as an oxy-fuel retrofit and is now referred to as FutureGen 2 (Flavelle-While 2010). At present, the plan is to retrofit the existing pulverized coal-fired Ameren 200 MW_e Unit 4 in Meredosia, Illinois, with oxy-fuel technology, but if this does not proceed, the project will look for a new site

(http://www.futuregenalliance.org/). If a retrofit is chosen, this will require a new boiler, ASU, and CO_2 purification and gas compression unit. About 90 % CO_2 is to be captured and transported by a new pipeline to a storage site yet to be determined. US DOE has committed US $1 billion to the project partners (State of Illinois, Ameren, Babcock & Wilcox, American Air Liquide, and the FutureGen Alliance). Construction is set to begin in 2012.

Conclusions

Oxy-fuel PF represents an advanced technology suitable for power generation with high levels of CO_2 capture (90 % plus). At this point in time, there has been more than 20 years of research done in this area, and the first large-scale demonstration units (30 MW_{th}) are already operating. There appear to be no major barriers to implementation other than the capital costs, and it seems likely that full-scale demonstration units will be operating by the end of the next decade (and in the case of retrofit installations, much earlier than that). By contrast oxy-fuel FBC technology is far less developed, and the first few pilot-scale units with flue gas recycle are only now being operated. Nonetheless, again there seem to be no major barriers to the technology, and Foster Wheeler, for example, is predicting that there will be full-scale demonstrations operating by 2020.

Acknowledgments The author gratefully acknowledges the assistance and advice of Dr. David Granatstein (Granatstein Technical Services/CanmetENERGY) and Drs. Yewen Tan and Murlidhar Gupta (CanmetENERGY), for a number of valuable discussions during the preparation of this chapter, as well as suggestions for various amendments and improvements, and he would also like to thank Professor Filip Johnsson of Chalmers University, Sweden, for valuable suggestions about potential problems for oxy-fuel CFBC.

Gasification Technology

Lawrence J. Shadle, Ronald W. Breault, and James Bennett

Contents

Abstract

Gasification is an enabling technology for the cleanup of fossil and biomass fuels for energy production. A history of gasifier development is told from the perspective of a technology evolving to meet the ever-changing market needs. The chemistry and physics of coal conversion include pyrolysis, combustion, gasification, mineral transformations, as well as a discussion of the materials

developed to meet the most challenging gasifier applications. Integrated gasification and combined cycle processes are discussed with respect to electrical power production. The distinguishing features for different types of gasifiers are described including fixed-bed, fluidized-bed, entrained-flow, and transport gasifiers. The twelve major gasifiers being marketed today are described. The hydrodynamics and kinetics of each are reviewed along with salient differences in performance, such as gas composition, when using a variety of fuels under different conditions. Critical operational features that are discussed include oxidizing media, air, or oxygen blown; the system pressure; fuel feedstock; and downstream cleanup. Thermal integration is discussed with respect to its impact on the gasifier performance. Gas cleanup is also considered with respect to the removal of potential pollutants and the shifting to environmentally benign transportation and process fuels.

Introduction

History of Gasification

The concept of progress has changed dramatically over the past century. The development of new industry was considered progress regardless of the impact on the environment. From the first time man could see images of the fragile planet earth, he has become increasingly aware that one must learn how to not only tap the earth's natural riches but also how to preserve and serve as guardians of her most common resources – air and water. Coal was one of the critical natural resources leading to the industrialization that allows man the luxury of planning the planet's future. As the world emerged into the Industrial Age, coal provided more than just the fuel for heat and industry. Coal gas also played a key role in the innovative development of tools, materials, and lighting. In 1609, Jean-Baptiste van Helmont first heated and observed the release of gas from coal. He wrote how the coal "did belch forth a wild spirit or breath . . . not susceptible of being confined in vessels, nor capable of being reduced to a visible body." Helmont surely wondered about this spirit and called it "gas" as derived from the Dutch word "geest" for ghost (Massey 1979). The first coal gasifier was used by Fontana in 1780 when he directed a flow of water (steam) over red-hot, or incandescent, coal that was partially burned in air. The process can be described using two reactions. Heat was provided by combustion of coal with air, and then the air was replaced with steam to gasify the hot char and produce synthesis gas, a combustible mixture of carbon monoxide and hydrogen. Fontana called the resulting coal gas "blue water gas," because it produced a pale blue flame when burned in air (Probstein and Hicks 1979).

Coal gasification supplied lighting and heating for industrializing America and Europe beginning in the early 1800s. The first public street lighting with coal-derived gas was in Pall Mall, London, on January 28, 1807. This was where coal-derived fuel gas became commonly known as "town gas." Town gas was a

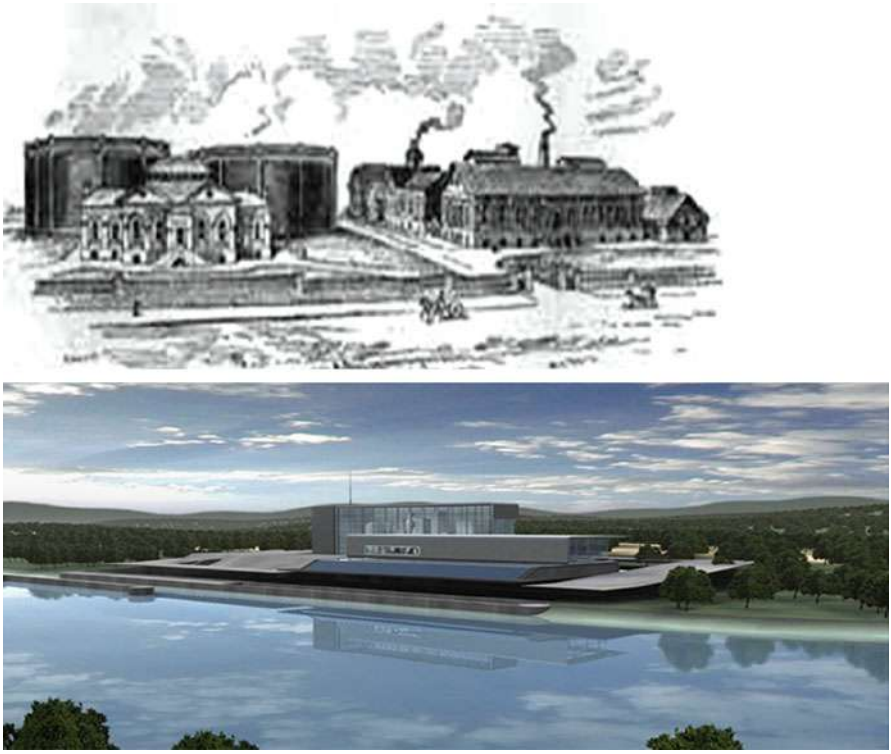

Fig. 1 Artists' view of Baltimore's Bayard Street Station (*on left*) from "Progressive Magazine" of 1889 picturing the plant prior to 1850 and a FutureGen power plant (*on right*) depicting a modern, green-field, zero-emission integrated gasification combined cycle (IGCC) plant

gaseous product from coal, containing nearly 50 % hydrogen, with the remainder made up of methane and carbon dioxide, and 3–6 % carbon monoxide. Not long after that, Baltimore, Maryland, began the first commercial gas lighting of residences, businesses, and streets in 1816. A typical town gas plant for the era is shown in Fig. 1 and contrasted to today's vision of a FutureGen power plant. Both images represent progress to different generations.

Gasification was the leading energy source in many industries in need of process fuel gas since the early 1800s. The light bulb was not discovered by Thomas Edison until late in the nineteenth century, 1879. The first electric power plant was not built until nearly two decades after the American Civil War in 1882. However, as early as 1792, Murdock, a Scotch engineer, used Fontana's process to produce a fuel gas and light his house. James Watt, the inventor of the steam engine, employed Murdock to light one of his foundries with this newly discovered coal gas (Shindman 1945). By 1875, every medium- and large-sized city in America and Europe developed coal gasworks and distribution networks. Gasworks were a large

number of batch gasifiers set up in series so that a continuous stream of fuel could be supplied to residential and industrial users.

The "blue water gas" produced from cyclic gas generators of the type used by Fontana was not directly usable for street or household lighting. While the heating value was high enough to sustain combustion, the blue flame was not bright enough. Early developers learned that the coal gas needed to add "illuminates," i.e., C_{2+} hydrocarbons, to provide a bright luminous yellow flame. However, too many or the wrong types of higher hydrocarbons would produce condensable species like tars and naphthalene, and the gas would eventually foul and plug the pipelines. Noxious and poisonous gases, such as hydrogen sulfide, hydrogen cyanide, and ammonia, were also produced. It was soon found that the undesirable components could be separated and cleaned from the coal gas. Cooling with a direct water spray and filtering of the gases were usually effective in removing the condensables and noxious impurities.

By the mid-1800s, there were two main types of coal gasifier cyclic gas generators similar to those first used by Fontana and gas producers. The cyclic gas generators produced a high-quality fuel gas. This high heat value is accomplished by collecting only the products during the steam blast and venting the products of combustion during the air blast. The carbureted gasifier produced "town gas" which was particularly well suited for lighting. The original cyclic gas generators were ideal industrial fuels used in kilns, boilers, brick ovens, and curing materials particularly where particulate impurities were to be avoided. These batch units were typically loaded by hand, and more importantly, the glowing hot ash or coke also had to be removed by hand – often with nothing more than a shovel.

In addition to the obvious benefits to gas workers of the time, many economic advantages were possible by making this cyclic process continuous. Gas manufacturers learned that they could improve both the rate and efficiency of gas making by introducing steam and air together into the coal. In this way the steam was available to gasify the carbon at the same time that heat was being produced from coal combustion. The result was the ability to substantially increase the overall conversion of coal to gas. This led to the development of the fully continuous gasifier of today with respect to both coal and air/steam. Thus, the modern gas producers were developed.

The development of gas producers did not, however, displace the cyclic gas generators. By 1936, the Federal Trade Commission reported that there were 3,800 machine-fed and still about 1,000 hand-fed gas producers in the USA (Wen and Dutta 1979). By firing air and steam simultaneously, the product gas in these producers now contained the unreactive, or inert, nitrogen that is present in the airstream fed to the gasifier. Air is, in fact, 79 % N_2 and only 21 % O_2 by volume. This added nitrogen is merely a diluent and plays no role in the combustion or gasification reactions. To make matters worse, this diluent must be heated both during the gasification process and later as the fuel is burned. As a result, the producer gas is only about one-half of the heating value compared to "town gas." There are several process ramifications when using this low-quality gas fuel. Economic transportation of producer gas is limited to a short distance.

Upon combustion the flame is longer, cooler, and more luminous. Still many industrial applications could take advantage of the peculiar flame properties of this low heating value fuel. For instance, the relatively low temperatures and long flame are useful to avoid hot spots and nonuniformities in glassmaking.

In contrast to traditional coal combustion, coal gasification processes can be thought to include: pyrolyzers, cokers, cyclic gas generators, and gas producers. All of these processes are heated with substoichiometric air, i.e., insufficient oxygen to completely convert the coal to the final products of combustion. The products of all of these processes are a solid fuel, condensable hydrocarbons and tars, and flammable gases. Both the quality and quantity of these products depend upon how the coal is heated, the gas atmosphere used during the process, and the temperature. The product distribution generated from these coal technologies is presented in Table 1. As is still true today, the coal gas in those early gasifiers was produced in several different reactors depending on the desired products and end use.

Gasification technology development has had its ups and downs. It is worthwhile to note some of the high points. Gasification was the foundation for modern chemical industry. In 1920 Fischer and Tropsch developed a catalyst to convert the hydrogen and carbon monoxide from coal gasifier gas to hydrocarbon liquids. By the mid-1930s, nearly two million liters of gasoline and oil per year were produced in German gasification plants. Individual reactors in the early Fischer-Tropsch plants yielded only about 5000 l of gasoline per day. Literally, 100 such gasifiers were used in these first plants. During the World War II, this coal-derived oil was one source of synthetic fuel for the German war machine. Gasification technology has been a mainstay in the refining industry for the production of synthesis gas from coal, heavy residual oils, and petroleum coke since the 1950s.

After World War II, South Africa required their own independent sources of oil and gas, when international economic sanctions cut off their access to world petroleum supplies in protest to their social policies of apartheid. While South Africa had no domestic oil and gas supplies, it had ample coal reserves. Gasification technology was chosen to supply the needed liquid transportation fuels, and the South African Coal, Oil, and Gas Company (SASOL) employed the Fischer-Tropsch process. The SASOL coal gasification plant has been operated since 1955 producing liquid fuels from coal. The individual reactors in these plants are 100 times larger than the plants used in Germany during the World War II.

SASOL operations were increased tenfold by their expansions in 1977 and 1982. Today SASOL has the largest gasification capacity in the world. By 1982, SASOL had a capacity of nearly 2.5 million gallons of oil and gasoline per day using Lurgi fixed-bed gasifiers. The SASOL plants remain the largest collection of coal gasifiers in the world today and include 80 Lurgi gasifiers with no spares (80 + 0) producing Fischer-Tropsch (FT) liquid transportation fuel as the product (Table 2).

Gasification has been used extensively in the last 50–60 years to convert coal and heavy oil into hydrogen – for the production of ammonia/urea fertilizer. The chemical industry and the refinery industry applied gasification in the 1960s and 1980s, respectively, for feedstock preparation. In 1984, the USA responded to pressure from oil-producing exporting countries to control oil prices by developing

the synthetic natural gas (SNG) plant in North Dakota known as the Great Plains Gasification Plant. Like SASOL, this large-scale demonstration selected fixed-bed technologies developed by Lurgi and Synthane. Coal gasifiers were also built in the late 1970s using entrained- (Texaco and Dow) and fluidized-bed gasifiers (U-GAS®) primarily in oil refineries and chemical plants.

In 1977, the USA passed the Clean Air Act Amendments which identified the concept of benchmarking technologies with respect to the best available control technology (BACT). This drove an interest in integrated gasification combined cycle (IGCC). Several utility-scale IGCC power trains were built in the 1990s as demonstration plants using entrained gasifiers including the Tampa Electric's TECO plant using 2 Texaco (now GE Energy) gasifiers and the Wabash plants using 2 E-Gas (now ConocoPhillips) gasifiers.

Coal-based plants using today's gasification technology are efficient and clean. Gasification has been demonstrated to be superior to conventional utility power systems in response to tightening environmental regulations and as a result of the development of the highly efficient gas turbines or the combined power cycles and the relative ease and level of maturity of the associated gas cleanup technology. However, the technology still lacks the experience base in the power sector and so has had difficulty to raise the large capital investments required. Technologies have been developed for gasifiers to shift the product stream from carbon dioxide to clean-burning hydrogen gas. When coupled with the well-proven acid gas removal technology, carbon dioxide can be removed and concentrated for market applications or to be sequestered. Gasification is posed to be a leading technology capable of addressing the challenges to global climate change.

Basics: Chemistry and Physics

Gasification has been around for more than 200 years, so why the interest in it now? There are many reasons, but the two most significant are the continuing high price of natural gas and highway transportation fuels. Granted that these prices are moderated occasionally. However, the price of gasoline has fluctuated widely over the past decade. The second significant reason is the need for energy independence. In other words, the use of domestic energy sources such as coal is needed not only for electricity production but also for synthetic natural gas (SNG) and liquids for transportation.

Gasification is a technology for converting coal to a gaseous product often called synthesis gas or fuel gas depending on the application. The product gas can literally be converted to almost anything, other than electrons, and can potentially be competitive even there (U.S. Department of Energy 2009). Gasification is often considered the baseline technology and foundation for developing many advanced carbon-based fuels and chemicals. For example, gasification is the key conversion step for converting coal to H_2, synthetic natural gas (SNG), liquid fuels, and the capture of CO_2 for sequestration. Gasification has excellent environmental performance such that some states' public utility commissions have identified integrated

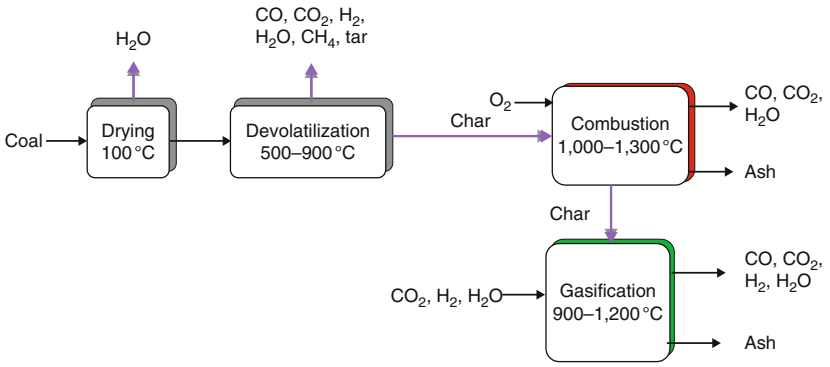

Fig. 2 Simplified schematic of reaction pathways contributing to coal conversion in a gasifier

gasification combined cycle (IGCC) plants for power generation as the best available control technology (BACT). In addition, the uncertainty of carbon management requirements and the potential suitability of IGCC for CO_2 controls make it an ideal choice for power.

So, what is gasification? Strictly speaking, gasification is the reaction of carbon with steam to produce carbon monoxide and hydrogen. Because this reaction is highly endothermic and because coal and biomass are not simply carbon, gasification technology is more complex than that. As compared to combustion, gasification is the conversion of organic matter to carbon monoxide and hydrogen by reaction of substoichiometric mixtures of the solid fuels and oxygen usually in the presence of excess water or steam. It is useful to consider the conversion processes involved in solid fuel gasification individually. Coal undergoes a series of chemical and physical changes as shown in Fig. 2.

As the coal is heated, most of the moisture is driven out when the particle temperature is about 105 °C. Drying is a rapid process and is essentially complete when the temperature exceeds the boiling temperature of water.

Devolatilization and Coal Dependence

A large percentage of coal weight is lost during devolatilization or pyrolysis. Pyrolysis occurs rapidly as the coal heats up above 300 °C and continues up to temperatures required for gasification. If the heating rate is slow, pyrolysis can reach completion at temperatures as low as 450 °C, but for rapid heating processes, pyrolysis continues as the coal heats up to 700–1000 °C required for gasification. Given and others (Given 1984; Given et al. 1986) describe the organic matter in coal as a macromolecular network with varying contents of lower molecular structures and components which are mobile but entrapped within that solid structure. During pyrolysis, mobile components evolve. Labile bonds are broken producing lower molecular weight fragments. Fragments and low molecular weight components vaporize and escape from the coal particle forming light gases and tar. The more reactive or higher molecular weight fragments with low vapor pressure

can remain in the coal under typical devolatilization conditions and reattach to the coal's macromolecular network. This can be thought of as the precursor to char. The devolatilization gases that do not condense at room temperature and pressure are called light or fixed gases and consist mainly of CO, CO_2, CH_4, H_2, and H_2O. The portion of the volatile matter that condenses at room temperature and pressure is called tar. Tar is a mixture of hydrocarbons with an average molecular weight ranging from 200 to 500 amu (Fletcher et al.). The yield and chemical nature of tar depend upon the coal rank; in general, higher-rank coal produces lower amounts of tar. The solid product left over from devolatilization is char. Devolatilization alters the coal porosity from 2 % to 20 %, typical of coal, to over 80 % in the char. The surface area increases from 10–20 m^2/g (coal) to 200–400 m^2/g as measured by with nitrogen gas in a BET (Brunauer-Emmett-Teller) apparatus (Gan et al. 1972; Walker 1981). This increased surface area increases the rate of subsequent combustion and gasification reactions.

The volatile yield, its composition, and the residual char reactivity depend upon the coal petrology, degree of geologic maturation, and process conditions (van Krevelen 1993; Chitsora et al. 1987; Hecht et al. 2010). Coal rank is the relative measure of the extent of maturation for an organic sediment due to exposing the deposited organic detritus to elevated pressures and temperatures during the geologic eras required for its burial, subsidence, and compaction (Teichmuller 1982). Organic materials increase in level of maturity from:

$$\text{BIOMASS} < \text{PEAT} < \text{LIGNITE} < \text{SUBBITUMINOUS} < \text{BITUMINOUS} < \text{ANTHRACITE}.$$

Maturation processes are characterized by first the loss of water and oxygen functionality, followed by increase in polymeric molecular size, and finally the condensation of aromatic structures.

Classification for low-rank coals, subbituminous coals, and lignites is based upon the inherent moisture content and their calorific value (ASTM D3172 07a). Low-rank coal volatiles contain a large proportion of the fixed gases and the tars produced are low molecular weight. Their tars are typically limited to one- and two-ring aromatic structures, but contain a wide variety of heteroatomic functionality. Chars produced from heating low-rank coals are open and exhibit a greater degree of disorder and more heteroatomic functionality (H, O, N, and S) than their higher-rank counterparts. As a result these chars have high gasification reactivities (Radovic et al. 1985; Mahajan et al. 1978). It is the potential for the reactive oxygen functional groups such as the carboxyl groups to chelate exchangeable cations that can atomically disperse catalytic species such as Ca, K, and Na to dramatically enhance gasification rates (Jenkins and Morgan 1986; Morgan and Jenkins 1986a, b).

Coals which are higher in rank than subbituminous have lower oxygen contents, but still substantial volatile matter. Reactive oxygen functionalities such as esters, carbonyl, and carboxyl groups are gone in the bituminous rank coals, but phenols, furan cyclic oxygen, and ether linkages persist [11]. The volatile matter consists of

less fixed gases, but higher molecular weight aromatic hydrocarbons with less heteroatomic functionality than the lighter counterparts formed from lower-rank coals. Bituminous coals are differentiated by their volatile matter content being classified as high-, medium-, or low-volatile bituminous coals. These high molecular weight compounds, when combined with the residual macromolecular network during heating, form what is known as metaplast (Fletcher et al.). The quantity, volatility, and solubility characteristics of tars in bituminous coals are favorable to dissolve or melt the coal's macromolecular network which makes up the bulk of organic matter in this rank coal. During metaplast formation, the particle traps evolving gases and swells to an extent which depends on its composition and the heating conditions. When rapidly heated in drop-tube reactors, bituminous coals produce char cenospheres often greater than three times the size of the feed coal (Maloney et al. 1982). A cenosphere is a remarkably spherical char structure which is essentially hollow formed when these coals are heated reaching a plastic stage while still evolving volatile gases. The residual chars formed after devolatilizing bituminous coal are more highly ordered carbons consisting largely of condensed polynuclear aromatic structures. Thus, in spite of their lower density and extremely high porosities, bituminous coal chars are inherently less reactive than their lower-rank counterparts.

Low-volatile bituminous coals can be distinguished from anthracite by the relative hydrogen to carbon content which decreases as the rank increases due to the condensation of aromatic rings into highly condensed and unreactive polynuclear aromatic structures. Tar yields from these high-rank coals are quite small and fixed gases evolved consist mainly of CO, H_2, and CH_4.

Process conditions also influence devolatilization and the products volatiles and char. Key parameters include heating rate, final temperature, and pressure. At slow heating rates (less than 1 K/s), the volatile yield is relatively low. It is under these conditions that the total volatile yield will be equal to the volatile matter content determined from the ASTM (American Society for Testing and Materials) proximate analysis, which is an analysis done at a slow heating rate. Under rapid heating rate (500–10^5 K/s), the volatile yield is 20–40 % more than that at slow heating rates (Wen and Dutta 1979). At any given temperature only a certain fraction of the volatiles is released. Significant devolatilization begins when the coal temperature is about 500 °C. As the temperature is increased, more volatiles are released. The maximum volatile yield occurs when the temperature is above 900 °C, the temperature at which ASTM proximate analysis is conducted. Higher gasifier temperature also reduces the amount of tar in the gasifier products because of increased cracking rate of tar into lighter gases.

The amount of tar also decreases with increasing pressure and decreasing heating rates. The predominant source of CH_4 in the gasifier product gas is the devolatilization process, and its production is favored by low temperature and high pressure. Therefore, the amount of methane in the product of moving-bed gasifiers, which operate at a low temperature, is higher than that in typical fluidized-bed and entrained-bed gasifiers (Moreea-Taha 2000).

As such it is apparent that predicting the early stages of gasification, devolatilization for coal is quite complex. While the rate is rapid and can be simulated as being coincident with coal heating, the yields, stoichiometry, physical characteristics, and resulting reactivity of the products are dependent upon many factors. One common, simple, and expedient approach is to scale the devolatilization yield with temperature based upon the ultimate yield determined in the ASTM proximate analysis (Syamlal and Bissett 1992). This provides a relative distribution of volatile matter in the gas phase that is dependent on the coal feedstock which can then be modeled to react further to produce fixed gases, depending on the thermal environment in the gasifier. The more rigorous two-stage pyrolysis model is often employed to explain the effects of heating rate and pressure on tar yields (Kobayashi et al. 1977). In this model primary tars are produced initially within the coal particle followed by their subsequent cracking and release via a second reaction. Thus, if the heat rate is fast enough to raise the particle temperature sufficiently for vaporization, the high molecular weight primary tars are released into the gas phase before they can reattach to the char. However, at lower heat rates or higher pressures, these low-volatile primary products stay longer within the particle and crack there to form lighter volatile products which can escape as well as fixed carbon which reattaches to the char.

Anthony et al. (1976) have demonstrated that thermal decomposition of the complex coal macromolecular structure can be modeled by a series of parallel reaction pathways in which the reaction progresses along the most favorable one which can be described by distributed activation energies. The activation energies increase as the extent of conversion increases. Another more rigorous approach is to characterize the evolution rates of these individual gas species themselves dependent on precursor species as identified by more detailed characterization of the cross-linked nature of coal. Such approaches have included the use of infrared (Solomon et al. 1990, 1993a; Solomon and Serio 1994; Solomon et al. 1991) and NMR spectroscopic analysis (Solomon et al. 1993b; Fletcher et al. 1991). These methods have been further refined through the development of volatile percolation models such as FLASHCHAIN (Niksa 1986; Niksa and Lau 1993; Niksa et al. 2003) and CPD (Coal Percolation and Devolatilization) (Fletcher et al.; Solomon et al. 1993b; Fletcher et al. 1991) to account for the variations in thermal and mass transfer during volatile release due to variations in process pressure, heating rates, and particle sizes. NETL's C3M efforts are designed to incorporate all of these models in a platform that can be used with various models (Van Essendelft et al. 2014).

Combustion

Char in an oxygen atmosphere undergoes combustion. In gasifiers partial combustion occurs in an oxygen-deficient or reducing atmosphere. Gasifiers use 20–30 % of the oxygen theoretically required for complete combustion to carbon dioxide and water. Carbon monoxide and hydrogen are the principal products, and only a fraction of the carbon in the coal is oxidized completely to carbon dioxide. The combustion reaction is written in a general form as follows:

$$(1+\lambda)\,C\ +\ O_2 \rightarrow 2\lambda\ CO\ +\ (1-\lambda)\,CO_2 \quad \Delta H^0_{298K} = \begin{array}{l} 172.5\lambda \\ -393.5\ \text{kJ/mol} \end{array}$$

where λ varies from 0 (pure CO_2 product) to 1 (pure CO product). The value of λ depends upon the gasification conditions and is usually close to 1. This is quite important since the ratio of CO/CO_2 determines how much of the carbon in the char is converted to gas. Computational models for coal oxidation under these conditions are quite common, but vary in the manner that they treat the value of λ. Arthur conducted tests on various carbons often cited to model the temperature dependence for this stoichiometric coefficient (Arthur 1951). As the temperature of reaction increases, carbon monoxide is favored. Wen (Wen and Dutta 1979; Wen and Chaung 1979) incorporated this concept by including a particle size dependence such that larger particles with greater thermal mass have a greater tendency to reach higher temperatures and higher values for λ and yield greater proportions of CO. Monazam et al. (1998) and Shadle et al. 2001) have employed Arthur's temperature dependence directly into plug flow and stirred-tank models.

The carbon-oxygen reaction is quite fast and highly exothermic. Under typical gasifier conditions, the carbon-oxygen reaction rate is controlled by the rate of the diffusion of oxygen to the particle surface. For a particle size of 50 μm, the diffusion rate is the rate-limiting step for temperatures above 750 K. For smaller particles the diffusion of O_2 into the particle becomes dominant only at a higher temperature (e.g., 1600 K for 20 μm particles). The heat released by the partial combustion provides the bulk of the energy necessary to drive the endothermic gasification reactions.

Gasification

As a result of these rapid oxidation kinetics, all oxygen is rapidly consumed in a combustion zone, near the injection of oxidant. Further conversion of char occurs through the much slower, reversible gasification reactions with CO_2, H_2O, and H_2.

$$C\ +\ CO_2 \leftrightarrow 2\,CO \quad \Delta H^0_{298K} = 172.5\ \text{kJ/mol}$$

$$C + H_2O \leftrightarrow CO + H_2 \quad \Delta H^0_{298K} = 131.3\,\text{kJ/mol}$$

$$C + 2H_2 \leftrightarrow CH_4 \quad \Delta H^0_{298K} = -74.8\ \text{kJ/mol}$$

The rate of gasification reactions depends upon the char properties and the gasification conditions. Typical orders of magnitude of the relative reaction rates for various oxidants are provided in Table 3.

In general, gasification rates increase with temperature according to the Arrhenius expression. The kinetic parameters reported by Wen et al. (Wen and Dutta 1979; Wen and Chaung 1979) are commonly used to model the kinetics of coal gasification. This is used by Syamlal et al. (1996) in MFIX (Syamlal et al. 1993) and by Slezak et al.(2010). During combustion and gasification, the particle mass and

Table 3 Relative gasification rates at 10 kPa and 800 °C

Reaction	Relative rate
$C + O_2$	10^5
$C + H_2O$	3
$C + CO_2$	1
$C + H_2$	10^{-3}

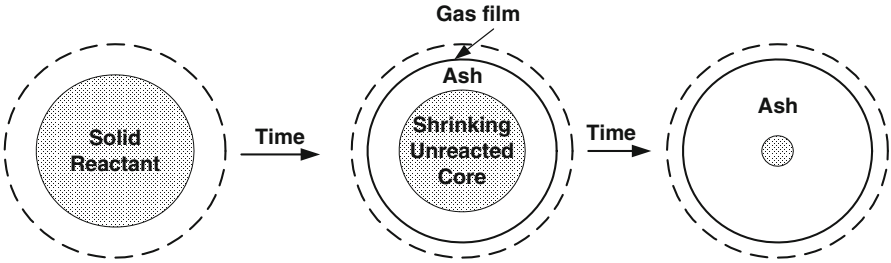

Fig. 3 Shrinking core model for the combustion of coal

temperature are governed by the following reactions developed from the mass and energy balances for a reacting coal particle:

$$\frac{dm_p}{dt} = -Rate$$

$$m_p C_p \frac{dT_p}{dt} = hA_p\left(T_\infty - T_p\right) + \frac{dm_p}{dt} h_{reac} + \varepsilon A_p \sigma\left({\theta_R}^4 - {T_p}^4\right)$$

where m_p is the reacting particle mass, C_p its heat capacity, T_p its temperature, A_p its area, h the gas-solid heat transfer coefficient, T_∞ the bulk process gas temperature, h_{reac} the heat of reaction, ε the voidage, σ the view factor, and θ_R the refractory wall temperature. The refractory wall is a corrosion- and heat-resistant brick often used to line the gasifier walls. The term on the left of the latter equation represents the change in the sensible heat in the particle during the coal conversion. At any instant in time, this is equal to the heat transferred between the gas and the particle (1st term on the right), plus the heat gained or lost due to the heat of reaction (2nd term on the right), plus the radiant heat transfer. The combustion reaction is normally modeled as a shrinking core model graphically shown in Fig. 3 where the coal particle is depicted initially, after the reaction front has progressed in time so that a coal ash layer has built up and when the reaction has progressed to nearly completion. In coal this is complicated by potential coal swelling initially. The initial gas-char reactions involve fast surface combustion of oxygen. These reactions occur at the surface because the processes are limited by the relatively slow diffusion of oxygen into the porous coal char at these temperatures. This is the shrinking particle and constant density stage of the process. After the oxygen is depleted, the gasification of char becomes relatively slow as compared to diffusion,

and so gasification reactions are kinetically limited. This second stage of heterogeneous gas-char reactions takes place uniformly throughout the particle volume and results in decreasing particle density and constant diameter.

The reaction rate (per unit area) for combustion and gasification is obtained from comparing the relative reaction rates associated with gas-solid film diffusion, chemical reaction, and diffusion through the reacted char layer:

$$rate = \frac{1}{\frac{1}{k_{diff}} + \frac{1}{k_r Y^2} + \frac{1}{k_{dash}}\left(\frac{1}{Y} - 1\right)} (P_i - P_i^*)$$

where k_{diff} is the gas film diffusion constant, k_r is the Arrhenius rate constant, k_{dash} is the ash film diffusion constant, Y is the char conversion factor defined as the ratio of the unreacted core radius to the initial radius of the particle, P_i is the partial pressure of reactant i, and P_i^* is the back reaction equilibrium pressure of reactant i (Wen and Chaung 1979).

Variations in the relative rates are normally accounted for by adjusting the frequency factor or pre-exponential term. Differences in char reactivity as a result of degree of disorder of the carbon structure are also treated by adjusting this pre-exponential factor (Monazam et al. 1998; Shadle et al. 2001). Differences in the degree of disorder in the char are due to differences in heat treatment history, number of imperfections due mainly to heteroatoms (i.e., organic O, S, and N), and degree of condensation in the aromatic structure (due to level of maturity in the sediment). In addition, it is important to note that elevated pressures increase the partial pressure of the oxidant and thus increase the gasification rate relative to the absolute increase in overall pressure (Monazam et al. 1998; Shadle et al. 2001).

Another important chemical reaction in a gasifier is the water-gas shift reaction:

$$CO + H_2O \leftrightarrow CO_2 + H_2 \quad \Delta H^0_{298K} = -41.2\,\text{kJ/mol}$$

The relatively low heat of this reaction contributes to the low activation energy and quick approach to equilibrium. As a result the gasifier product distribution can often be estimated from the conversion and the equilibrium constant for this reaction. However, this equilibrium constant if dependent on temperature and the equilibrium will be frozen at the process or downstream temperature depending on the effective quench rates in the various processes. Thus, the equilibrium temperature for a different process configuration must be experimentally established. Detailed computational modeling has the potential to incorporate all of these complex reaction pathways to provide insight into how to predict changes in this effective equilibrium temperature and thus how modifications will alter gasifier product distributions.

Mineral matter in the coal catalyzes this gas-phase reaction. Other gas-phase reactions are the combustion of CO, H_2, and CH_4 and tar cracking. One intermediate product from these gas-phase reactions in a gasifier is the formation and further conversion of soot. This can play a pivotal role in determining the performance, reliability, and efficiency of the downstream cleanup process units as well as determining the overall process performance.

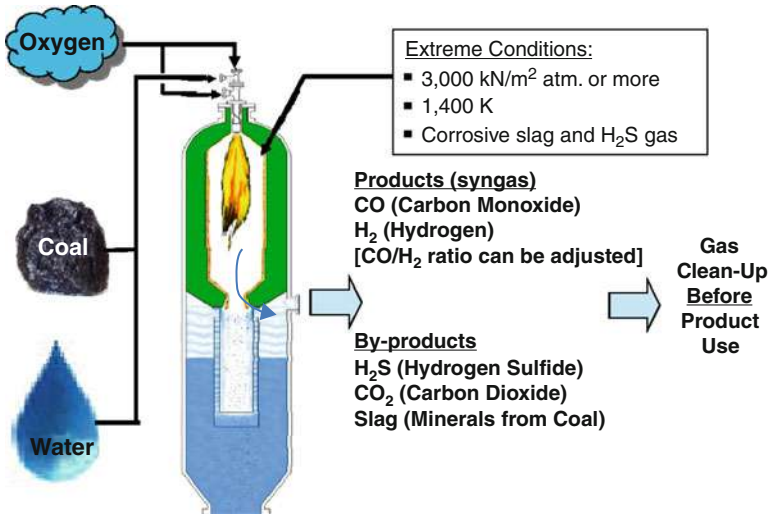

Fig. 4 Gasification process basics

Gasification turns any carbon-containing material into synthesis gas as depicted in Fig. 4. Carbon reacts with water, in the form of steam, and oxygen at relatively high pressure, typically greater than 3000 kN/m^2, and at temperatures typically reaching 1,500 K to produce raw synthesis gas or syngas. Syngas is a mixture composed primarily of carbon monoxide and hydrogen and some minor by-products. The by-products are removed to produce a clean syngas that can be used as a fuel to generate electricity and steam. Syngas is the basic chemical building block for a large number of uses in the petrochemical and refining industries. Syngas production is the first step in the efficient manufacture of the clean-burning hydrogen fuel. Gasification adds value to low- or negative-value feedstocks by converting them to marketable fuels and products.

There are a number of previous reviews and extended writings on gasification available to get a deeper understanding of the process and various gasification technologies. These include the book by Higman (Higman and van der Burgt 2008), the Gasification Technologies Council website http://www.gasification.org/, the DOE Gasification website http://www.netl.doe.gov/technologies/coalpower/gasification/index.html, and numerous conferences including Gasification Technologies Annual Conference, the Clearwater Conference, and the Pittsburgh Coal Conference.

Coal Minerals and Their Transformations

Coal is a sedimentary deposit comprising mainly the remains of swampy forest plants that accumulated and subsided beneath the soil to escape the carbon cycle. As such it is a combination of the organic matter from biological source, as well as inorganic matter depending on the geological formation in which it was deposited.

The coals that we find in the ground today have matured to different levels depending on its age, depth of burial, and associated geology. Up until now we have considered primarily the organic matter in coal; however, the processes that use coal are often affected in very important ways by the amount and type of minerals in it.

The coals in the USA have low mineral contents (often <10 % wt.), and those minerals often occur in discrete particles that can be readily separated from the organics. Eastern US geological basins are older and more mature, being from the Carboniferous age, than their Western counterparts which are from the Cretaceous age. As a result the Western coals have alkaline earth metals in the form of ion-exchangeable cations associated with oxygenated functionality in the coal that catalyze many thermal conversion processes. The most common minerals in US coals are clays, but the Eastern coals often have sulfur in the form of pyrite due to the brackish depositional environment in which they were deposited. The depositional environments in the Western coals were more variable, and besides clays, the coals may have quartz and calcite but pyrite is more rare. By contrast, coals in the Southern hemisphere, often referred to as Gondwanaland coals after the supercontinent that once encompassed all of the land masses there, are characterized by the high inorganic content (40–80 % wt.) distributed uniformly creating a coal that is not amenable to physical separation or beneficiation.

The mineral composition of the coal will influence its thermal behavior. Upon heating in air, coal yields ash in which the pyrite is converted to hematite, and carbonates are calcined producing metal oxides. By contrast, a gasifier will produce reduced metal ash, forming pyrrhotite from pyrite and forming sulfides or reduced metal oxides depending on the presence of sulfur. The clays are dehydrated in either case. The composition of the ash will determine its thermal behavior: melting temperature and slag viscosity. Gasifiers are generally categorized according to how they handle the mineral waste.

Gasifiers which operate at high temperature, melting the minerals, are referred to as slagging gasifiers. Slagging gasifiers operate at temperatures high enough that mineral or organic impurities in the carbon feedstock become molten, and if contact is made with other particles or the gasification chamber sidewalls, coalescence can occur to form slag. Dry bottom gasifiers handle the mineral matter waste by either operating at temperatures below the melting temperature or by extracting the heat from the combustion zone to resolidify any slag that is formed. Both types of gasifiers use refractory to improve performance and maintain reactor vessel integrity.

Slagging gasifiers operate at temperatures between about 1325–1575 °C, a temperature determined by the fluidity of the slag contacting the gasifier sidewall that must flow from the gasifier. If the slag is not fluid enough to flow from the gasifier (high viscosity), it will build up on the gasifier sidewalls or in the solid waste exit, causing gas flow to become restrained, with either higher gasification temperatures used to remelt slag so it flows from the gasifier or shutdown of the gasifier occurs so solidified slag can be physically removed from the gasifier. Note that if high temperatures are needed to cause build up slag to flow from the gasifier,

Table 4 Range of ash chemistry found in over 300 Eastern coals and 9 petcoke carbon feedstock found in the USA due to mineral and metal-organic impurities (Vassilev et al. 2002; Conn 1995; Bryers 1995)

	Coal (wt pct)			Petcoke (wt pct)		
Compound	Avg.	Std. dev.	High to low	Avg.	Std. dev.	High to low

corrosive wear of the refractory liner in the gasifier increases, shorting the service life of those materials. The amount of solid waste removed from a gasifier can be high, representing the mineral matter content of the fuel feedstock, highlighting the importance of a smoothly operating system. Slag fluidity (viscosity in poise) must be low enough so it can flow from the gasifier, but not so high that refractory wear becomes excessive. Gasifier operators typically target a viscosity range between two temperature values, t_{100} and t_{250}, although other values can be used. The t_{100} temperature is higher, and produces a fluid slag, while the t_{250} temperature produces a thicker slag that takes more time to flow a specific distance. Viscosity values higher than t_{250} become too thick to flow from the gasifier, while viscosity values lower than t_{100}, as mentioned previously, involve temperatures that accelerate refractory wear and increase the likelihood that syngas cooler fouling will occur and will occur faster than at lower temperatures. Gasifier operators prefer carbon feedstock that will produce a wide temperature range between t_{100} and t_{250} viscosity values, giving them a greater degree of operational flexibility. A carbon feedstock viscosity can be altered by blending different materials or by using additives (typically mineral) to produce slag viscosities in a desired temperature range. A viscosity versus temperature curve for a synthetic slag mixture of an average Eastern coal (Table 4) evaluated under a gasification condition of 10–8 atm oxygen partial pressure is shown in Fig. 5.

The two most commonly used slags in slagging gasifiers are coal, petcoke, or mixtures of them. The chemistry ranges of average coal and petcoke ashes found in the USA are shown in Table 4. Coal averages about 10 wt% mineral impurities, although quantities can be lower or higher, depending on where the coal was mined. The major impurities in coal are minerals high in oxides of Si, Al, Fe, and Ca, although other elements can be high depending on the coal source. Petcoke averages about 1 % impurities which are typically metal-organic compounds high in V, Ni, Si, and Al. Examples of impurities found in coal and petcoke are given in

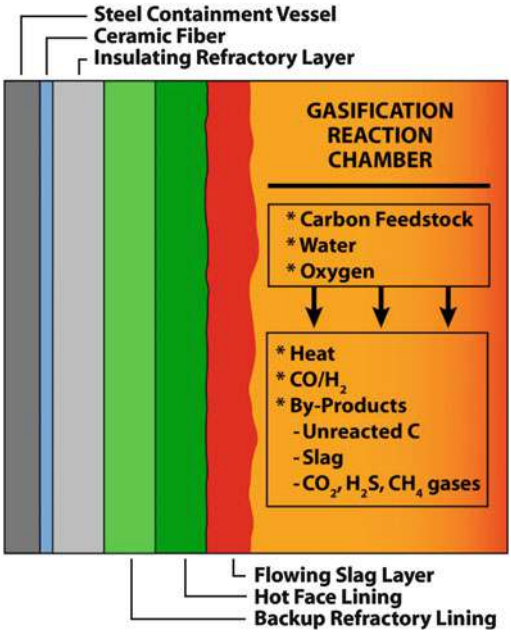

Fig. 5 Sidewall of a refractory-lined slagging gasifier

Table 4. Petcoke is the solid by-product from oil refinery operations derived from the thermal treatment (coking) of the higher molecular weight fractions of petroleum. In general, petcoke slags are considered by gasifier operators to have similar refractory liner behavior to coal slags. It is worth noting that on a microscopic level, differences between coal and petcoke slag interactions with refractories do exist. Limited thermodynamic information exists, however, on vanadium slags formed under the high temperature and low oxygen partial pressures of gasification, limiting modeling of petcoke slags. Work done by Nakano (Vassilev et al. 2002) on synthetic vanadium slags has indicated that V_2O_3 is the stable phase in the low oxygen partial pressure of gasification at high temperatures. This phase is important because when a slag is saturated with it, the amount of vanadium phase existing as crystalline material impacts slag viscosity.

Materials for Slagging Gasifiers

Because of the extremely harsh environment, high temperatures, and reducing environment, slagging gasifiers present unique design and material challenges. Because of the high temperatures, the walls are either cooled by air or water. Both require refractory lining to sustain the gasifier metal wall integrity and strength. A highly cooled gasifier (water cooling) produces a colder interior wall where a slag layer deposits and builds up or sloughs off depending on the operating conditions. However, these heat losses result in reducing the process thermal efficiency and so must be balanced with process operability and reliability. The alternative is to use less cooling (air-cooled wall) with higher temperature

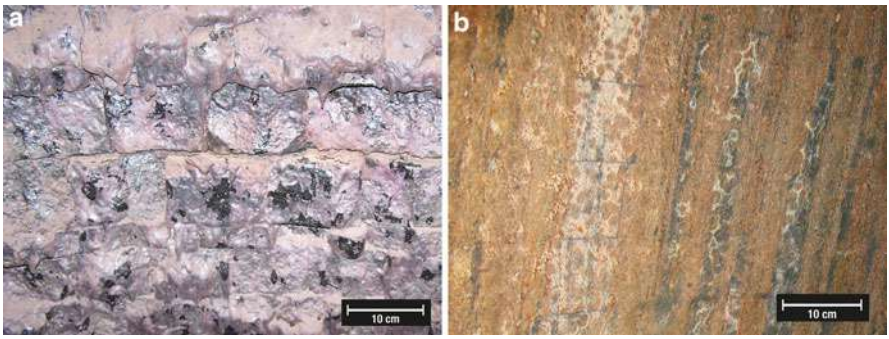

Fig. 6 Air-cooled slagging gasifier refractory wear as seen from the gasifier interior. (**a**) Typical surface wear on conventional refractory materials caused by slag and (**b**) refractory wear in newly developed liner materials

refractory-lined walls, which reduce heat losses, thereby increasing process efficiencies, but require maintenance and servicing. Examples of both types of technologies are available (see below).

The failure of a refractory lining in a slagging gasifier causes gasifiers to be shut down for repair or replacement, a process that can take 1–3 weeks, depending on the extent of repairs needed. Failure can be one or more bricks and occurs because of excessive heat transfer to the steel containment vessel (see Fig. 5). Much of the focus of laboratory research has been on the air-cooled slagging gasifiers because of the shorter service life of refractory liner materials versus the longer life of the cooling screen design materials (about 3 years of service life versus approximately 8 years for cooling screen designs). Examples of the refractory lining wear in air-cooled gasifier refractory lining are shown in Fig. 6. Note the cobbled or rough surface appearance on the hot face refractory surfaces in the gasification chamber that occurs on the surface of traditionally used refractory materials (Fig. 6a) versus the smoother surface of newer formulations of refractory materials being put into service (shown in Fig. 6b). The rough surface is caused by slag penetration into the porous refractory materials leading to a process called spalling, where surface sections of the refractory material spall off in chunks, accelerating material wear. Spalling wear causes the rough surface visible in Fig. 6a and has nearly been eliminated by newer types of refractories, as shown in the image in Fig. 6b. Spalling in a cross section of a refractory is shown in Fig. 7a and is caused by slag penetration into refractory pores, with thermal cycling or continued slag penetration leading to thermal expansion mismatches, causing stress cracking of the refractory to occur parallel to the hot face. It is a repetitive process that removes portions of the refractory lining surface, as shown in Fig. 7b, accelerating refractory wear caused by refractory dissolution.

The general types of refractory liner materials used in slagging gasifiers are shown in Table 5, with newly developed spalling-resistant materials containing phosphate additives. It is worth noting that refractory wear is not caused by one or two material interactions, but can be caused by a number of issues, as shown in

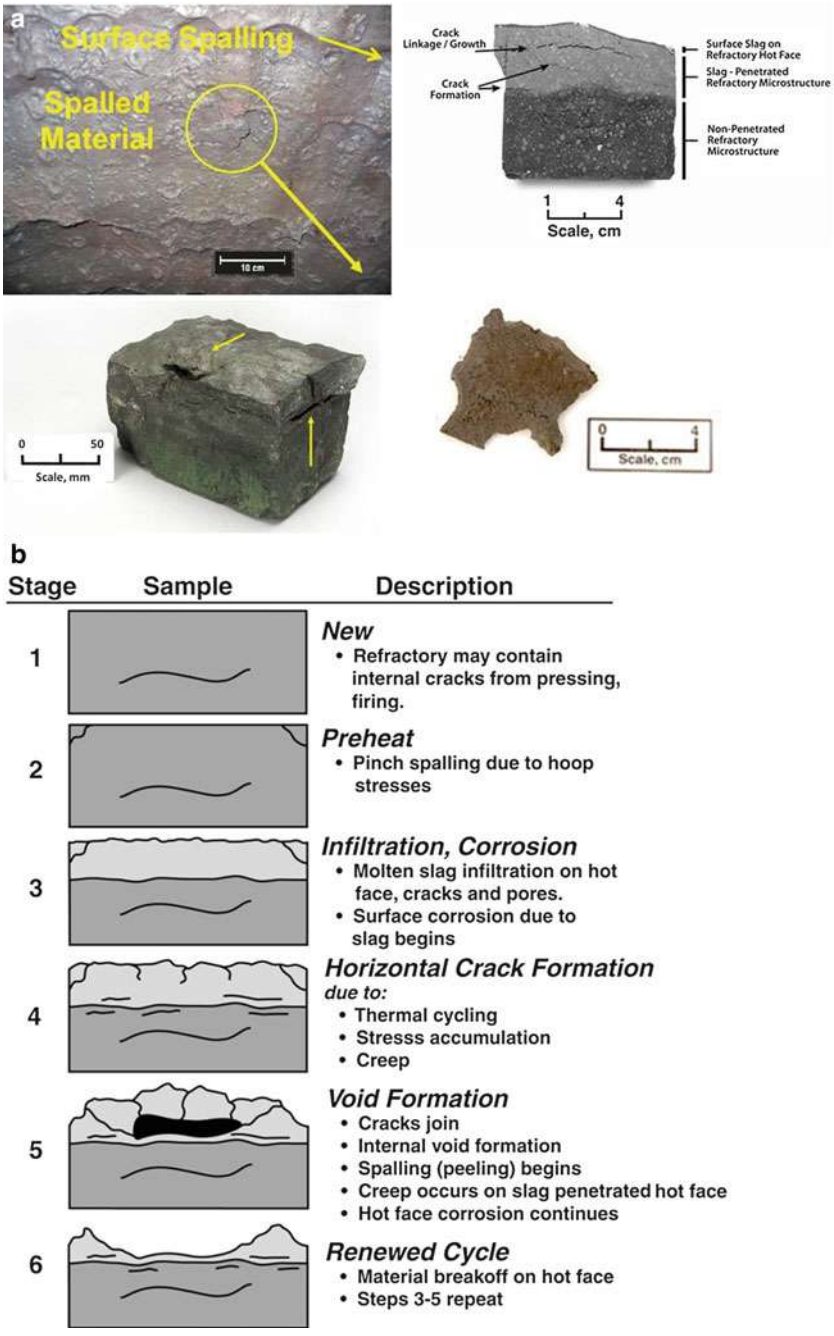

Fig. 7 Refractory spalling occurring within a used refractory brick (**a**) and an illustration as to how the process reoccurs during gasifier operation (**b**)

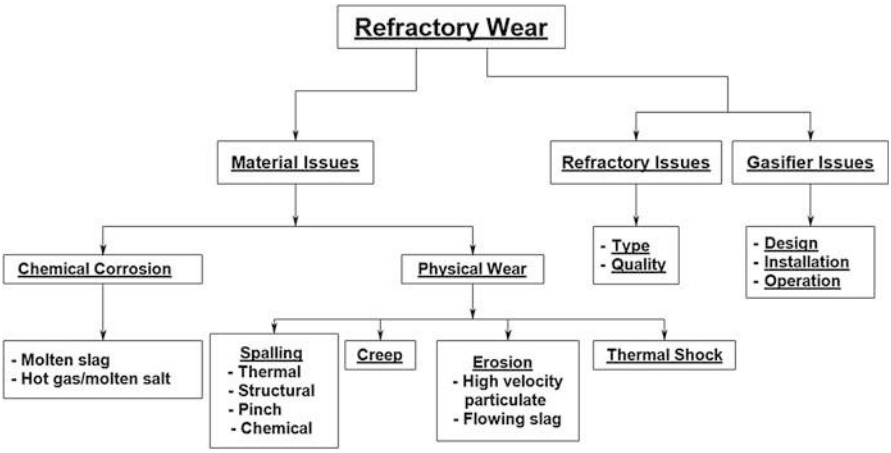

Fig. 8 A breakdown as to the possible causes of refractory wear during carbon feedstock gasification

Fig. 8. Along with spalling, chemical dissolution of a refractory material is also a major cause of refractory liner wear and leads to the gradual dissolution of a refractory lining into the slag flowing on the brick surface. Interactions between the slag and the refractory can lead to mineral phases being created on the refractory surface, which impact and slow the dissolution process. Because chrome oxide forms high-melting mineral phases with oxide components such as iron in slag, the dissolution of a high chrome oxide lining into slag occurs slowly compared to most other materials considered for use in a gasifier. Phases that form on a refractory surface when exposed to a coal slag are shown in Fig. 9 and are the core reason why chrome oxide has superior performance over other refractory oxides in the gasification environment. Note the solid solution spinel layer of $(Fe,Mg)(Al,Cr)_2O_4$ on the refractory surface and the formation of $(Fe,Mg)(Cr,Al)_2O_4$ forming on the surface of the chrome oxide grain. Both materials have high melting points and slow dissolution in the slag. These changes in mineral compositions at different

locations can be discerned using the powerful combination of scanning electron microscopy (SEM) and energy-dispersive spectroscopy (EDS).

Besides ways to reduce refractory wear through the development of new or improved performance materials, research is evaluating how to control slag chemistry to reduce refractory wear. Slag chemistry can be managed by blending carbon feedstock, using of additives such as MgO, or changing the refractory liner to be more chemically compatible with the slag. The impact of changing slag chemistry must take into consideration viscosity changes, which has made this approach difficult.

Gasification Versus Combustion

Gasification and combustion can essentially be considered as two ends of a continuum for reactions of coal and oxygen, where water can be added as a reactant to

Table 6 Gasification and combustion chemistry

Reaction process	Chemical formula	Change in enthalpy
Gasification with oxygen	$C + ½O_2 \rightarrow CO$	−9,123 kJ/kg C
Combustion with oxygen	$C + O_2 \rightarrow CO_2$	−32,822 kJ/kg C
Gasification with carbon dioxide	$C + CO_2 \rightarrow 2CO$	14,577 kJ/kg C
Gasification with steam	$C + H_2O \rightarrow CO + H_2$	11,048 kJ/kg C
Gasification with hydrogen	$C + 2H_2 \rightarrow CH_4$	−6,215 kJ/kg C
Water-gas shift	$CO + H_2O \rightarrow CO_2 + H_2$	−1,512 kJ/kg CO
Methanation	$CO + 3H_2 \rightarrow CH_4 + H_2O$	−7,399 kJ/kg CO

increase the H_2 content of the products. Table 6 is a list of the most significant reactions and the enthalpy change associated with each of these reactions with respect to weight of carbon or carbon monoxide. Looking at the first two reactions in the table, it is seen that coal denoted here with a C for carbon is reacted with one oxygen atom denoted here as 1/2 O_2 to get carbon monoxide and with two oxygen atoms (2) to get carbon dioxide. In reality, this second reaction is not a one-step process as the solid-phase carbon reacts with one oxygen atom to produce carbon monoxide which then reacts with the second oxygen atom to form carbon dioxide. All of the reactions in the table are exothermic except the two reactions identified as gasification with steam and gasification with carbon dioxide. These two endothermic reactions are the reactions that are most often referred to as gasification, where the solid carbon is turned into a reactive gas through a reaction with a "nonreactive" gas (H_2O or CO_2). In addition to these two reactions being endothermic, they also require high temperatures to proceed.

In Table 7 combustion and gasification are compared and contrasted. Combustion is referred to as full oxidation and gasification as partial oxidation. Combustion occurs in an oxidizing (excess oxygen) environment, and gasification occurs in a reducing (oxygen-depleted) environment. For power production, gasification using a gas turbine is more efficient and has lower emissions and competitive capital costs compared to combustion. With respect to the competitiveness of the cost, it is the cost of electricity that is nearly the same for both technologies; the higher capital cost of gasification is offset by the improved efficiency. Combustion is the dominant power-producing technology in the world and as such has lower risk with demonstrated reliability.

Integrated Gasification Combined Cycle

IGCC plants as shown in Fig. 10 convert carbonaceous fuels/materials into electricity and could be considered first-generation plants – those not requiring CO_2 separation or sequestration. In these plants, the carbon-containing material is fed to the gasifier along with oxygen and steam to produce the raw syngas. The raw syngas is cleaned of particulate matter and sulfur. The clean syngas is fed to the

Table 7 Contrasts between combustion and gasification (U.S. Department of Energy 2009)

	Combustion	Gasification
Chemical process	Full oxidation	Partial oxidation
Chemical environment	Excess oxygen (air) – oxidizing	Oxygen starved – reducing
Primary product	Heat (e.g., steam)	Syngas (CO and H_2)
"Downstream" products	Electric power	Electric power, pure H_2, liquid fuels, chemicals
Current application	Dominates coal-fired power generation worldwide	Mostly chemicals and fuels, power generation demonstrated
Efficiency	35–37 % (HHV[a])	39–42 % HHV[a]
Emissions	~NSPS[b]	~1/10 NSPS[b]
Capital cost	$1,000–1,150 /kW	Competitive
Maturity/risk	High experience, low risk	Reliability needs to be improved

[a]HHV is the high heating value or gross calorific value as determined by bringing all the products of combustion back to the original precombustion temperature and condensing any water vapor produced
[b]NSPS is the new source performance standards

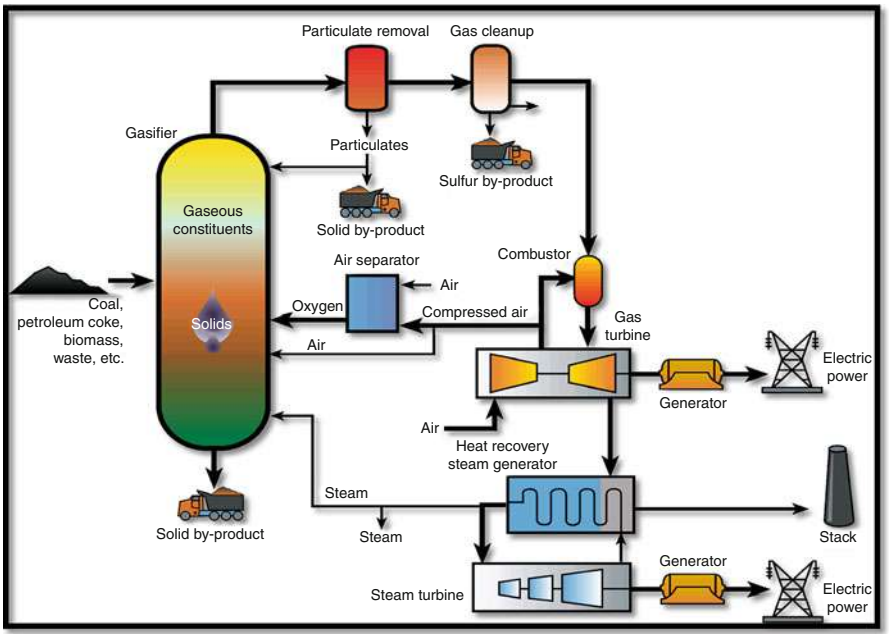

Fig. 10 IGCC system without carbon capture (U.S. Department of Energy 2009)

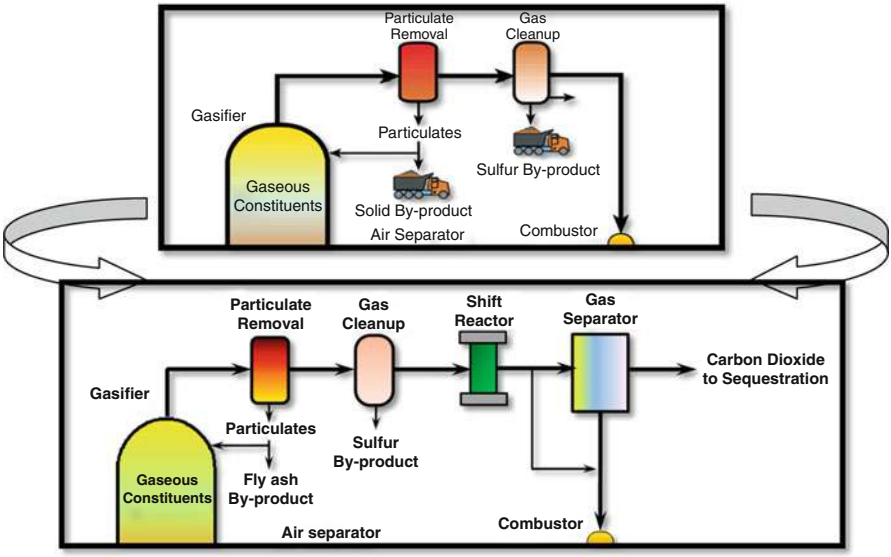

Fig. 11 Changes in the downstream IGCC process flow schematic with carbon capture (U.S. Department of Energy 2009)

combustion turbine with the products going to a heat recovery steam generator and steam turbine.

IGCC systems with carbon capture (Massey 1979) are similar to IGCC systems without carbon capture as can be seen by comparing Figs. 10 and 11. In Fig. 11 the IGCC system is shown with precombustion capture of the carbon for sequestration. The primary difference between the two processes is that the clean syngas passes through a shift reactor and an absorption tower to remove the carbon in the form of carbon dioxide. The shift reactor converts the CO in the syngas by reacting it with water over a catalyst to form H_2 and CO_2 with the latter going to sequestration.

A conceptual poly-generation IGCC plant (one that generates multiple products) is depicted in Fig. 12. In this concept, the clean syngas is shifted to change the CO/H_2 ratio. A partial shift adjusts the ratio to be comparable to the end hydrocarbon product being synthesized. If power is being made as the product, the gas stream will undergo a full shift.

Gasification Processes

Gasifiers fall into four primary configurations: moving bed, fluidized bed, entrained flow, and transport as shown in Fig. 13. Each of these is defined based upon how the reactor brings about contact with the coal and the reactive gas. The gas and solid (coal particle) temperature differs dramatically as they traverse through the gasifier. In a typical moving-bed gasifier designed for coal, the solids are loaded into the top

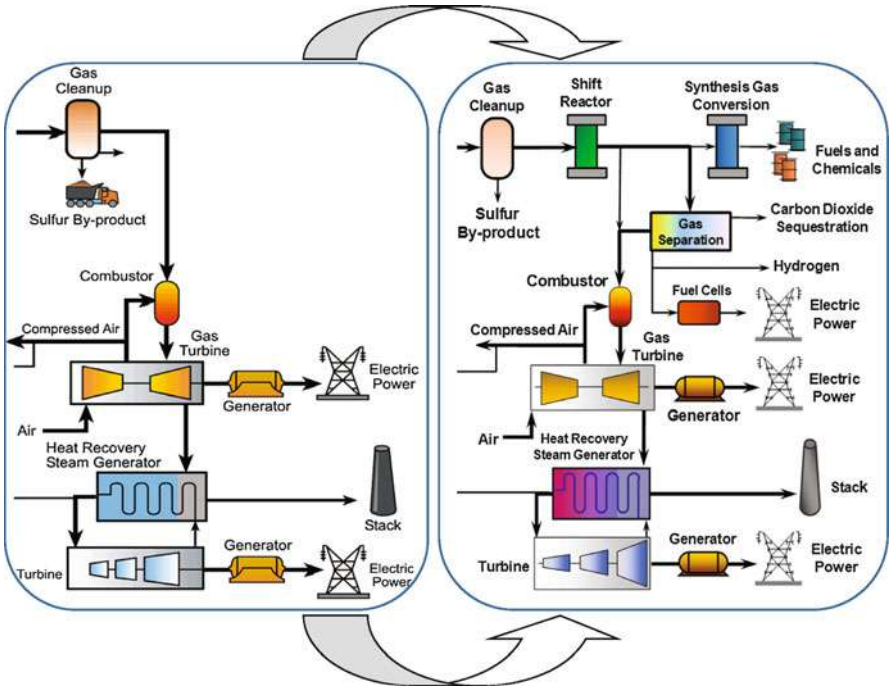

Fig. 12 Changes in the downstream IGCC process flow schematic for a poly-generation plant (U.S. Department of Energy 2009)

of the gasifier and move slowly down in a packed moving bed as the coal below is consumed and converted to gas. The oxidant gas is introduced in the bottom of the gasifier gases and the settling coal char and ash. After gasification reactions slow due to dropping gas temperatures, the product gas still holds sufficient sensible heat to pyrolyze, dry, and preheat the coal before it exits the reactor at a relatively low temperature. The sensible heat is the heat absorbed or evolved by a substance solely due to a change in temperature. The greatest part of time in the moving-bed gasifier is spent in this drying, heat-up, and pyrolysis region of the gasifier as is apparent by the long thermal heat up portrayed in Fig. 13. The volatile matter released during devolatilization undergoes a vaporization and condensation depending on the volatility of the tars which results in some secondary cracking but ultimately results in the production of significant quantities of tars in the product stream.

For very high-volatile matter coals and biomass, an alternative cocurrent configuration is often preferred to reduce the quantity of complex tar products. In this configuration the oxidizing gases are primarily introduced along with the coal at the top of the gasifier and product gas withdrawn at the bottom along with the solid waste. The result is twofold: the tars must traverse through the combustion zone and are cracked and partially combusted, and the product gas temperature is relatively high similar to the fluidized-bed gasifiers.

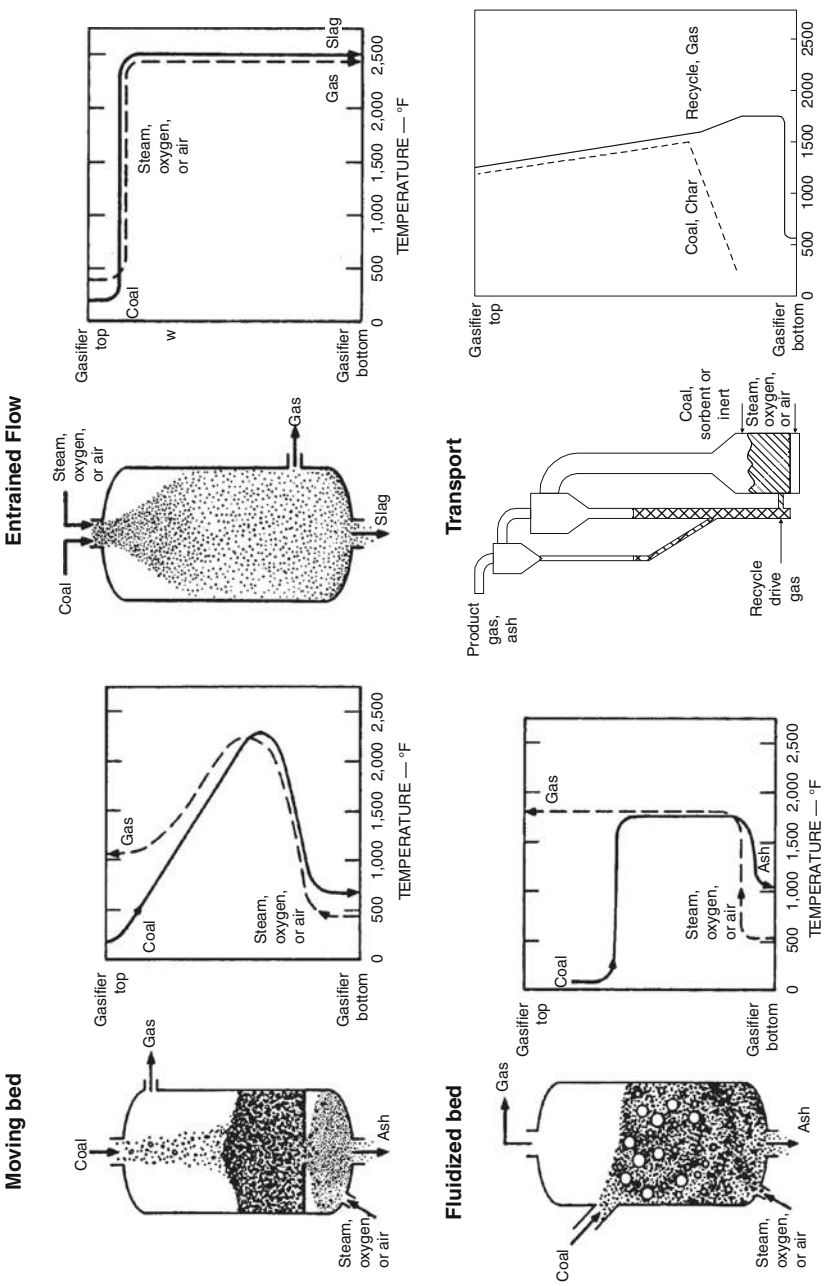

Fig. 13 Four basic coal gasifier types (U.S. Department of Energy 2009)

In a fluidized-bed gasifier, the oxidant gas is introduced at the bottom with sufficient flow and velocity to support the weight of the entire inventory of coal, char, and ash or sorbents. The coal may be introduced at the top or deeper into the fluidized bed to reduce the amount and vapor pressure of tars. Both are heated rapidly to gasification temperatures near 1000 °C and mixed thoroughly approaching the performance of a stirred-tank reactor. The inventory is sufficient to obtain 10–30 min solid residence time. Pyrolysis, combustion, and gasification reactions take place throughout the reactor. The solids may be taken off either through an overflow stream or an underflow removal system depending on process concept goals. The product gas is removed off of the top at process temperature and must be cooled and any entrained fines removed. Due to the mixing, large solid surface area, and relatively low temperatures, the product gases are richer in hydrocarbons from the cracking of tars and relatively high CO/CO_2 ratio. The solids are withdrawn at low temperatures below mineral melting temperatures, dry, either from the top of the reactor to be sent to a combustor for complete conversion or from the bottom as a mineral enriched solid waste as shown in Fig. 13.

An entrained gasifier may be upflow or downflow, but it is dilute cocurrent flow with both coal and oxidant gas moving in the same direction rapidly approaching 1500 °C (Fig. 13). The coal spends less than 10 s residence time, and all minerals are melted and removed from the gasifier as molten slag. In that time the coal particle must be dried, heated, pyrolyzed, and then combusted and gasified in essentially a plug flow reactor. The product gas exits the gasifier at these high reaction temperatures and must be quenched either directly or indirectly in order to further clean by removing particulates and then sulfur and other acid gases.

The transport gasifier is a blending of the fluidized-bed and entrained-bed gasifiers with the oxidant entering the gasifier at the very bottom with recycle solids and unreacted coal char. The concept is to deplete all the oxygen prior to adding the coal. The coal is rapidly dried, heated, and pyrolyzed and gasified with steam. The product gas exits the gasifier after 3–10 s, but the tars are cracked over the high loading of hot mineral surface area. The char and inert minerals in the transport gasifier experience internal mixing spending 10–50 s residence time. These solids are captured using two stages of disengagers and/or cyclones, excess solids are extracted and cooled, but the bulk of the solids are recycled back into the transport reactor to maintain process temperature, avoid agglomeration, and assist cracking of low-volatile hydrocarbons.

A comparison of the four basic gasifier types is presented in Table 8. The moving-/fixed-bed gasifier category refers to the Lurgi Mark IV (dry bottom) and the British Gas/Lurgi (slagging) with both having dry coal feed systems. These are both countercurrent flow systems which operate principally as plug flow reactors. There are three principal entrained-flow gasifiers produced by ConocoPhillips, General Electric, and Shell. The Shell unit is a dry feed gasifier whereas the ConocoPhillips and the General Electric are slurry-fed gasifiers. The moving-bed gasifiers utilize coarsely crushed coal and require the long residence times as a result, while the entrained-flow reactor uses finely crushed coal and the residence

Table 8 Comparison of salient features for each of the four different gasifier types

	Moving bed		Fluidized bed		Entrained flow	Transport flow
Ash condition	Dry	Slagging	Dry	Agglomerate	Slagging	Dry
Coal Feed	~2 in	~ 2 in	~ ¼ in	~ ¼ in	100 mesh	~ 1/16 in
Fines	Limited	Better than dry ash	Good	Better	Unlimited	Better
Coal rank	Low	High	Low	Any	Any for dry feed	Any
Oxidant req.	Low	Low	Moderate	Moderate	High	Moderate
Steam req.	High	Low	Moderate	Moderate	Low	Moderate
Issues	Fines and hydrocarbon liquids		Carbon conversion		Raw gas cooling	Control carbon inventory and carryover

times are correspondingly short. On the other hand, the fluidized-bed and the transport gasifiers are dry fed and non-slagging gasifiers. These are well-mixed reactors operating with lower peak temperatures than the plug flow reactors. These gasifiers have coal residence intermediate between the moving-bed and the entrained gasifier and thus utilize intermediate particle sizes. Each of these four gasifier types has process options which make it possible to gasify any coal types. The moving bed is the most efficient and thus requires the least oxidant, while the entrained gasifier has the greatest coal throughput (feed rate per cross-sectional area). The transport gasifier was developed in order to maximize coal throughput while utilizing lower-quality feedstocks which are unattractive in entrained gasifiers. The issues associated with each gasifier type are also listed in Table 8.

Fixed-/Moving-Bed Gasifiers

A sketch of the fixed-/moving-bed gasifiers is shown in Fig. 14. Lurgi produces the non-slagging unit of this type, while British Gas designed the slagging version of this technology, often referred to as the British Gas/Lurgi (BGL). These units are both countercurrent flows and are characterized by very high combustion zone temperatures and low gas and solid exit temperatures. The high combustion temperatures provide the thermal energy required to drive the highly endothermic gasification reactions located immediately above. The reactor configuration effectively recoups the sensible energy in the gas by exchanging the heat with the incoming coal in the devolatilization and coal drying zones giving these gasifiers the highest cold gas efficiency of any of

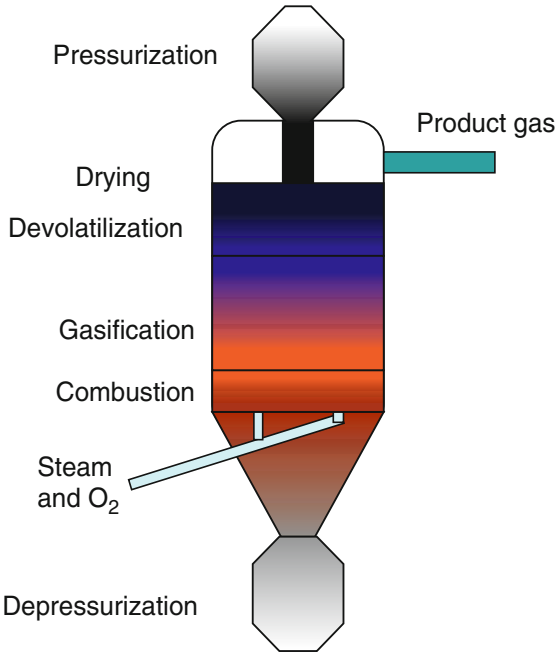

Fig. 14 Typical configuration for dry and slagging moving bed

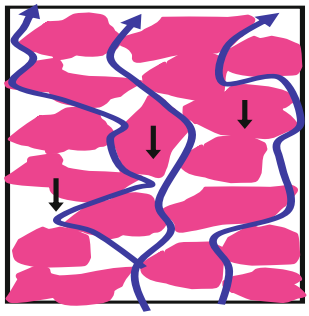

Fig. 15 Moving-bed gas-solid flow patterns

the gasifier types. As a result, however, the product gas contains hydrocarbons, tar, and water released in the devolatilization and drying zones of the gasifier.

Hydrodynamically, the reactors resemble flow through a porous medium as shown in Fig. 15. Although in this gasifier, the continuous (gas) and the discrete (solids) phases flow countercurrently, i.e. the solids move down while gas moves up. These types of reactors can be problematic due to nonuniform flow which may be a result of particles agglomerating and overpacking with fines. All of these issues lead to poor interphase mixing, unreacted carbon, hot spots, and lower conversion.

Kinetically, the moving bed is a low-temperature reactor operating in the kinetically controlled shrinking core reaction mode pictured in the sketch shown

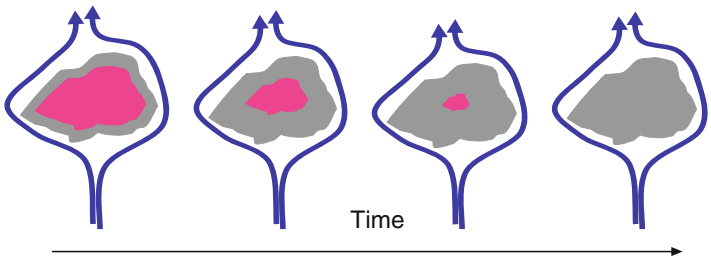

Fig. 16 Particle time history in moving bed showing the progressive conversion of unreacted coal (*red*) into char and ash (*gray*)

in Fig. 16. The burnout time or conversion time for a particle fed to the top of the gasifier is

$$\tau = \frac{2\rho_B R}{kC_{O_2}}$$

where: τ is the time for complete conversion, ρ_B is the coal particle density, 2 is 1/stoichiometric coefficient for O_2, R is the particle radius, k is the combined kinetic and mass transfer rate constant, and C is the concentration of O_2 (Levenspiel 1998).

Table 10 presents typical product gas compositions for air-blown operation of the Lurgi dry bottom configuration for subbituminous and bituminous coals. Lower-rank coals produce more CO_2 and hydrocarbons because of their lower heating value and higher volatile content. More process energy is required to provide sensible and latent heat for the lower-quality fuel, thereby driving the combustion reaction further to completion. Lower-rank coals have inherently greater oxygen content and release more carbon dioxide directly from pyrolysis. In addition, the lower-rank coal char is more reactive and thus reacts faster and so maintains a lower process temperature producing a greater relative proportion of CO_2/CO.

Typical product compositions are provided in both Tables 9 and 10.

A study of the relative impact of different process parameters for a moving-bed gasifier was reported by Monazam and Shadle (Monazam et al. 1998; Shadle et al. 2001). A plug flow model was developed including mass and energy balances for the major gas and solid product streams during devolatilization, gasification, and combustion of coal. Then a sensitivity study was conducted on each of the operating and design parameters for the gasifier when operated under a given coal feed rate. The base conditions are presented in Table 11. The average responses and normalized response factors are summarized for each independent parameter in Table 12. As expected from review of the kinetic equations above, increased process pressures and gas velocities (air/coal) were the two most significant factors influencing (increasing) the rate of conversion or burning rate. Increased particle size resulted in slower conversion. Steam/air ratio was the most critical parameter impacting the temperature and gas composition over the range tested. Only variations in the efficiency factor had significant impact on the gas product quality.

Table 9 Typical product compositions for oxygen-blown moving-bed gasifiers (Lowry 1963; Elliot 1981; Stultz 1992)

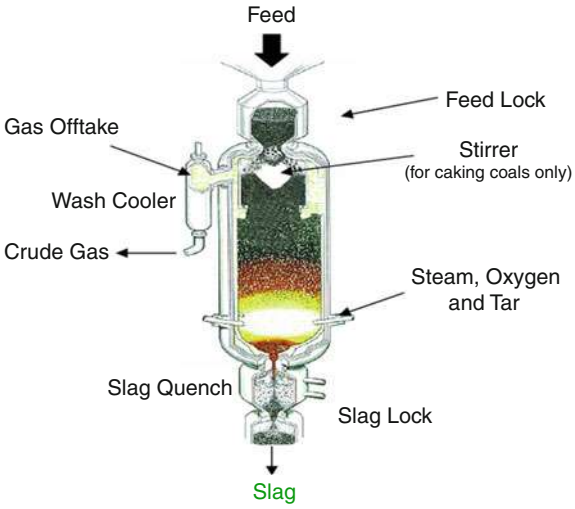

Fig. 17 British Gas/Lurgi gasifier (U.S. Department of Energy 2009) where ASC/SVC-type feed system was that developed by Allied Syngas Corporation (ASC) at the Sekundarrohstoff-Verwertungszentrum Schwarze Pumpe (SVZ) waste recycle plant in Saxony, Germany

1958 to 1965 at the Gas Council Midlands Research Station where it operated 4 m gasifier, 380 kg/h (Seed et al. 2007). It is a dry feed, oxygen-blown, refractory-lined gasifier. It is good for a wide range of coals including opportunity fuel blends with RDF (refuse derived fuel), tires, and wood waste. It is a modular design by Allied Syngas which will build, own, and operate it in North America. A 19,000 kg/h demonstration plant operated from 1986 to 1990. And the first commercial plant at Schwarze Pumpe operated 2000–2005.

Multipurpose Gasifier (MPG)

Lurgi developed the MPG technology shown in Fig. 18 based on its fixed-bed gasification process. It is an oxygen-blown, down-fired, refractory-lined gasifier good for a wide range of feedstocks including petroleum coke (petcoke) and coal slurries as well as waste. It operates in a quench configuration for coal/petcoke feedstocks. Lurgi demonstrated a "reference plant" at Schwarze Pumpe which has been in operation since 1968.

Lurgi Mark IV Gasifier

The Lurgi Mark IV gasifier is an extension of the original proven moving-bed Lurgi gasifier. As shown in Fig. 19, it has a dry feed system with lock hoppers to provide the pressure seal. It is an oxygen-blown, dry bottom gasifier. There is extensive experience worldwide with low-rank coals. There are eight plants operating worldwide including one in North Dakota producing 18,600 MW_{th} syngas in 14 gasifiers. The plant has two trains of seven gasifiers each. It was originally designed to have one unit as a spare in each train. Operating all seven gasifiers has improved the plant's economic performance.

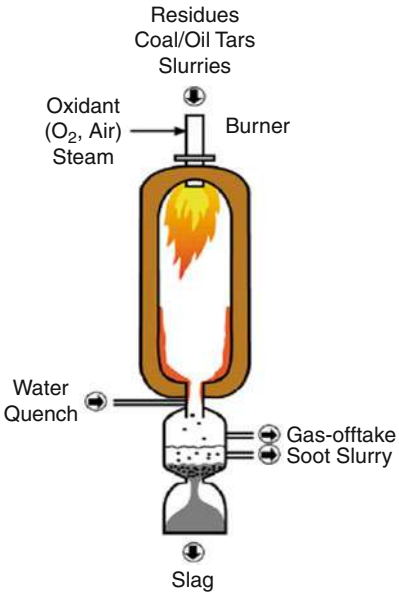

Fig. 18 Lurgi multipurpose gasifier (U.S. Department of Energy 2009)

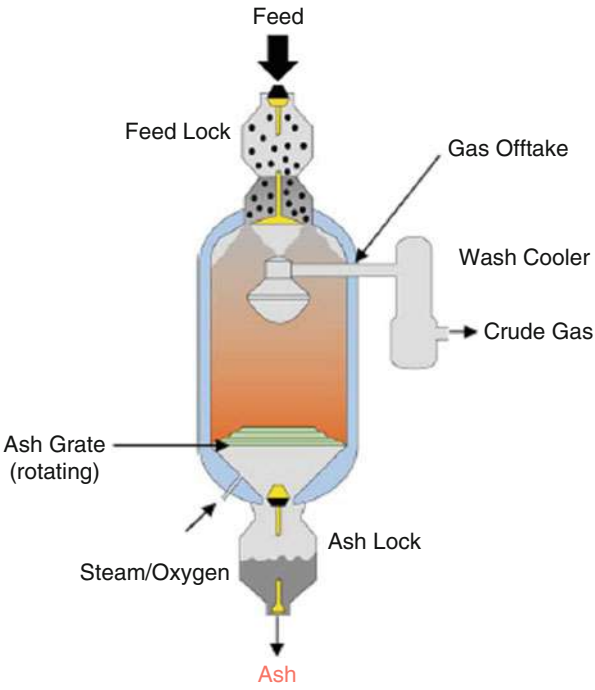

Fig. 19 Lurgi Mark IV gasifier (U.S. Department of Energy 2009)

Plasma Gasification

Plasma gasification is an electrically heated gasifier utilizing a plasma, generated by passing air through electric arcs in plasma torches, to create a very high-temperature (~5,000 °C) gasification environment. Figure 20 depicts an example, Westinghouse Plasma Corporation's plasma gasifier (Summary of Qualifications and Westinghouse Plasma Gasification Technology 2013). Feedstock (coal, biomass, solid water, etc.) is added to the gasifier along with air or oxygen, which descends through the vessel essentially in a moving-bed configuration, reaching an injected plasma zone. The extremely high temperatures and relatively long residence time allow complete conversion of the feedstock, even otherwise difficult to convert materials such as high-moisture biomass feedstocks and sludge, and municipal and industrial wastes containing high amounts of inerts such as glass and metal. The high operation temperatures produce syngas devoid of tars and hydrocarbons and convert inerts into slag, similar to the results of entrained-flow gasifiers. Furthermore, this is accomplished without the strict requirements on feedstock preparation and quality associated with entrained-flow gasifiers.

Many commercial instances of plasma gasification involve destruction of hazardous wastes. Unlike conventional incineration, hazardous constituents are completely converted in the extreme gasification conditions, making this an effective option for these and other more difficult to manage municipal, commercial, industrial, and medical wastes. Plasma gasification's great versatility to handle almost any type of carbonaceous feedstock with little or no pretreatment is

Fig. 20 Westinghouse plasma corporation gasifier (Summary of Qualifications and Westinghouse Plasma Gasification Technology 2013)

considered its main advantage. On the other hand, plasma gasifiers have high operating costs (due to electricity use) and initial capital investment. Also, these gasifiers are operated at ambient or slightly negative pressure, which may be considered a limitation in some process contexts.

Fluidized-Bed Gasifiers

Figure 21 represents a typical configuration of a fluidized-bed gasifier. Operating in the fluidized-bed mode, these reactors are very well mixed. All processes take place simultaneously throughout the bed. Lime, limestone, or dolomite can be added for in-bed sulfur removal. The requirement to capture sulfur can limit the maximum temperature in these gasifiers to about 1273 K or less which also keeps the ash from slagging. Gasification kinetics determines bed volume and the fluidization velocity determines cross-sectional area such that the bed height is fixed. Tar is cracked in freeboard. The Gas Technology Institute's (GTI's) U-GAS® process and Winkler gasifier are examples of fluidized-bed gasifiers.

Hydrodynamically, fluidized beds are more complicated than fixed-bed reactors where bubbles of excess gas induce and promote mixing as shown in Fig. 22. The better mixing of gas and solids leads to better interphase transport and better

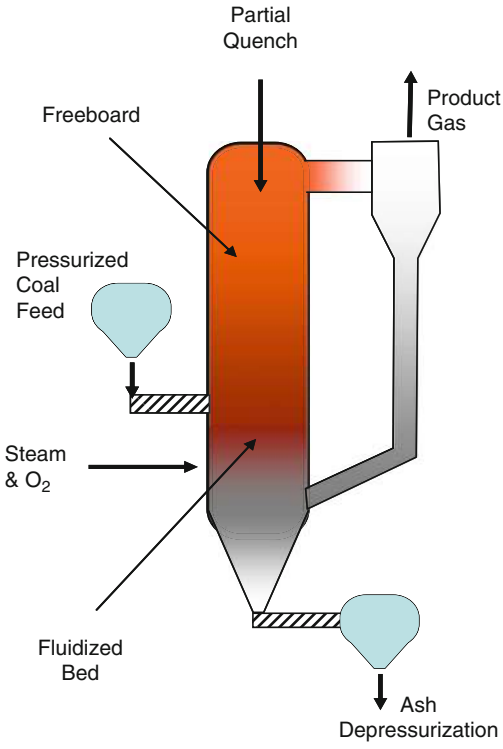

Fig. 21 Fluidized-bed gasifier concept

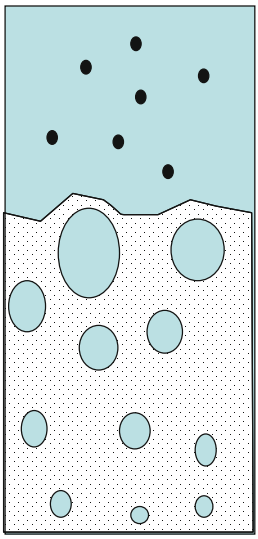

Fig. 22 Bubbling fluidized-bed hydrodynamics showing bubbles rising through denser emulsion phase and splashing particles and cluster in the freeboard

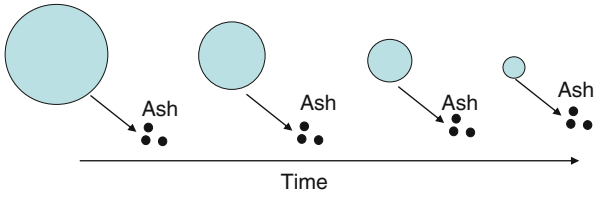

Fig. 23 Particle time history in fluidized bed depicting the reduction in size of a coal particle and release of ash due to mixing as conversion proceeds with time

conversion of the coal. In addition, the mechanical movement of the solids against each other essentially scrubs the ash from particles. Fluidized-bed gasifiers have been conceived with indirect heating due to the high heat transfer rates with heat exchange surfaces; however, the most successful processes have been directly heated. The reactors' performance approaches that of a continuous stirred process.

Kinetically, because of the scrubbing of the reacted layer, the burnout or conversion follows a shrinking particle as pictured in Fig. 23. The conversion time can be calculated from the equation

$$\tau = \frac{2\rho_B R}{kC_{O_2}}$$

where τ is the time for complete conversion, ρ_B is the cal particle density, 2 is 1/stoichiometric coefficient for O_2, R is the particle radius, k is the combined kinetic and mass transfer rate constant, and C is the concentration of O_2 (Levenspiel 1998).

Table 13 Gas composition for oxygen-blown fluidized-bed gasifiers (Lowry 1963; Elliot 1981; Stultz 1992; Huang et al. 2003)

Coal type	Lig	Bit

These units have moderate cold gas efficiencies and they accept a broad range of coals. Typical gas compositions are presented in Table 13 for oxygen-blown gasification in a fluidized bed when using lignite and bituminous coal. Table 14 presents air-blown gas composition data for the same coal types.

Examples of Fluidized-Bed Gasifiers

U-GAS®

The U-GAS(® process is a fluidized-bed gasifier incorporating a dry feed system as shown in Fig. 24. It can operate on all coals and coal/biomass blends. It is highly efficient in either the air- or oxygen-blown configuration producing a non-slagging/bottom ash. There is presently a 30-year license agreement with Synthesis Energy Systems (SES) in place. There is 20+ years of experience including plants in Shanghai, Finland, and Hawaii. Two plants are presently in operation producing 520 MW_{th} syngas.

High-Temperature Winkler Gasifier

The high-temperature Winkler gasifier, shown in Fig. 25, is a fluidized-bed gasifier utilizing a dry feed and operating either in the oxygen- or air-blown modes. It produces a dry bottom ash. It was developed to utilize lignite coal but is capable of efficiently gasifying a broad range of feedstocks. The R&D is complete and has been marketed for waste materials as the Uhde PreCon process. A demonstration

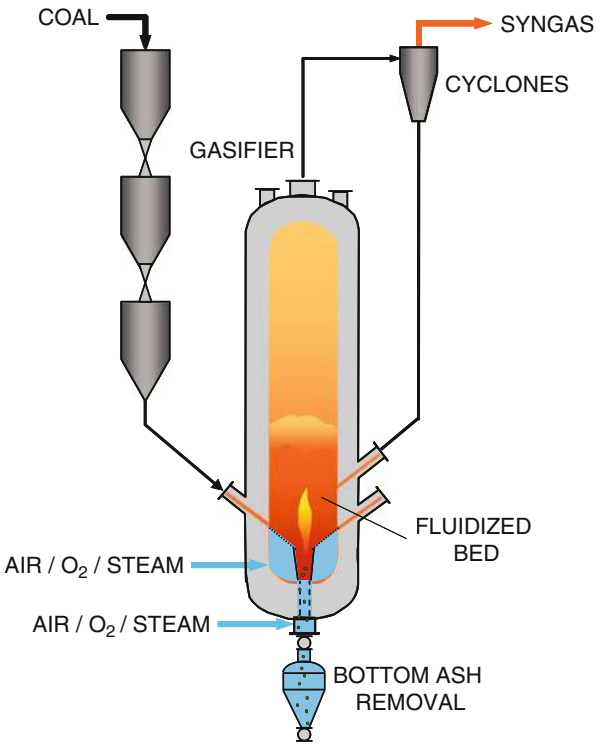

Fig. 24 U-GAS process (U.S. Department of Energy 2009)

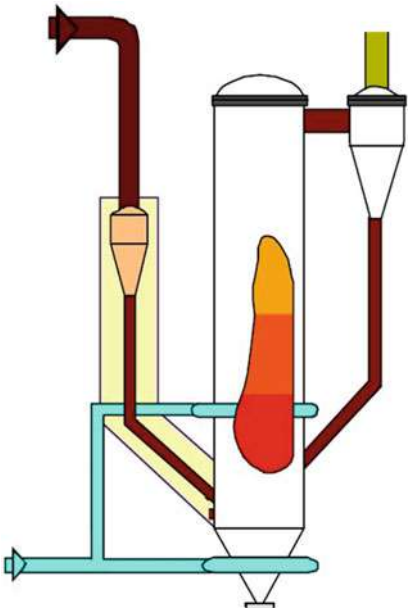

Fig. 25 High-temperature Winkler gasifier (U.S. Department of Energy 2009)

plant shut down in 1997. It under went 20 years of testing for 67,000 operating hours gasifying 1.6 million metric tons dry lignite to produce 800,000 metric tons methanol.

Entrained-Flow Gasifiers

There are seven entrained-flow gasifiers in the marketplace at this time. These are the ConocoPhillips E-Gas, GE (formerly Texaco), Shell, PRENFLO™, MHI, Siemens, and MPG gasifiers. A general sketch of these units is depicted in Fig. 26. In these gasifiers, widely dispersed very fine particles are radiantly heated to high temperature for slagging and rapid gasification. Some of the issues are obtaining uniform feed, slurry drying, and separation of gas production from the heat recovery. The volume is determined from conversion time for average particle. These units have a relatively low cold gas efficiency and high O_2 demand.

Hydrodynamically, entrained-flow gasifiers are quite simple with respect to the conversion of the coal particle and the reacting gas. They operate in a cocurrent manner with the solids and gas moving either in upflow or downflow as shown in Fig. 27 and are characterized as plug flow processes. The solid concentrations are less than 2 or 3 % by volume and they spend less than 10 s in the reactor. Nonuniform flow can occur which can lead to poor bulk mixing, unreacted carbon, and hot spots.

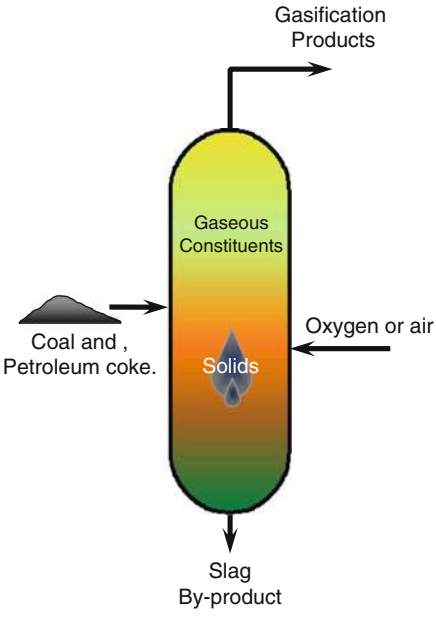

Fig. 26 Typical entrained-flow gasifier (U.S. Department of Energy 2009)

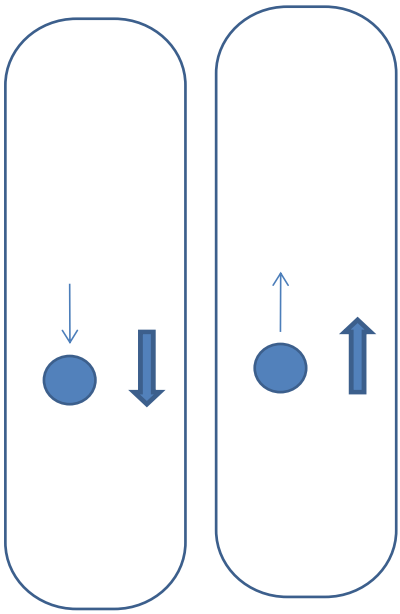

Fig. 27 Hydrodynamics for entrained-flow gasifiers showing coflow and countercurrent configurations

The conversion of a coal particle in an entrained-flow gasifier is shown in Fig. 28. The kinetic model to predict the burnout or total conversion of a coal particle in an entrained-flow gasifier is

$$\tau = \frac{2\rho_B R}{3k_g C_{O_2}}$$

where τ is the time for complete conversion, ρ_B is the coal particle density, 2 is the reciprocal of the stoichiometric coefficient for O_2, k_g is the mass transfer rate constant, and C is the concentration of O_2 (Levenspiel 1998).

These gasifiers can burn a fairly wide range of fuels when operated with a dry feed but are more limited when firing the fuel as a slurry since a large amount of energy is required to vaporize the water in the slurry. Typical gas compositions for these gasifiers are presented in Table 15.

The majority of particles flow from an entrained gasifier as slag; however, some portion remains airborne within the syngas and flows into the syngas coolers. Most large particulate material ends up in the quench chamber, where it is broken into small particulates and periodically removed from the gasifier. It is worth noting that the portion of the particulate remaining airborne during gasification flows with the raw syngas, where it can build up on the radiant or convective syngas cooler surfaces, solidifying on cooling surfaces and leading to a condition called fouling. Two types of entrained-flow slagging gasifiers using air-cooled sidewalls and syngas coolers are shown below in Figs. 31 and 32. Fouling from gasifier solid by-products in the radiant and convective syngas coolers caused by carbon

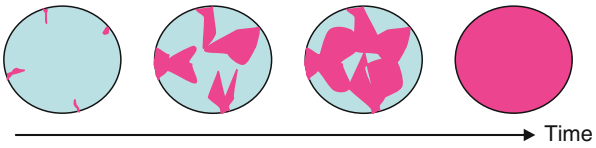

Fig. 28 Bulk diffusion-controlled conversion in entrained-flow gasifiers in which oxidant (*red*) penetrates through macropores and diffuses through the solid or coal matrix (*blue*)

Table 15 Typical gas composition for entrained-flow gasifiers (Stultz 1992; Huang et al. 2003)

Oxygen blown				
Gasifier	Dry entrained			Slurry entrained
Coal type	Brown/lignite	Subbit	Bit	Bit
Pressure, atm	30	30	25–30	42
Gas composition (dry)				
CO	62.01	64.48	61.53–64.97	49.46
CO_2	6.88	1.33	0.81–1.63	12.30
H_2	30.42	33.37	30.61–32.08	35.95
N_2	0.34	0.51	0.51–4.80	0.97
CH_4	0.00	0.00	0.00–0.00	0.36
H_2S	0.23	0.31	1.33–1.42	1.33

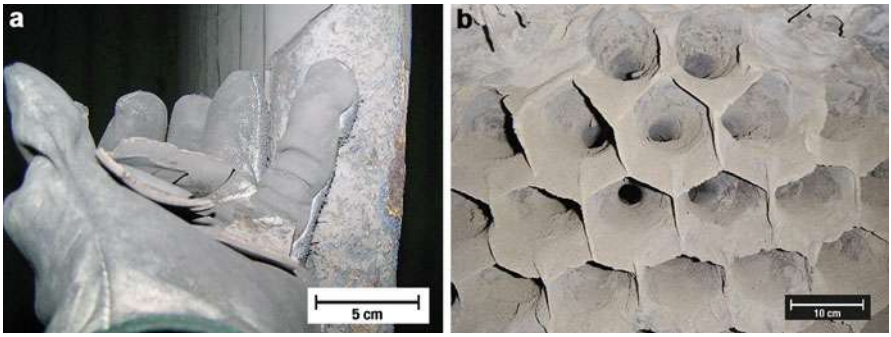

Fig. 29 Examples of fouling buildup caused by molten ash/slag and carbon char in the radiant (**a**) and convective (**b**) syngas coolers

feedstock in these types of convective coolers is shown in Fig. 29. Waste solid by-products for the most part do not remain airborne, instead flowing as slag or dropping from the syngas stream as large particles that are collected in the quench chamber where they are granulated and periodically removed from the gasifier. The appearance of that granulated waste is shown in Fig. 30 and is a mixture of ash, slag, and unburned carbon (called char).

There are two general types of entrained-bed gasifiers: those used in air-cooled systems (GE gasifier and CB&I design) and those using water cooling screen

Fig. 30 Solid waste (mixture of ash, slag, and carbon char) removed from an entrained-flow slagging gasifier during operation

designs (Shell, Siemens, MHI, and PRENFLO). Differences exist in each of the gasifier designs, but in general, those that are air cooled are slightly more efficient (Vassilev et al. 2002) than the water cooling screen designs. The refractory liners in air-cooled gasifiers are typically sintered brick that are high in oxides of chrome and aluminum and, depending on how the gasifier is operated, last from about 6–36 months, although in some gasifier types with newer materials such as those containing phosphates, the service life could be longer. Slagging gasifiers designed around cooling screens depend on the high conductivity of the refractory lining to limit refractory wear and maximize refractory service life, which can be 8 years or more. Lining material could be castable or plastic ram mixtures of SiC particles and alumina, which with water cooling on one side, would cause slag to solidify on the refractory surface, protecting it from corrosive wear. Linings of this type can operate 8 years or more before a lining needs replacement unless the refractory material separates from the cooling coils or the studs holding the refractory break, causing refractory material to rapidly fail.

Examples of Entrained-Bed Gasifiers

GE Energy

The GE Energy gasifier shown in Fig. 31 was initially developed by Texaco which became the Chevron-Texaco gasifier upon the merger of those two companies which eventually sold the technology to GE. The technology is a coal-water slurry-fed, oxygen-blown, entrained-flow, refractory-lined slagging gasifier. Two versions of the gasifier have been offered: gasifier with radiant cooler and a full-quench gasifier with the latter taking precedence currently. The gasifier is good for bituminous coal, petcoke (petroleum-derived coke), or blends of petcoke/low-rank coals. Commercially, GE Energy provides gasification technology in an EPC

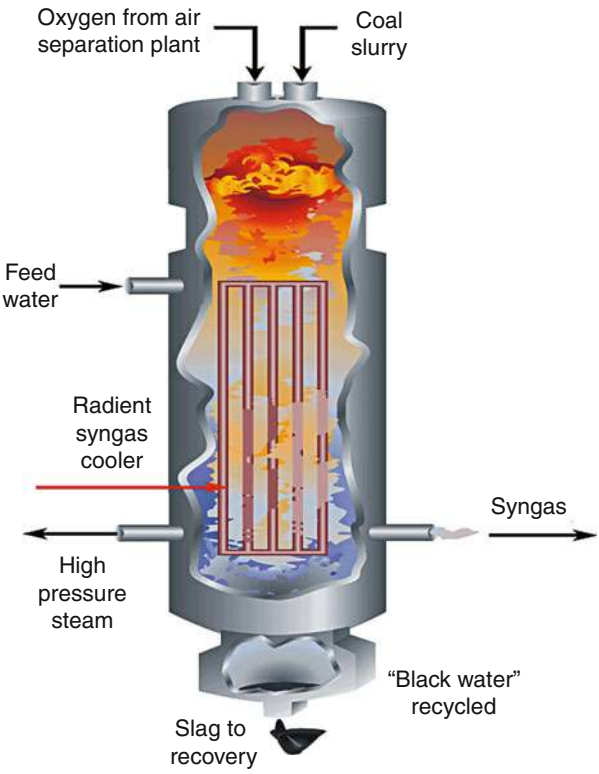

Fig. 31 GE Energy gasifier (U.S. Department of Energy 2009)

(engineer-procure-construct) alliance with Bechtel for guarantees on total IGCC plant. Presently, there are 64 plants operating, producing more than 15,000 MW_{th} syngas. There are six plants in the planning phases.

ConocoPhillips E-Gas

The ConocoPhillips E-Gas gasifier shown in Fig. 32 was originally developed by DOW Chemicals and demonstrated at the Louisiana Gasification Technology Inc. (LGTI) from 1987 through 1995. It is a two-stage gasifier with 80 % of feed to first stage (lower). The gasifier is coal-water slurry-fed, oxygen-blown, refractory-lined gasifier with continuous slag removal system and dry particulate removal. The E-Gas process is good for a wide range of coals, from petcoke to Powder River Basin (PRB) subbituminous coal to bituminous coal and blends. Commercially, ConocoPhillips provides gasification technology and process guarantee. Project-specific EPC and combined cycle supplier alliances provide balance of plant components and guarantees. There is one 590 MW_{th} syngas plant operating and six plants in planning.

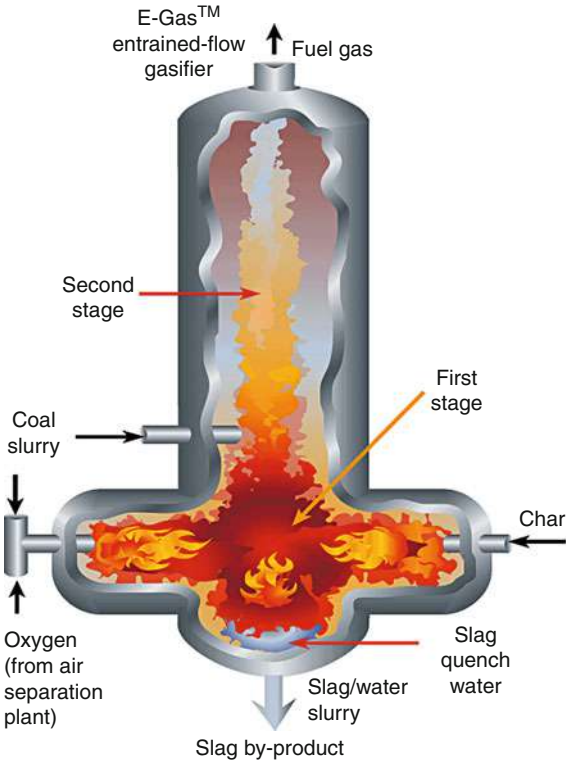

Fig. 32 CB&I ConocoPhillips E-Gas (U.S. Department of Energy 2009)

Shell

The Shell gasifier has its roots dating back to 1956 leading to their first demonstration facility in 1974 (Mark et al. 2009). In the Shell gasification process, coal is crushed and dried and then fed into the Shell gasifier as a dry feed. The gasifier, as shown in Fig. 33, is an oxygen-blown, waterwall gasifier eliminating refractory durability issues. It is good for a wide variety of feedstocks, from petcoke to low-rank coals, and has been run on biomass as well. Commercially, Shell provides the gasification technology and has alliances with both Black & Veatch and Uhde to provide the EPC. There are 26 plants operating producing 8,500 MW_{th} syngas. There are 24 plants in planning.

Siemens

The Siemens gasifier was initially developed in 1975 for low-rank coals and waste by Deutsches Brennstoffinstitut in Freiberg, Germany, and was first demonstrated at Schwarze Pumpe in 1984 at a thermal rating of 200 MW (Higman and van der Burgt 2008). The technology was marketed under the name GPS by the Noell Group and later under the name Future Energy until purchased by Siemens in 2006. The gasifier, as shown in Fig. 34, is a dry feed, oxygen-blown, top-fired reactor with a waterwall screen in the gasifier. It is good for a wide variety of feedstocks, from

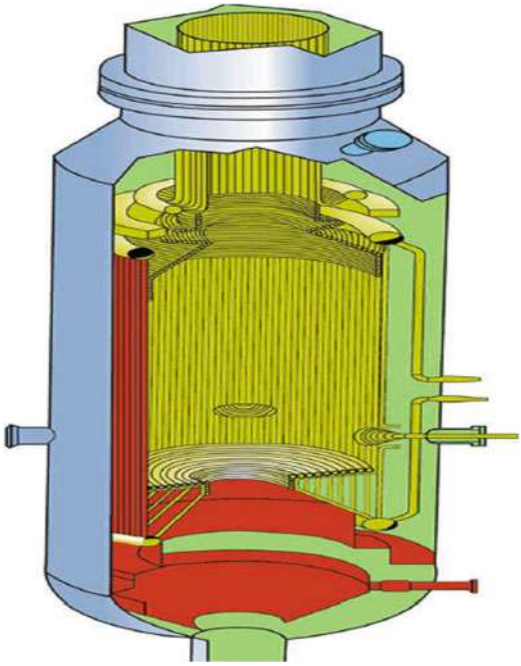

Fig. 33 Shell gasifier (U.S. Department of Energy 2009)

bituminous to low-rank coals. Siemens provides the gasification island and power block. They recently were awarded $39 million contract for two gasifiers 500 MW each for China's Shenhua DME (dimethyl ether) Project. Presently, there is one plant operating producing 787 MW_{th} syngas and they have one plant in planning.

MHI Gasifier

The Mitsubishi Heavy Industries (MHI) gasifier is based upon the Combustion Engineering air-blown slagging gasifier and codeveloped between Combustion Engineering (and its subsequent owners) and MHI. As shown in Fig. 35, it has a dry feed system, suitable for low-rank coals having high moisture contents. It is an air-blown two-stage entrained-bed slagging gasifier utilizing membrane waterwall construction. There is one demonstration plant in operation producing 250 MW_e and located in Nakoso, Japan. It started operations in September of 2007.

PRENFLO™ Gasifier/Boiler (PSG)

The PRENFLO™ gasifier/boiler is a pressurized entrained-flow gasifier with steam generation being marketed by Uhde. As shown in Fig. 36, it is an oxygen-blown, dry feed, membrane wall gasifier that is able to gasify a wide variety of solid fuels including hard coal, lignite, anthracite, refinery residues, etc. A demonstration plant in Fürstenhausen, Germany, gasified 48 t/day. The technology is used in the world's largest solid-feedstock-based IGCC plant in Puertollano, Spain.

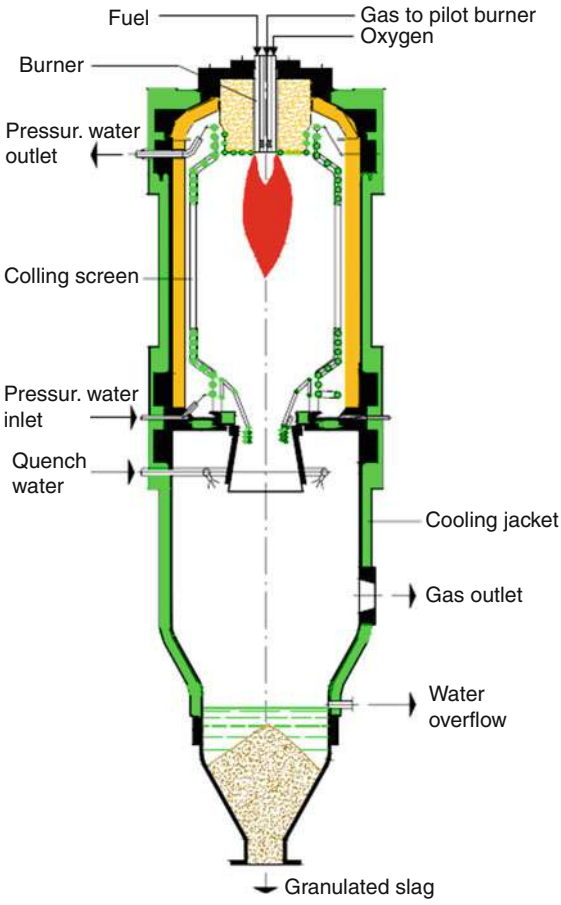

Fig. 34 Siemens gasifier (U.S. Department of Energy 2009)

Transport Gasifier

Kellogg, Brown, and Root (KBR) has developed the transport gasifier at the Department of Energy's (DOE's) Power Systems Development Facility at Southern Company Services, Wilsonville, Alabama, plant (Ariyapadi et al. 2008). The transport gasifier (Fig. 37) is based upon the hydrodynamic flow field that exists in KBR's catalytic cracking technology. It has excellent gas-solid contact and very low mass transfer resistance between gas and solids. It has a highly turbulent atmosphere that allows for high coal throughput and high heat release rates at a low temperature that avoids problems with slag handling and liner erosion.

Hydrodynamically, transport reactors are circulating fluidized beds which have more complicated hydrodynamics than fixed-bed reactors or bubbling fluidized beds have. In this type of reactor both excess gas and excess solids are fed to the reactor where the high gas velocity carries the solids upward. The excess solids tend to form clusters which act like large particles and fall back into the lower riser

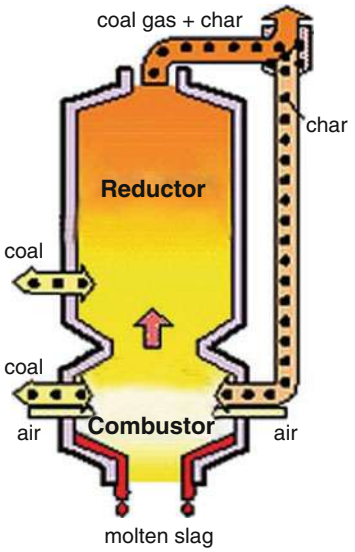

Fig. 35 MHI gasifier (U.S. Department of Energy 2009)

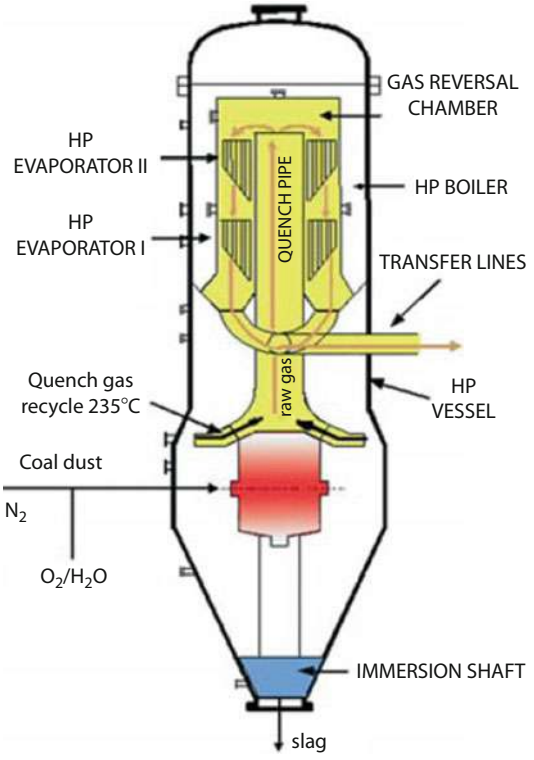

Fig. 36 PRENFLO™ (U.S. Department of Energy 2009)

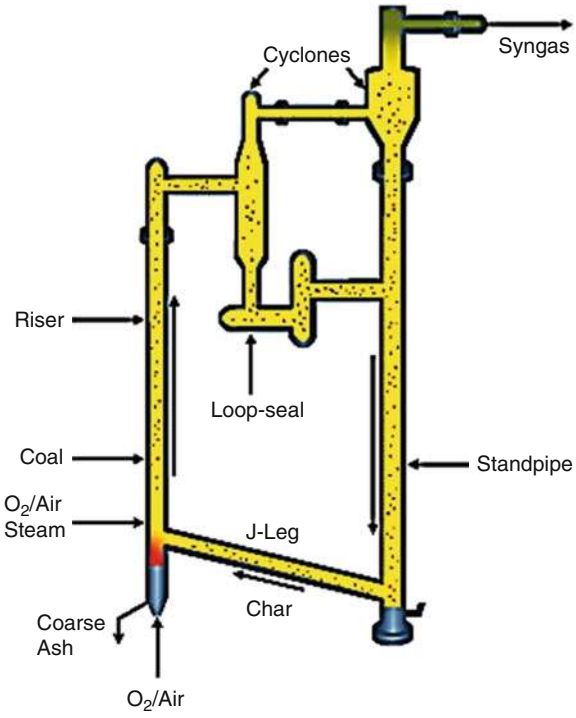

Fig. 37 KBR transport gasifier. The gas-solid separators include dual cyclones with nonmechanical valves designed to transfer solids but provide resistance to gas flows

where they break up and start to rise again. The results of an Eulerian-Eulerian simulation of the process is presented in Fig. 38 where the deep blue is a gas void and the yellow and red areas are clusters moving down while the other solids are moving up. These reactors have better mixing of gas and solids which leads to better interphase transport and better conversion of the coal. In addition, the mechanical movement of the solids against each other essentially scrubs the ash from particles.

Kinetically, because of the scrubbing of the reacted layer, the burnout or conversion follows a shrinking particle as pictured in Fig. 23. The conversion time can be calculated from the equation

$$\tau = \frac{2\rho_B R}{kC_{O_2}}$$

where τ is the time for complete conversion, ρ_B is the coal particle density, 2 is 1/stoichiometric coefficient for O_2, R is the particle radius, k is the combined kinetic and mass transfer rate constant, and C is the concentration of O_2 (Levenspiel 1998). These units have moderate cold gas efficiencies and they accept a broad range of

CH_4	2.6	4.8	1.6	2.9	2.0	3.9

coals. Typical gas compositions for thee different coals from the experimental facility are presented in Table 16.

KBR Transport Gasifier

The KBR transport gasifier operates in either oxygen- or air-blown configurations. For power generation it is operated air blown, but it can be fired using oxygen for liquid fuels and chemicals. It has a high reliability design based on years of designing and building FCC (fluidized catalytic cracking) units for the petroleum industry. It is a non-slagging gasifier with no burners and utilizing a coarse, dry low-rank coal feed. Presently, there is a 560 MW_e IGCC with a 2 × 1 combined cycle to be owned by the Mississippi Power Company in Kemper County, MS, in design.

Carbon Capture Technologies

Conventional Acid Gas Control Technologies

Acid gas control technologies remove the sulfur and CO_2 from the syngas. There are a number of commercial technologies that can be classified as physical sorbents, chemical sorbents, and single-species processes. Physical sorbent processes are known by their commercial names: Rectisol™, Selexol™, Purisol™, and Morphysorb™. Chemical sorbents are represented by MDEA (methyldiethanolamine) and other amines. There are two commercial single-species processes: CrystaSulf™ for sulfur control and Fluor Solvent™ for CO_2 control. A general schematic of an IGCC power plant with a desulfurization-decarbonization process is shown in Fig. 39 (Carbon Capture Technology Research and Breakthrough Concepts). This particular configuration is the preferred configuration when using one of the physical sorbents like Selexol™ as shown and a sour shift. The advanced warm desulfurization technologies being developed by DOE are more efficient, use a sweet-shift process, and then finally remove the CO_2. There are many configurations that can be assembled to achieve a site-specific optimum design.

The plant configuration in Fig. 39 utilizes an oxygen stream of 95 % purity produced from a cryogenic air separation unit (ASU), no air extraction from the syngas combustion turbine. It produces 122.5 Atm., 537 K superheated steam with a single 535 K reheat. The CO_2 is captured at high pressure from a relatively low syngas volume and produces CO_2 at high pressure which is then boosted to 15,200 kN/m^2 for sequestration.

Physical Sorbent Processes

The physical sorbent processes are known by their commercial names: Rectisol™, Selexol™, Purisol™, and Morphysorb™. These systems operate at low temperature with Rectisol™ operating at −40 °C. As one would expect, there is a large heat penalty paid for using these processes, but the level of purity achievable warrants and pays for that expense – particularly when producing high-value chemicals.

Rectisol™

The Rectisol™ is a physical acid gas removal process using an organic solvent (methanol) at subzero temperatures, nominally −40 °C. It can purify synthesis gas down to very low total sulfur and CO_2 levels. The main advantages of the process are the rather low utility consumption figures for regeneration as compared to the chemical sorbents, the use of a cheap and easily available solvent, and the flexibility in process configurations. With regard to performance, the Rectisol™ process is capable of achieving total sulfur (H_2S + COS) in the 0.1–1 ppm range and CO_2 levels in the 10–50 ppm range and limits the H_2S in CO_2 by-product to levels on the order of 5 ppm. Further detail can be found in review articles (RECTISOL® Wash; Hochges 1970; Newman 1985; Burr and Lyddon 2008; Acid Gas Removal and Sulfur Recovery).

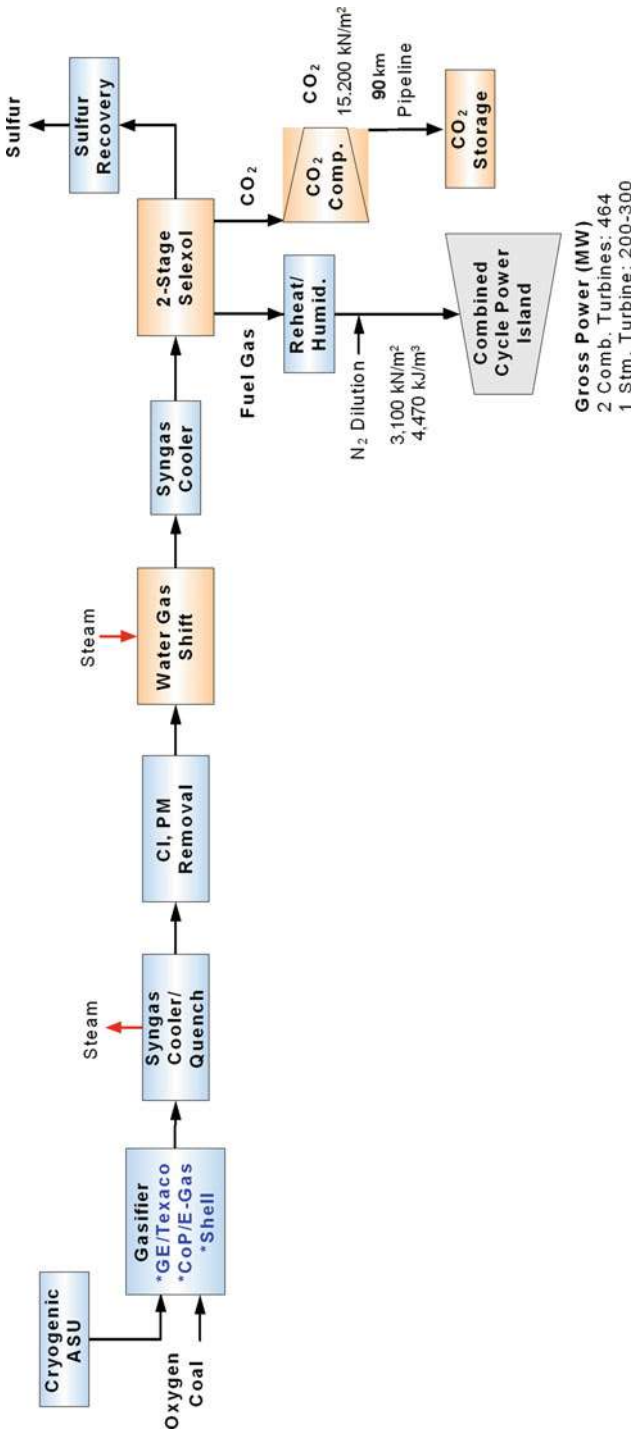

Fig. 39 Precombustion current technology IGCC power plant with CO_2 scrubbing (Adapted from Smith 2007)

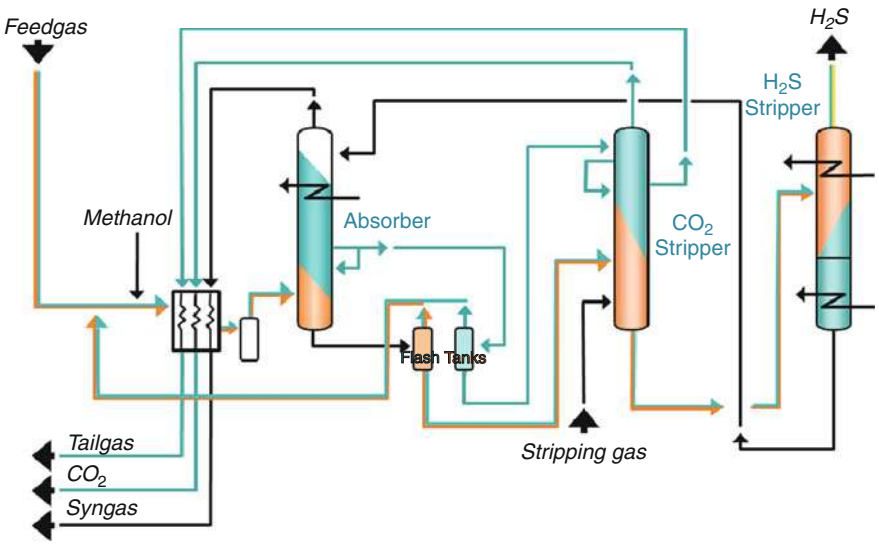

Fig. 40 Basic flow diagram/process scheme for Rectisol™ (Adapted from Carbon Capture Technology Research and Breakthrough Concepts)

The simple process flow diagram is displayed in Fig. 40. The syngas is mixed with methanol and enters the absorber column where H_2S, COS, and CO_2 are absorbed. The pure or cleaned syngas leaves the top of the column where it passes through a heat exchanger to cool the incoming syngas and methanol mixture. The CO_2 and sulfur compounds are removed in separate fractions as the solvent flows through a two-stage stripper. A pure CO_2 product is recovered from the top of the first stripper after passing through a heat exchanger to help cool the incoming syngas and methanol mixture. An H_2S/COS enriched Claus gas fraction is recovered from the top of the second stripper and passes through a heat exchanger to help cool the incoming syngas and methanol mixture.

CO_2 capture with Rectisol™ scrubbing is based on low temperature (refrigerated methanol ~ -40 °F or C) which is capable of deep total sulfur removal as well as CO_2 removal. It is the most expensive AGR process giving the deepest cleaning. It is predominantly used in chemical synthesis gas applications where total sulfur requirements are less than 0.1 ppmv. It has been proposed for use in IGCC for CO_2 removal but no published cost studies presently exist.

Selexol™

The Selexol™ process uses a physical solvent to remove acid gas from streams of synthetic or natural gas. The process may be regenerated either thermally, by flashing, or by stripping gas. The Selexol™ process is ideally suited for the selective removal of H_2S and other sulfur compounds or for the bulk removal of CO_2. The Selexol™ process uses Union Carbide's Selexol™ solvent, a physical solvent made of a dimethyl ether of polyethylene glycol (DPG or DEPG or

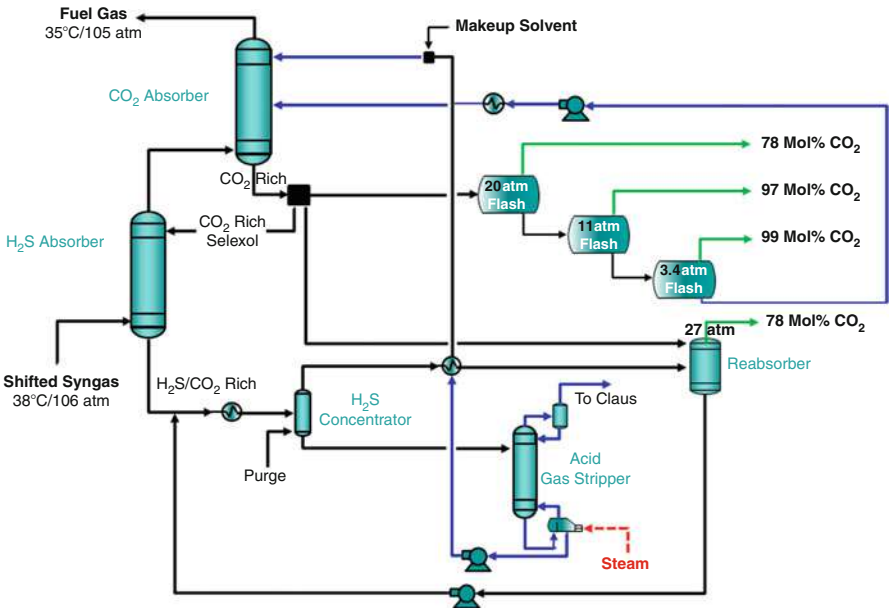

Fig. 41 Selexol™ process flow chart (Adapted from Acid Gas Removal and Sulfur Recovery)

DMPEG). The Selexol™ solvent is chemically inert and is not subject to degradation. The Selexol™ process also removes COS, mercaptans, ammonia, HCN, and metal carbonyls. This process allows for construction of mostly carbon steel due to its nonaqueous nature and inert chemical characteristics (Hochges 1970; Newman 1985; SELEXOLTM PROCESS; SELEXOL™solvent; 2009).

The Selexol™ process can be tailored for either bulk or trace acid gas removal. Because of the staged separation of acid gases (Fig. 41), Selexol™ is primarily used in the following applications and markets:

1. Selective removal of H_2S and COS in integrated gasification combined cycle (IGCC), with high CO_2 rejection to product gas (85 % +) and high sulfur (25–80 %) feed to the Claus unit
2. Selective removal of H_2S/COS plus bulk removal of CO_2 in gasification for high-purity H_2 generation for refinery or fertilizer use
3. Treatment of natural gas to achieve either LNG or pipeline specification with dew-point reduction

The Selexol™ process was introduced over 30 years ago. It has been and continues to be the dominant acid gas removal system selection in gasification project awards within the past several years.

A process flow diagram for a Selexol process for a gasification plant to remove CO_2 is shown in Fig. 42. It has two absorber tower stages. The first stage is for removing H_2S and the second is for removing the CO_2. The H_2S is separated from

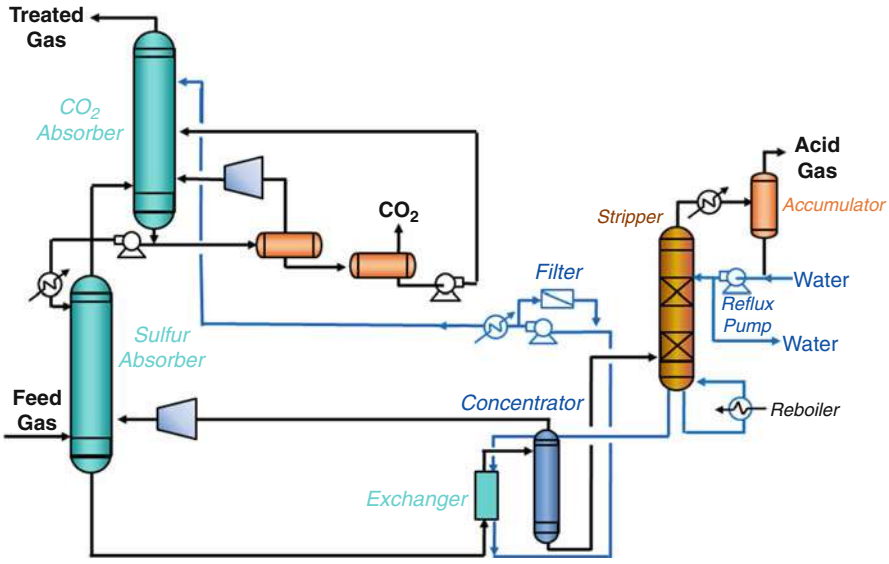

Fig. 42 Selexol™ scrubbing for CO_2 capture (Adapted from SELEXOL™solvent)

the solvent in an acid gas stripper column, while the CO_2 is removed from the solvent in a series of flash drums.

Selexol™ has a number of beneficial properties. It is a physical liquid sorbent, capable of having high loadings at high CO_2 partial pressure levels. It is highly selective for H_2S and CO_2 such that there is no need for a separate sulfur capture system. A big advantage of Selexol™ and other physical sorbents is that there is no heat of reaction (ΔH_{rxn}) with only a small heat of solution. The Selexol™ sorbent is chemically and thermally stable and has a low vapor pressure – keeping losses to a minimum. There is 30+ years of commercial operating experience on 55 plants worldwide. Selexol™ does have a couple of disadvantages. Namely, it requires gas cooling to about 35 °C (~100 °F), and it requires considerable heat for CO_2 regeneration by flashing.

Purisol™

The Purisol™ process is a second acid gas removal process developed by Lurgi. It uses normal methyl pyrrolidone or NMP as the solvent. Its operating conditions and overall process configuration are similar to that of Selexol™; however, it is not as widely used. Additional information can be found elsewhere (RECTISOL® Wash; Hochges 1970).

Morphysorb™

Morphysorb™ is a proprietary solvent CO_2 removal process developed by GTI and owned by both GTI and Uhde. It uses *N*-formyl morpholine/*N*-acetyl morpholine mixtures (see Fig. 43). It can be used for both bulk or trace removal of acid gas

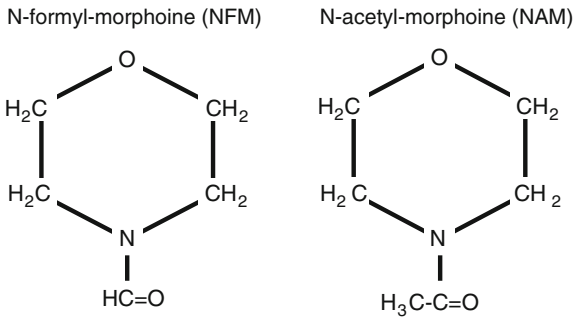

Fig. 43 Morphysorb™ chemicals

components in subquality natural gas upgrading to either pipeline or LNG specification, selective removal of H_2S from natural/synthesis gas for generation of acid gas stream suitable for Claus plant feed, and selective removal of H_2S, CO_2, COS, CS_2, mercaptans, and other components from coal/oil gasification syngas at IGCC facilities (Lippin; Kowalsky et al. 2003).

Morphysorb™ offers a number of benefits relative to chemical and some other physical sorbents. It has higher solvent loading which leads to either lower circulation or higher throughput. It has lower co-absorption of hydrocarbons which translates into fewer losses or, in other words, less recycle gas flow for recovery of these hydrocarbons. It has lower CO and H_2 absorption. It assists in the hydrolysis of COS. It is low in corrosivity and, thereby, low environmental hazard as well as low capital and operating costs.

There is one natural gas commercial application owned by Spectra Energy™ Transmission which was started in late 2002. It processes 450 MMscfd after a plant expansion of 50 %. The solubility of the mophysorb sorbent is presented in Fig. 44.

Chemical Sorbents

There are a number of chemical sorbents that have been used for acid gas control. All of these fall into the chemical category called amines. Primary, secondary, and tertiary amines have all been used (Fig. 45). Primary amines are monosubstituted ammonia like monoethanolamine (MEA). Secondary amines are bi-substituted ammonia like diethanolamine (DEA). Tertiary amines are trisubstituted ammonia like methyldiethanolamine (MDEA).

The process flow diagram for a typical amine-based process is shown in Fig. 46. The absorption of acid gases (H_2S, SO_2, CO_2) in amine solution is conducted with a two-column operation. The acid gas is absorbed in the first column. The second column is used to regenerate the amine. The process relies on countercurrent flow to achieve optimum mixing. A lean solution (low acid gas) enters the top of the absorber and flows to the bottom while acid gas enters the bottom of the absorber tower and bubbles to the top. The rich amine (high acid gas) liquid enters the stripper where the acid gases are released and the "clean" amine is returned to the absorber. The acid gases exit from the top of the stripper. The MEA/DEA/MDEA is

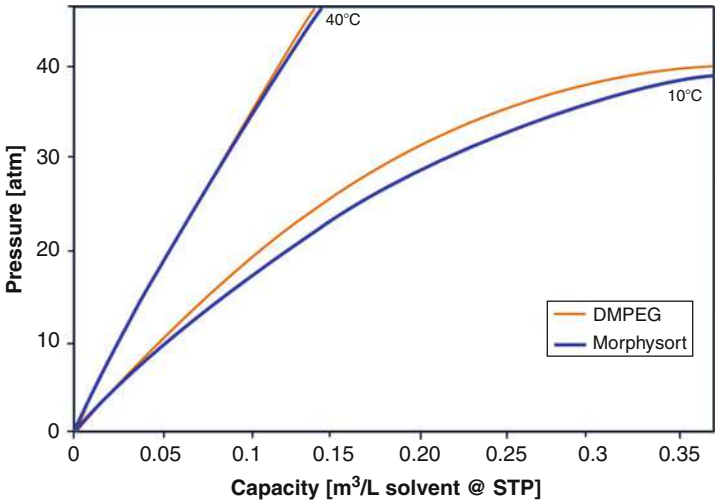

Fig. 44 Morphysorb™ CO_2 solubility (2009)

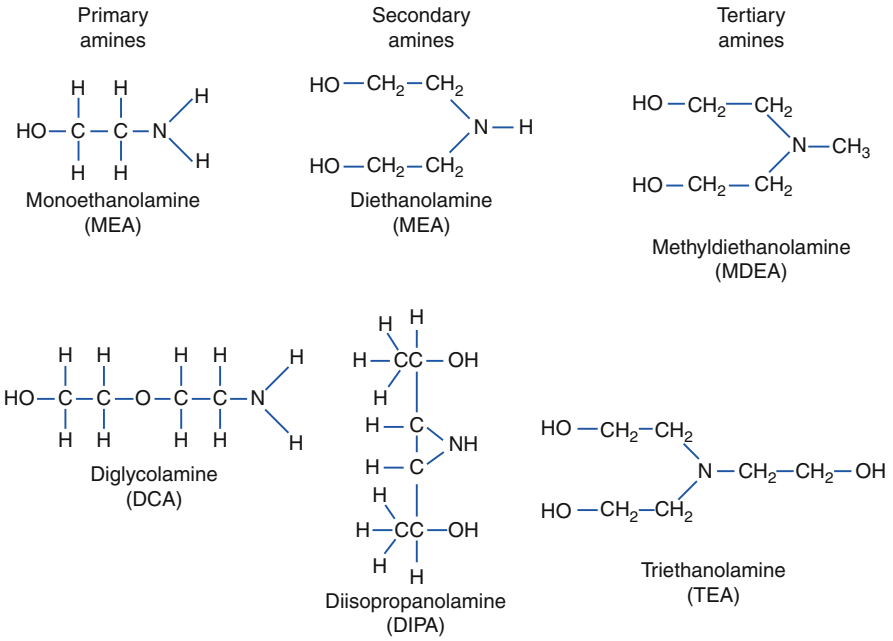

Fig. 45 Commonly used amine-based chemical sorbents

regenerated in the stripper column. It is beneficial to be sure the amine concentration is at proper level in order to optimize the H_2S, SO_2, and CO_2 removal. The final amine concentration can be controlled by the adding amine makeup. Additional information can be found online (Burr and Lyddon 2008).

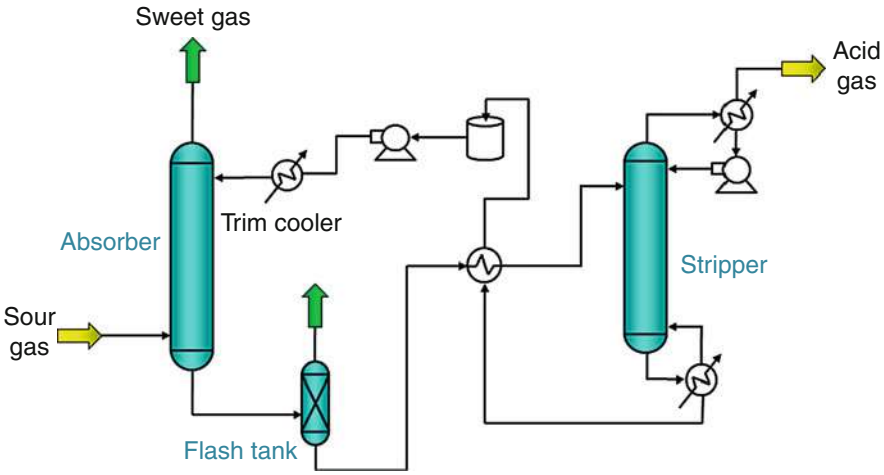

Fig. 46 Process flow diagram of a typical amine treating process used in industrial plants

Single-Species Processes

CrystaSulf™: Sulfur Control

The CrystaSulf™ process for direct treatment of sour gas can be used for recovering sulfur from gas streams that contain as little as 0.2–25 LPD of sulfur which have historically been problematic. In this size range, the operating costs of throwaway H_2S scavenging chemicals are too high, and traditional amine/Claus approaches are unwieldy and capital intensive. Aqueous-iron redox systems showed promise in this range, but often proved unacceptable because of their operating problems. Therefore, the new breakthrough sulfur recovery technology, CrystaSulf™, can remove sulfur economically without the operating problems of aqueous-iron systems for plants of this size. Using a gentle SO_2 oxidant, CrystaSulf™ converts inlet H_2S to elemental sulfur. Elemental sulfur is soluble in the CrystaSulf™ solution; thus, there is no danger of sulfur plugging high-pressure equipment that plagues aqueous-iron systems. Meeting pipeline H_2S specifications is easy, and CO_2 has been shown to have no effect on the CrystaSulf™ process (Rueter et al. 2002).

The process has a number of advantages, particularly for these medium-scale systems. It has lower capital cost, lower overall treatment cost, and much lower maintenance and cleanout costs. It can directly treat high-pressure streams with a solid-free solution which is easy to pump and requires a very low circulation rate. The nonaqueous solvent has high solubility for elemental sulfur and therefore has no sulfur particles in circulating liquor and needs no sulfur settling additives or surfactants. It avoids problems of foaming and plugging associated with aqueous-iron redox system. It produces large sulfur particles in a crystallizer that separates and purifies easily, yielding a much higher sulfur purity product than possible with aqueous-iron redox systems. A process flow diagram for the process is shown in Fig. 47.

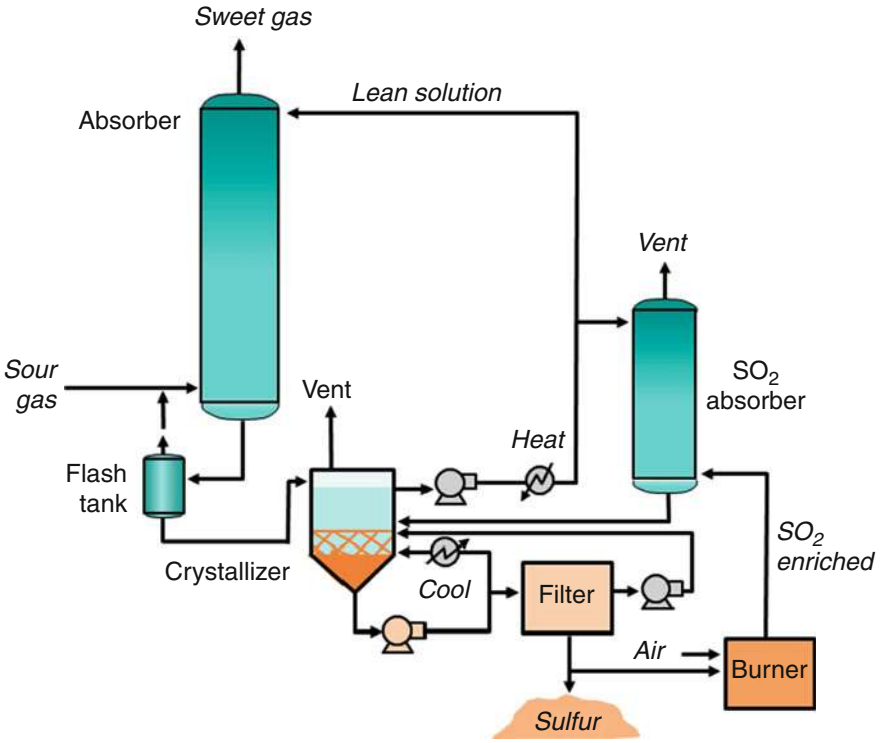

Fig. 47 Process flow diagram for CrystaSulf™ process

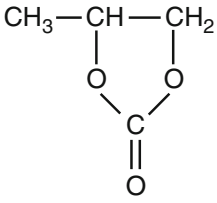
Fig. 48 Fluor solvent chemical structure



Fluor Solvent: CO_2 Control

The Fluor Solvent process has significant advantages over an amine treating process in an offshore environment when treating large gas volumes where the CO_2 partial pressure is high. The Fluor Solvent process configuration is much simpler. It requires no heat for solvent regeneration. It requires no makeup water. It produces a dry product gas. The solvent is minimally corrosive, resistant to foaming, and biodegradable. The chemical structure is shown in Fig. 48.

Figure 49 shows the configuration of the Fluor Solvent process for low to medium CO_2 content applications (Mak et al. 2003). The process consists of an absorber and two flash drums. A pressurized flash drum with low-, medium-, and

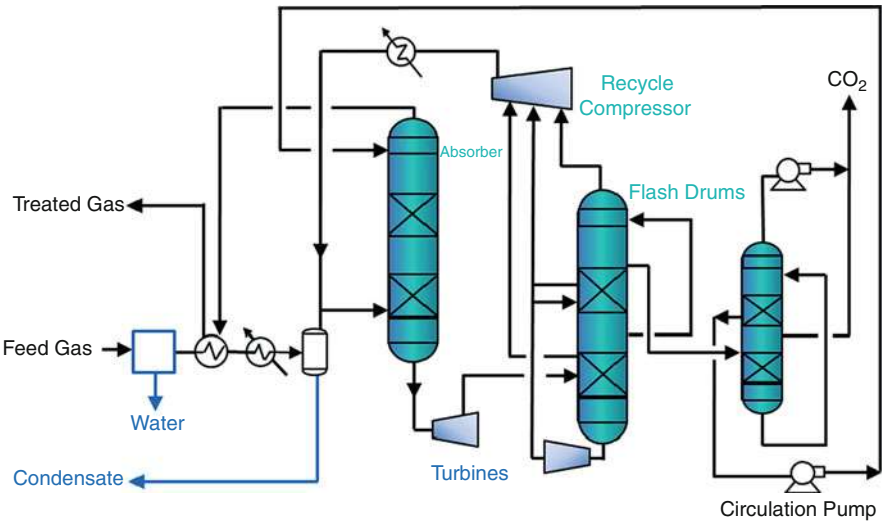


Fig. 49 Fluor Solvent process schematic (Adapted from Rueter et al. 2002)

high-pressure zones and a vacuum flash drum with zones at atmospheric pressure and at vacuum.

Future Directions in Research and Development

Recent Gasification Systems Studies

The use of advanced gasification power systems was identified as the most favorable coal alternative for reducing carbon dioxide emissions (Klara 2007). The cost of capturing 90 % of the carbon dioxide from a coal gasifier was compared with coal combustion in both conventional and new ultra-supercritical steam systems and natural gas-fired power systems. The capital, operating, and maintenance costs were evaluated for a green field 640 MW_e power plant based upon reasonable process design alternatives for each. Without carbon capture, both IGCC and pulverized coal (PC) combustion can achieve 39 % efficiency based upon the high heating value (HHV) for bituminous coals. Available commercial capture technology can remove 90 % of CO_2, but at significant increase in COE. The total IGCC plant cost was found to be ~20 % higher than PC, but with carbon capture and sequestration, the total for PC exceeded that of IGCC. With carbon capture and sequestration, IGCC was the lowest coal-based option (in 2007 dollars) (Klara 2007):

- Natural Gas Combined Cycle: 96 mills/kWh
- IGCC: 105 mills/kWh (average)
- PC: 116 mills/kWh (average)

where 1 mill is equal to 0.001 USD. This indicates that when considering the capital, operating, and maintenance costs and including carbon management systems, IGCC has a lower relative cost of producing electricity than PC power plants. The gas cleanup system is smaller for gasifiers because they have lower product fuel gas volume as compared to the flue gas from coal and natural gas combustors.

The carbon footprint for various coal gasification scenarios has been considered using a life cycle analysis (Reed 2007). Life cycle analysis considers the energy and costs required from cradle to grave including mining, mine reclamation, transportation, mineral preparation, processing, waste disposal, sequestration, and monitoring of the wastes. Coal biomass mixtures were considered in various power systems and compared against a baseline natural gas power system. Gasification with biomass coal co-firing was found to be able to match natural gas performance. It was found that a combination of gasification and biomass co-firing when used with shift cleanup and sequestration could dramatically reduce the carbon footprint relative to natural gas.

Gasification R&D

The US Department of Energy is involved in a wide range of research, development, and demonstration (RD&D) activities to improve the fuel and product versatility, process efficiency, and system. The challenge is to achieve widespread market penetration in the most large-scale markets including power generation, chemical processing, and gas and liquid synthesis. The program goals are to improve gasifier efficiency and process control; improve process train reliability, reducing downtime and expenses from redundant process components; and improve the flexibility of gasification processes to handle a wider variety of grades and types of feedstocks. Research is being funded on the capture and sequestration of carbon dioxide (CO_2). The DOE's Office of Fossil Energy conducts the Gasification Technologies Research and Development (R&D) Program. The focus of the Advanced Power Systems Program is on electricity production, and its intent is to foster public-private partnerships and provide technology to utilize the extensive US fossil fuel resource. Having collaborated with industry over the decades of the 1980s and 1990s to bring coal gasification to commercial-scale demonstration plants, the emphasis is now shifting to refining and expanding gasification potential to bring the technology to its potential as a near-zero-emission clean coal technology. The Gasification Technologies R&D Program consists of four distinct areas: (1) adaption of gasification technologies to a range of coal feedstock varieties, better control of gasifier performance and gas production, and improved overall efficiency; (2) cleanup of produced gases to meet increasingly stringent environmental standards; (3) better separation of product gases and oxygen from air to improve economics and efficiency and facilitate gas cleanup; and (4) identification of economic and infrastructure issues with various gasification applications (http www netl doe gov technologies coalpower gasification gasifipedia 8 research).

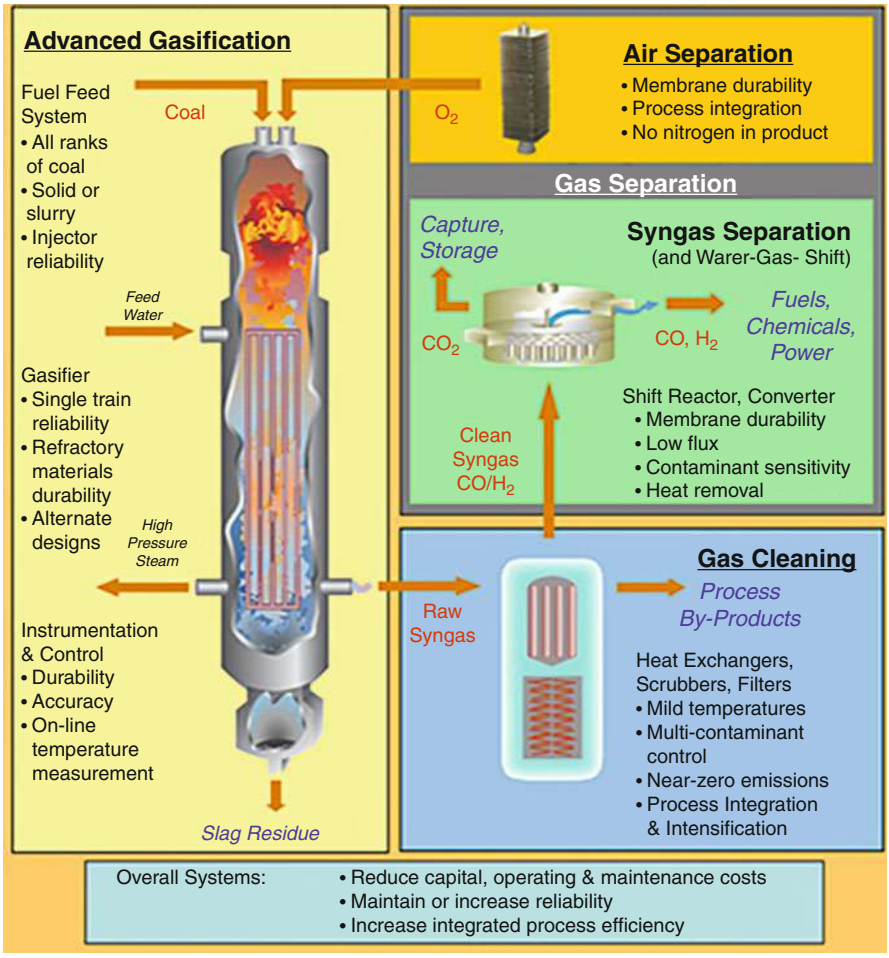

Fig. 50 Gasification research and development areas and major technology issues

The key issues identified in the US DOE's programs are listed in each of these research areas in Fig. 50. Gasifiers need to be able to be efficient operating on lower-grade fuel feedstocks including low rank, high mineral contents, and biomass. In order to be efficient in using these resources, utilities must be able to introduce these lower-quality fuels into gasifiers without using quantities of water in excess to what is required for rapid gasification. Otherwise, the large latent heat of water vaporization will increase the inefficiencies due to unrecoverable heat losses. The reliability of the solid fuel feed system has historically been the single most frequent cause for unplanned shutdown in coal-fired systems. The lack of reactor availability due to downstream fouling, refractory failures, and loss of the solid fuel feed systems is being addressed by research on fly-ash formation,

refractory durability, alternative gasifier concepts, as well as improved diagnostics, instrumentation, and control systems.

Gas Cleanup and CO_2 Capture Research

Gas cleaning systems research funded by the US DOE includes improving heat exchangers, scrubbers, and filter technologies. For example, researchers at the Power System Development Facility have demonstrated improvements in particulate filtration reliability and filter element durability and developed fail-safe devices to insure removal of particulate matter to protect downstream turbines and cleanup systems (Dahlin and Landham 2008; Guan et al. 2005). One research goal is to intensify and better integrate cleaning processes by taking steps where possible to develop multicomponent cleanup systems, thereby reducing the number of process units. Alternative gasifiers such as the transport reactor employ milder temperatures which reduce the severity of the environment with which the process materials must survive. These milder temperatures allow the use of more robust cleanup technologies.

Research is being supported on gas separations in order to remove, capture, and sequester CO_2. Commercial cryogenic air separation units have the greatest share of the oxygen production from air separation; however, the energy-intensive nature of this process has targeted this process operation as having a high potential for improvement. In addition to developments in cryogenics, leading alternatives include pressure swing absorption and membranes. Gas separations are also critical to gas cleanup and to tailor the product distribution. In a zero-emission gasifier power plant, the product syngas is shifted to CO_2 and H_2, and the CO_2 must be separated from the mixture. Shift reactors utilize the water-gas shift reaction (see above) and catalytically convert the product distribution in the direction desired. Shift reactors employed in gasifier facilities such as the Great Plains Gasification facility in North Dakota are required to alter the H_2/CO ratio from ~1.5:1 produced in the gasifier to 3:1 to optimize production of synthetic natural gas (CH_4, methane). The process demands (selectivity and yields) are different to produce H_2 as a clean-burning fuel. Research is also needed to improve the separation systems at the elevated temperatures and pressures consistent with water-gas shift catalyst operations. Contamination of membranes and other separation systems are potential poisons potentially damaging sorbents and catalysts. A recent review of some novel methods for CO_2 separations includes electrochemical pumps, membranes, and chemical looping (Granite and O'Brien 2005).

Chemical looping is a process in which the oxidant in a combustor or gasifier is supplied from an oxygen-carrying particle such that the products of combustion or gasification are separated from the nitrogen in the air. The chemical looping process is shown in Fig. 51. Beginning with the air reactor or oxidizer, the reduced or oxygen-depleted carrier is reacted with air to fully oxygenate it by essentially burning the carrier particles through the exothermic reaction. The air reactor produces a vitiated airstream (i.e., air partially depleted in oxygen) and hot oxygenated

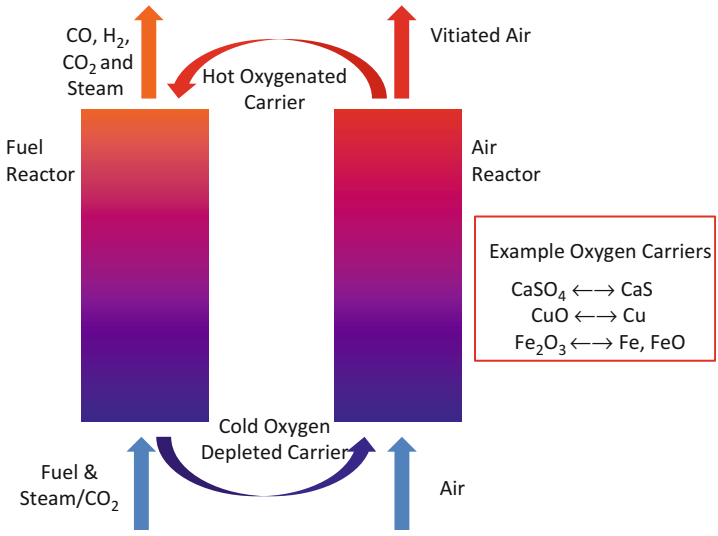

Fig. 51 Chemical looping concept

particle that convey heat and oxygen to the fuel reactor. The carrier particles are thereby reduced by reaction with the hydrocarbon fuel. After oxidizing the fuel, the reduced carrier is transferred to an air reactor where it is reoxidized – completing the loop. Depending on the stoichiometry, the gaseous product from the fuel reactor is CO_2 and water when excess oxygen is supplied by the carrier (combustion) or syngas when excess fuel is supplied to the reactor relative to the oxygen in the carrier (gasification). The result is a gas from the fuel reactor without nitrogen. A variety of carriers have been proposed: metal oxides such as nickel, iron, and copper and sulfates such as calcium sulfate. Technical and economic analyses have indicated very promising results (Yu et al. 2003; 2013).

Increasing regulatory limits on the release of CO_2 could give gasification a competitive advantage in future markets. Gasification has a distinct economic advantage over competing technologies in capturing and sequestering CO_2 from process streams. Acid gas cleanup systems presented above have been traditionally used to remove trace pollutants such as sulfur, but the scale required to remove one of the principal gases, i.e., CO_2, from utility-scale gas streams elevates the need to significantly increase the efficiency and reduce the cost of the process. The US Department of Energy's research goals keep the cost of removing 90 % of the carbon from the product gas stream to less than 30 % increase over the cost without carbon capture. What was considered acceptable energy costs when removing trace pollutants becomes onerous when scrubbing out 15 % of the gas stream. CO_2 sorbent or solvents operate by absorbing carbon dioxide at low temperature, transferring the sorbent to a regenerator and releasing the carbon dioxide by increasing the temperature. This is known as a temperature swing absorption and regeneration process. Amines form an ionic bond with acid gases such as carbon

dioxide. Traditional scrubbing is conducted in aqueous or methanol solutions; however, these liquid processes lose significant quantities of latent heat of vaporization of these liquids. Methods to improve heat integration, increase heat exchange, and reduce latent and sensible heat losses are under investigation. Low-volatile ionic liquids (mostly amines) and solid-supported amines are being developed to optimize these processes. After surveying the performance in terms of capacity and absorption rates of over 100 solid-supported sorbents, several very promising sorbents were identified for use in flue gas. The sorbent capacity target of over 2 mol of CO_2 per kg of sorbent (Fisher and Keller 2006) was achieved using a polyamine bonded to a mesoporous silica developed at NETL (Monazam et al. 2013, 2014). This sorbent is currently being evaluated in a circulating fluidized-bed process at a 1 kW scale on a utility slipstream.

Acknowledgments The authors would like to express their gratitude to the US Department of Energy in making resources and the time available to prepare this manuscript. In addition we would also like to extend appreciation to Peter Smith, Ranjani Siriwardane, Esmail Monazam, Tom O'Brien, and Mehrdad Shahnam for their contributions.

Conversion of Syngas to Fuels and Chemicals

Steven S. C. Chuang and Long Zhang

Contents

Abstract

This chapter examines the reaction pathways and the selectivity of the catalysts for the conversion of syngas to liquid hydrocarbons and ethanol fuels. Rh is by far the most active catalyst for ethanol synthesis. Co- and Fe-based catalysts exhibit excellent activity for hydrocarbon fuel synthesis from high H_2/CO and low H_2/CO ratio syngas, respectively. Regardless of the differences in the catalyst selectivity, all of these CO hydrogenation catalysts produce methane as one of the major products. So far, no approaches are effective in suppressing CH_4 formation. Development of a cost-effective liquid-fuel process from syngas with a low net fuel cycle CO_2 emission requires consideration of (1) the overall

system, including the source of raw materials and by-products and (2) analysis of carbon footprint of each step from raw materials to the desired products and undesired by-products.

Introduction

Synthesis gas (syngas), a mixture of CO and H_2, has long been recognized as an important building block for manufacturing a wide range of chemicals and liquid fuels (Anderson 1983; Keim 1983). Figure 1 illustrates the pathways from raw materials (i.e., coal, natural gas, and biomass) to syngas and syngas to liquid fuels. Syngas can undergo the water-gas shift reaction to produce high-purity H_2 and the reversed water-gas shift reaction to produce high-purity CO. Individual CO and H_2 are important precursor for a number of reaction processes such as ammonia synthesis, carbonylation, and hydrogenation.

The driving force for the development of syngas to liquid fuel and chemicals has been mainly from the cost of crude oil and natural gas. Growing concerns on the effect of CO_2 on climate changes and the potential for stringent regulations on CO_2 emission demand consideration of the carbon footprint (i.e., a measure of the total quantity of all greenhouse gases emitted by a specific entity or process over a period of 1 year) of producing, distributing, and using liquid fuels. Liquid hydrocarbon fuel is the dominant form of the transportation fuel of which combustion produces more than 19 lb of CO_2 per gal of the fuels (Treptow 2010). It is very unlikely that a cost-effective approach could be developed for capture of CO_2 produced from the use of transportation liquid fuels. The use of coal- and natural gas-derived transportation fuels will lead to a net fuel cycle CO_2 emission. In contrast, the use of biomass, which is produced from the photosynthesis reaction of CO_2 with H_2O, has been expected to lower the net fuel cycle CO_2 emission, given similar level of carbon footprint of producing the liquid fuels (Larson et al. 2010).

The key differences in raw materials (i.e., coal, natural gas, and biomass) and their usage include the hydrogen to carbon ratio, contaminants, and cost. These different characteristics have a significant impact on the net fuel cycle CO_2 emission. Biomass is generally considered as an environmentally benign fuel; biomass has also been misconstrued as a fuel with zero net fuel cycle CO_2 emission. However, biomass suffers from low energy density and the diversity of its sources. The latter introduces the complexity of preprocessing steps which require the sophisticated control of gasification and syngas cleanup processes. The extent of

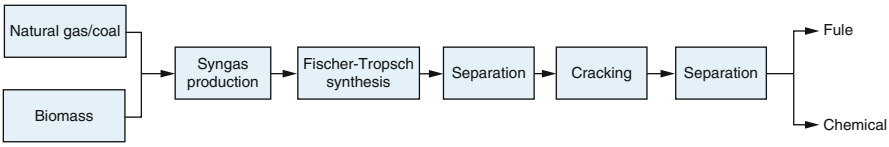

Fig. 1 Syngas production and conversion pathways

lowering carbon footprint of using biomass-derived fuel can only be determined from careful analysis of the energy usage in collection, preprocessing, syngas generation, and cleanup. A recent study has shown that coupling use of coal and biomass as a feedstock with (1) electricity and liquid-fuel production and (2) CO_2 capture and storage could be a promising approach for the production of liquid fuels with a low net fuel cycle CO_2 emission (Larson et al. 2010).

The primary use of syngas has been in methanol synthesis and Fischer-Tropsch (FT) synthesis. Methanol can serve as a fuel or a precursor for the synthesis of many industrial chemicals. Hydrocarbons and oxygenates from the FT synthesis can serve as an excellent clean fuel – an alternative to petroleum-based fuel because it is free of sulfur and nitrogen compounds commonly present in the petroleum-based fuels. This chapter will focus on direct synthesis of hydrocarbons and oxygenates from synthesis gas on heterogeneous catalysts.

Direct synthesis of hydrocarbons and oxygenates from syngas has been a subject of extensive studies due to its importance in the production of liquid transportation fuels. The syngas reaction process (i.e., CO hydrogenation) was first reported on nickel catalysts, producing methane at 1 atm (0.1 MPa) and 200–300 °C (473–573 K) (Keim 1983). Increasing reaction pressure and replacing Ni with Co leads to the formation of liquid hydrocarbons. Further increasing reaction pressure and temperature to 150 atm and 450 °C on alkalized Fe catalysts leads to the formation of oxygenates. Extensive studies have shown that Group VIII metals and some of their sulfides are active catalysts for CO hydrogenation (Wender 1996; Chuang et al. 1985a; Chuang 1990; Vannice 1975a; Burtron and Davis 2009; Dry 1981a). FT synthesis, methanol synthesis, and ethanol synthesis involve the use of the same reactants, CO and H_2. Each of these syntheses is a subclass of CO hydrogenation reactions. The development of the synthesis process such as CO hydrogenation reaction generally involves a sequence: thermodynamics, catalyst preparation, mechanistic study on a molecular scale, kinetics studies on a micro-reactor, scale-up of the reactor on a macroscale, and system integration, shown in Fig. 2. An effective catalyst development strategy must take both physical and chemical characteristics of the catalytic process into account, considering the active sites, reaction pathways, catalyst shape, pore structure, and the reactor type. The thermodynamics of the synthesis reaction can be easily calculated and have widely been reported (Ertl et al. 2008). The reactions for producing hydrocarbons and oxygenates are highly thermodynamically favorable, except for methanol. ΔG, the change in Gibbs free energy for the formation of C_n product (i.e., the species containing *n* number of carbon atoms), decreases as the product carbon number increases. Most scientific literature on this synthesis reaction can be classified into three areas: (1) mechanistic studies for elucidation of catalytic reaction mechanisms, i.e., reaction pathways and the nature of active sites (Ichikawa and Fukushima 1985); (2) catalyst preparation, characterization, and reaction kinetics studies (Underwood and Bell 1986); and (3) reactor modeling (Hedrick and Chuang 2003). The catalytic reaction steps have been shown to occur in sec scale (Balakos and Chuang 1995); the reactor process in min scale depends on the

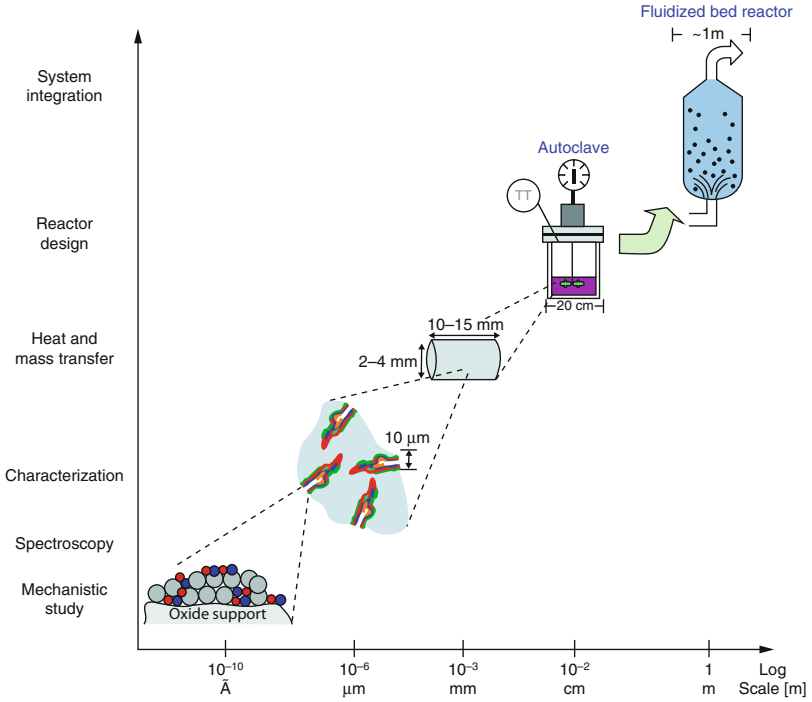

Fig. 2 The relationship among different levels of catalytic process research and development

reactant residence time. This chapter will elaborate on our current understanding of the reaction mechanism, discuss the approach for preparation of durable catalysts, and touch on the reactor modeling and scaling up issues.

Reaction Pathway

The reaction pathway and selectivity for hydrocarbon and oxygenate formation from the CO hydrogenation are governed by reaction conditions and catalyst compositions. A summary of these catalysts and a description of their typical selectivities are given in Table 1.

The reason for the formation of a wide range of C_1 to C_n products (i.e., C_1, methane and methanol; C_2, ethylene, ethane, ethanol, and acetaldehyde; C_3, propylene, propane, propanol, propionaldehyde, and acetone, C_n, species containing n number of carbon atoms) can be traced to the polymerization and network characteristics of the reaction which consists of a large set of parallel and series reaction pathways, shown in Fig. 3.

Depending on the types of metals and metal oxides, listed in Table 1, as well as their surface state and structure, these catalysts are able to catalyze each rate of the steps in the reaction network to a certain extent.

Table 1 Typical product selectivity of various CO hydrogenation catalysts

Key catalyst component	Selectivity
I. Group VIII metals	
Fe and Co	Linear and branched hydrocarbons: alkanes/alkenes and oxygenates: 1-alcohols, aldehydes, esters, ketones (Dry 1981b; Soled et al. 2003; Rao and Gormley 1982)
Ru	Methane, hydrocarbons, and polyethylene at high pressures (Kellner and Bell 1981)
Ni and Pt	Methane, low carbon-number hydrocarbons
Rh	C_2 oxygenates, including ethanol, acetaldehyde, and acetic acid (Underwood and Bell 1988a; Chuang and Pien 1992a)

The first set of steps in the overall CO hydrogenation reaction network is adsorption of reactants, H_2 and CO. All of the CO hydrogenation catalysts must possess the ability to chemisorb hydrogen dissociatively, $H_2 + 2^* \rightarrow 2H^*$ (2^*: two empty sites) and chemisorb CO in either a dissociative or non-dissociative form. Group VIII metals have shown such a capability of adsorbing H_2 and CO. A surface science study shows the ability of metals to dissociate CO which is related to their position in the periodic table (Table 2) (McCash 2001).

This relationship is a result of the difference in the Fermi energy, E_f, reflecting in the ability of the metal in electron back donation to the $2\pi^*$ vacant orbital of CO, as illustrated in Fig. 4 (McCash 2001). This back donation would weaken the CO bond and stabilize the M-C bond. Metals such as Fe on the left-hand side of the ambient temperature line that possess E_f above the level of the $2\pi^*$ orbital tend to dissociate adsorbed CO. In contrast, metal on the right-hand side of 200–300 °C (473–573 K) line such as Pd, Pt, and Cu exhibit activity for chemisorbing CO non-dissociatively. Metals between these two lines would possess moderate CO dissociation ability and produce both adsorbed CO and adsorbed carbon on their surface. Although the practical catalysts containing supports and additives are significantly more complex

than the simple metal surface, the relationship in Table 2 holds for a number of SiO_2-supported catalysts. The CO dissociation activity decreases in the order: $Ni/SiO_2 > Ru/SiO_2 > Rh/SiO_2 > Pd/SiO_2$. The ranking of CO dissociation activity is consistent with the prediction by the above theoretical mode of electron back donation from the metal surface to the $2\pi^*$ empty orbital of adsorbed CO and the Fermi level of metals.

The most direct impact of the CO dissociation activity is on the selectivity of the reaction. High CO dissociation activity favors the formation of adsorbed carbon which can further hydrogenate to form CH_x, leading to the formation of hydrocarbons such as CH_4. In contrast, poor CO dissociation activity allows adsorbed CO to be hydrogenated to methanol. Metals such as Rh in the forms of either single-crystal or supported catalysts with moderate CO dissociation activity exhibited good selectivity toward C_2 oxygenates (Watson and Somorjai 1982). This observation is consistent with the proposed C_2 oxygenate formation mechanism that C_2 oxygenates are produced from both dissociatively and non-dissociatively adsorbed CO (Chuang et al. 2005).

The Nature of Active Sites

The active sites responsible for CO dissociation have been shown to be the reduced metal ensemble sites which consist of a number of surface atoms. Chain growth step involves more than two CH_xO or CHx species and would be expected to occur on the ensemble sites. In contrast, CO insertion has been demonstrated to occur on a single Rh site. Results of Rh single-crystal studies indicated that oxidized Rh sites catalyze for CO insertion (Watson and Somorjai 1981; Castner et al. 1980); the observation that sulfided Rh catalyzes the formation of propionaldehyde from ethylene hydroformylation further confirms that the Rh^+ site is an active site for catalyzing CO insertion (Konishi et al. 1987). Rh^0 and Rh^+ sites chemisorb CO in various forms which yield specific infrared bands as shown in Fig. 5. Due to the low tendency for electron back donation from Rh^{2+} and Rh^{3+}, these sites chemisorb CO, giving high-wave number IR bands in the 2,120–2,145 cm^{-1} range (McKee and Worley 1988). The structure of chemisorbed CO and its wave number are closely related to the nature of the sites it resides on. From the position of the IR band of adsorbed CO, information about the site that it is adsorbed onto can be inferred. For example, observation of vibrational bands corresponding to bridged CO on Rh implies that surface sites are in a reduced state as well as that the sites exist as an ensemble (i.e., not isolated). Similarly, from the position of linear CO, the oxidation state of the metal site can be deduced as well (i.e., Rh^0, Rh^+, Rh^{2+}, etc.). It is interesting to note that adsorbed CO on Rh-based catalysts exhibits infrared bands with excellent resolution and intensity. In contrast, infrared spectra of adsorbed CO on Fe- and Co-based catalysts have been vague and seldom reported in the literature. This may be due to the difficulty in keeping Fe and Co in the reduced state during in situ infrared study of CO adsorption.

The formation of high carbon-number products involves C-C bond formation steps which have been shown to occur via CH_x chain growth steps specifically on Rh/SiO_2 catalysts, as illustrated in Fig. 3. This reaction pathway consists of a subset of the overall CO hydrogenation reaction network, where (1) higher hydrocarbon intermediates, C_nH_x species, are produced from chain growth; (2) high hydrocarbon products, C_nH_{2n} and C_nH_{2n+2}, are produced from hydrogenation of C_nH_x; and (3) higher oxygenates are produced from the insertion of adsorbed CO into C_nH_x species. Chain growth resembles radical propagation, while hydrogenation and CO insertion correspond to chain termination steps of the polymerization kinetics and mechanism. Both methylene ($^*CH_2$) and methyl ($^*CH_3$) species have been proposed to serve as precursors for the chain growth (Underwood and Bell 1986; Hedrick and Chuang 2003; Balakos and Chuang 1995). Due to a lack of experimental techniques for in situ studies of such adsorbed intermediate species, the exact structure of chain growth precursor (i.e., x for CH_x) remains to be determined.

Owing to the polymerization characteristics of the reaction, carbon-number (C_n) distribution in hydrocarbon and oxygenated products generally follows the Anderson-Schulz-Flory (ASF) distribution in which the concentration of C_n product is inherently greater than that of C_{n+1} product (Biloen and Sachtler 1981). Variations in reaction conditions and catalyst composition allow adjustment of the chain

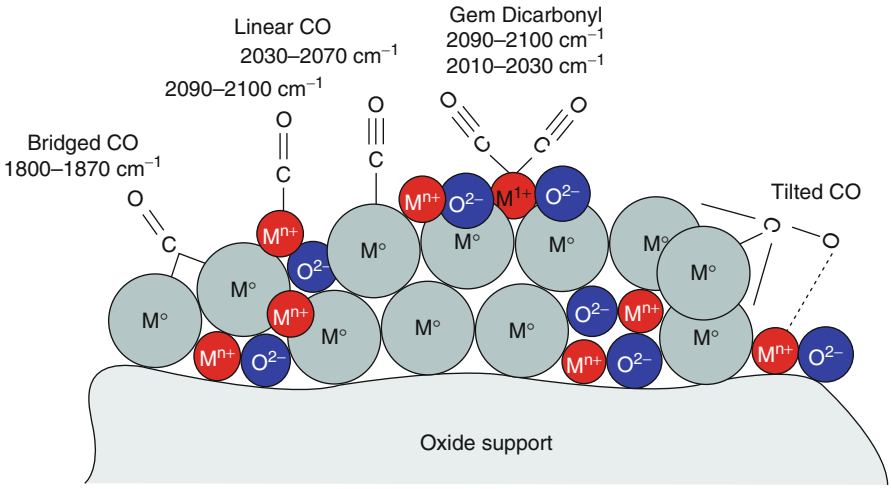

Fig. 5 Adsorbed CO on supported Rh catalysts

growth probability parameter, $\alpha(\alpha = k_1/(k_1 + k_2 + k_3)$: chain growth probability – k_1, the rate constant for chain growth; k_2, the rate constant for hydrogenation; and k_3, the rate constant for CO insertion). High temperature (i.e., temperatures above 300 °C) and 1 atm pressure shift the product distributions toward CH_4 and lower hydrocarbon products; intermediate temperature (230–275 °C) and pressure (10–50 atm) shift the products toward higher oxygenates.

Ni-, Ru-, Fe-, and Co-based catalysts exhibit excellent activity for the synthesis of higher hydrocarbons. Ru is the most active catalyst which produced primarily long chain hydrocarbons via the CH_x chain growth pathway. The reaction pathways on Fe- and Co-based catalysts have been studied extensively by probe molecules and isotope tracing techniques. Results of ^{14}C-tracing studies suggest that the chain growth proceeds primarily via oxygenated intermediates, $C_n H_x O$ on Fe-based catalysts and partially on Co-based catalysts (Davis 2001). In this pathway, oxygen dissociates from the $C_n H_x O$ intermediate in the chain termination. Mixed oxide catalysts catalyze methanol as a major product and higher alcohols (i.e., ethanol, propanol, and various isomers of C_4 alcohols) as minor products through the $CH_x O$ chain growth pathway, shown in Fig. 3. Mo-based catalysts also follow the same $CH_x O$ pathway to produce higher yields of higher alcohols than the mixed oxide catalysts, but require operating at very high pressure (>200 atm).

Circumventing Fischer-Tropsch Chain Growth Kinetics

The most significant challenge in the investigation and development of FT synthesis chemistry is the selective synthesis of C_{2+} hydrocarbons or oxygenates without producing methane. Voluminous work has been done on circumventing this

selectivity limitation of ASF. Various approaches, including (1) unsteady-state operation, (2) use of shape-selective supports, (3) interception of intermediate products, and (4) addition of olefins to the reactant stream, have been studied.

While unsteady-state operation can skew the product distribution to a certain extent, it inherently produces methane and significantly increases the difficulty in reactor operation and control. The use of shape-selective supports such as zeolites was expected to limit the chain growth through either geometric or diffusional constraints. However, the shape-selective effects have been shown to be temporary or the results of errors in data analysis. At present, no definite evidence to support the lasting shape-selective modification of the ASF has been reported. The approach of intercepting reaction intermediates utilized either multifunctional catalysts or multistep processes for catalyzing the secondary reaction processes such as isomerization and hydrocracking. FT/zeolite catalysts use metals such as Co, Fe, or Ru to catalyze the formation of FT products and the acidic function of zeolites to isomerize and crack FT products. Two-step processes with two different reactors are used if conditions for the cracking, isomerization, or other processes are significantly different from those of the FT synthesis. Addition of an olefin to the CO/H_2 feed stream has been shown to increase the higher hydrocarbon yields through chain incorporation. This approach is not economically viable due to the cost of the added olefin and the high tendency of olefin hydrogenation.

All of these attempts have failed to produce steady-state product distributions that deviate significantly from the ASF kinetics. Methane and methanol (C_1 products) have always been produced with higher yields than C_2 or higher carbon-number products. An alternative to higher hydrocarbon synthesis is the selective synthesis of C_2 oxygenates from syngas. C_2 oxygenates may be produced with high selectivity since they share the common precursor, CHx, with methane. Theoretically, both C_2 oxygenates and methane should be considered as C_1 products in the ASF kinetics. In fact, a high C_2 oxygenate selectivity (up to 75 % carbon efficiency) has been achieved on promoted Rh catalysts at 573 K and 10 MPa (Chuang et al. 2005). This selectivity is significantly higher than the maximum selectivity of 25 % for C_2 products predicted by ASF distribution, further supporting the theoretical basis of considering C_2 oxygenates as a C_1 product in ASF. Nevertheless, high hydrogenation activity of Rh leads to methane formation.

Improved control of the chain termination and chain growth steps are needed to circumvent ASF distribution of the FT synthesis. A number of studies have shown that different types of adsorbed hydrogen are responsible for the chain termination (i.e., hydrogenation of alkyl species) and chain growth steps (Stroch et al. 1951; Nunan et al. 1989; Chuang and Pien 1991; Chuang et al. 1991; Tatsumi et al. 1986; Li et al. 1998). Results from these studies suggest the possibility of controlling ASF distribution by manipulating the hydrogen reactivity. Examination of the FT mechanism in Fig. 3 shows that the suppression of termination requires inhibition of both hydrogenation and CO insertion. If the site for hydrogenation of surface carbon to form CH_x is the same as that for hydrogenation of CH_x to form methane, inhibition of hydrogenation could suppress the CH_x formation, decreasing the FT synthesis rate. A great deal of work has shown that alkali promoters enhance higher

hydrocarbon formation and decrease methane/paraffin formation, indicating that the site for CH_x formation is not the same as that for hydrogenation of CH_x (Stroch et al. 1951; Nunan et al. 1989; Chuang and Pien 1991; Chuang et al. 1991; Tatsumi et al. 1986). NMR studies show that the suppression of methane/paraffin formation is a result of limited migration of adsorbed hydrogen brought about by potassium promoters (Chuang et al. 2005). Although complete suppression of methane formation may never be achieved, it remains to be determined what extent of methane suppression can be achieved through limiting migration of adsorbed hydrogen. The challenge is to suppress methane formation and enhance CO insertion for further improving C_2 oxygenate selectivity.

Ethanol Synthesis Catalysts

Ethanol is one of the oxygenated products (i.e., alcohols, aldehydes, and acids) synthesized from CO hydrogenation (i.e., the reaction of CO with H_2). The catalytic synthesis of C_{2+} oxygenates (ethanol, propanol, and higher alcohol; acetaldehyde, propionaldehyde, and higher aldehydes; acetic acid, propanoic acid, and higher acids) has been a subject of intensive interest because of their high value-added and versatile applications (Anderson 1983; Biloen and Sachtler 1981). The early developments of C_{2+} oxygenates synthesis from CO hydrogenation took place in Germany. In 1913, BASF discovered that cobalt and osmium catalysts produced a mixture of oxygenates, including alcohols, aldehydes, ketones, and acids at pressures above 20 MPa and temperatures up to 673 K (Schindeler 1989). Since that time, a significant amount of work has been done to determine the activity, selectivity, and durability (i.e., deactivation characteristics) of catalysts for the higher oxygenate and Fischer-Tropsch (FT) synthesis (Chuang et al. 1985a; Davis 2001; Klier et al. 1988; Vannice 1975b).

Most studies on the effect of additives on C_{2+} oxygenate synthesis have been focused on Rh/SiO_2 (Nonneman et al. 1990; Yoneda 1989), which give a moderate selectivity toward acetaldehyde and ethanol as compared to Rh/La_2O_3 and Rh/TiO_2. Additives such as Mn (Boffa et al. 1994), Na (Dry 1981b), Sc, Ti, and La enhanced CO dissociation; Ag, Cl, Zr, Zn, S (Chuang 1990), Ti, La (Underwood and Bell 1988b), and V promoted CO insertion (Ichikawa and Fukushima 1985; Ichikawa et al. 1985); alkali species promoted CO dissociation and suppressed hydrogenation.

With the knowledge of the specific additive effect and extensive catalyst screening studies, Rh-Mn-Fe-Li (1:1:0.1:0.1 in the atomic ratio)/SiO_2 catalyst with a 4.5 wt% Rh loading emerged as one of the most active and selective catalyst for C_2 oxygenate synthesis, exhibiting ethanol selectivity up to 44 % and a total C_2 oxygenate selectivity of 56 % with about 0.178 mol/Kg-h in the ethanol production rate at $CO/H_2 = 0.5$, 50 atm, 270 °C, SV (space velocity) = 12,000 h^{-1} in the Japanese C_1 chemistry program in the 1980s (Yoneda 1989). Note that SV is defined as the ratio of the reactor volume to the inlet volumetric flow rate at room temperature. Researchers in China have rediscovered the high activity and

selectivity of the Rh-Mn-Fe-Li (1:1:0.075:0.05 in the weight ratio) with a 1 wt% Rh loading showing 27 % in ethanol and 56 % in C_2 oxygenate selectivity and 9.1 mol/kg-h in the C_2 oxygenate production rate at $CO/H_2 = 0.5$, 30 atm, 320 °C, SV (space velocity) = 12,000 h^{-1} (Yin et al. 2003). The best C_2 oxygenate selectivity obtained in our laboratory with a Rh-Ag (1:1 in the atomic radio)/SiO_2 with a 3 wt% Rh loading was 59 % with a 0.25 mol/kg-h in C_2 oxygenate production rate at $CO/H_2 = 1$, 20 atm, 240 °C, SV (space velocity) = 11,000 h^{-1} (Chuang and Pien 1992a). This Rh-Ag catalyst showed negligible activity toward ethanol. These results are summarized in Table 3 for comparison. While it is difficult to compare the results of these studies due to the use of different conditions, the rate data at various temperatures can be further adjusted with the activation energy of 23 kcal/mol-K, the average value found from literature (Chuang et al. 1985b), to the rate at 280 °C. The production rates at 280 °C show that the C_2 oxygenate rate on these promoted catalysts are in the range of 0.23–2.2 mol/kg-h which are close to the rates of higher hydrocarbon formation in the Fischer-Tropsch synthesis (Dry 1981b). The results of the rate comparison suggest that the size of pilot or commercial scale ethanol synthesis reactors should be in the same range of the Fischer-Tropsch synthesis reactors. Although the results of the study by Yin et al. are significantly higher than those of others, further verification is needed (Yin et al. 2003).

Studies on the effect of reaction conditions show increasing temperature and pressure increased the rate of C_2 oxygenate formation and further increasing temperature above 320 °C can shift the reaction selectivity toward methane and cause a rapid catalyst deactivation. This is the reason why the long-term pilot scale study is conducted at 280 °C in the Japanese C_1 chemistry program (Yoneda 1989). Use of a 200 cm^3 (about 400 g) of Rh-Mn-Li/SiO_2 and 200 cm^3 of Cu-Zn/SiO_2 catalyst mixture in a pilot scale unit showed that the mixed catalysts produced 0.14 mol/kg-h in the ethanol production rate with 70 % ethanol selectivity at $CO/H_2 = 0.5$, 40 atm, 280 °C, SV (space velocity) = 16,000 h^{-1} decayed less than 15 % of its activity in a period of 1 year. The results of this study are the only pilot scale data available in the literature. Examination of the catalyst preparation procedures and their characterization results showed that the activity, selectivity, and durability of the Rh-based catalysts for ethanol synthesis can be further improved with adjusting the following catalyst characteristics:

Control of Rh particle size. The average Rh particle size of 3.5 nm has been shown to give the highest selectivity for C_2 oxygenate synthesis (Yoneda 1989). The single reduced Rh site chemisorbing linear CO has been demonstrated to be active for CO insertion (Chuang and Pien 1992b); Rh ensemble sites (i.e., a group of surface Rh atoms) are active for CO dissociation. 3.5 nm Rh particle appears to contain the appropriate ratio of the sites for CO dissociation and CO insertion to give the highest C_2 oxygenate selectivity.

Fine-tuning promoter composition. On the basis of the mechanistic information and results of previous studies, the optimum catalysts for ethanol synthesis will be a multicomponent catalyst which consists of 3.5 nm Rh particle size and appropriate

Table 3 Comparison of Rh-based catalyst activities and selectivities

Catalyst	Experimental conditions	C_2 oxygenate/ethanol selectivity (%)	C_2 oxygenate production rate (mol/kg-h)	C_2 oxygenate production rate at 280 °C (mol/kg-h)	Reference

amount of each promoter to enhance CO dissociation and CO insertion and to balance hydrogenation of C and CH*x*. The role of each promoter based on our and other studies discussed above is summarized below:

- Ag: Suppress CO dissociation and promote CO insertion.
- Mn: Enhance CO dissociation and CO insertion.
- Li: Suppress hydrogenation.
- Fe: Promote CO insertion.
- Cu: Promote hydrogenation of acetaldehyde and acetic acid to ethanol without promoting hydrogenation of CH_x species (Yoneda 1989). Cu-based catalysts, which lack CO dissociation activities, are not able to accommodate CH*x* species and catalyze hydrogenation of CH_x to the undesired methane (i.e., CH_4). Cu-based catalysts will be especially useful to promote ethanol formation from Rh-Ag catalysts which showed high C_2 oxygenate selectivity, but low ethanol selectivity. Although the specific role of each promoter has been identified, it remains unclear about the optimum composition of the promoters for enhanced ethanol synthesis.

Hydrocarbon Synthesis Catalysts

The above ethanol synthesis catalysts serve as an excellent example to illustrate the importance of identifying the role of each component in a multicomponent catalyst. In fact, almost all of practical heterogeneous catalysts consist of multicomponents. The FT′s Fe- and Co-based catalysts consist of more than four components (Davis and Occelli 2009).

The traditional FT Fe catalysts are either in the formed fused iron oxides or coprecipitated catalysts. The fused Fe catalysts prepared at 1,500 °C contain K_2O as chemical promoter and MgO or Al_2O_3 as the structural promoters. These structural promoters can atomically disperse in the Fe oxide phase and serve as the spacers between metal crystallite after reduction of Fe oxides. The coprecipitated catalyst is prepared by coprecipitation of Fe and Cu nitrate solution with Na_2CO_3. The concentration of catalyst precursors, the precipitation temperature, and the pH govern the final catalyst form, i.e., the types of oxides, the surface area, and the porosity. Prior to the reaction, the fused catalyst has to be activated by hydrogen reduction; the coprecipitated catalysts are activated by syngas. Removal of reduced product, H_2O, from reduction is necessary to avoid sintering of reduced metals and accelerate the activation process. It is interesting to note that the commonly used impregnation method is not used because a large fraction of the chemical promoters could end up adsorbing on or reacting with the support.

In contrast to Fe-based catalysts, cobalt-based catalysts are prepared by impregnation on high surface area supports with a low cobalt loading, i.e., 20 wt% or less. Co-based catalysts may contain Cu or noble metals to facilitate the reduction of cobalt oxide particles; oxidic promoters such as lanthanide, thorium, cerium, titania, and zirconium oxides to stabilize the Co dispersion on the support; and Mn to suppress hydrogenation and to enhance chain growth.

Both Fe-based and Co-based catalysts show increase in the selectivity toward high hydrocarbon at low temperature and H_2/CO ratios. Selection of either Fe- and Co-based catalysts requires further consideration of issues of cost, deactivation, the CO/H_2 ratio of syngas gas, and the overall net fuel cycle CO_2 emission. Co-based catalyst is less sensitive to H_2O deactivation. The cost of Co-based catalyst is significantly higher than that of Fe-based catalysts. In addition to the cost and H_2O sensitivity issues, Co catalysts produced H_2O and do not have the water-gas shift activity; Fe catalysts produced CO_2 with a high water shift activity. Thus, Fe catalysts are used for the low H_2/CO ratio syngas from coal; Co catalysts are considered for the high H_2/CO ratio syngas from natural gas.

Reactor Issues

CO hydrogenation is a highly exothermic reaction releasing 140–150 kJ/mol of the heat per CH_2 added onto the C_n products or 165–180 kJ/mol CO converted. Rise in reactor temperature will lead to catalyst deactivation and the enhanced formation of

undesired methane. Commercial FT reactors include multitubular fixed bed, slurry bubble column bed, fixed fluidized bed, and entrained fluidized bed. These reactors are designed for maximum heat removal to avoid catalyst deactivation. The fixed bed reactor possesses the advantage of simplicity and low cost as well as the disadvantage of difficulty in controlling the reaction temperature. Slurry bubble reactors contain high heat capacity inert media which facilitate the removal of the reaction heat; however, it may cause complications due to attrition of the catalyst particles. Ethanol synthesis from syngas is also a highly exothermic process. So far, ethanol synthesis has only been reported to be carried out in the fixed bed reactor.

Future Directions

Almost every element in the periodic table has been tested as promoter for both hydrocarbon and ethanol syntheses. The effects of concentration of promoters generally follow a trend: increasing the promotion effect in the low concentration range and decreasing the promotion effect in the high concentration range. Without gaining an in-depth understanding of the promoter-metal, metal-support, and promoter-support interaction, as well as the effect of these interactions on the nature of active sites for the rate-determining step, further variation in the concentration of promoters and the addition of different sequences and combinations of promoters are unlikely to generate the breakthrough results in catalyst selectivity and durability. The emphasis on the basic research should be placed on in situ studies since the nature of the catalyst surface is strongly influenced by the reaction environment where both reactants and products are present. The rate-determining step can be identified by careful design and use of transient techniques. The use of transient techniques coupling with isotope tracer has been shown to be highly effective in determining the rate-determining step (Chuang and Guzmanm 2009). In addition to determining the effects of the promoters on the catalyst activity, selectivity, and durability, the focus should be placed on the promoter effects on the rate-determining step.

Catalyst development deals with catalyst activity, selectivity, and deactivation resistance. The deactivation usually resulted from sintering and sulfur poisoning. Sintering of metal crystallite may be addressed by addition of the nanoscale spacer to serve as the barrier for the migration of small reduced metal crystallite. Sulfur compounds bind strongly on the reduced metal sites. Instead of modifying metal surface site to impart the sulfur resistance, it may be more effective if a cost-effective approach can be developed to remove sulfur compounds and sulfur content of the syngas to the ppb level.

The global emphasis on development of the low carbon dioxide emission technologies shifted the focus from the use of coal-based syngas to biomass-based syngas. The challenge in the biomass routes will lie at the cost of biomass gasification and purification of its syngas. The issues such as the cost of shipping and pretreating are common for all of biomass-related conversion processes. Syngas conversion to fuel processes has to be examined by considering the overall system, including the life cycle of each species in the process and the energy efficiency of each processing step.

Chemical Looping Combustion

Edward John (Ben) Anthony

Contents

Abstract

Chemical looping combustion (CLC) and looping cycles in general represent an important new class of technologies, which can be deployed for direct combustion as well as be used in gasification applications. In this type of system, a solid carrier is used to bring oxygen to the fuel gas, so that it can be subsequently released as a pure CO_2 stream suitable for use or, more likely, for sequestration.

The solid is then regenerated in a reactor using air, so that the technology effectively achieves oxygen separation from air without the use of a cryogenic process or membrane technology. In a sense, cycles using liquids, such as amine scrubbing, could also be regarded as a type of looping cycle, the key being that the carrier must be regenerated and reutilized for as long as possible. However, this chapter will restrict itself to considering the uses of solid carriers only and, more specifically, those in which oxygen is transported and not CO_2 as is the case for calcium looping. Particular focuses of this chapter will be on the use of this technology for H_2 production and gasification applications, as well as its use with solid fuels. Another issue that will be discussed is high-pressure cycles, which are ultimately necessary if such systems are to be integrated into high-efficiency electrical energy cycles.

Introduction

Chemical looping combustion (CLC) was first suggested by Lewis, Gilliland, and Reed in a paper published in *Industrial and Engineering Chemistry* (Lewis et al. 1949). In this paper, they carried out an experimental investigation of the use of CuO to oxidize methane to CO and H_2 using a small fluidized bed reactor at a temperature of 925 °C to avoid both the use of oxygen and high net heat requirements normally required in the reforming process. Subsequently, these workers proposed the use of this approach for the production of pure CO_2 from a hydrocarbon gas (Lewis and Gilliland 1954). Later, the idea of using a metal oxide to combust a gaseous hydrocarbon was again proposed as a method of achieving "controlled combustion" by Richter and Knoche (1983), who explored the Ni system and proposed the Cd system based on a theoretical analysis (although, since Cd has a low melting point of around 321 °C, this would seem to preclude its use, even if its noted toxicity did not). Although the work of Richter and Knoche clearly references the earlier work of Lewis and his colleagues in 1949, the contribution of Lewis and his colleagues in proposing the basic ideas of CLC seems to have been largely ignored in subsequent developments. In subsequent work Richter emphasized the potential benefits of employing such a cycle in combination with a solid oxide fuel cell and stressed the potential benefits of producing three separate fluid streams, namely, CO_2, H_2O, and N_2 (when air is used to oxidize the carrier) (Harvey and Richter 1994). In a thermodynamic study done by Jerndal et al. (2006), 27 possible systems were examined, based on the potential of an oxide to achieve complete or near-complete conversion of CH_4, H_2, and CO. Factors like stability in air and melting temperatures were also examined, and metal oxides based on Ni, Cu, Fe, Mn, Co, W, and sulfates of Ba and Sr were shown to offer possible chemical looping systems, although for some reason the sulfate of Ca was not considered. However, it is to the Ni-, Cu-, and Fe-based systems that most of this chapter will be devoted.

Early experimental work was done extensively in either thermogravimetric analyzers (TGAs) or subsequently in fixed bed reactors in Japan by various workers including, most notably, Ishida and his coworkers (Ishida and Jin 1994a, b), using

primarily Ni-based carriers, all of which demonstrated that the reaction was fast enough to be employed in practice and that soot formation or carbon deposition on the particles did not appear to be a major problem if the oxidation reaction was carried out at a high enough temperature (Hatanak et al. 1997). This work uses the term chemical looping combustion and also clearly identifies the benefits of such an approach in terms of producing a pure stream of CO_2 for sequestration after water has been removed. Subsequent research has been heavily directed to pilot plant studies, using fluidized beds, and has been carried out most notably in places like Chalmers University, Sweden, with a major focus on developing practical systems (Lyngfelt et al. 2001). These developments will be discussed in considerable detail below since it is the practical application of these technologies and their demonstration at the industrial scale in the next several decades that is key to their contribution to a carbon-constrained world.

Chemical Looping Combustion Concept

Until quite recently, when efforts have been made to use these cycles with solid fuels, nearly all of the proposed cycles involved reaction of a gaseous hydrocarbon with a metal oxide that is taken from a higher to a lower state of oxidation, following the global reaction scheme:

$$(2n+m)\mathrm{M}_y\mathrm{O}_x + \mathrm{C}_n\mathrm{H}_{2m} = (2n+m)\mathrm{M}_y\mathrm{O}_{x-1} + m\mathrm{H}_2\mathrm{O} + n\mathrm{CO}_2 \quad (1)$$

Alternatively, if a reforming step is being considered, the amount of oxidant is reduced to allow for the production of CO and H_2, as in the original concept of Lewis et al. (1949):

$$n\mathrm{M}_y\mathrm{O}_x + \mathrm{C}_n\mathrm{H}_{2m} = n\mathrm{M}_y\mathrm{O}_{x-1} + m\mathrm{H}_2 + n\mathrm{CO} \quad (2)$$

In the case of combustion (Rx. 1), after the water produced from hydrocarbon oxidation is removed, the flue gas stream contains an effectively pure stream of CO_2 suitable for sequestration. The metal oxide is regenerated in a separate reactor by reaction with air (Rx. 3), and the regenerated solid can be transferred back for further reaction with the fuel gas (Fig. 1):

$$\mathrm{M}_y\mathrm{O}_{x-1} + \mathrm{Air} = \mathrm{M}_y\mathrm{O}_x \quad (3)$$

Typically, the oxidation reaction is strongly exothermic and the reduction step is not (an exception is the CuO/Cu cycle in which both oxidizing and reducing cycles are exothermic (Chuang et al. 2008)), so that overall, the system yields the heating value of the fuel. Such a cycle represents an elegant way of oxidizing a fuel gas by effectively achieving air separation, without using cryogenic or membrane technology, and, in addition, avoiding or minimizing the formation of fuel-NO_x. In practice,

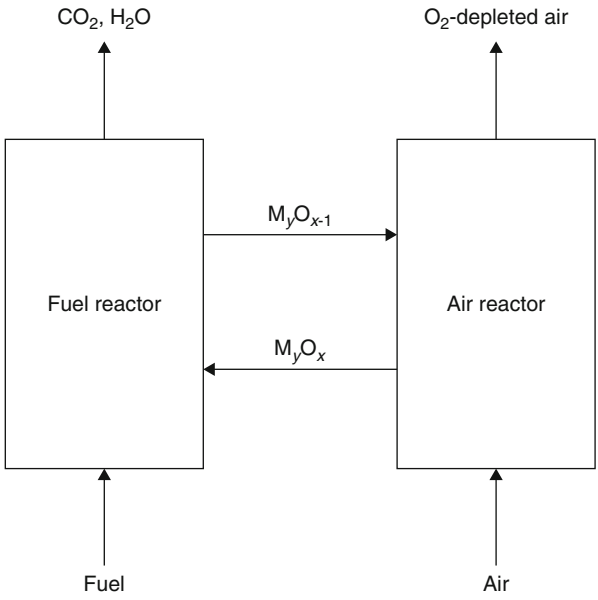

Fig. 1 Typical metal oxide looping cycle

these cycles typically operate at temperatures in the range of 800–1,200 °C, which normally ensures that the reactions occur at a sufficient rate to be compatible with a fluidized bed system and to ensure that agglomeration and sintering are minimized. In principle, they can be run either at atmospheric or high pressure, although the vast bulk of the research done to date has been at atmospheric pressure. It should also be noted that Rx. 1 and 2 are idealized since many oxides permit multiple oxidation states, and complete conversion of the oxide need not necessarily occur in either Rx. 1, 2, 3 to ensure effective use of the chemical looping reagent (Bohn et al. 2008).

Choices of Oxide Carriers

Any given oxide system will have a carrying capacity, which can be defined as

$$\mathrm{Rx} = (m_{\mathrm{ox}} - m_{\mathrm{red}})/m_{\mathrm{ox}} \tag{4}$$

where m_{ox} is the mass of the fully oxidized sample and m_{red} is the mass of the reduced sample. The values of m_{ox} for the common systems (Fe_2O_3/Fe_3O_4, Ni/NiO, Cu/CuO) are 0.03, 0.22, and 0.24, respectively, and the oxidation reactions are of the type shown below:

$$3Fe_2O_3 + CO/H_2 = 2Fe_3O_4 + CO_2/H_2O \tag{5}$$

$$CuO + CO/H_2 = Cu + CO_2/H_2O \quad (6)$$

$$NiO + CO/H_2 = Ni + CO_2/H_2O \quad (7)$$

Other systems of course exist, such as the Mn_3O_4/MnO and CoO/Co systems:

$$Mn_3O_4 + CO/H_2 = 3MnO + CO_2/H_2O \quad (8)$$

$$CoO + CO/H_2 + CO + CO_2/H_2O \quad (9)$$

which have received limited investigation (Johansson et al. 2006a). There is one notable nonmetallic system, the $CaSO_4$/CaS system, that has the highest carrying capacity of all, at 0.47, and this system will be discussed later. It should also be mentioned that there has been some success in preparing oxygen carriers with mixed oxide systems, which together show better overall performance. For example, the addition of small amounts of Ni was shown to improve the performance of various oxygen carriers, and it is suggested that this arises because Ni^0 can catalyze methane conversion by methane pyrolysis and steam reforming (Johansson et al. 2006b).

In practice, it is more usual and useful to consider the carrying capacity of the particles themselves, since they contain an inert substrate to support the active component and the oxygen-carrying capacity figures will be lower and depend on the formulation of the particle itself. Also, in some instances, the carrier itself will form a compound with the support material that is itself inert, an example of this being Al_2O_3 with Ni, which forms a Ni spinel ($NiAl_2O_4$) that is not itself active as an oxygen carrier and consumes some of the Ni otherwise available for reaction (Gayán et al. 2009). Thus, for instance, Abad et al. (2007a) give figures for three oxygen carriers based on Fe, Ni, and Cu, showing that their actual carrying capacities are 0.013, 0.084, and 0.02, respectively.

While the carrying capacity of the material and the particles made from it will be of major significance, there are obviously a number of other factors that must be considered. Kinetics is clearly one, and based on an evaluation of 600 different oxygen carriers (i.e., predominantly the Ni, Cu, and Fe systems with different inert substrates), Johansson concluded that Ni and Cu were the most reactive (Johansson 2007). Another potential concern is the melting point of the active material since sintering will be significantly enhanced if the carrier must be operated near its melting point for kinetic reasons. Here, the material with the lowest melting point of those commonly considered for chemical looping cycles is Cu, which has a melting point of 1,083 °C, and since operation of chemical looping systems is normally in the range of 700–1,000 °C, this has been somewhat of a concern for the copper system; however, extensive experimentation has shown that Cu-based chemical looping systems can be operated satisfactorily with Cu at a temperature range of up to 950 °C (Johansson 2007). Another issue is thermodynamic limitations for the oxidation cycle; thus, the Ni/NiO cycle cannot convert a hydrocarbon completely to CO_2 and H_2O, having a conversion of 98.8 %, for instance, at 1,000 °C, with higher conversions at lower temperatures. In the case of CoO/Co,

the thermodynamics are even less favorable with a conversion of 93 % at 1,000 °C (Johansson 2007).

Finally, there are the issues of toxicity and availability. Ni is a known carcinogen, and Co would be considered as toxic in other than trace amounts, at which levels it is a micronutrient. Copper also has minor toxicity issues. However, the factors that are more likely to limit the use of such materials are their availability, cost, and reactivity. In this situation, there will always be a tendency to prefer iron-based systems if their reactivity can be increased sufficiently for practical applications, since iron-based materials are always likely to be more available, less costly, and less toxic than any other metal/metal oxide system. Unfortunately, the iron-based systems have a rather low carrying capacity and are the least reactive of the common systems being considered, that is, Ni, Cu, and Fe systems. Nonetheless, as will be seen below, because of their relatively low costs and essential lack of toxic or environmental concerns, iron-based systems continue to receive considerable attention.

Preparation of Chemical Looping Particles and Related Issues

In a detailed analysis of the cost limits for looping cycle materials, Abanades et al. (2007) noted that:

A makeup flow of sorbent is required to compensate for the natural decay of activity and/or sorbent losses during many sorption/desorption cycles. It must be emphasized that this decay is to some extent always unavoidable because of [a] wide range of chemical and physical interactions of the sorbent inside the reactor and transport lines and the sorbent losses associated with gases leaving the system.

In consequence, in the analysis of Abanades et al. (2007), they stressed that in order for costs to be kept to a reasonable limit, it is necessary to reduce the amount of makeup of expensive sorbents by increasing the number of reaction cycles to a figure approaching tens of thousands.

Unfortunately, unlike, say, Ca looping for CO_2 capture or the $CaS/CaSO_4$ looping cycles, where one can envisage using natural limestones or natural anhydrite materials, respectively, nearly all of the earlier efforts at making chemical looping reagents envisage using relatively expensive materials that have to be prepared in the form of synthetic particles, an exception being the use of natural ilmenite ($FeTiO_3$) (Prőll et al. 2009). This issue was apparent with the pioneering work of Lewis et al. (1949), who noted that CuO itself did not work well due to a rapid growth in particle sizes and instead used Cu on supports including silica gel, alumina gel, and kaolin, with the carriers ground to the required size and the metal deposited on it. In the work of Lewis et al. (1949), a copper nitrate solution was mixed with the carrier and the copper deposited on the particles by thermal decomposition in an oven. Variants of this approach include the so-called dissolution method adopted by Japanese workers, a typical recipe for which is as follows:

$Ni(NO_3)_2 \cdot 6H_2O$ and $Al(NO_3)_3 \cdot 9H_2O$ were dissolved into a mixture of distilled water and 2-propanol, and the solution dried at 100 °C for 3 h, at 150 °C for

Table 1 Synthesis of a CLC particle

The oxygen carrier particle was prepared by freeze-granulation and was composed of 40-wt% active material of CuO and 60 % ZrO_2
A water-based slurry was prepared by mixing CuO (Panreac No. 141269) and ZrO_2 (Sigma-Aldrich No. 24.403-1)
This mixture was ball milled for 24 h A small amount of dispergent was also added to this mixture in order to improve slurry characteristics
After milling, an organic binder was added to the slurry to keep the particles intact during later stages in the production process, that is, freeze-drying and sintering
Spherical particles were produced by freeze-granulation, that is, the slurry is pumped to a spray nozzle where passing atomizing air produces drops, which are sprayed into liquid nitrogen where they freeze instantaneously
The frozen water in the resulting particles is then removed by sublimation in a freeze-drier operating at a pressure that corresponds to the vapor pressure over ice at 10 °C
After drying, the particles were sintered at 950 °C for 6 h using a heating rate of 5 °C/min

5 h, and finally at 500 °C for 3 h. Subsequently, the agglomerates were crushed in a ball mill and water slurry introduced into a spray dryer. The resulting particles were then baked in an oven for 10 h, during which baking a $NiAl_2O_4$ support is produced on which the active Ni component is maintained (Ishida et al. 2002).

An alternative approach also used in some of the earlier Japanese work was to grind the oxide together with the carrier after wetting (for periods of up to 2 days) and then sinter the particles for 10–12 h, after which they were sieved and held in a desiccator (Ishida et al. 2005). More recently, freeze-dry granulation has been explored at Chalmers University in Sweden (e.g., Johansson 2007; Mattisson et al. 2009), and an example of the procedure employed is found in Table 1.

Yet another approach, the so-called sol–gel method, is also being developed and involves the formation of a colloidal suspension (sol) and gelation of the sol to form a wet gel, which after drying forms a "dry gel" state (xerogel), which is then processed to make sorbent particles (Zhao et al. 2008). However, the procedure of producing the carrier outlined by these workers is of considerable complexity to that outlined in Table 1. Numerous other efforts are under way, such as efforts to develop a cheap wet impregnation method (Gayán et al. 2009). Very recently, Jerndal et al. (2010) have reported considerable success in producing suitable particles by means of spray drying, which is a technology that could be used to scale up the production to make the large amount of carrier particles needed by an industrial unit at a reasonable cost. This must be regarded as a very positive, if early, result, although spray drying produced a high degree of cenospheric particles.

What is clear from the above is that, while making reactive materials is important for any practical applications, their longevity, especially if they are used in fluidized bed systems, which transport materials from one vessel to another (oxidizer, regenerator), will be critical, and there will be major pressure to reduce the cost of such carriers for large-scale applications such as what will be required if CLC is to be employed in thermal power generation. To date, such tests as have been done in

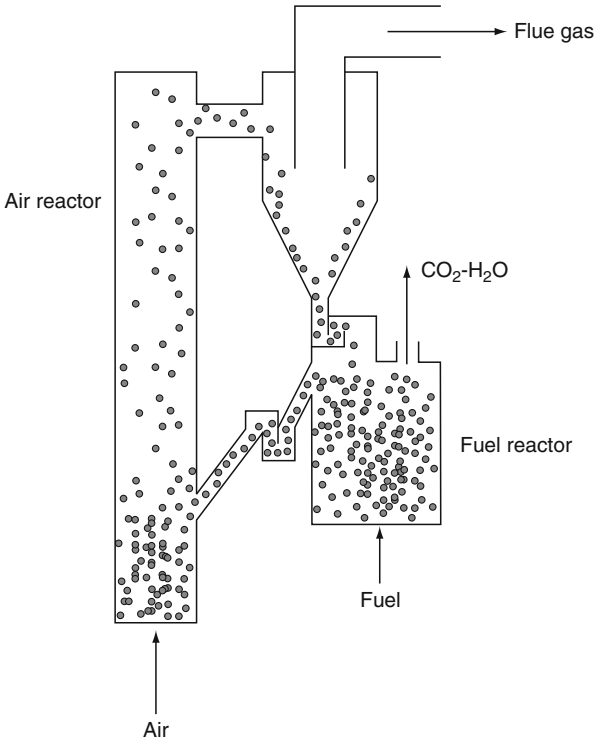

Fig. 2 Schematic of Grace 10-kW chemical looping reactor

pilot-scale equipment, supplemented with crush tests to measure the individual strength of particles under ambient conditions, have suggested that the best particles produced are strong enough to survive extremely well in the small-scale units that have been studied (Lyngfelt et al. 2004; De Diego et al. 2005, 2007). Thus, De Diego et al. (2005) suggest that a loss of 0.01 % per cycle is reasonable based on their experimental work, implying a lifetime of particles of 10,000 cycles (5,000 h in their tests), which they suggest is equivalent to a particle cost of less than 1 €/t of CO_2 captured. Similarly, in a later paper, De Diego et al. (2007) suggested a loss of 0.04 wt%/h, with a particle lifetime of approximately 2,400 h, or replacement of the bed inventory 3.4 times per year. Very similar conclusions were reached by Lyngfelt et al. (2004) for the Grace Reactor (Fig. 2) where these workers suggested that particle lifetimes of 40,000 h were possible. The same workers studying the $NiO/NiAl_2O_4$ particles in a 1,016-h test using their 10-kW reactor reported that the largest decrease of fines occurred in the first 100 h and estimated that a particle lifetime of 33,000 h could be achieved with these particles (Linderholm et al. 2009).

Nonetheless, as large demonstrations and early efforts at commercialization are being developed, the production of large quantities of such materials by less complicated and, hence, less expensive methods will continue to be a priority as

will verifying the fact that such materials can withstand full-scale operation with minimal carrier loss, especially if they are used directly with solid fuels.

$CaS/CaSO_4$ System

As noted above, the $CaSO_4$/CaS system has the highest carrying capacity of all, at 0.47, and is also unique in that it employs a nonmetallic system. Coupled to the very high carrying capacity, it has another obvious advantage in that anhydrite ($CaSO_4$) and gypsum are available in large quantities in the natural environment and can, therefore, be obtained at relatively low cost. CaS itself might be more problematic in that it can react with water to release H_2S, but otherwise this system seems at first sight particularly promising. Unfortunately, there are some obvious problems, firstly, that the system can lose SO_2 via direct oxidation of CaS:

$$CaS + 3/2C_2 = CaO + SO_2 \tag{10}$$

as well as the well-known reaction:

$$CaS + 3CaSO_4 = 4 \quad CaO + 4SO_2 \tag{11}$$

which occurs in the temperature region above 900 °C (Partington 1939), where one might expect to operate a chemical looping system, which means that unless conditions are carefully controlled, the active system will lose sulfur in the form of SO_2. Secondly, one can reasonably expect such natural materials to sinter and to lose activity rapidly as is the case, for example, with natural limestone in Ca looping cycles, where CaO is used to remove CO_2 from hot flue gases (Blamey et al. 2010). In addition, one would expect the attrition from such systems to be relatively high when compared with other chemical looping carriers unless synthetic materials are prepared, in which case the system loses some of its obvious advantages.

The loss of SO_2 was demonstrated in studies done by the researchers of Southeast University in China, who used a natural anhydrite (94.4 % pure), with an oxygen capacity of around 0.444, which they tested in a fixed bed reactor (24-mm dia.) (Song et al. 2008a). They found that conversion of natural gas was low unless temperatures were in the range of 950 °C but that high temperatures were associated with a loss of SO_2 from the reactor of up to 6 % in the flue gases. These workers also noted that there was a small loss of SO_2 even at 850 °C. In addition, there was some agglomeration of particles at higher temperatures. These workers also explored the performance of this system for simulated syngases, again using the same natural anhydrite, but this time in a small fluidized bed reactor (25-mm dia.), and found that the mass conversion rate for this system was considerably less than the metal oxide systems. They also noted that CaO became the main component after the 20th oxidation cycle, due to the loss of SO_2 (Song et al. 2008b, c). In a study by Shen

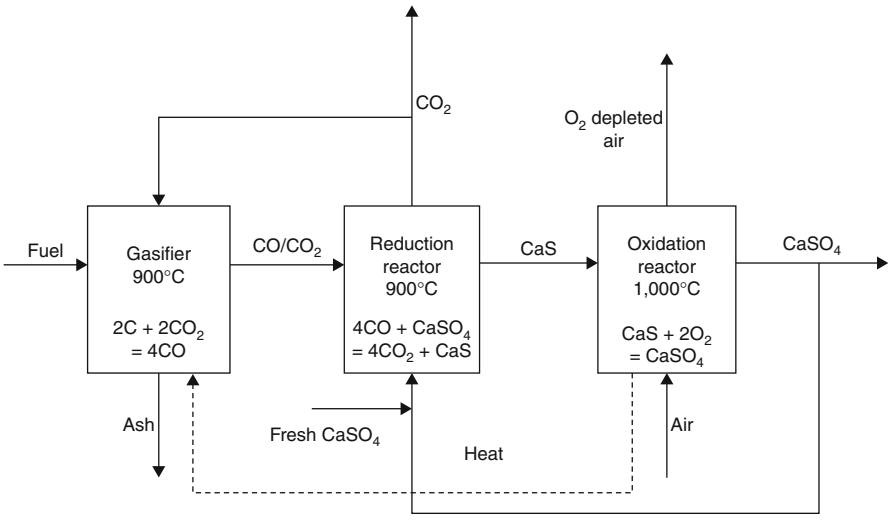

Fig. 3 Schematic of chemical looping process for combustion of solid fuels using the $CaSO_4$/CaS system (From Wang and Anthony (2008))

et al. (2008), Rx. 11 was identified as the main cause of sulfur loss from the system, and these workers recommend recapturing the SO_2 by feeding a small amount of limestone into the system. They further recommend that the air reactor should be between 1,050 °C and 1,150 °C, while the fuel reactor should be operated between 900 °C and 950 °C.

These problems with this system might well suggest that it would not be the first to be explored despite its obvious advantages. However, it is clear that a more detailed examination of other sources of the natural oxidizers could be explored or that one could consider making synthetic carriers such as sulfating dolomite, in the hope that the magnesium component might reduce sintering, and/or adding a guard bed to capture any SO_2 escaping the system, perhaps in the form of CaS or $CaSO_4$ so that the material could be recycled back to the reactor. Wang and Anthony (2008) also proposed such a system (Fig. 3) in which syngases from a material like petroleum coke are oxidized by $CaSO_4$, which is then regenerated in a separate reactor that can be used to generate heat and power, and supported their ideas with an ASPEN™ simulation. In this system, any loss of SO_2 will occur together with the oxidized syngas stream and must be separated from the CO_2 stream or sequestered with it. They also proposed the possible use of dolomites if reactivity issues were significant and made similar points to that of Song et al. (2008c) who discussed the use of this cycle with solid fuel. They stated that these materials are intrinsically cheap and so, having a fairly high makeup rate, may be acceptable for this system, whereas it would most certainly not be for a more expensive carrier. In the work by Song et al. (2008c), they suggest that complete separation of carrier and ash might not be problematic, because for a really cheap natural sorbent, even if there are ash-sorbent interactions, sintering issues, or losses of SO_2 leading to high losses of

sorbent/carrier, it may still be possible to operate economically with such a cycle, although this clearly would not be ideal. Yet another suggestion for dealing with the problem of loss of SO_2 comes from the work of Tian and Guo (2009), whose research noted that the amount of SO_2 released was also dependent on the partial pressure of CO and suggested that in a pressurized system the release rate of SO_2 could be minimized if the partial pressure of CO was high enough, even at 1,000 °C.

This brings us to the final reason for considering this system, and that is that it was proposed by Alstom Ltd., as part of a $4-million US Department of Energy Program from the National Energy Technology Laboratory (NETL) Existing Plants Program, aimed at demonstrating the conversion of solid fuels in a specially designed 3-MW_{th} pilot plant (Andrus et al. 2010). The system considered by Alstom has a number of looping cycles working together: a $CaSO_4$–CaS cycle, a $CaCO_3$–CaO cycle for CO_2 removal, and a thermal loop involving bauxite. This system is evidently of considerable complexity as has been critically noted by Wang and Anthony (2008) but apparently has very attractive potential costs for avoided CO_2 ($11–13/ton of CO_2) (Andrus 2007). The pilot plant is expected to be running sometime in 2010–2011, and interested readers can follow developments for this system via the US DOE website (US DOE 2010).

Cu System

The copper system was the first chemical looping system to be explored with the groundbreaking work of Lewis et al. (1949), and it was also used to provide an example of a chemical looping process in the paper by Richter and Knoche (1983). Copper is attractive because it can be used to make extremely reactive oxygen carriers and is in addition a reasonably inexpensive material with relatively low toxicity. In addition, it has one interesting feature, namely, that both the oxidation and reduction are exothermic; this property can feed into a number of schemes, the most obvious of which is a fuel reactor that does not need to be supplied with heat, as is the case for other systems. However, its tendency to agglomerate with the potential to cause defluidization in fluidized bed systems is still an important consideration (Chandel et al. 2009). This is also the view presented in two reviews carried out on chemical looping in 2006 and 2008; based on the available literature, both stress the tendency of copper carriers to agglomerate and the need to avoid higher temperatures. In the first review, Tan et al. (2006) suggest that Cu-based carriers are restricted to relatively low temperatures because of a tendency to agglomerate above 800 °C, while in a review published 2 years later, Hossain and de Lasa (2008) explicitly state that "Cu also has a relatively low melting point (1,085 °C) and as a consequence cannot be used above 900 °C."

An early exception to these views can be found in the work of De Diego et al. (2005) who note that, under proper conditions, it is possible to produce Cu-based carriers with high reactivity and low attrition rates, which also do not agglomerate in a fluidized bed, thus negating the main reason to avoid such carriers. In this paper, they also note that they have carried out tests for 20 cycles at 950 °C in

a fluidized bed reactor without evidence of problems. Moreover, it can be argued, however, that the more recent literature suggests a somewhat more positive picture, although temperatures above 900 °C are generally still avoided. Thus, a number of workers have reported good success with CuO supported on Al with trials of up to 200 h in a 10-kW reactor, showing very little signs of agglomeration, albeit that the temperatures were around 800 °C (De Diego et al. 2007; Adánez et al. 2006a), and these workers note that theirs is the first demonstration of good performance exhibited by a Cu-based material operating at high temperature in a continuous chemical looping process. Equally, Chuang et al. (2008) have argued that coprecipitated CuO–Al_2O_3 carriers perform better than wet-impregnated carriers and show no sign of copper redistribution in the carrier or agglomeration in the temperature range of 800–900 °C, while Tian et al. (2008) report excellent performance of nanostructured Cu–BHA (barium hexa-aluminate) carriers over the temperature range of 700–900 °C. Finally, Mattisson et al. (2009) have argued that, based on the work of Adánez and his coworkers (De Diego et al. 2005; Adánez et al. 2006a, b, De Diego et al. 2004), it should be possible to manufacture Cu-based oxygen carriers that do not agglomerate at higher temperatures. This is important for the work Mattisson et al. (2009) are discussing, because they are interested in using copper oxide systems for a process they call chemical looping with oxygen uncoupling, in which the metal oxide releases gaseous oxygen. This phenomenon is potentially valuable in gasification schemes for solids, which are otherwise rate-limited by the reaction rate of H_2O or CO with the solid, and this will be discussed in more detail later in this chapter. It is interesting to note in the experiments described by Mattisson et al. (2009) that the copper carrier (CuO/ZrO_2) is regenerated at temperatures of 905 °C and 955 °C. Finally, it is worth remarking that Cao et al. (2006) suggested that the Cu/CuO system was particularly suited for the conversion of solid fuels due to its exceptional reactivity, based on thermogravimetric and differential scanning calorimetry experiments (Cao et al. 2006). The subject of solid fuel conversion will be discussed later on.

Fe System

As noted earlier, this is the least reactive of the common systems (i.e., Ni, Cu, and Fe); however, it is the most environmentally benign, and potentially it is also the cheapest. There has as a result been considerable interest in this system, and work has been done both on synthetic and natural hematite carriers (Fe_2O_3) (Mattisson et al. 2001) and natural ilmenite ($FeTiO_3$) (Prőll et al. 2009; Leion et al. 2008a, b). Early work in a fixed bed reactor using hematite showed that the particles developed cracks, and the authors suggested that a binder would probably be desirable in manufacturing a synthetic carrier (Mattisson et al. 2001), and later work was almost exclusively focused on systems using a carrier; thus, for instance, in his list of studies (Tables 1–5 of his work), Johansson (2007) lists 7 studies with Fe_2O_3 and 38 for Fe_2O_3 with various carrier materials. In a study of an Al_2O_3-supported carrier with

40 % Fe_2O_3, Abad et al. (2007b) carried out tests for 40-h duration at temperatures ranging from 800 °C to 950 °C in a 300-W fluidized bed reactor. They noted that there was no sign of agglomeration under conditions examined but that the conversions of CH_4 were relatively low with combustion efficiencies reaching 94 %, as compared to 99 % with syngas, which reflects the general realization that iron-based oxygen carriers can be expected to be less reactive. Experiments done in a fixed bed reactor at 900 °C with an iron-based carrier supported on titania prepared by a wet impregnation method showed that the Fe reacted with the TiO_2 to form ilmenite. Although the amount of active carrier was reduced, reasonable performance with CH_4 was achieved, but the reactivity of the Fe-based carrier was less than what would have been expected for Cu- or Ni-based carriers (Son and Kim 2006; Corbella and Palacios 2007). An interesting method of dealing with the reactivity problems associated with the iron system is to add Ni at a low level, and Rydén et al. (2008a, b) report that by adding 10 % NiO/$MgAl_2O_4$ they were able to produce a material with similar behavior to a pure NiO/$MgAl_2O_4$ carrier. In later work, they report that addition of the equivalent of 5 wt% of a NiO material changed the combustion efficiency in a small fluidized bed operated at 900 °C from 76 % to 90 % for the conversion of CH_4 (Rydén et al. 2010).

Pröll and his colleagues (2009) have carried out experiments with ilmenite in a 120-kW dual fluidized bed system and reported what they describe as reasonable fuel conversions (between 60 % and 90 %) at 950 °C for syngas (mixtures of CO and H_2) but much more limited performance with CH_4, around 30–40 %. They also found that low load was associated with poorer conversion and the addition of natural olivine, at a level of 18 % of the bed material, helped to achieve a moderate increase in CH_4 conversion. These results are fairly similar to those obtained earlier by Leion et al. (2008a), who carried out tests in a small fluidized bed reactor (22-mm dia.) at a nominal 950 °C, in which they looked at either pure methane or syngas (50 % CO and 50 % H_2) conversion; again they report good conversion of syngas but much poorer conversion of CH_4.

It is also interesting that, unlike Cao et al. (2006), Rubel et al. (2009) who carried out experiments on a beneficiated high-carbon coal gasification char, using a thermal analyzer–differential scanning calorimeter–mass spectrometer system, recommended Fe-based carriers as the best for solid fuel conversion. In particular, they noted that their experiments showed that Fe_2O_3 and an iron-based catalyst remained more durable through multiple oxidation/reduction cycles.

Finally, it is interesting to note that some research has recently been done on syngas production from mixed cerium–iron systems with natural gas (He et al. 2009; Li et al. 2010). Both the cerium and iron are considered to contribute to oxidation in the fuel reactor, and in the work of He et al., the Cu and Mn oxide systems were also explored. Ce/Fe molar ratios of greater than 1 were found to perform best by He et al. (2009), and similar results were obtained by Li et al. (2010). Perhaps the only negative comment that can be made is that any benefits of price in terms of using the iron system must be compromised for such systems, even allowing for the fact that cerium is the most abundant of the rare earth elements.

Ni System

The vast majority of chemical looping research work has concentrated on using Ni-based carriers, and, thus, as an example of the 105 studies recorded by Johansson (2007) (Tables 1–5 of his work), 67 of them employed Ni-based carriers. It also appears to be extensively addressed in the early work of Ishida's group in Japan (Ishida and Jin 1994a, b; Ishida et al. 2002; Jin et al. 1999). Despite the concerns with the cost of Ni and potential toxicity problems as discussed earlier, and the fact that the reaction does not go to completion with CH_4 (conversions of 99 % at 1,000 °C) (Jerndal et al. 2006), its excellent performance and stability on suitable inert matrices, such as Al_2O_3 and YSZ (yttria-stabilized zirconia) in particular at temperatures up to 1,000 °C, have meant that it is the preferred candidate for research work at least. Numerous other inert matrices have been explored such as titania-supported nickel oxide (Corbella and Palacios 2007; Corbella et al. 2006); bentonite (Siriwardane et al. 2007), with MgO as an additive to Al_2O_3 and $NiAl_2O_4$ to prevent agglomeration under reducing conditions (Kuusik et al. 2009) and $NiAl_2O_4$ acting as the inert matrix in $NiO/NiAl_2O_4$ particles (Redman et al. 2006; Mattisson et al. 2008); SiO_2; and sepiolite ($Mg_4Si_6O_{15}(OH)_2 \cdot 6H_2O$) (Ksepko et al. 2010), and all of these have been reported as successful, although it appears that Al_2O_3 and YSZ are probably the most successful and commonly used and there appear to be some problems with SiO_2 as an inert matrix (Ksepko et al. 2010; Zafar et al. 2005). $NiAl_2O_4$ is an interesting carrier in that it can also, in principle, react with CH_4, but in the presence of NiO in the particle, it is assumed to be inert (Redman et al. 2006; Mattisson et al. 2008). Work has also been done on the use of Ni with a lanthanum-modified γ-Al_2O_3 inert substrate (Hossain et al. 2009). These workers noted that the lanthanum addition improved the reducibility of the oxygen carrier and speculated that the lanthanum inhibits nickel aluminate formation.

Very recently, an interesting suggestion has been made to reduce the cost of a Ni-based carrier, and that is to combine it with ilmenite, and based on a limited set of experiments done in a 120-kW_{th} dual fluidized bed reactor, it has been suggested that the performance of a properly designed NiO-based carrier will be close to that of the NiO-based carrier with up to 90 % ilmenite (Mayer et al. 2010). However, an overall conclusion that can be drawn from the literature is that at least to date the Ni/NiO oxide system is preferred for most research work; whether that translates into the commercial scale of course waits to be demonstrated.

Pilot Plant Research

In a review article published in 2006, Johansson et al. (2006c) list 11 studies carried out in 10-W, 40-W, 300-W, and 1-kW reactors using the NiO, Fe_2O_3, Co_3O_4, Mn_3O_4, and CuO systems with different stabilizers and test durations ranging from 3 to 60 h. Nearly all of the research was done with natural gas, although one study was done with CH_4 and another with a synthetic gas mixture. Since that date, there has been considerable focus on achieving longer trials in larger reactors, albeit that

reactor sizes at university laboratories at least are generally limited for practical reasons. More importantly, it is now commonplace to carry out trials for several hundred hours, and the Grace Project (Lyngfelt et al. 2004) carried out at Chalmers University, in Sweden, and tests done by Adánez et al. (2009a) on a 500-W_{th} chemical looping system using an impregnated Ni-based oxygen carrier, this time built and operated at the Instituto de Carboquímica, in Spain, are two examples of this type of facility and longer-duration testing. Equally impressive, the operation of a 10-kW_{th} unit using the copper system (CuO–Al_2O_3 carrier) has been demonstrated with no evidence of significant agglomeration (De Diego et al. 2007; Adánez et al. 2006a), and tests of 1,016-h duration have been achieved with a Ni-based system, carried out again at Chalmers University, Sweden, in their 10-kW unit (Linderholm et al. 2009). From the point of view of duration, these tests give as much reasonable assurance as one could ask that it is possible to operate these systems indefinitely.

Finally, it should be remarked that implicit in this discussion is the idea that dual fluidized bed reactors are likely to be used for commercial-scale operation, and this is, for example, the assessment of Hossain and de Lasa (2008) in their review of the literature. However, it is worth noting that some workers are considering the possibility of building industrial-scale fixed bed systems (Kimball et al. 2010). Arguments they make against dual fluidized bed systems include concerns that the gas-particle separation cyclones required between the two reactors are likely to be very expensive for commercial-scale systems and will also be associated with damage to the oxygen carrier particles and that attrition of fines will be a problem for gas turbines, something which has been an issue for pressurized fluidized bed systems, for instance (Cuenca and Anthony 1995).

Use of Natural Gas in Chemical Looping Systems

A fairly obvious caveat that can be raised about nearly all CLC R&D until 2008 or 2009 is that it depends on the use of natural gas and/or syngas and, moreover, it is somewhat limited in temperature to around 1,000 °C due to the sintering of the solid carriers. This point was made strongly by Tan et al. (2006), who noted that at the time of writing, the technology was only suitable for use with gaseous fuels. They also expressed concerns about the carryover of char if the technology was used with gasification. However, they did note that it appeared to offer significant flexibility for use with industrial boilers, gas turbines, and even fuel cells. This limitation is obviously considerable for thermal power systems because natural gas by itself is an ideal fuel, offering extremely high efficiencies and the cheapest power generation. What the technology clearly offers is very effective CO_2 removal, and it is interesting to explore what other advantages it might have with natural gas.

The group of Professor Bolland, at the Norwegian University of Technology and Science, has carried out significant work performing simulations of CLC plants. In 2004, it carried out a simulation of a CLC power station, using the NiO system, with a circulating fluidized bed for the oxidation or regeneration and a fluidized bed

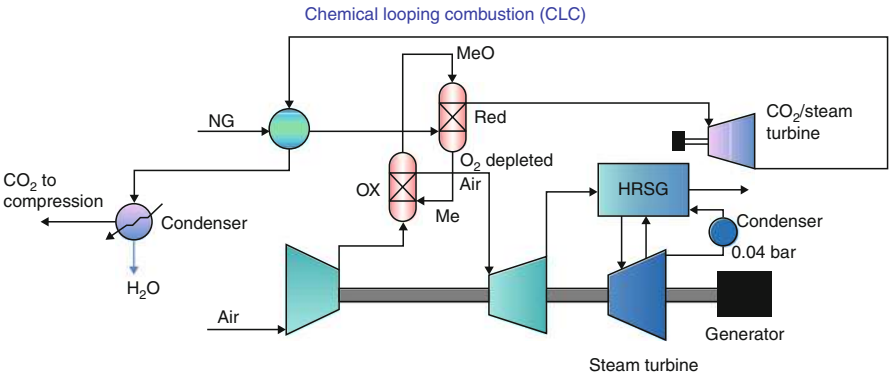

Fig. 4 Natural gas-fired chemical looping scheme (Taken with permission of Professor Bolland, Norwegian University of Science and Technology, from the paper by Kvamsdal et al. (2007)). *NG* natural gas, *HRSG* heat recovery steam generator

(bubbling) for the fuel reactor. The simulation demonstrated that the oxidation reactor exhaust temperature and the oxidation reactor air inlet temperature were very significant, but making various assumptions, the work indicated an optimum efficiency of 55.9 %. In an examination of the effect of part load on plant efficiency, for a natural gas-fired power cycle using CLC, Naqvi et al. (2007) noted a drop of 2.6 % in efficiency when reducing the load down to 60 % for a CLC concept but stated that this system performed better than a conventional combined cycle system. The same group subsequently looked at nine concepts for natural gas firing, including six oxy-fuel and two precombustion capture systems (Kvamsdal et al. 2007), and concluded that chemical looping technology showed among the best results, with a plant efficiency of 55.1 %, exceeded only by an advanced zero-emissions power plant and a solid oxide fuel cell integrated with a gas turbine. Figure 4 shows the scheme considered by these workers. However, they noted that CLC and other advanced concepts might not be realized at the scale of the analysis.

Wolf et al. (2005) made a comparison of the nickel- and iron-based systems for power generation with natural gas with CO_2 capture and concluded that overall efficiencies of almost 53 % were achievable for a natural gas combined cycle incorporating a chemical looping system, provided that the temperature of the air reactor could be kept at 1,200 °C. Here, they considered two interconnected pressurized fluidized beds. However, they did note that this efficiency strongly depended on the exit temperature of the air reactor being only 1,000 °C, and the system did not look any better than conventional technology with backend CO_2 removal.

Consonni et al. (2006) carried out an analysis of a chemical looping cycle for a utility-scale application using natural gas and came to the conclusion that employing chemical looping combustion should not pose a significant problem when using commercially available gas turbine technology, an important consideration because, as they note, unless CLC becomes the technology of choice for power generation, it is unlikely that manufacturers will ever offer a gas turbine

specifically designed to operate at the optimum conditions for an integrated chemical looping combined cycle system. In their simulations, unfired configurations with maximum process temperatures were able to reach net efficiencies of 43–48 %, while fired configurations, where the temperature is raised from 850 °C to 1,200 °C by supplementary firing, could achieve 52 % net efficiency. A possible limitation is that a preliminary economic analysis indicated that the cost of CO_2 avoided by integrated chemical looping combined cycle plants with a maximum CLC temperature of 850 °C is about 50 €/t for both fired and unfired concepts. The authors of this study note that this compares unfavorably with the cost of alternative technologies; however, considerable caution should be exercised about such conclusions given that no practical carbon capture and sequestration technology currently exists at the utility scale. Finally, it is of interest that Damen et al. (2006) made a detailed study of various schemes for electricity and hydrogen production with CO_2 capture and suggested that chemical looping combustion was promising and that net electric efficiencies might reach between 50 % and 55 % for CO_2 capture of 85–100 % for CLC systems.

Solid Fuels in Chemical Looping Combustion

The use of solid fuels is evidently an extremely desirable goal. Unfortunately, syngas must first be made, albeit that it is likely to be very reactive as has been demonstrated in fluidized bed experiments (Dueso et al. 2009), while natural gas represents a premium fuel, with the lowest greenhouse gas potential of any fossil fuel even if burned in a conventional cycle. Unfortunately, the direct use of such fuels evidently poses significant problems. If fluidized beds are to be used, there is the issue of making sure that a significant amount of char carbon does not enter the air reactor, reducing the benefit of the inherent separation, although this is perhaps not as much of a problem as has been occasionally suggested, since even amine scrubbing is likely to be operated with only 80–85 % CO_2 removal for large-scale units (Rao and Rubin 2006). In addition, choices will have to be made in terms of the amount of steam and/or CO_2 to be used for fluidization in the fuel reactor.

Another problem of course is the potential of ash interaction with the oxygen carrier, which, as has been seen here, is likely to be expensive unless an iron-based natural ore can be used; in short, it will very strongly and adversely affect the economics of a chemical looping system if the makeup of an expensive carrier becomes excessive (Abanades et al. 2007). However, by far the biggest problem is that direct solid–solid reactions are not favored in this system. After the solid fuel (presumed to be coal but could be petroleum coke) has devolatilized, CO_2 and H_2O in the system must first gasify the resulting char by Rx. 12 and 13, and this process is inherently slow in fluidized bed environments, at least for most coals (a possible exception is lignite), which is why coal gasification is normally done at high temperatures and pressures with fine particles in entrained flow systems (Higman and van der Burgt 2008):

$$C + H_2O = CO + H_2 \quad (12)$$

$$C + CO_2 = 2CO \quad (13)$$

It should be noted that Siriwardane et al. (2010) have proposed that if there is sufficient contact between the fuel carbon and the carrier, genuine solid–solid reactions are possible, and they call this mechanism "fuel-induced oxygen release." Furthermore, they have demonstrated this by work with pure carbon and CuO. Specifically, they suggest that reaction of CuO in the bulk of the particle may proceed by carbon–CuO contacts produced by surface melting of metallic copper at temperatures as low as 500–600 °C, and they note that the Tammann temperature for copper (i.e., half the absolute melting point of the substance, which is the temperature at which bulk diffusion becomes rapid in a solid) is particularly low (406 °C).

Nonetheless, it seems most unlikely that this process by itself could achieve or explain the good conversions in a fluidized bed of char carbon by copper oxide recently reported by Dennis and Scott (2010). They used relatively large particles (+600 mm, −1190 mm) of porous alumina, impregnated with copper, so that the direct contact between the copper and the char was relatively limited. They proposed (Dennis and Scott 2010) that the conversion of the char by the chemical looping agent, when the bed was fluidized by nitrogen, was in fact mediated by gaseous CO_2 (produced by the reaction itself), reacting with the char to produce an intermediate of CO, which was then rapidly converted to CO_2 via reaction with the oxygen carrier. Unfortunately, their model was not able to fully account for the conversion seen. Subsequent work using an iron-based oxygen carrier (Brown et al. 2010) was able to account for the conversion of the char in a bed fluidized by nitrogen, without the need to invoke a solid–solid reaction. In this case, a model that only incorporated the Boudouard reaction and the combustion of the CO intermediate by the oxygen carrier was sufficient to quantitatively account for the observed conversions. The model was found to be very sensitive to the kinetics of conversion of the char by CO_2, which may explain, in part, the difficulties encountered by Dennis and Scott (2010).

It is difficult to rule out some contribution from a direct solid–solid reaction between the oxygen carrier and the char, and the controlling mechanism may depend on temperature, the metal oxide, and the degree of contact between the char and the oxygen carrier. This problem was previously of interest for the reduction of iron oxides, and the idea that the reaction may proceed by gaseous intermediates and the Boudouard reaction under some conditions (e.g., higher temperatures, more reactive chars) and direct reduction under others (e.g., vacuum, lower temperatures) is not new (see, e.g., Srinivasan and Lahiri 1975). The experiments of Dennis and Scott (2010) and Brown et al. (2010) were carried out at temperatures high enough for the Boudouard reaction to be significant, with reactive chars, while those by Siriwardane et al. (2010) used finer particles and observed some reaction at temperatures at which the Boudouard reaction can be neglected.

This mechanism does, however, appear to offer an explanation for the finite rate of reaction reported by Dennis and Scott (2010) in the following words: "However,

the observation of finite rates of conversion in a bed of active carrier, fluidized by nitrogen is a curiosity, which we have not been able to explain satisfactorily."

Despite the potential problems, the idea of using solid fuels in a chemical looping cycle was explored over a decade ago, and the work of Lyon and Cole (2000) provides an extremely interesting example of this early attention. These workers called the concept unmixed combustion and looked at the possibility of using the Cu/CuO, FeO/Fe_2O_3, and Ni/NiO systems with the oxygen carriers supported on γ-Al_2O_3 for a number of applications including a dual fluidized bed combustion scheme working at elevated pressure. To support this work, they also carried out a limited series of tests in batch mode with coal and Fe_2O_3 in a small fluidized bed, as well as a number of other experiments with methane, and concluded that the chemical looping approach had considerable promise for a range of applications including solid fuel conversion.

In 2007, Chalmers University started a series of experiments on petroleum coke (Leion et al. 2008b, 2007; Berguerand and Lyngfelt 2008a). Petroleum coke, unlike most coals, normally has extremely high carbon contents (~80 % plus), low ash (~1 % or less), high sulfur (5–8 %), low volatiles (5–10 %), and elevated V (a potential agglomerating agent in fluidized beds) in the ash. Furthermore, it is a relatively unreactive fuel for fluidized bed applications, and primarily its high energy value and low price are the driving force for its use (Anthony 1995). Hence, success with this fuel would be a very positive result for the application of chemical looping technology for solids under standard fluidized bed conditions. The first reported set of experiments was conducted in a small quartz fluidized bed, using 20 g of oxygen carrier (60 % Fe_2O_3/40 % $MgAl_2O_4$) at a nominal temperature of 950 °C, and the carrier was subjected to 100 cycles (~100 h). This work showed that conversions were sensitive to the amount of steam in the fluidizing gas and rose with the addition of SO_2, which, as noted by Lyon and Cole (2000), can effectively oxidize char carbon.

In a second series of tests, this time using a 10-kW_{th} chemical looping combustor, an 11-h operation was logged, at a nominal temperature of 950 °C, using ilmenite as the oxygen carrier (Berguerand and Lyngfelt 2008a), and the resulting carbon conversions were in the range of 60–75 %. While these are low figures, the authors commented that improved reactor design would enhance performance, and it must be remarked that the oxygen carrier is known to be one of the less reactive carriers.

More recently, the same group has looked at petroleum coke combustion, this time using a CuO carrier for a temperature range of 850–950 °C in a batch fluidized bed (Mattisson et al. 2009). Here, the carrier actually releases oxygen in a process that can be described in the following manner:

$$Me_xO_y = Me_xO_{y-2} + O_2 \tag{14}$$

and this process, which the authors call chemical looping with oxygen uncoupling (CLOU), allows much faster rates of reaction, rather than depending on the gasification reactions Eqs. 12 and 13. In the case of Cu, the overall global reaction is

$$4CuO + C = 2Cu_2O + CO_2 \quad (15)$$

and the use of this reaction with solid fuels is also discussed much earlier in the patent of Lewis and Gilliland (1954).

In work with a South African coal, again using their 10-kW_{th} fluidized bed facility and ilmenite as the oxygen carrier, Berguerand and Lyngfelt (2008b) report solid fuel conversions in the range of 50–80 %, and they stress the problems associated with loss of carbon fines from their cyclone and suggest various ways in which performance could be improved. These workers have also carried out a more extensive series of trials on petroleum coke and five different coals (South African, Chinese, Indonesian, Taiwanese, and French) using a quartz fluidized bed reactor and two oxygen carriers, a synthetic iron-based carrier ($Fe_2O_3/MgAl_2O_4$) and ilmenite (Leion et al. 2008a), at a temperature of 950 °C. This work again confirmed the importance of steam levels for high conversions and found that the two carriers performed similarly. These workers have also recently developed a model for residence time analysis of the CLC of solid fuels, which can give the mass-based reaction rate for chars from the batch tests (Markström et al. 2010).

The NiO oxide system with $NiAl_2O_4$ inert (77 %) has also been examined at Southeast University in China for a bituminous coal from Inner Mongolia using a small, electrically heated fluidized bed and 1 g (nominal) of coal samples (Gao et al. 2008). These workers noted that the gasification rate was slow compared with syngas, and they suggested that 100 % steam as a gasification agent would improve the performance; they found that the best performance was achieved at the highest temperature they explored, 900 °C. A small amount of Ni-containing material was found in the cooler designed to remove water vapor, and they suggested that in a commercial system, a nitric acid treatment of these "ashes" might be used to recover the Ni. In a more recent paper, the same group explored the use of a dual fluidized bed system consisting of a spouted fluidized bed fuel reactor and a fast fluidized bed as the air reactor (Shen et al. 2009) using the same bituminous coal as in previous studies. Again they used the NiO system with a very similar amount of $NiAl_2O_4$ inert (67.3 %). As with previous studies, carbon conversions were somewhat limited, and in these experiments it reached only 92.8 %, even at a temperature of 970 °C in the fuel reactor.

These workers at Southeast University have also studied the use of $CaSO_4$ as an oxidizing agent for coal in a small, electrically heated fluidized bed (Zheng et al. 2010). This work showed that increasing the steam/CO_2 ratio improved the gasification of coal and overall performance, but again they had problems with loss of SO_2 from the system. Another problem was that sintering of the natural anhydrite became worse at 950 °C, effectively negating the benefits of operating at higher temperatures.

Chemical looping has also been considered for use with lignite and lignitic char (Dennis and Scott 2010; Brown et al. 2010; Scott et al. 2006; Dennis et al. 2006), which, because of their low rank, provide the most reactive coals with the highest volatile content and, thus, might be a particularly good choice of solid fuel for chemical looping. In their first study on lignite (Hambach, Germany)

and its char, they explored the possibility of a process in which the coal is fed batchwise for a limited period into the reactor, its feed is then stopped until the char content in the bed is sufficiently small, and then air is reintroduced into the system to regenerate the solid oxide carrier (Scott et al. 2006). Their first experiments were done with a small bubbling bed quartz reactor, using Fe_2O_3 as the oxygen carrier at a nominal temperature of 900 °C, fluidized with N_2 and CO_2 mixtures or steam or air, and while they note that the process was not optimized in their experiments, the initial results were sufficiently encouraging to suggest that this approach offered a potentially interesting process. These workers subsequently carried out more detailed work with the same system operating at temperatures of 800–900 °C with fluidizing gases consisting of mixtures of nitrogen, air, CO, and CO_2 as desired (Brown et al. 2010). They note that combustion of char also occurred when the bed was fluidized only with nitrogen, and they suggest that this is most unlikely to be due to a solid–solid reaction, but rather by small amounts of residual oxygen forming CO and CO_2. In their most recent paper, these workers have also looked at the copper system and again found a reaction when the bed is fluidized with N_2, which they also suggest cannot be due to a solid–solid reaction. These experiments were done at 900 °C for up to 20 cycles and showed no significant deterioration in the performance of the CuO carrier.

Given the challenges of solid fuel conversion, Xiang et al. (2006) suggest that "direct reaction between the coal and oxygen carrier in the CLC is not expected to be feasible because the reaction rate is likely to be too slow." They also note that coal ash interactions with carriers may reduce the reactivity of the carrier and raise the issue of carbon bypassing to the air reactor, all of which they suggest will cause the advantages of easy CO_2 separation to be lost. Instead, they suggest that coal slurry should be fed through the air reactor and the resulting syngases used to reduce the carrier in the fuel reactor. In this way, this concept was supported by an ASPEN™ simulation, and the authors suggest this is a particularly promising route, although they do note that there are some issues with "pipe gasification."

Xiao et al. (2010a, b) have examined the performance of a Chinese bituminous coal in a small fixed bed reactor at pressures up to 0.6 MPa, with an iron ore-based oxygen carrier using a laboratory-scale fixed bed reactor. In this work, the cycle responsible for providing oxygen was assumed to be Fe_2O_3/Fe_3O_4. The primary focus of these studies was to determine what effect pressure had on performance rather than reactor design or scale-up, and therefore, issues such as the amount of carrier required per MW_{fuel} were not examined in these studies. In the initial study by Xiao et al. (2010a), these workers looked at three to five reaction cycles and found that increasing the pressure up to about 0.5 MPa enhanced the reduction of the oxygen carrier but that slightly lower conversions were obtained at 0.6 MPa, which was the highest pressure examined in this work. In a subsequent study, experiments were carried out for up to 20 cycles (Xiao et al. 2010b). Interesting results from this study included: no evidence of agglomeration or the formation of large grains, a high stable average CO_2 production (96 %), and no evidence of deterioration of the oxygen carrier.

Effects of Sulfur

Fairly recently the potential effects of sulfur have started to receive attention (Ksepko et al. 2010; Adánez et al. 2009b; Foero et al. 2010; Shen et al. 2010). Sulfur may be reasonably expected in natural gas prior to cleaning, in various industrial gases, and, of course, in coal syngas. Concerns expressed for the effects of sulfur include possible poisoning of the oxygen carrier, release of sulfur compounds in the gases from the air and fuel reactor, and, in the case of Ni, the possibility of melting and agglomeration phenomena due to the low melting point of Ni_3S_2 (melting point 791 °C). In a study of a Ni-based carrier with alumina inert support, Adánez et al. (Adánez et al. 2009b) looked at the behavior of methane, ethane, and propane, as well as performed experiments with H_2S addition in their 500-W_{th} unit. Without H_2S they obtained excellent performance with high hydrocarbon conversion and no evidence of carbon formation, which was a concern especially for the higher hydrocarbons (these tests showed no signs of agglomeration or carbon formation, with or without the addition of H_2S), but there was deterioration in the performance of the oxygen carrier when H_2S was added to the system and sulfur compounds were found in emissions from both the air and fuel reactors. What is an extremely positive result from this work is that the oxygen carrier fully recovered its activity after the carrier was oxidized in the air reactor, suggesting that sulfur compounds do not do damage to the long-term performance of such carriers. However, it is the conclusion of these workers that high concentrations of sulfur should best be avoided in a chemical looping system operating with a Ni carrier.

Ksepko et al. (2010) have also recently done tests on the NiO system using a range of inert supports including sepiolite (a complex magnesium silicate), SiO_2, ZrO_2, and TiO_2, with simulated coal-derived synthesis gas in a thermogravimetric analyzer, including tests in which 4,042 ppm of H_2S was added. This work also supported the work of Adánez et al. (2009b) in showing the formation of nickel sulfide compounds, and again they showed that sulfur in these compounds was released in the oxidation stage. Another such study has been performed by Shen et al. (2010) using a Ni-based oxygen carrier prepared by a coprecipitation method, with Al_2O_3 as a support using both a thermogravimetric analyzer and a small 1-kW_{th} reactor consisting of a spouted fluidized bed as the fuel reactor and a fast fluidized bed operating as the air reactor. This work takes a very detailed look at possible reaction mechanisms with sulfur and also produces similar findings to the two other studies reported here on the Ni system. Finally, the group of Adánez has now looked at the Cu system with γ-Al_2O_3 as the inert support with their 500-W_{th} reactor for reaction with CH_4 with H_2S addition (Foero et al. 2010). Here, the fuel reactor was operated at 800 °C and 900 °C, and the compound of concern is Cu_2S, although with a melting point of 1,130 °C, it seems unlikely that it would perform worse than Cu (1,085 °C), other than by the formation of eutectic mixtures. Overall, their results were extremely positive with no evidence of impairment of combustion efficiency, even with H_2S levels at 1,300 vppm, or agglomeration; the majority of the sulfur compounds were found in the emissions from the fuel reactor with very little being

released from the air reactor, except at low equivalence ratios (Ø) of less than 1.5, where there was evidence of Cu_2S formation. (Here Ø is defined as the oxygen requirement of the fuel, divided by the potential oxygen release from the carrier, with a value of 1 being equivalent to the complete conversion of the fuel to CO_2 and H_2O.) One interesting result was that in experiments done to explore a possible regeneration of the carrier, where the H_2S feeding to the air reactor was suspended and the fuel feed was decreased to achieve an equivalence ratio of 1.9, there was a sudden release of SO_2 (3,300 ppm) and the gas composition returned to values corresponding to normal combustion for this system. These workers attribute this to a solid–solid reaction:

$$Cu_2S + 2CuO = 4Cu + SO_2 \tag{16}$$

and these results can reasonably be interpreted to be in agreement with the work of Siriwardane et al. (2010), who suggest that the copper system is capable of significant solid–solid reaction at standard chemical looping conditions.

Hydrogen Production and Reforming

Applications Relating to Hydrogen Production

The production of H_2 is important for many reasons, some of them being longer term, such as introducing the H_2 economy, possibly with the use of fuel cells, and encompassing the transportation industry (McGlashan 2010), rather than just stationary power sources or industrial processes, as are the bulk of examples considered in this chapter. However, H_2 itself is an important chemical, produced in very large amounts (of the order of 65 million t/a (Harrison 2009)), and is of profound interest to some national economies, such as in the case of Canada for oil sand upgrading, where current needs are around one million t/a, but have been predicted to rise to 7.7 million t/a by 2030 (Larsen et al. 2004). Thus, cheap methods of producing H_2 are desired, especially if this can be produced in a CO_2-neutral manner, since about 48 % of H_2 is produced from natural gas while another 48 % comes from oil or coal, with electrolysis supplying the rest (Harrison 2009).

The idea of using H_2 to fuel CLC was considered early on by Jin and Ishida (2001), but reasonably most of the research and development has been concentrated on various schemes for H_2 production (Zafar et al. 2005; Chiesa et al. 2008; Go et al. 2009; Xiang et al. 2010). Thus, Zafar et al. (2005) looked at the possibility of integrated hydrogen and power production for the CuO, Mn_2O_3, NiO, and Fe_2O_3 systems with SiO_2 as a support. For their experimental work, they used a small quartz fluidized bed reactor and they looked at performance for the fuel-rich situation. The concept they proposed was that methane is first converted into CO_2 and H_2 and then shifted in a separate reactor; in particular, they were interested in the potential performance of the oxygen carriers, which they ranked in the order of decreasing reactivity as $NiO/SiO_2 > CuO/SiO_2 > Mn_2O_3/SiO_2 > Fe_2O_3/SiO_2$.

An interesting study has been performed by Chiesa et al. (2008), which envisages the use of three reactors using the iron system and natural gas. Here, in the fuel reactor, hematite (Fe_2O_3) is reduced primarily to Wüstite ($Fe_{(1-y)}O$ where $0.05 < y < 0.17$ (Bohn et al. 2008)) by oxidizing the natural gas; in the steam reactor, most of the reduced FeO reacts with steam to form magnetite (Fe_3O_4), and finally, in the third reactor, the Fe_3O_4 is reoxidized to Fe_2O_3. Among the interesting points about such a scheme is that, unlike most chemical looping schemes, it involves the metal in more than two oxidation states, and the result of the simulation performed suggested that it was economically preferable simply to produce H_2, rather than H_2 and electricity. This study suggested that the economics of such a scheme were comparable with those of other approaches but that the environmental benefits in terms of 100 % CO_2 capture were better, given that the best alternative would at most achieve no more than 80 % CO_2 capture.

A fairly similar scheme, again with an iron-based carrier, has also been explored using coal as the fuel source by Xiang et al. (2010) for the simultaneous production of hydrogen and electricity, again with three reactors, using an ASPEN™ plus simulation. For the system considered by the authors, they note that the costs of such a system are high but the environmental benefits are significant. One limitation they see in a scheme producing both H_2 and electricity is that it is not possible to greatly vary the ratio of hydrogen production to electricity because this is dependent on the circulation rates for the oxygen carrier and hence the heat balance for the three reactors. The iron system with H_2 production from coal syngas, using an ASPEN™ simulation based on bench-scale results, is also explored by Fan et al. (2008), again with a very positive evaluation.

This scheme has also been explored experimentally, but this time using mixtures of CO, CO_2, and N_2 as the fuel source, in a small packed bed reactor (dia. 103 mm), by workers at the University of Cambridge (Bohn et al. 2008) whose work supported the general feasibility of such a scheme for producing very pure H_2. In 2009, these same workers carried out simulations of the same scheme, looking at steam pressures of 0.1 and 1 MPa, and showed that it was possible to achieve the necessary heat integration (Cleeton et al. 2009). Finally, this scheme has also been explored experimentally using a lignitic coal and its chars (Yang et al. 2008) and a small fluidized bed reactor using batches of hematite or Fe_2O_3 and demonstrated successful reduction of the hematite with potassium carbonate-promoted chars, production of H_2 via the reaction of water with the FeO, Fe produced by reaction with char, and final oxidation of the resulting magnetite (Fe_3O_4) to hematite (Fe_2O_3) by reaction with air.

Reforming

The chemical looping process can be utilized for reforming by using the oxygen carrier to supply heat to drive reactions such as

$$CH_4 + CO_2 + = 2CO + 2H_2 \tag{17}$$

or the more familiar

$$CH_4 + H_2O = CO + 3H_2 \quad (18)$$

Alternatively, chemical looping can be used simply to make a syngas containing CO and H_2 directly (as in Rx. 2; i.e., an autothermal scheme), which was the subject of the first published paper on chemical looping using the copper system (Lewis et al. 1949). A detailed review of R&D in Europe within the framework of the CACHET project was produced by Rydén et al. (2008a). This evaluation, which looks at results from thermogravimetric analyzers, and various batch and continuous fluidized bed facilities (up to a scale of 140 kW_{th}), including a semicontinuous pressurized facility (with reforming pressures up to 1 MPa), has suggested that autothermal reforming is feasible with the standard metal oxide systems (NiO, Fe_2O_3, Mn_3O_4, and CuO) with syngas compositions close to those expected on thermodynamic grounds and that carbon formation can be avoided provided that the fuel is diluted with around 30 % by volume of steam. The work reported in this study suggests that adding Ni to Fe- and Mn-based carriers is a promising approach to improve the performance of these systems, with Ni also acting as a catalyst to promote the formation of CO and H_2 from CH_4. The work at elevated pressure was also successful, with no adverse pressure effects or evidence of carbon formation over the range of conditions examined. With respect to carbon formation, Rydén et al. (2008c) make the interesting point that any carbon formation in the fuel reactor is not necessarily problematic since it can be converted to CO_2 in the air reactor and this could be seen as another benefit of the chemical looping process.

Recently, De Diego et al. (2009) have carried out reforming trials of up to 40-h duration using a Ni-based carrier and a 900-W_{th} continuous atmospheric chemical looping reforming pilot plant with a temperature in the air reactor of 950 °C and in the fuel reactor ranging from 800 °C to 900 °C. They report excellent CH_4 conversions of greater than 98 %. The product gases are strongly dependent on the oxygen carrier circulation rate, and these workers recommend a NiO-reacted/CH_4 molar ratio of around 1.25. In this work, no deterioration of the carrier, agglomeration, or defluidization issues were detected and the attrition rate was negligible. In recent tests done in a 140-kW reactor using two different NiO-based carriers (with $NiAl_2O_4$ and $MgAl_2O_4$ as inerts), excellent performance has been reported (Pröll et al. 2010). No carbon formation occurred for global air/fuel ratios larger than 0.4, even though the steam/carbon ratio was less than 0.4, and no CO_2 emissions were detected from the air reactor.

An unusual choice, the $CaSO_4$ system has also been analyzed for propane reforming (as an analog for liquefied propane gas, LPG) by Kale et al. (2010). They suggested that at a recommended temperature of about 700 °C, significant carbon or methane formation should be avoided, and they also noted that sulfur release is unlikely below about 780 °C. Unfortunately, there is no experimental work to support this analysis, and issues with the kinetic rate for reaction and sintering of a natural form of $CaSO_4$ could reasonably be expected to be problematic, in line with

the work done so far for use of this system in combustion. This work also suggests that, by using the CO_2 and H_2O for reforming with more propane, the "risks" of carbon sequestration are eliminated; however, any benefits of CO_2 reduction depend entirely on the subsequent fate of the syngas.

Pressurized Chemical Looping Systems

The use of pressure is of interest for a number of reasons. For thermal power, the dominant reason is the possibility of high-efficiency cycles via combined cycle operation and, in addition, depending on the pressure of operation, less or no energy would be needed to compress the CO_2 to levels necessary for pipeline transportation for final sequestration. This approach has had its most notable commercial successes with gasification and integrated gasification combined cycle operation (Higman and van der Burgt 2008). However, pressurized fluidized bed technology, although it has been developed to the 350-MW_e demonstration size, has not had the same success, and the largest of such unit will shortly be closed down because of poor availability and other problems (Shimuzu 2010). In general, problems with access to the equipment due to the existence of the pressure vessel (which translate into availability problems) and, above all, the need to operate with expensive ruggedized turbines have meant this technology could reasonably be considered moribund at this point. However, given the very low attrition rates observed, as discussed earlier in this chapter, from hot beds of oxygen carriers, it is to be hoped that for gaseous fuels at least, pressurized applications might have less problems.

Normally, in pressurized gasification and combustion applications, it is the oxidant (either air or oxygen) that is compressed; in the case of pressurized chemical looping cycles, the fuel gas must be pressurized, and this will mean that the amounts of solid oxide carrier to be circulated to the fuel reactor must be significantly increased.

A very early examination of the effect of pressure on the Ni system, using a thermogravimetric analyzer (Jin and Ishida 2001) for H_2 conversion, showed that increased pressure (up to 909 kPa) reduced the temperature for the commencement of both reduction and oxidation (by about 50 °C) and that the oxidation rate was nearly independent of pressure. In a subsequent study, looking at $NiO/NiAl_2O_4$ and CoO-NiO/YSZ particles in a TGA, with simulated coal gas, the same workers found evidence of methanation and carbon deposition, but the carbon deposition could be resolved by increasing the H_2O/CO ratio from 0.5 to 1 at elevated pressure (up to 909 kPa) (Jin and Ishida 2004). They also reported that the overall reaction rate increased with increasing pressure.

However, a later study using a pressurized thermogravimetric analyzer (PTGA), carried out with pressures up to 3 MPa using H_2/N_2 and $CO/CO_2/N_2$ mixtures, showed that increasing total pressure reduces the reaction rate of the oxygen carriers examined, and it was speculated that increasing pressure might affect the internal structure of the oxygen carrier (Garcia-Labiano et al. 2006). In analyzing this study to map the range of operation conditions for Cu-, Fe-, and Ni-based carriers

(Abad et al. 2007a), the same group notes that there will be a need for higher solid inventories than expected due to the increase in gas concentrations at higher pressure and suggests that even at 1 MPa the iron system might present problems because of the upper limit for transport capacity of solids in the riser.

Siriwardane et al. (2007) looked at the behavior of a nickel oxide (60 % by wt) oxygen carrier supported on bentonite, using a high-pressure flow reactor operating at 101–690 kPa, and showed a rather more complicated picture for this system, with improved reaction at the highest pressure. However, the same workers also examined a copper oxide carrier using bentonite with a tapered-element oscillating microbalance, at pressures up to 690 kPa, and concluded that reaction pressure has a negative effect on reaction rates (Adánez et al. 2006b), in agreement with work by Garcia-Labiano et al. (2006).

Future Directions

What is now missing in the development of CLC are the first commercial- or near-commercial-scale demonstrations of the technology, similar to those being developed, for instance, by the US DOE for the $CaSO_4$ system (US DOE 2010). In a related effort, Tobias Pröll of the Technical University of Vienna has informed the author that they have developed a process flow sheet and design criteria for a 10-MW_{th} demonstration plant firing natural gas. For this work, the overall efficiency estimated is only 36 %, but it is suggested that this is reasonable considering the size of the plant. It is the practical application of these technologies and their demonstration at the industrial scale in the next several decades that are key to their contribution to a carbon-constrained world.

Although this chapter is devoted to considering primarily fossil fuels, or syngas derived from them, and focuses in particular on CH_4, syngas, and coal, there are of course numerous other possible applications for chemical looping processes. Examples include the synthesis of methanol from methane with a reduced carbon footprint (Zeeman and Castaldi 2008), a novel methanol power system using chemical looping with low-temperature reduction of methanol (Zhang et al. 2008), and a number of schemes involving chemical looping including coal to liquids, as explored by Professor Fan's group at Ohio State University (Fan et al. 2008). No attempt to consider these in detail is made here; they are noted simply to indicate the vast range of possibilities associated with the future of this technology.

Conclusions

Chemical looping is a relatively new technology, which had its beginnings some 60 years ago. However, it only began to receive major attention in the last 25 years or so. Major strides have been made taking the technology from work primarily involving fixed beds and thermogravimetric analyzers to numerous small pilot-scale fluidized bed reactors, with trials achieving upward of 1,000 h. In addition,

numerous possible systems have been explored, although the bulk of research has focused on Ni-, Cu-, and Fe-based carriers together with a vast number of possible inert substrates. Straight combustion of natural gas and, more recently, solid fuels has been explored including various schemes for the production of hydrogen. There has also been significant development in the area of reforming using this technology. What is currently lacking are larger-scale demonstration units, and the development of such facilities is urgently needed if the technology is to progress. However, for now, this technology can be seen as one of the most interesting and promising, available for use in a future carbon-constrained world.

Acknowledgments The author gratefully acknowledges the assistance and advice of Dr. David Granatstein (Granatstein Technical Services/CanmetENERGY) and Dr. Stuart Scott (Lecturer in Sustainable Energy, Department of Engineering, University of Cambridge) for a number of valuable discussions during the preparation of this chapter as well as for suggesting various amendments and improvements.

High Temperature Oxygen Separation Using Dense Ceramic Membranes

Jaka Sunarso, Kun Zhang, and Shaomin Liu

Contents

Abstract

Mixed ionic–electronic conducting (MIEC) ceramic membrane has rapidly become an attractive alternative technology to conventional cryogenic distillation for oxygen separation from air. Given the heat integration opportunity in most energy generation processes, this technology offers lower cost and energy penalty due to its capability to produce pure oxygen at high temperature

(>800 °C). Using pure oxygen for combustion in turn facilitates the production of concentrated carbon dioxide gas downstream which can be easily captured and handled to mitigate the greenhouse gas effect. This chapter overviews and discusses all essential aspects to understand oxygen selective MIEC ceramic technology. The basics behind the formation of defects responsible for high-temperature ionic transport are explained together with the transport theory. Two major family structures, e.g., fluorite and perovskite, which become the building blocks of most MIEC materials are discussed. Specific structure and properties as well as the advantages and the drawbacks of each family are explained. Some important structural considerations, e.g., crystal structure packing and Goldschmidt tolerance factor, are elaborated due to its strong relationship with the properties. Two additional concepts, e.g., dual-phase membrane and external short circuit, are given to address the drawbacks associated with fluorite and perovskite MIEC materials. Various geometries and types of MIEC membranes can be prepared, e.g., disk, tube, hollow fiber, or flat plate, each of which fits particular application. A short paragraph is presented at the end of the chapter on another possible application of this technology to facilitate a particular reaction to synthesize value-added products.

Introduction

Oxygen plays a vital role in industry with applications in almost every industry sector such as steel and aluminum or other metals manufacturing, chemicals, pharmaceuticals, petroleum, glass, cement, ceramics, pulp and paper, metal cutting and welding, waste treatment, rocket fuel, medical, and healthcare and other life support systems. The annual global oxygen production is predicted to reach hundreds of millions of tons from air separation and contributes to the largest section in the industrial gases market with the kept rising global demand foreseen to reach US$6 billion in 2018 (http://www.prweb.com/releases/2013/11/prweb11347927.html). As we are transferring the energy infrastructure from fossil fuel-based energy technology to a cleaner and more sustainable technology, oxygen has been recognized as an important component in the mitigation of greenhouse gas emission.

In current oxygen market, steel industry alone accounts for more than 50 % of the consumption where oxygen is used to enhance blast furnace iron production. In contrast, energy generation industry only uses 4 %. With increased attention and stricter regulations toward environmental compliance, the oxygen will also be used in clean energy generation technologies such as integrated gasification combined cycle (IGCC) and oxy-fuel projects. These technologies require pure oxygen or a mixture of oxygen and carbon dioxide as the feed gas. It is estimated that by 2040, the energy sector will occupy 60 % shares of the market, translating to approximately two million tons of oxygen per day (http://www.world-nuclear.org/info/energy-and-environment/-clean-coal–technologies/). While oxygen is available free of cost directly from air, obtaining it at a concentration higher than 21 % entails cost and energy penalty associated with the enrichment or separation

processes. At the moment, industrial tonnage oxygen is produced at a lower purity (<93 %) on an intermediate scale by pressure swing adsorption or at a high purity (>93 %) on a large scale (>1000 t per day) by cryogenic distillation. Both processes are capital and energy intensive. In particular, cryogenic distillation is a quite old technology which has been used for more than a century, therefore leaving no space for improvement.

Recently, a more efficient alternative technology relying on gas separation through membrane has emerged which also facilitates easy carbon capture and storage (CCS). This less mature technology offers higher energy efficiency and less capital cost. Several different types of membranes are available. Polymeric membranes have restricted applications due to their low selectivity and permeability as well as their organic nature which hinders operation to high temperature. Inorganic porous membranes, the so-called "molecular sieving" membranes such as zeolite, silica, and carbon membranes, provide good selectivity and permeability, but they are difficult to be scaled up. Thus far, dense mixed ionic–electronic conducting (MIEC) ceramic membranes have attracted the largest attention from research communities, industries, and governments of developed countries given their absolute selectivity and robustness in addition to the capability to operate at high temperature (>800 °C) and harsh conditions. For example, starting from 1997, Air Products and Chemicals and US Department of Energy (US DOE) have initiated one of the longest and biggest investments worth US$150 million to advance this technology, referred as ion-transporting membrane (ITM) technology (Foster 2008). Research in this topic actually began in the early 1980s with the current efforts directed more toward improving materials stability in reducing acidic gas in the atmosphere (Sunarso et al. 2008; Teraoka et al. 1985). The availability of stable materials with high oxygen permeability is expected to favor a wide application of MIEC technology for energy sector and industries.

The objective of this chapter is to provide an introductory overview of important aspects of MIEC ceramic membrane technology which is not covered (or detailed) in the more comprehensive reviews elsewhere (Sunarso et al. 2008; Zhang et al. 2011). Some overlaps with these reviews exist but nonetheless are included to make this chapter an independent reading for the beginners in this topic.

Transport Theory

Transport Mechanisms

Oxygen transport through MIEC ceramic membrane is made possible by the formation of substantial amount of defects, e.g., oxygen vacancies or oxygen interstitials at high temperatures (>800 °C). Even at a room temperature, numerous oxides readily exhibit defects due to "nonstoichiometry," where the cation and anion have different effective charges. This has been manifested in some cations and/or anions emptied from the lattice for the charge neutrality to be maintained in the compound (Kingery et al. 1976; Tilley 2013).

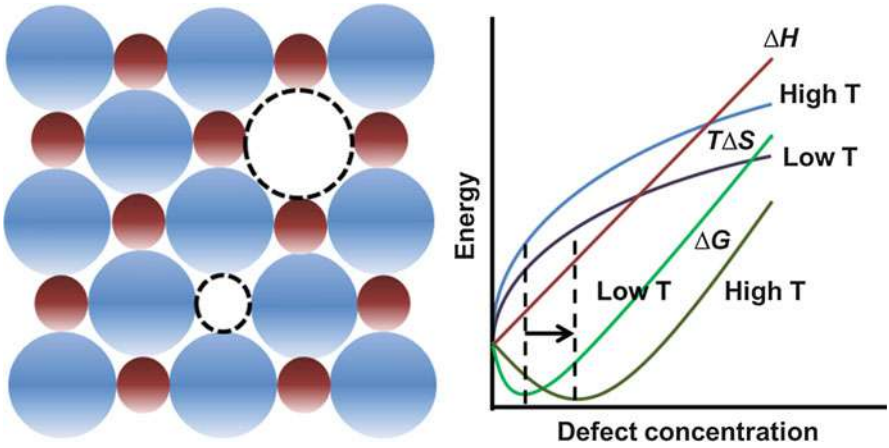

Fig. 1 Typical defects represented by Schottky defect (*left*) and relative Gibbs energy versus defect concentration at low and high temperature (*right*)

In general, defects form as a consequence of the lowering of Gibbs energy obtained from increased entropy, e.g., the vacancies of some cations or anions allow more possibility of distinct arrangements within the crystal lattice (Kingery et al. 1976). Typical defect formation is depicted in Fig. 1 (left) which shows that one cation and one anion are missing, e.g., Schottky defect. Other defect types are also available which are not discussed here (Kingery et al. 1976; Tilley 2013). Gibbs energy is represented by

$$\Delta G = \Delta H - T\Delta S \tag{1}$$

Figure 1 (right) illustrates the relative Gibbs energy for low- and high-temperature scenarios. At a certain temperature, a minimum energy is achieved when an optimum amount of defects form. Increasing temperature results in the increased $T\Delta S$ for every concentration, and therefore the minimum energy is also shifted to larger defect concentration. Simply put, increasing temperature favors larger defect concentration.

In MIEC compound, the presence of defects, e.g., oxygen vacancies, provides a pathway for oxygen ionic diffusion (where oxygen ion hops from one empty site to another empty site) and is the main contributor to its oxygen ionic conductivity. In addition, electronic conductivity also exists due to the presence of transition metal in the oxides framework (mostly in perovskite compounds without ruling out fluorite compounds). Notably, transition metals can have more than one oxidation state during reduction and oxidation reaction. The formation of oxygen vacancies at increasing temperature is often accompanied by the reduction of the transition metal components (mostly in perovskite oxide) simultaneously accompanied by electron transfer reactions (Feldhoff et al. 2009; Arnold et al. 2009).

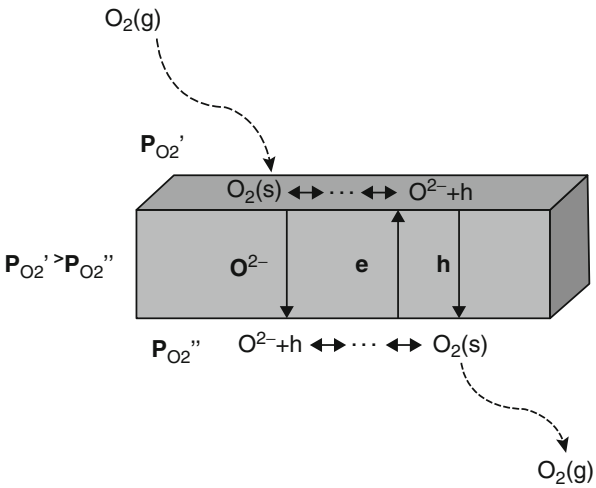

Fig. 2 Schematic diagram of oxygen transport through mixed ionic–electronic conducting (MIEC) ceramic membrane (Reproduced from Zhang et al. (2011))

The existence of this simultaneous ionic and electronic conductivity defines its "mixed ionic–electronic conducting" name (Sunarso et al. 2008; Zhang et al. 2011). During membrane operation, a driving force is established normally through oxygen partial pressure difference between two different membrane sides. Figure 2 provides the schematic of the process. Oxygen gas on high partial pressure side of the membrane approaches the surface of the membrane, adsorbed on the surface (in some cases), and, upon receiving electron, becomes an oxygen ion. This oxygen ion then diffuses through the membrane (via the oxygen vacancies throughout the membrane), the process of which is accompanied by simultaneous electron transfer (or hole) in the opposite direction (same direction) to maintain the charge balance. The oxygen ion arrives at the other side of the membrane and, upon releasing electron, becomes an oxygen gas again. The first and the third processes are defined as surface exchange reactions, while the second process is defined as bulk diffusion. In the absence of any mechanical defect and assuming a perfect sealing, dense MIEC membrane permeates only oxygen to the other side, thus achieving an absolute selectivity in such system.

Limiting Steps

The oxygen transport rate through the membrane, i.e., the flux, is limited by the slowest step, either bulk diffusion or surface exchange reaction (Sunarso et al. 2008). Consequently, thickness of the membrane becomes an important variable. For a relatively thick membrane, bulk diffusion tends to dominate, and as the thickness is reduced, surface exchange reaction becomes more prevalent.

The incorporation of oxygen from the atmosphere (high oxygen potential) into the lattice and the subsequent release of lattice oxygen back to the atmosphere (low oxygen potential) can be described by two simple surface reactions:

$$\frac{1}{2}O_2 + V_{\ddot{o}} + 2e' \rightarrow O_O^x \text{ (high } O_2 \text{ potential)} \tag{2}$$

$$O_O^x \rightarrow \frac{1}{2}O_2 + V_{\ddot{o}} + 2e' \text{ (low } O_2 \text{ potential)} \tag{3}$$

Here, O_2, $V_{\ddot{o}}$, e', and $O_O{}^x$ represent molecular oxygen, oxygen vacancy, electron, and lattice oxygen, respectively. Albeit their oversimplicity to address the complexity of the real surface reactions, they can be used as a starting point. The consequence of oxygen incorporation into the lattice and the release of lattice oxygen back to the atmosphere is the generation of chemical potential gradient across the membrane (when one side is exposed to low oxygen potential), and because of the mobility of the charge carrier species, a net flux of oxygen will occur toward the lower potential side.

Bulk Diffusion

If bulk diffusion is predominant, oxygen flux can normally be described using Wagner equation as a function of the conductivity of the charge carrier species and the oxygen partial pressure (Wagner 1975):

$$J_{O_2} = \frac{RT}{4^2F^2L}\int_{\ln P'_{o_2}}^{\ln P''_{o_2}} \frac{\sigma_{el}\sigma_{ion}}{\sigma_{el}+\sigma_{ion}} d(\ln P_{O_2}) \tag{4}$$

Here, σ_{el}, σ_{ion}, P_{O2}, R, F, and L represent electronic conductivity, ionic conductivity, oxygen partial pressure, ideal gas constant, Faraday constant, and membrane thickness, respectively.

If the oxygen vacancies are proportional to the ionic conductivity (i.e., if all vacancies do not associate among each other), an assumption which is valid at low vacancy concentration, the ionic conductivity can be expressed by Nernst–Einstein equation:

$$\sigma_{ion} = \frac{4F^2[V_{\ddot{o}}]D_V}{RTV_m} \tag{5}$$

Here, D_V is the vacancy diffusion coefficient and V_m is the molar volume of the oxide. This relationship implies that the electronic conductivity is not limiting, e.g., when it is substantially higher than the ionic conductivity. Therefore, Eq. 4 simplifies into

$$J_{O_2} = \frac{D_V}{4V_mL}\int_{\ln P'_{o_2}}^{\ln P''_{o_2}} [V_{\ddot{O}}] d(\ln P_{O_2}) \tag{6}$$

The vacancy diffusion coefficient can be determined via experimental measurement of chemical diffusion coefficient and tracer diffusion coefficient, e.g., via ^{18}O–^{16}O isotope exchange experiments. The oxygen vacancy concentration can be derived as a function of oxygen partial pressure at low concentration of defects

which leads to simplification. More details on the various simplifications pertaining to different special cases can be found elsewhere (Sunarso et al. 2008).

Surface Exchange Reaction

Surface exchange reaction normally involves a series of steps with each one may become the limiting step. The possible steps are adsorption from the gas phase, charge transfer reaction between the adsorbed species and the bulk, and surface diffusion of intermediate species (Sunarso et al. 2008). Further additional steps are possible when every other gas impurity components such as CO, CO_2, and CH_4 which are exposed to the surface are taken into account. Oxygen flux equation can be derived theoretically by assuming the slowest step among the proposed reaction steps and using the law of mass action related to the oxygen partial pressure or empirically, examples of which can be found elsewhere (Sunarso et al. 2008).

An important variable defined as L_c, i.e., a characteristic thickness, signifies the membrane thickness below which surface exchange dominates while above it, bulk diffusion dominates. It is quite accurate to say that at L_c, oxygen transport is equally determined by surface exchange and bulk diffusion (Bouwmeester et al. 1994). L_c however is not an intrinsic property as it generally depends on the surface morphology and the operating conditions such as oxygen partial pressure and temperature (Sunarso et al. 2008).

Membrane Developments, Limitations, and Improvements

Fluorite

Oxide compounds with fluorite structure are often used as an ionic conductor (an electrolyte) due to its predominant ionic conductivity at a certain temperature range. The ideal fluorite structure is illustrated in Fig. 3. Fluorite compounds have a general formula of AO_2, exemplified by calcium fluoride (CaF_2). In such structure,

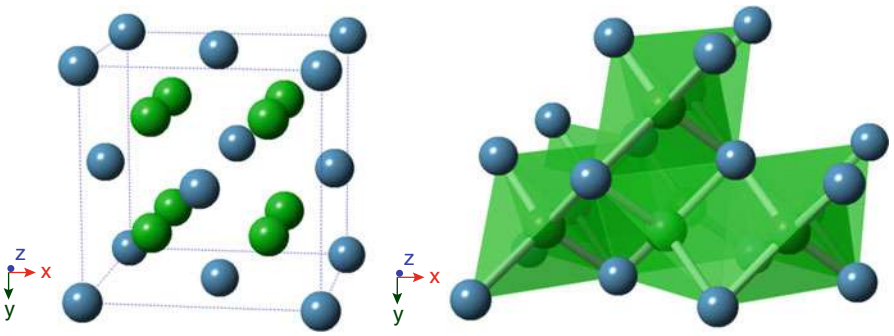

Fig. 3 Ideal fluorite structure for AO_2 compounds represented by CaF_2 (*left*) and its packing (*right*). *Blue* atoms, A (Ca); *green* atoms, O (F)

the A cations form cubic close packing and occupy the face-centered cubic positions, while the O anions occupy the tetrahedral interstices (Megaw 1973).

Zirconia (ZrO_2) represents the classical example of oxides with fluorite structure which forms an important family of electrolytes in conventional solid oxide fuel cells. It requires temperature above 700 °C to have substantial conductivity. Zirconia exhibits phase transition from monoclinic to tetragonal between 1100–1200 °C and tetragonal to cubic at 2300 °C (Aldebert and Traverse 1985). The cubic phase can be stabilized to room temperature by (about 10 mol%) Zr^{4+} substitution with lower valence cations, e.g., Ca^{2+}, Mg^{2+}, and Ln^{3+} (lanthanides). The tetragonal phase can also be stabilized using a less amount (about 3 mol%) of specific dopant such as Y^{3+}. The drawback of using zirconia lies on the very high temperature required to achieve substantial oxygen ionic conductivity which is closely related to the structure. The ionic conductivity of the monoclinic ZrO_2 is negligible, i.e., 10^{-7}–10^{-6} S cm^{-1} which is improved for its tetragonal phase to 10^{-3}–10^{-2} S cm^{-1} and reaches 10 S cm^{-1} for cubic ZrO_2 beyond 2100 °C. Higher conductivity can also be obtained at lower temperature by partially substituting ZrO_2 with CaO, resulting in a conductivity value close to 10^{-1} S cm^{-1} at 1300 °C.

An attractive alternative to zirconia is bismuth oxide. Bismuth oxide also experiences phase transition from monoclinic (α-phase) to cubic (δ-phase) at 730 °C prior to melting at 825 °C (Sammes et al. 1999). The cubic δ-phase of Bi_2O_3 has fluorite structure with ordered defects in the oxygen sub-lattice and is attractive in terms of its 1–2 orders of magnitude higher conductivity than yttria-doped zirconia, i.e., 1 S cm^{-1} at 650 °C. This superior ionic conductivity is attributable to the vacancy of a quarter of oxygen sites in the lattice, the electronic configuration of Bi^{3+} comprising $6s^2$ lone pair electrons which leads to the high polarizability of the cation (and high oxide ion mobility) and Bi^{3+} ability to accommodate highly disordered surroundings (Sammes et al. 1999). The cubic phase can be stabilized to room temperature by partially substituting Bi with Dy, Er, Gd, Ho, Lu, Tb, Tm, Y, and Yb (despite existing dispute on the resultant structure), among which Dy-, Er-, Ho-, and Tb-doped ones show the highest conductivity of 0.1–0.4 S cm^{-1} between 650 °C and 700 °C.

Another fluorite compound of interest is ceria (CeO_2). Pure CeO_2 is actually a mixed conductor showing almost similar ionic and electronic conductivities (Inaba and Tagawa 1996). This is quite consistent with the fact that cerium can change its oxidation state depending on the oxygen partial pressure, i.e., Ce^{4+} may be reduced to Ce^{3+} under reducing atmosphere (and the opposite) (Kuharuangrong 2007). The ionic conductivity of the ceria can be made predominant by partially substituting Ce with other metal cations having lower and fixed valence. The interest on ceria-based materials comes from its high oxygen ionic conductivity, i.e., its conductivity at 750 °C is similar to that of yttria-doped zirconia at 1000 °C. Despite the superior conductivity of Bi_2O_3-based materials, they are not stable and can be reduced easily in reducing atmosphere. In contrast, ceria-based materials are quite stable and therefore have been largely used to replace yttria-doped zirconia as an electrolyte for lower temperature operation (<800 °C) (Inaba and Tagawa 1996). A relatively high oxygen ionic conductivity of 10^{-2} S cm^{-1} at 500 °C is reported for

gadolinium-doped ceria, $Ce_{0.9}Gd_{0.1}O_{1.95}$. In spite of variations in the conductivity values reported as well as various possible dopants, e.g., Ba, Ca, Dy, Gd, Ho, La, Mg, Nd, Sm, Sr, Y, and Yb, to improve the conductivity, generally Gd- and Sm-doped cerias provide the highest conductivity values (Inaba and Tagawa 1996; Eguchi et al. 1992). Sm-doped ceria, $Ce_{0.8}Sm_{0.2}O_{1.9}$, particularly is the most attractive one to replace yttria-doped zirconia given its lowest reducibility among the doped ceria compounds (Eguchi et al. 1992).

As a trend, the oxygen fluxes of the fluorite compounds are lower by two to three orders of magnitude with respect to the perovskite compounds due to its limited electronic conductivity. Multivalent cations can be incorporated as a dopant although the improvement of the electronic conductivity is marginal and therefore does not contribute substantially to the resultant oxygen flux (Sunarso et al. 2008). The compilation of the oxygen fluxes for fluorite compounds is available elsewhere (Sunarso et al. 2008).

Perovskite

Research and development of MIEC materials have been heavily focused on perovskite compounds due to their high ionic and electronic conductivity. The ideal perovskite structure is schematized in Fig. 4. Perovskite compounds have a general ABO_3 formula and contain two different metal cations with different sizes. Typical compound with this structure is $SrTiO_3$. Perovskite framework consists of corner-shared BO_6 octahedra where the large A cation sits in the center of the cavity between 8 octahedra (Megaw 1973). In perovskite, each B cation is surrounded by 6 O anions forming 6 equidistant B–O bonds and likewise each A cation is surrounded by 12 O anions forming 12 equidistant A–O bonds. The effective valence state of A and B may vary as exemplified by the formula of $A^{2+}B^{4+}O_3$ or

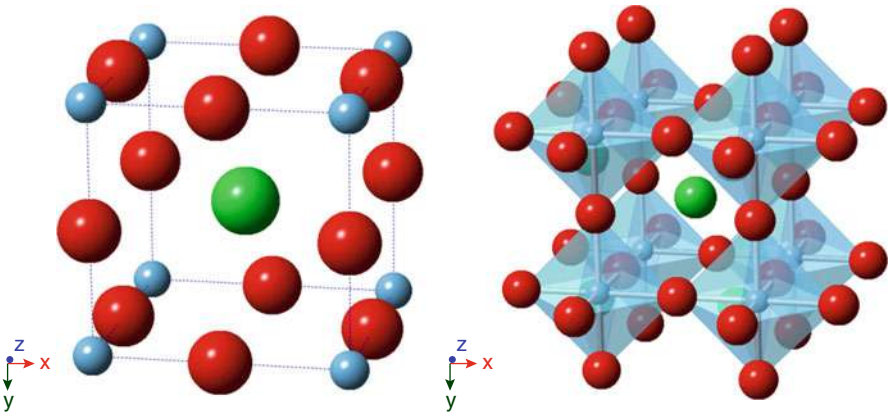

Fig. 4 Ideal perovskite structure for ABO_3 compounds represented by $SrTiO_3$ (*left*) and its packing (*right*). *Green* atoms, A (Sr); *light blue* atoms, B (Ti); *red* atoms, O (O)

$A^{1+}B^{5+}O_3$ or $A^{3+}B^{3+}O_3$. In general, A cation and B cation can have ionic radius between 1.1–1.8 Å and 0.62–1 Å, respectively (Bhalla et al. 2000). A-site cation can be lanthanides, e.g., La, Pr, and Gd, or alkaline earth metals, e.g., Ba and Sr, while B-site cation can be transition metals, e.g., Mn, Co, Ni, Cr, and Fe, or non-transition metals, e.g., Al and Ga (Sunarso et al. 2008).

Perovskite represents one of the best examples for "nonstoichiometry" mentioned above. Depending on the effective valence states of A and B cations, O anions may be missing. This manifests in a formula of $ABO_{3-\delta}$. The δ represents the nonstoichiometry parameter which is enhanced by the incorporation of metal cations having low valence value, e.g., A^{2+}.

Within a cubic structure, A and B cations fulfill a simple geometric relationship where A cation can be viewed to touch B cation and vice versa. For the cube shown in Fig. 4, the edge is equal to twice the sum of ionic radius of B cation and ionic radius of O anion, while the face diagonal is equal to twice the sum of ionic radius of A cation and ionic radius of O anion. Pythagorean theorem can be used here to relate the face diagonal to the edge, resulting in

$$R_A + R_O = \sqrt{2}(R_B + R_O) \tag{7}$$

$$1 = \frac{R_A + R_O}{\sqrt{2}(R_B + R_O)} \tag{8}$$

$$t = \frac{R_A + R_O}{\sqrt{2}(R_B + R_O)} \tag{9}$$

Ionic radius values for A, B, and O should comply with Eq. 7 for the cubic structure to form. This equation can then be modified into Eq. 8, where a value of 1 is obtained for the ratio of the sum of ionic radius of A and O to root square of 2 multiplied by the sum of ionic radius of B and O. This ratio (Eq. 9) is defined as Goldschmidt tolerance factor (due to the contact criterion between A and B cations) which is very useful as a predictor (whether cubic structure will form) but not to rationalize structure. The empirical ionic radius value for metal cation is available; the most widely used ones have been compiled by Shannon and Prewitt (1969).

The interest to perovskite MIEC compounds is derived from the perovskite capability to host numerous metal oxides represented by $A_{1-x-y}A'_xA''_yB_{1-x-y}B'_xB''_yO_{3-\delta}$. As such, the structure and properties of the resultant perovskite can be adjusted by compositional tailoring to fit particular applications to obtain high ionic conductivity, electronic conductivity, or catalytic activity. When MIEC properties are desired, oxygen vacancies (nonstoichiometry) and electronic conductivity can be promoted by incorporating metal cation with low valence into A site so that the total valence of the cation is substantially less than 6 and incorporating transition metal elements into B-site. If electronic conductivity is to be eliminated, non-transition metal can be chosen such as Ga. $LaGaO_3$, for example, is as an excellent ionic conductor (Ishihara et al. 1994).

Development of MIEC perovskite membranes has been largely concentrated on the compositional tailoring since the initial report by Teraoka and coworkers (1985). They reported that the oxygen flux through $La_{1-x}Sr_xCo_{1-y}Fe_yO_{3-\delta}$ increases with the Sr or Co content. A very high flux of 1.79×10^{-6} mol cm^{-2} s^{-1} (equal to 2.4 ml cm^{-2} min^{-1}) at 850 °C was obtained for 1-mm-thick $SrCo_{0.4}Fe_{0.6}O_{3-\delta}$ membrane (Teraoka et al. 1985). Later on, they also reported that for $La_{0.6}Sr_{0.4}Co_{0.8}B_{0.2}O_{3-\delta}$ compounds, oxygen flux decreases in the order of B = Cu, Ni, Co, Fe, Cr, and Mn (Teraoka et al. 1988). Likewise, for $La_{0.6}A_{0.4}Co_{0.8}Fe_{0.2}O_{3-\delta}$, flux decreases in the order of A = Ba, Ca, Sr, Na, and La, while for $A_{0.6}Sr_{0.4}Co_{0.8}Co_{0.2}O_{3-\delta}$, flux decreases in the order of A = Gd, Sr, Nd, Pr, and La. A cation instead of B cation has more substantial effect to the onset permeation temperature. $SrCoO_{3-\delta}$ is also quite attractive although it does not exhibit cubic structure at room temperature. Rather, it undergoes phase transition from hexagonal to cubic at 900 °C. $SrCo_{0.8}$(Cr,Cu,Fe)$_{0.2}O_{3-\delta}$ also experiences such "order–disorder" transition (Kruidhof et al. 1993). Oxygen permeation through $Sr_{0.7}$(La,Nd,Sm,Gd)$_{0.3}CoO_{3-\delta}$ was reported to decrease in the order of La, Nd, Sm, and Gd. This trend is explained by the reduction of the A cation radius (Kovalevsky et al. 1998). Partial substitution of Sr with Ba in $SrCo_{0.8}Fe_{0.2}O_{3-\delta}$ can stabilize the cubic structure into room temperature, therefore retaining the high oxygen flux to lower temperature (Shao et al. 2000a).

The performances of the most commonly studied perovskite MIEC materials are listed in Table 1 to provide some pictures on the flux magnitudes (Teraoka et al. 1985, 1988; Shao et al. 2000b; Tsai et al. 1998; Ten Elshof et al. 1995). A more comprehensive list is also available elsewhere (Sunarso et al. 2008).

A trade-off occurs between the oxygen permeability and the structure stability. Perovskite compounds with large nonstoichiometry tend to provide high oxygen fluxes with the drawback of low structure stability. The cubic phase of $Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-\delta}$ (BSCF), for example, is unstable below 850–900 °C. After 10-day annealing at 750 °C, the cubic phase of BSCF partially converts into lower symmetry hexagonal phase (Švarcova et al. 2008). Perovskite compound

Table 1 Summary of perovskite membrane materials and performances

Material	Thickness (mm)	$\mathbf{J(O_2)} \times 10^6$ (mol cm^{-2} s^{-1})	Temp. (°C)	Note	Ref.
$BaBi_{0.5}Co_{02}Fe_{0.3}O_{3-\delta}$	1.50	0.55	925	Disk	(Shao et al. 2000b)
$Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-\delta}$	1.80	1.56	900	Disk	(Shao et al. 2000a)
$La_{0.6}Sr_{0.4}CoO_{3-\delta}$	1.00	0.38	870	Disk	(Teraoka et al. 1985)
$La_{0.6}Sr_{0.4}Co_{0.8}Fe_{0.2}O_{3-\delta}$	1.50	0.46	860	Disk	(Teraoka et al. 1988)
$La_{0.4}Sr_{0.6}Co_{0.2}Fe_{0.8}O_{3-\delta}$	0.55	0.08	900	Disk	(Tsai et al. 1998)
$La_{0.9}Sr_{0.1}FeO_{3-\delta}$	1.00	0.02	1000	Disk	(Ten Elshof et al. 1995)

with low nonstoichiometry and low fluxes such as $La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-\delta}$ is generally more stable for long-term operation (Schlehuber et al. 2010). Alkaline-earth metal containing perovskite is also prone to acidic gases such as CO_2. CO_2 readily reacts with the alkaline metal to form carbonate, leading to the deterioration of the original structure (Klande et al. 2013; Chen et al. 2011).

Dual-Phase Membrane

The limited electronic conductivity of the fluorite compounds can be resolved by adding another phase with predominant electronic conductivity as depicted in Fig. 5. The advantage of this strategy is that the stability of the fluorite compounds in reducing and acidic atmosphere is also imparted to the final composite. This composite concept was brought forward by Mazanec et al. to provide internal short circuit to electrolyte material, i.e., (8 mol%) yttria-doped zirconia utilizing Pd-, Pt-, and B-doped $MgLaCrO_x$ and InPr (Mazanec et al. 1992). For the dual-phase membrane to work, both the ionic and electronic conductor phases should have continuous (or percolative) networks which extend from one side to the other side of the membrane. The minimum content of electronic phase required for this phase to form a continuous network is called the percolative threshold. The percolative threshold can be determined by measuring the electrical conductivity of the composite as a function of the electronic phase content. Furthermore, the thermomechanical properties of both phases should be compatible with each other to obtain high density and avoid cracks formation and structure deterioration during thermal cycling. In most cases, fluorite compounds are used as an ionic conductor, while metal or perovskite compounds can be used as an electronic conductor.

Lee et al. prepared Ag-$(Bi_2O_3)_{0.8}(BaO)_{0.2}$ composite with different Ag vol.% from 0 % to 45 %. They found that the conductivity increased significantly at 17 vol.% of Ag which indicated this composition as the percolative threshold. Above this threshold, all membranes showed comparable (similar or slightly

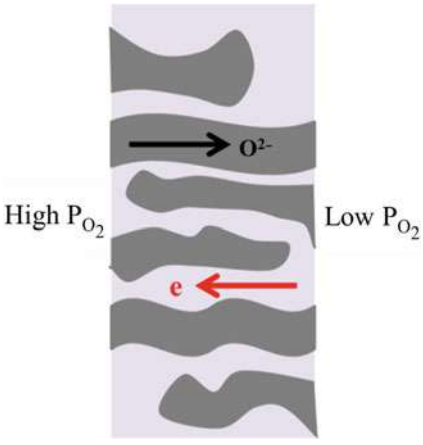

Fig. 5 Dual-phase membrane; *dark gray* matrix is the oxygen ionic conductor phase and light purple matrix is the electronic conductor phase

improved) oxygen fluxes (Lee et al. 2000). Chen and Burggraaf reported oxygen permeability of composite of Ag (or Au – 40 vol.%) with erbium-doped bismuth oxide made by mixing (and grounding) the powders and sintering using low heating and cooling rate. They found that the electrical resistance at the room temperature for composite was very low which suggested the formation of percolative electronic phase network. The silver-based composite has an order of magnitude higher flux than the gold-based composite due to the higher catalytic activity for silver (Chen and Burggraaf 1999). Wu et al. measured the oxygen flux through Ag-$(Bi_2O_3)_{0.74}(SrO)_{0.26}$ composite (Wu et al. 2001). Kim and Lin synthesized Ag (30 and 40 vol.%) and $Bi_{1.5}Y_{0.3}Sm_{0.2}O_3$ composites. The electronic conductor phase in the 30 vol.% composite was not percolative while that in the 40 vol.% was percolative. This was confirmed by energy dispersive X-ray analysis and four orders of magnitude higher electrical conductivity for the 40 vol.% composite (relative to the 30 vol.% composite). The 40 and 30 vol.% composite showed flux improvement by a factor of 50 and 10, respectively, relative to the $Bi_{1.5}Y_{0.3}Sm_{0.2}O_3$ membrane. Despite its non-percolative electronic phase, the 30 vol.% composite benefited from the presence of Ag which increased the surface reaction rate (Kim and Lin 2000).

Recently, doped ceria becomes more attractive as the ionic conductor phase. The fact that Ce can be reduced in reducing atmosphere may contribute toward electronic conductivity enhancement. Samson et al. combined $Ce_{0.9}Gd_{0.1}O_{1.95}$ ionic conductor with electronic conductor material, e.g., Ag–CuO (promising for low temperatures), and various perovskite MIEC materials, e.g., $LaCoO_3$, $La_{0.6}Sr_{0.4}CoO_{3-\delta}$, and $(La_{0.6}Sr_{0.4})_{0.99}Co_{0.2}Fe_{0.8}O_{3-\delta}$ (for applications between 1 and 10^{-3} atm) or $La_{0.6}Sr_{0.4}FeO_{3-\delta}$ and $La_{0.75}Sr_{0.25}Cr_{0.97}V_{0.03}O_{3-\delta}$ (for applications down to 10^{-19} atm) (Samson et al. 2014). Among these materials, they found that $Ce_{0.9}Gd_{0.1}O_{1.95}$-$La_{0.6}Sr_{0.4}CoO_{3-\delta}$ (52 vol.%) composite showed the highest oxygen flux despite the micro-crack formation due to the large mismatch between the thermal expansion coefficients of the two phases (Samson et al. 2014). Kim et al. prepared dual-phase membrane of $Ce_{0.9}Gd_{0.1}O_{2-\delta}$-$Sr_{0.95}Co_{0.5}Fe_{0.5}O_{3-\delta}$ (50 vol.%) and found that the perovskite MIEC phase was stable under the condition where it normally undergoes phase transformation as a single phase (Kim et al. 2014). The stability of $Ce_{0.9}Nd_{0.1}O_{2-\delta}$-$Nd_{0.6}Sr_{0.4}FeO_{3-\delta}$ (40 wt%) composite under CO_2 was confirmed by the reversibility of oxygen flux when the sweep gas was changed between He and CO_2 (Luo et al. 2014). Li et al. prepared dual-phase hollow fiber of $Ce_{0.8}Sm_{0.2}O_{2-\delta}$-$La_{0.8}Sr_{0.2}MnO_{3-\delta}$ (38 wt%) and found that the flux decreased slightly using CO_2 as a sweep gas with respect to that obtained using He (Li et al. 2009a). Dual-phase disk membrane of $Ce_{0.8}Sm_{0.2}O_{2-\delta}$ with $Sm_{0.6}Ca_{0.4}CoO_{3-\delta}$ and $Sm_{0.6}Ca_{0.4}FeO_{3-\delta}$ was reported by Li et al., the fluxes of which were stable for 100 h of operation using CO_2 as a sweep gas (Li et al. 2014). As a comparison, yttria-doped zirconia ($Zr_{0.84}Y_{0.16}O_{1.92}$)–lanthanum strontium manganite ($La_{0.8}Sr_{0.2}MnO_{3-\delta}$, 43 wt%) hollow fiber composite was also prepared. The oxygen flux of the fiber at 950 °C was not changed when the sweep gas was changed from helium to high concentration of CO_2 (Li et al. 2009b).

Table 2 lists the performances of some of the dual-phase membranes which include the electronic phase from metals and perovskite MIEC materials (Lee

Table 2 Summary of dual-phase membrane materials and performances

Ionic conductor phase	Electronic conductor phase	Ratio	Thickness (mm)	$J(O_2) \times 10^6$ (mol cm^{-2} s^{-1})	Temp. (°C)	Note	Ref.

et al. 2000; Chen and Burggraaf 1999; Wu et al. 2001; Kim and Lin 2000; Samson et al. 2014; Kim et al. 2014; Luo et al. 2014; Li et al. 2009a, b 2014). Dual-phase membranes generally have oxygen flux values between that of fluorite and perovskite MIEC membranes. Recent efforts on the development of dual-phase membranes exclude metals as a component due to its high cost.

External Short-Circuit Concept

An alternative to dual-phase membrane was devised recently where external short circuit is applied to compensate the inability to conduct electrons through the membrane (Zhang et al. 2012). Rather than using the classical configuration depicted in Fig. 6 (left) where an external metal wire is employed as an electron pathway, metal layer can simply be pasted over the disk circumferential surface as an electron pathway (Fig. 6 (right)). This circumferential metal layer is continuously connected with the metal layers over the top and bottom of the disk to ensure efficient electron collections on the high oxygen potential side and the low oxygen potential side.

This concept was demonstrated using $Sm_{0.2}Ce_{0.8}O_{1.9}$ disk membrane where by itself showed zero oxygen fluxes at 500–800 °C. Ag (35 wt%)-$Sm_{0.2}Ce_{0.8}O_{1.9}$ dual-phase disk membrane exhibited a very low fluxes only above 700 °C which reaches a maximum of 0.022×10^{-6} mol cm^{-2} s^{-1} (equal to 0.03 ml cm^{-2} min^{-1}) at 800 °C. Using configuration shown in Fig. 6 (left) with Ag layers over the top and bottom of $Sm_{0.2}Ce_{0.8}O_{1.9}$ disk, the oxygen flux was improved to 0.02×10^{-6}–3.87×10^{-6} mol cm^{-2} s^{-1} (equal to 0.027–0.52 ml cm^{-2} min^{-1}) between 600 °C and 800 °C. These oxygen fluxes were comparable to the fluxes obtained using simplified configuration displayed in Fig. 6 (right), denoting the feasibility of this concept which offers less complexity than using external wire or preparing dual-phase

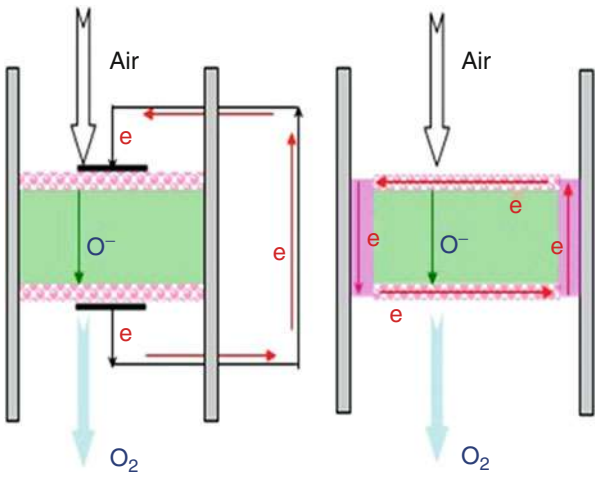

Fig. 6 Short-circuit concept. (*Left*) Metal layers over the *top* and *bottom* disk surfaces and external electron circuit and (*right*) metal layers over the *top* and *bottom* disk surfaces and metal (paste) layer over the disk circumferential surface

membrane (Zhang et al. 2012). The external short-circuited $Sm_{0.2}Ce_{0.8}O_{1.9}$ disk membrane was also tested in terms of CO_2 stability where it was subjected to 10 % CO_2 in helium (as a sweep gas) for 500 h. Upon switching back to helium, the original flux value was recovered.

It is also possible to use perovskite MIEC materials for short-circuiting layers as reported by Wang et al. (2013), and Imashuku et al. (2013). The external short-circuit concept can also be extended to internal short-circuit by inserting metal wires within the membrane as detailed elsewhere (Zhang et al. 2013).

Membrane Type and Preparation

Oxygen selective mixed ionic–electronic conducting (MIEC) ceramic membranes have been prepared in different types depending on the application purpose.

Dense Disk Membranes

This membrane configuration represents the most universal configuration found in numerous research papers used particularly for screening purpose in the laboratory and fundamental research studies (Sunarso et al. 2008). Disk membrane is the easiest one to fabricate. Its fabrication involves synthesizing ceramic oxide powder precursor through solid-state, co-precipitation, sol–gel, or other synthesis routes followed by the calcination of the powder (at 700 °C or below) to remove the organic content and, in some cases, also to form the structure of interest. The powder is then poured into and fitted within the pellet press die set or mold where following this (a hydraulic or an isostatic or a uniaxial) pressure is applied onto the powder, resulting in the so-called green disk. This "green disk" is finally sintered at a temperature substantially higher than the initial calcination temperature (at least 1000 °C) to obtain a pore-free disk membrane (Sunarso et al. 2009). The sintering process can be observed using the high-temperature microscope and quantified by the density measurement (Itoh et al. 1994). The formation of dense body is indicated by the attainment of a final density of at least 90 % of the theoretical density. The sintering temperature normally depends on the particle size and the specific preparation route of the powder. Smaller particle size provides larger surface area and therefore is favorable toward acquiring higher density and sinterability. The effects of sintering temperature, dwell time, and pressure to the final density and grain size of typical disk membrane are discussed by Asadi et al. (2012). Temperature generally has the most influence followed by dwell time while pressure has the least influence. Nevertheless, optimum values always exist for these variables which vary for different system.

Given the relatively high thickness of the disk membrane, its oxygen ionic transport is often limited by the bulk diffusion process. While theoretically the oxygen fluxes can be improved by reducing the thickness to submicron thickness, decreasing the disk membrane thickness to below 1 mm is considered impractical

from the mechanical strength perspective. Another drawback of this configuration is its very low surface to volume ratio (Luyten et al. 2000).

Porous Substrate Supported Thin-Film Disk Membranes

To overcome the thickness limitation without compromising mechanical integrity, an asymmetric structure can be developed by combining porous substrate with a thin dense layer. The porous layer provides the mechanical strength while allowing gas transport through its porous channels. Most of these studies are also performed in disk geometry. The suitable porous substrate has several required characteristics (Watanabe et al. 2008a, b):

(i) Similar thermal expansion coefficient to that of the thin dense layer to prevent structure cracking during sintering
(ii) Adequate gas diffusion flow to supply oxygen gas to the dense layer (minimum permeance is claimed as 6×10^{-4} cm^3 min^{-1} Pa^{-1} cm^{-2})

To ensure the thermal expansion properties of the dense layer matches that of the porous layer, same material is usually used on both layers. Watanabe et al. utilized simple slurry dropping method to form a 10-μm-thick dense layer of $La_{0.6}Ca_{0.4}CoO_3$ (LCC) on top of a 2-mm-thick porous disk of LCC (Watanabe et al. 2008a, b). Ethanol-based slurry containing 1 wt% of LCC powder was dropped onto the porous support followed by sintering. A simpler technique such as a three-stage uniaxial compaction procedure was also used to fabricate three-layer asymmetric disk membrane of $Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-\delta}$ (BSCF), the final structure of which consisting 1.05-mm-thick porous and 30–300-μm-thick porous layers sandwiching a 170-μm-thick dense layer (Kovalevsky et al. 2011). For the first layer, a pore former was added into the powder followed by compaction at 100 MPa. The process is similar for the second layer except that a pore former was excluded to facilitate a dense layer formation. Accordingly, for the last layer, pore former was also included. A substantially higher pressure of 300 MPa was used during the last compaction process. Nonetheless, the oxygen permeation fluxes were only improved by 1.5 times relative to 1-mm-thick dense disk membrane which highlights the inability of such process to provide optimized porous structure with favorable gas diffusivity. A more complicated procedure was reported by Araki et al. (2012). To synthesize hierarchical structure, they prepared three identical compositions of $Ca_{0.8}Sr_{0.2}Ti_{0.7}Fe_{0.3}O_{3-\delta}$ (CSTF) powders made from different routes, e.g., solid-state route, citrate method, and supercritical hydrothermal route. Solid-state CSTF powder was used to form the porous disk substrate onto which the citrate CSTF powder was applied as a buffer layer by spin coating followed by drying and sintering. In the final step, hydrothermal CSTF powder was deposited. Such systematic and precise procedure involves the usage of powder with gradually reduced particle size (from that of the substrate) upon each additional step and enabled the fabrication of a defect-free 20-μm-thick asymmetric

membrane allowing high flux. In addition, tape casting was employed to prepare asymmetric BSCF membrane containing 20-μm-thick dense layer and 0.9-mm-thick porous substrate (Li et al. 2013). The resultant oxygen permeability under vacuum pressure (in the permeate side) is very high, reaching a maximum of 24.10 $\times 10^{-6}$ mol cm^{-2} s^{-1} (equal to 32.5 ml cm^{-2} min^{-1}) at 900 °C. Serra et al. made a $La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-\delta}$ asymmetric disk membrane by tape casting (Serra et al. 2013). The membrane which has 30-μm-thick dense layer and 630-μm-thick layer of porous support showed a maximum flux of 8.83 $\times 10^{-6}$ mol cm^{-2} s^{-1} (equal to 11.87 ml cm^{-2} min^{-1}) at 1000 °C.

The performances of several asymmetric disk membranes are summarized in Table 3 (Watanabe et al. 2008a, b; Kovalevsky et al. 2011; Araki et al. 2012; Li et al. 2013; Serra et al. 2013).

Tubular and Hollow Fiber Membranes

The interest on the tubular and hollow fiber membranes is associated with the need to enlarge the surface to volume ratio when industrial application is envisaged. Dense tubular membranes with uniform dense structure throughout the cross-section can be made using isostatic pressing method and plastic extrusion method. The plastic extrusion method is usually more widely reported where the calcined powder precursor is mixed with solvent, dispersant, binder, and plasticizer to form viscous liquid mixture which can be extruded into a tube to form "green tubular membrane." The "green tubular membrane" is then sintered to obtain dense body (Wang et al. 2002). The typical sintered tube geometry has an outside and inside diameter of 8 mm and 5 mm, respectively, and length of 30 cm, all of which can be modified by changing the extruder tube size and length. Despite the marginal improvement in the oxygen flux (maximum value of 2.31 $\times 10^{-6}$ mol cm^{-2} s^{-1} (equal to 3.1 ml cm^{-2} min^{-1}) at 900 °C) relative to the dense disk membrane, this membrane allows the application of compressed air on the shell side and vacuum on the inner channel side due to its robust structure. As such, the driving force is effectively increased so that higher fluxes can be achieved.

A better alternative to tubular dense membrane is hollow fiber membrane. Such fiber can be prepared using a phase inversion technique and sintering (Luyten et al. 2000; Liu et al. 2001, 2004; Sunarso et al. 2011). Analogous with the tubular membrane, the calcined powder precursor is mixed with polymeric binder, e.g., polyethersulfone or polyetherimide, and solvent, e.g., 1-methyl-2-pyrrolidone (NMP). Polyvinylpyrrolidone can be added to adjust the viscosity of the solution mixture. After degassing, the mixture is then spun through a tube-in-orifice spinneret with typical orifice diameter and inner tube diameter of 2 mm and 0.72 mm, respectively. The inner and outer coagulant can be chosen to adjust the phase inversion process. Normal coagulant during the spinning process is water which favors fast coagulation and results in dense layer formation. If slower coagulation is preferred to facilitate the porous layer formation, either on the outer or inner circumferential side of the fiber, NMP can be added as an outer or inner coagulant

Table 3 Summary of asymmetric disk membrane materials and performances

Dense layer		Porous layer		$J(O_2) \times 10^6$ (mol cm^{-2} s^{-1})	Temp. (°C)	Note	Ref.
Material	Thickness (mm)	Material	Thickness (mm)				
$La_{0.6}Ca_{0.4}CoO_3$	10	$La_{0.6}Ca_{0.4}CoO_3$	2000	1.24	930	Slurry dropping	(Watanabe et al. 2008a; Watanabe et al. 2008b)
$Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-\delta}$	170	$Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-\delta}$	30–300 and 1050	1.05	950	Three-stage uniaxial compaction/2 porous layers and 1 dense layer	(Kovalevsky et al. 2011)
$Ca_{0.8}Sr_{0.2}Ti_{0.7}Fe_{0.3}O_{3-\delta}$	20	$Ca_{0.8}Sr_{0.2}Ti_{0.7}Fe_{0.3}O_{3-\delta}$	500	2.50	950	Spin coating using powders from citrate and hydrothermal route	(Araki et al. 2012)
$Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-\delta}$	20	$Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-\delta}$	900	24.10	900	Tape casting/permeation under vacuum pressure	(Li et al. 2013)
$La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-\delta}$	30	$La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-\delta}$	630	8.83	1000	Tape casting	(Serra et al. 2013)

Fig. 7 (*Top left*) Typical sintered disk membrane (*bottom*), sintered hollow fiber (*middle*) and green hollow fiber (*top*), (*top right*) tube-in-orifice spinneret to synthesize hollow fiber and (*bottom*) hollow fiber membrane module consisting of 889 fibers

component. As is known, phase inversion process involves the polymer transformation from the initial liquid state to solid state upon contacting non-solvent (also referred as coagulant) at the same time as the solvent diffuses from polymer solution to water. Due to the different polymer precipitation rate, the asymmetric cross-sectional structure is formed on the hollow fiber precursor just like the morphology of polymeric membranes. The asymmetric structure where the dense middle layer is sandwiched by two porous layers is commonly attained when water is used as the internal and external coagulants. The "green fiber" shrinks during the sintering process due to the removal of organic materials and densification, but their original structure is normally retained.

For the sake of comparison, disk membrane and hollow fiber membrane are depicted in Fig. 7 (top left). The spinneret used during the hollow fiber synthesis is also displayed in Fig. 7 (top right). A perovskite membrane module consisting of 889 $La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-\delta}$ hollow fibers which can be operated for more than 1167 h with the maximum oxygen production rate of 3.1 L min^{-1} and the lowest purity of 99.4 % between 960 °C and 1070 °C was developed recently and is depicted in Fig. 7 (bottom) (Tan et al. 2010).

Other configurations such as multiple planar cell stack and monolith are available. In fact, the flat-plate multicell stack design was already developed by Air Products and Chemicals and Ceramatec to separate oxygen from air (Dyer et al. 2000). Monolithic structure, albeit its potential to provide large surface area

and has been used largely for catalytic reactors, has problems associated with complex manifold and sealing of different gas streams due to its large number of channels (Kapteijn et al. 2001).

Other Important Applications

Oxygen selective MIEC membrane enables simultaneous separation and reaction to be carried out, e.g., as a membrane reactor for chemical synthesis (Balachandran et al. 1995, 1997; Tsai et al. 1997; Jin et al. 2000; Ishihara and Takita 2000). This is beneficial, for example, toward syngas production from methane (CH_4). There is a high interest to convert methane into liquid petroleum products such as methanol, formaldehyde, and/or alkenes given the abundant amount of methane as well as higher price and higher practical value of the products (the latter, e.g., can be easily transported and contained). Two options are available for the conversion, i.e., via direct conversion process of methane to liquid products which is not efficient due to the low selectivity since the products are more reactive than the reactants or via indirect conversion processes which involve either steam reforming (Reaction 1 – Eq. 10) or partial oxidation of methane to form syngas (Reaction 2 – Eq. 11) followed by Fischer–Tropsch or methanol synthesis to convert syngas to liquid products:

$$CH_4 + H_2O \rightarrow CO + 3H_2 \quad \Delta H\,(25\,^{o}C) = 49.2\ \text{kcal mol}^{-1} \tag{10}$$

$$CH_4 + \tfrac{1}{2}O_2 \rightarrow CO + 2H_2 \quad \Delta H\,(25\,^{o}C) = -8.5\ \text{kcal mol}^{-1} \tag{11}$$

Steam reforming requires operating at 15–30 atm pressure and 850–900 °C temperature in the presence of Ni/Al_2O_3 catalyst due to its endothermic nature. Partial oxidation on the other hand can be carried out at 13 atm pressure with no external energy supply due to its exothermic nature, therefore providing a more economical alternative. While air (79 % N_2 and 21 % O_2) can be used in Reaction 2, the resultant separation of nitrogen (N_2) from the gas products (i.e., N_2 should be removed for downstream reactions) would entail high energy penalty and cost especially if conventional technology such as cryogenic distillation is employed. Oxygen selective MIEC membrane technology offers several advantages here, i.e., high product selectivities, exclusion of N_2 and thus the absence of NO_x, less flame formation risk since the oxygen input rate is diffusion-limited, and reduced cost associated with gas compression for downstream process.

Balachandran et al. prepared tubular $SrCo_{0.5}FeO_x$ membrane through plastic extrusion technique for partial oxidation of CH_4 (Balachandran et al. 1995, 1997). They operated the membrane reactor at 850 °C for 70 h in the presence of Rh-based reforming catalyst during which the reactor provided methane conversion efficiency of >98 %, CO selectivity of ~90 %, and H_2 yield twice that of CO. Tsai et al. reported the same reaction using disk $La_{0.2}Ba_{0.8}Fe_{0.8}Co_{0.2}O_{3-\delta}$ membrane incorporating $Ni/\alpha\text{-}Al_2O_3$ catalyst where they observed during 500-h operation the

increasing CH_4 conversion from 17 % to 80 % in conjunction with constant CO selectivity of ~99 % and H_2/CO ratio of 2 (Tsai et al. 1997). Beyond 500 h up to 700 h, the conversion remained constant while CO selectivity decreased slightly to ~95 %. Jin et al. utilized tubular $La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-\delta}$ membrane (made by isostatic pressing) and Ni/γ-Al_2O_3 catalyst and observed CH_4 conversion larger than 96 % with CO selectivity larger than 97 % (at low CH_4 feed concentration) between 825 °C and 885 °C (Jin et al. 2000). Ishihara and Takita reported partial oxidation of CH_4 using disk $La_{0.8}Sr_{0.2}Ga_{0.6}Fe_{0.4}O_3$ membrane with the presence of Ni and $La_{0.6}Sr_{0.4}CoO_3$ catalysts where they obtained CH_4 conversion of 30.6 %, CO yield of 29.2 %, and H_2 yield of 30.2 % at 1000 °C (Ishihara and Takita 2000). Membrane reactor for industrial scale applications requires membrane materials which can tolerate harsh conditions, i.e., operate under reducing and acidic gas atmosphere such as CH_4, H_2, and CO_2 at high temperatures (>800 °C). In this context, perovskite MIEC membranes have very limited applicability. Fluorite MIEC membranes, on the other hand, show more potential (Zhang et al. 2014).

Future Directions

Substantial advances in the oxygen selective MIEC ceramic membrane technology have been demonstrated over the past decades as represented by systematic and multitude approaches and concepts which leads to several orders of magnitude improvement of oxygen fluxes relative to those obtained in the 1980s. These aspects were reviewed throughout this chapter. In terms of oxygen production, the MIEC perovskite membranes are successful with the operation mode of high pressurized air as the feed gas as these perovskite membranes have sufficient material stability under such gas atmosphere. However, in many cases of clean energy applications, pure oxygen is not required. For example, to continuously use the existing power generation infrastructure under the oxy-fuel concept (one of the clean energy schemes), an O_2/CO_2 mixture for combustion with not very high flame temperature is required to get highly CO_2-concentrated flue gas. In such case, air separation via these MIEC membranes operated by sweep gas mode using part of the flue gas (CO_2) instead of high pressurized feed gas mode will be more economical. The prerequisite for such operation is the robust membrane stability under acidic gases at high temperatures. Thus, future directions of this technology will be placed on materials development with improved operational stability under severe gas atmospheres containing CO_2, CH_4, H_2, SOx, and so on. Once there is a breakthrough, the applications of such MIEC ceramic membranes will be expanded from the field of air separation to chemical synthesis like syngas production from methane partial oxidation with much savings in capital investment and operation cost.

Climate Change Mitigation: Advanced Technologies

Photocatalytic Water Splitting and Carbon Dioxide Reduction

Nathan I. Hammer, Sarah Sutton, Jared Delcamp, and Jacob D. Graham

Contents

Abstract

Photocatalytic water splitting, which involves the simultaneous reduction and oxidation of water-producing hydrogen and oxygen gas, provides a means of harnessing the sun's power to generate an energy source in a clean and renewable fashion. Photocatalytic reduction of carbon dioxide to form hydrocarbons such as methane not only promises reduced emission of an important greenhouse but also a new source of fuel. Concerns over the effects of global climate change and the eventual demise of fossil fuels make the search for clean alternative energy sources a top priority. This chapter details the progress in these two increasingly important areas: hydrogen production by photocatalytic water splitting and photocatalytic carbon dioxide reduction.

Introduction

It is an understatement to say that the consumption of energy is a critical requirement for modern human civilization. The rapid industrialization and technological progress that permeate every facet of life would not be possible without the cheap and abundant energy sources enjoyed by mankind today. Annual worldwide energy consumption reached 497 exajoules in 2006, and with current conditions, energy demands are expected to grow 44 % by the year 2030 (Energy Information Administration and International Energy 2009). Currently, fossil fuels provide the vast majority of this energy as they are easily obtainable, abundant, and energetically dense. In order to keep up with this pace, society's reliance on fossil fuels will grow dramatically in the coming years if alternative sources of energy are not developed.

It is now well accepted in society that human dependence on fossil fuels presents a number of problems. Competition for fossil fuel-based sources of energy will have destabilizing geopolitical effects as the supply of these valuable resources declines. However, the most publicized consequences of the continued use of fossil fuels come in the form of environmental pollution. Sulfur dioxide, nitrogen oxides, cadmium, and mercury are all released as a result of burning fossil fuels, with coal being the largest contributor. Under the right conditions, these pollutants produce easily visible results in the form of acid rain and smog, while other combustion products, such as carbon dioxide, may not appear to have an immediately visible effect. Although CO_2 can generally be considered harmless (at least physiologically to plants and animals – including humans), the quantities released annually into the atmosphere (about six billion tons) could possibly result in climate-altering effects. Concerns over "global warming" and, more recently, "global climate change" have captivated the attention of world governments and are currently transforming society in areas ranging from concern over automobile emissions to managing carbon footprints (Hansen and Sato 2004; Fischer et al. 1999; Luthi et al. 2008; McMichael and Woodruff 2004; Jackson and Schlesinger 2004; Schimel et al. 2000; Armaroli and Balzani 2007; Caetano et al. 2008; Zhang et al. 2007).

Certain atmospheric gases such as CO_2 are thought to trap long wavelength, thermal radiation in the Earth's atmosphere through the "greenhouse effect" and CO_2 itself is considered a greenhouse gas. Other important greenhouse gases include water, methane (CH_4), nitrous oxide (N_2O), and ozone (O_3). The historical development of the greenhouse effect is rather quite interesting and dates back to the nineteenth century and scientists including Svante Arrhenius (Arrhenius 1896). The basic mechanism behind the greenhouse effect is depicted in Fig. 1. Radiation from the sun is absorbed by the Earth and is converted to heat. This heat is radiated back into space but some wavelengths of radiation corresponding to the vibrational normal modes of greenhouse gases are absorbed by these gases. This energy is then reemitted in all directions, including back toward the Earth, rather than into space. The overall effect is a "trapping" of heat energy in the atmosphere.

Ice core samples possess trapped gaseous bubbles that reveal atmospheric CO_2 concentrations dating back as far as 800,000 years (Fischer et al. 1999; Luthi et al. 2008). They have shown a correlation between higher CO_2 concentration and

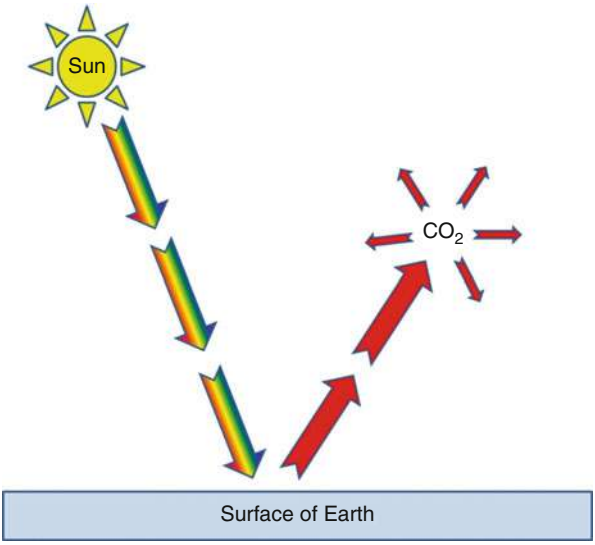

Fig. 1 Various wavelengths of solar radiation are absorbed by the Earth's surface and transformed into heat, which is eventually reradiated back into space. Greenhouse gases, such as CO_2, absorb some of this infrared radiation and reemit it in all directions, including back toward the Earth's surface

higher average global temperatures. However, this correlation is delayed from the effect of the oceans and other buffer systems (Hansen and Sato 2004). With current conditions, an eventual average global temperature increase of several degrees Celsius is possible. Along with sea level rise, acidification of the oceans, and glacial melt, the rise in average temperature could destabilize much of the Earth's current ecology with altered fauna migration and flowering times. These circumstances also would likely diminish food supplies as environmental conditions change.

Although the dangers of global climate change have been in public thought for decades, solutions remain elusive for technical and economic reasons (Keith 2009). The possible solutions to global warming are numerous and varied, but most can be divided into two avenues of approach: removing sources of CO_2 or capturing released CO_2. An example of a geoengineering form of the latter would be injecting CO_2 underground. Groundwater is the major sink for CO_2 injected underground, and the possibility of long-term containment is difficult to predict (Gilfillan et al. 2009). While removing CO_2 from the atmosphere would help in reversing the trend of global warming, replacing current fossil fuel-dependant energy sources with non-CO_2-emitting energy sources is a more long-term solution. Of all the 6 billion tons of CO_2 released annually, 80 % is due to the burning of fossil fuels. Nuclear, geothermal, wind, hydroelectric, and solar methods of energy production emit no CO_2 and are much cleaner sources of energy than fossil fuels. A geothermal, wind, or hydroelectric energy supply is renewable and clean but has limited implementation in specific areas. Nuclear energy is a very real alternative to fossil fuels but is not renewable, and fissile materials will eventually be depleted. Solar-derived energy has the most potential as a permanent replacement for fossil fuels and as a means by which to transform one form of energy into another, and photovoltaics have emerged as perhaps the most promising avenue for that capture and conversion.

Although the development of solar energy as an alternative energy source seems like the perfect solution to society's energy needs, long-term storage and realistic energy density are obstacles. Many have touted hydrogen gas as an attractive alternative to fossil fuels as an energy carrier (Barreto et al. 2003; Crabtree et al. 2004; Dunn 2002; Moriarty and Honnery 2009). Hydrogen's reaction with oxygen yields only water and heat, and this heat can easily be used as a source in automobiles or generators (Crabtree et al. 2004). Hydrogen storage in tanks involves high-pressure or cryogenic storage (Schlapbach and Zuttel 2001; Zuttel 2004). Other methods involve hydrogen adsorption onto certain specialized surfaces with metal hydrides having the highest hydrogen storage density (Zuttel 2004). Currently, most hydrogen production is dominated by steam reformation of natural gas (Crabtree et al. 2004). An efficient, cheap, and renewable method of hydrogen production would allow hydrogen gas to become the primary energy carrier in automobiles and in stationary applications. Coupling the storage and transportation potential of hydrogen gas with solar energy-based production would allow for the creation of an inexpensive and highly useful source of energy.

It is often noted in reviews and by advocates of solar energy that the sun provides many thousands of times the annual energy consumption of the Earth, and harnessing only a fraction of this energy would be adequate. Shown in Fig. 2 is a solar emission spectrum obtained on the campus of the University of Mississippi. This emission mimics a blackbody curve, and it is readily apparent that most of the light from the Earth's yellow sun that reaches the Earth's surface is in the visible region of the electromagnetic spectrum. The number of photons reaching the Earth's surface drops dramatically as ultraviolet (UV) wavelengths are approached. Dips in the spectrum correspond to absorption by different atmospheric gases such as water vapor. Various methods exist for harvesting solar energy, but the use of photocatalysts provides perhaps the most viable option with their reversible

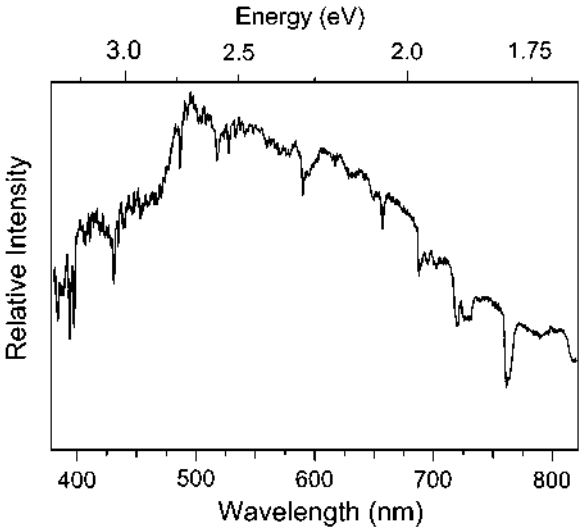

Fig. 2 Solar emission spectrum obtained at the University of Mississippi

oxidation–reduction capabilities. Photocatalytic water splitting, which involves the simultaneous reduction and oxidation of water-producing H_2 and O_2, provides a means of harnessing the sun's power to generate an energy source in a clean and renewable fashion. Besides the production of an alternative to fossil fuels, photocatalytic processes can turn the tide against global climate change in a more direct way. Photocatalytic materials can reduce carbon dioxide to form hydrocarbons such as methane and ethanol, essentially taking exhaust and turning it back into fuel. This chapter details the progress in these two increasingly important areas: hydrogen production by photocatalytic water splitting and photocatalytic carbon dioxide reduction.

Photocatalytic Processes

A photocatalytic process relies on a semiconductor's adsorption of light to create stored energy and the use of that energy to do some form of useful work – in this case, serving as a catalyst for the production of a desired reaction product. In semiconductors, groups of closely spaced electronic energy levels form bands, namely, the conduction and valence bands, as shown schematically below in Fig. 3. When incident light has energy that is greater than that of the band gap of the semiconductor material, electrons in the valence band of the material are excited to the conduction band. At the same time, holes are created in the valence band. Photocatalytic reactions then occur on the surface of the semiconductor, where these newly generated electrons and holes are located. Many important considerations go into the engineering of a useful photocatalyst. A few of these include matching the band gap to the radiation wavelength (or frequency/energy) to be employed, the suppression of the recombination of electron–hole pairs, and appropriate sensitization by other materials.

The conduction band is higher in energy and less populated with electrons than the valence band, and the energy separation of these two bands is commonly referred to as the band gap. This band gap limits the minimum energy (or wavelength) of incident photons able to be absorbed. Photons that are absorbed promote electrons (e^-) across the band gap from the filled valence band into the empty conduction band creating a hole (h^+) in the valence band. Thermal relaxation of the electron–hole pair to the band edge can occur or recombination of the electron–hole pair can result, although this takes longer to occur (on a picosecond timescale). While the electron–hole pair exists, the photocatalyst can perform useful reduction and oxidation reactions by accepting electrons into its valence band or donating the promoted electrons in its conduction band. When an electron moves to the surface of the photocatalyst and has the correct potential, anion radicals (A^- in Fig. 3) are produced, while cation radicals (B^+ in Fig. 3) are produced from electron holes at the surface.

As mentioned above, there are a number of design considerations to keep in mind in order to create a useful photocatalytic material. Suppression of the recombination of electron–hole pairs in a photocatalyst is essential to improving its efficiency

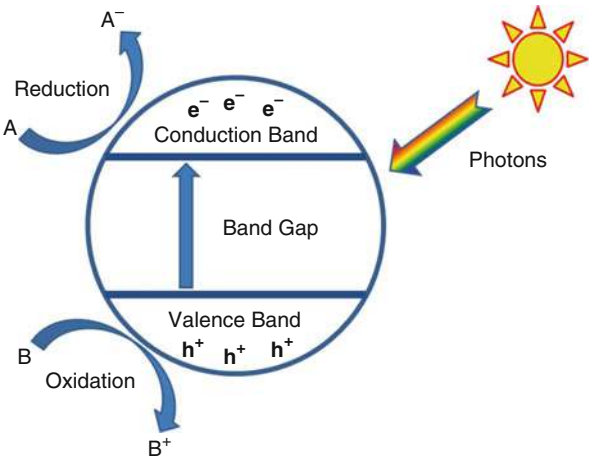

Fig. 3 In a semiconductor, electrons (e^-) are promoted from the valence band to the conduction band when photons of light are absorbed. Electron holes (h^+) are created with the excitation of electrons. The creation of this electron–hole pair allows for the reduction and oxidation of other species

(Hurum et al. 2005; Mohapatra et al. 2008; Fox and Dulay 1993; Colombo and Bowman 1996; Kaneco et al. 1998). Trapping of a promoted electron, hole, or both impedes the detrimental recombination process. An example of electron–hole trapping would be using a sacrificial reagent to donate electrons to a photocatalyst after excitation. Electrons donated into the valence band provide a longer lifetime for the excited electron in the conduction band. Oxygen and several inorganic oxidizing species have been shown to serve as good recombination inhibitors (Fox and Dulay 1993). Sensitization of semiconductors by dye molecules is another important design element employed to both increase the excitation rate and extend the excitation wavelength window (Fox and Dulay 1993; Younpblood et al. 2009). Photoelectrons are provided by a photosensitive dye that is in contact with the semiconductor material, and charge separation occurs at the surfaces between the dye, semiconductor, and electrolyte. The semiconductor serves primarily as the charge carrier, rather than the source of electrons and holes.

Physically adsorbing the molecules to be reduced or oxidized (A and B, respectively, in Fig. 3) by the photocatalyst is another important design element that is essential to successful catalytic activity (Fox and Dulay 1993; Li et al. 2008). This is because of the fact that the recombination of photogenerated electrons and holes is very fast. There is no time for diffusion of the charge acceptor to the site of oxidation or reduction. Electron transfer is kinetically competitive only when the donor or acceptor molecule is adsorbed before the reaction of interest is to take place (Fox and Dulay 1993). Doping of other atoms and molecules into semiconductor photocatalysts to modify the electronic structure is also an important area of research in recent years that will be discussed in the later sections of this chapter (Fox and Dulay 1993; Yeredla and Xu 2008; Bhattacharyya et al. 2008; Choi et al. 1994; Yan et al. 2005; Wang et al. 2000; Bae et al. 2008; Livraghi et al. 2008; Jagadale et al. 2008; Graciani et al. 2008; Kesselman et al. 1997; Fang et al. 2008; Varghese et al. 2009; Gai et al. 2009; Hong et al. 2005; Hidalgo et al. 2009; Usubharatana et al. 2006; Osterloh 2008; Domen et al. 2000; Kudo and Miseki 2009).

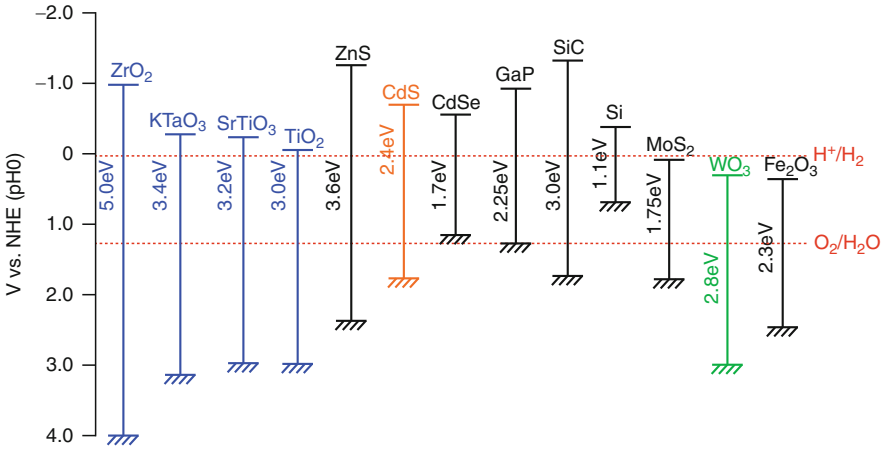

Fig. 4 Band structures of common semiconductor photocatalysts relative to NHE. Note that in this representation, the valence band is at the bottom and the *conduction band is on the top* (Reproduced with permission from Kudo and Miseki (2009))

The number of photocatalysts developed for water splitting and carbon dioxide reduction increases more each year and many of these materials are cataloged below in the following two sections of this chapter. Important considerations already mentioned above in creating an effective photocatalyst include suppressing electron–hole recombination and achieving effective charge separation. Another important consideration is the selection of the best semiconductor for the desired photocatalytic reaction. The choice of semiconductor material and the other species that are incorporated into it such as sensitizers and dopants are critical in achieving the optimal overlap of band gap with the wavelengths of light. Shown in Fig. 4 are the band structures of a few representative semiconductor photocatalysts relative to the normal hydrogen electrode (NHE) at pH = 0 (Kudo and Miseki 2009). In the NHE, hydrogen's standard electrode potential is defined as zero ($2H^+ + 2e^- \rightarrow H_2$, E = 0.0 V), and the potential of all other electrode reactions are defined as relative to hydrogen. To effectively use the abundant visible solar radiation shown in Fig. 2, the band gap (the height of the bar in Fig. 4) needs to be less than about 3 eV. This energy corresponds to photons of about 400 nm, right at the visible edge of the solar emission spectrum. However, to be effective in water splitting or carbon dioxide reduction, the location of the top and bottom of the band gap is also very important.

Photocatalytic materials have promising and practical uses in many areas as wide ranging as organic synthesis (Fox and Dulay 1993; Kudo and Miseki 2009) and the degradation of hazardous waste (Bahnemann 2004; Hoffmann et al. 1995). Here, the interest is in the application of semiconductor photocatalysts to the splitting water to create a new source of hydrogen gas and the reduction of carbon dioxide to useful forms. In the following two sections, the application of photocatalytic semiconductor materials for these purposes is discussed and many examples of recently developed materials are listed.

Photocatalytic Water Splitting

Water splitting is the simultaneous reduction and oxidation of water to produce H_2 and O_2. In the early 1970s, the Honda–Fujishima effect was reported, in which water splitting was achieved with a TiO_2 electrode under ultraviolet (UV) irradiation (Fujishima and Honda 1971, 1972). In their configuration, which is illustrated in Fig. 5, a platinum electrode and a TiO_2 electrode are connected through an external load and immersed in water. When irradiated with UV light, current flows from the platinum electrode to the TiO_2 electrode. Oxidation proceeds at the TiO_2 electrode, while reduction proceeds at the platinum electrode. These processes are given by:

$$\text{Oxidation} : 2h^+ + H_2O \rightarrow \frac{1}{2}O_2 + 2H^+ \tag{1}$$

$$\text{Reduction} : 2e^- + 2H^+ \rightarrow H_2 \tag{2}$$

where h^+ are electron holes. The overall chemical equation for this process is thus:

$$H_2O \rightarrow \frac{1}{2}O_2 + H_2 \tag{3}$$

Not all semiconductor materials are appropriate for the photocatalytic splitting of water. As mentioned above, it is important to choose a semiconductor material that exhibits a band gap appropriate for the desired photochemical reaction. In the case of water, the top level of the valence band must be more positive than the oxidation–reduction potential of Eq. 1 – the oxidation of water to form oxygen gas and two protons. This reaction occurs at 1.23 V relative to NHE. The lower level of

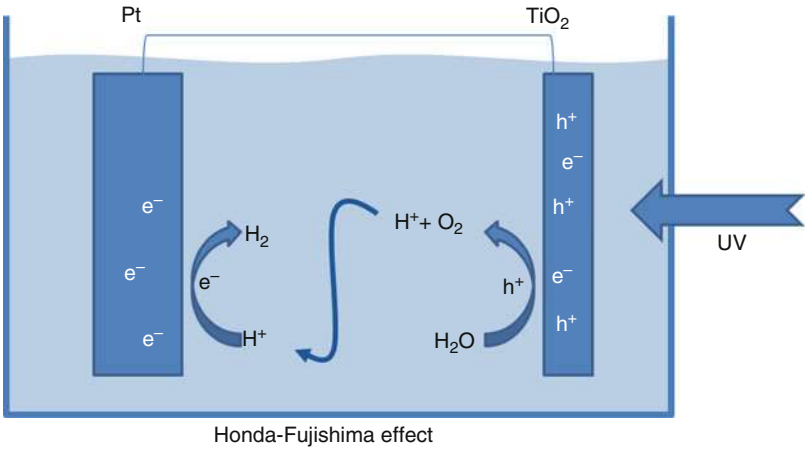

Fig. 5 Cartoon schematic of the photocatalytic water splitting setup employed by Fujishima and Honda (1971, 1972)

the conduction band must be more negative than the oxidation–reduction potential of Eq. 2, the reduction of the hydrogen cation, to create the desired product hydrogen gas. This, as all freshman chemistry students can attest to is 0 V relative to NHE. Honda and Fujishima's choice in their original paper was TiO_2. As evident from Fig. 4, the band gap for TiO_2 is approximately 3.2 eV (different sources report 3–3.5 eV, depending if the TiO_2 is in the rutile or anatase form), requiring photons with wavelengths less than about 400 nm. This energy requirement is right on the edge of usable visible light and therefore either violet or ultraviolet photons are required to mobilize electron–hole pairs in TiO_2. This is unfortunate since most photons hitting the Earth are longer in wavelength as illustrated from Fig. 2. For this reason, there have been many attempts to improve on the efficiency of the photocatalytic water splitting process.

Since Honda and Fujishima's initial discovery, a number of architectures for achieving efficient photocatalytic water splitting using both ultraviolet and visible light have been developed. However, the overall quantum efficiencies of these architectures have been less than stellar (less than 10 % for catalyzing Eq. 3) (Osterloh 2008), and wide-scale utilization has still not been achieved. For solar-based water splitting to be practical, several goals must be met. One is that the photocatalyst must efficiently adsorb solar radiation. TiO_2, for example, requires UV light, while most of the sun's photons have energy in the visible region of the electromagnetic spectrum (or longer wavelengths) as shown in Fig. 2. The band gap of the photocatalyst must also be tuned so that both the reduction and oxidation processes necessary for water splitting are energetically possible. This requirement is indicated in Fig. 4 with dotted lines intersecting the various photocatalyst materials for these two processes. Another consideration is that these reduction and oxidation reactions be spatially separated to prevent recombination of the freshly produced H_2 and O_2. This last requirement needs clever engineering of the photocatalytic material and is one reason for the large number of publications in this area each year.

Excellent reviews summarize the extensive literature that has been amassed over the past few decades on the subject of photocatalytic water splitting. These reviews detail the various photocatalytic materials employed and the clever architectures that have been engineered to improve the efficiency of this process. Table 1 catalogs a number of the reports described in detail in these literature reviews (Osterloh 2008; Kudo and Miseki 2009; Yang et al. 2005; Navarro et al. 2009; Zong and Wang 2014; Vaneski et al. 2014; Abe 2010; Hernández-Alonso et al. 2009; Kudo et al. 2004; Xie et al. 2013; Zhang and Guo 2013; Janáky et al. 2013). The band gap of the photocatalyst material and the light source employed to mimic solar radiation in most cases are listed. Also included in Table 1 are the H_2 and O_2 activities reported from these studies. High-powered mercury (Hg) and xenon (Xe) arc lamps are commonly employed as the light sources in experiments that test the photocatalytic ability of newly developed materials. It is not feasible to use actual solar radiation in experiments to test for photocatalytic activity because a constant flux of a known range of wavelengths is desired so that the photocatalytic responses of different materials can be directly compared. Hg lamps are useful for high-powered, short-wavelength UV excitation, and Xe lamps cover both longer-wavelength UV and are

good mimics for the visible solar spectrum. Later, in the section of this chapter describing carbon dioxide reduction, a photograph of a photocatalytic setup employing a 450 W Xe arc lamp is shown.

The materials in Table 1 are grouped as best as possible into categories based on the photocatalytic material. These include materials based off of Honda and Fujishima's original choice, TiO_2, or materials that incorporate tungsten or sulfides. Mixed materials with multiple metals are evident with such combinations changing not only the band gap of the photocatalyst but also the crystal structure and geometry of the photocatalyst surface. Such considerations are important when trying to develop a photocatalyst that not only has the correct electronic properties but also allows for effective charge separation. In addition to metal oxides, both CdS and ZnS have proven to be successful photocatalytic materials for water splitting. Of these two, CdS offers the added benefit of access to visible regions of the electromagnetic

spectrum with a band gap of only 2.4 eV, which corresponds to the green (~515 nm) region of the spectrum. Unfortunately, however, these materials exhibit instability due to photoanodic corrosion. One of the most popular new building blocks for photocatalytic water splitting is graphene oxide (Xie et al. 2013).

Photocatalytic CO_2 Reduction

The facile conversion of carbon dioxide to usable forms such as methane or ethanol would solve two important problems simultaneously. Not only would there be an outlet for the ever-growing supply of CO_2 gas, but concerns over dwindling energy supplies would also be partially mediated. The process for the photocatalytic reduction of carbon dioxide resembles that of water splitting, but rather than having just one reactant (two water molecules) and one set of products (H_2 and O_2), multiple reactants and a variety of products can be obtained. The resulting products depend upon the use of specific semiconductor materials and the choice of reductant. Possible products include carbon monoxide, alkanes, alcohols, aldehydes, ketones, and carboxylic acids.

The photoreduction of carbon dioxide in aqueous solution was first demonstrated by Inoue et al. in 1979 using mercury and xenon arc lamps for excitation. In that report, formaldehyde (HCHO), formic acid (HCOOH), methanol (CH_3OH), and methane were produced using water as the reductant. The authors compared a number of photocatalysts that included TiO_2, WO_3, ZnO, CdS, GaP, and SiC. The band structures of most of these materials are shown in Fig. 4. Equations 4, 5, 6, 7, 8, 9, 10, 11, and 12 detail the important reactions that lead to the various observed organic products in this and later studies:

$$\text{Initial Oxidation} : 2h^+ + H_2O \rightarrow \frac{1}{2}O_2 + 2H^+ \tag{4}$$

$$\text{Initial Reduction} : e^- + H^+ \rightarrow {}^\bullet H \tag{5}$$

$$\text{Initial Reduction} : e^- + CO_2 \rightarrow {}^\bullet CO_2^- \tag{6}$$

$$\text{Subsequent Reactions} : {}^\bullet CO_2^- + 8{}^\bullet H + h^+ \rightarrow CH_4 + 2H_2O \tag{7}$$

$${}^\bullet CO_2^- + 6{}^\bullet H + h^+ \rightarrow CH_3OH + H_2O \tag{8}$$

$${}^\bullet CO_2^- + 2{}^\bullet H + h^+ \rightarrow CO + H_2O \tag{9}$$

$${}^\bullet CO_2^- + 2{}^\bullet H + h^+ \rightarrow HCOOH \tag{10}$$

$${}^\bullet CO_2^- + 4{}^\bullet H + h^+ \rightarrow HCHO + H_2O \tag{11}$$

$${}^\bullet CO_2^- + 12{}^\bullet H + 2h^+ \rightarrow C_2H_5OH + 3H_2O \tag{12}$$

Heterogeneous CO_2 Reduction

Shown in Fig. 6 is a photograph of a setup employed at the University of Mississippi for the photocatalytic reduction of carbon dioxide (Chen et al. 2012). A 450 W Xe arc lamp is employed as a substitute for solar radiation. The light is directed using a high-reflection focusing mirror into a flask containing the reaction solution. This solution contains the photocatalyst (such as TiO_2), gaseous CO_2, water, and other reductants. After irradiation for an extended period of time (6–10 h), the resulting hydrocarbon products can be determined using quantitative and qualitative analytical methods. Compared to water splitting, photocatalytic carbon dioxide reduction is much less developed in the literature. Since Inoue's first report, a number of new photocatalytic materials have been developed in attempts to improve upon both the conversion efficiency of carbon dioxide to hydrocarbons and the variety of hydrocarbon products possible. A number of excellent reviews summarize this work and Table 2 lists a number of these studies (Usubharatana et al. 2006; Hernández-Alonso et al. 2009; Habisreutinger et al. 2013; Izumi 2013; de Richter et al. 2013; Dhakshinamoorthy et al. 2012; Liu et al. 2012; Tahir and Amin 2013; Roy et al. 2010; Kondratenko et al. 2013; Kočí et al. 2008; Navalón et al. 2013).

As in the case of photocatalytic water splitting, TiO_2-based materials dominate the carbon dioxide reduction literature. This includes pure TiO_2 with varying choice of reductants or TiO_2 doped with other species such as copper (Cu) that aid in red-shifting the absorption profile more into the visible region of the electromagnetic spectrum. The reasons for the dominance of TiO_2 in both water splitting and carbon dioxide reduction include TiO_2's good photoactivity, inertness, ready availability,

processability, abundance, resistance to corrosion, and low cost (Kočí et al. 2008). Newer materials based on materials such as WO_3 offer alternatives to TiO_2, but to date, titanium dioxide remains the most successful and widely employed material. For carbon dioxide reduction, using water as a reductant is a cheap and effective option that would be ideal for widespread adoption of this technology. However, the solubility of carbon dioxide in water is low, and the reduction of CO_2 in water has to compete with the formation of hydrogen gas (H_2) and hydrogen peroxide (H_2O_2). For these reasons, other reductants and mixtures of various reductants in different conditions have been investigated. In particular, the use of basic solution offers advantages over pure water with hydroxide ions acting as hole scavengers and extending the recombination time of the electron–hole pairs (Kočí et al. 2008; Tseng et al. 2002).

Homogeneous CO_2 Reduction

Homogeneous catalysis offers the opportunity to relatively simply and precisely tune catalyst structures leading to changes in properties such as product selectivities and catalyst photoreduction rates. Homogeneous photocatalytic reduction of CO_2 has received less attention than the heterogeneous counterpart and is in a relatively early stage of development with initial reports in molecular catalysis dating to circa 1980. Currently, the homogeneous photocatalysis field is undergoing a resurgence in activity which has led to several excellent reviews (Reithmeier et al. 2012; Benson et al. 2009; Xiaoding and Moulijn 1996; Morris et al. 2009; Savéant 2008; Mikkelsen et al. 2010; Schneider et al. 2012).

Several major challenges face homogeneous catalysis including catalyst lifetimes, catalytic rates, and electron/proton sources. Ideally, the stability of semiconductor-based photocatalysts and the selectivity of photocatalyst systems could be combined to give long-lasting selective photocatalytic systems. Several noteworthy examples have arisen exploring this concept with highly encouraging catalyst lifetime improvements (Kumar et al. 2012; Anfuso et al. 2012; Linsebigler et al. 1995; Wang et al. 2011; Sekizawa et al. 2013; Ha et al. 2014; Kou et al. 2014; Ettedgui et al. 2011). This chapter will focus on various molecular catalyst systems, which have been explored in fully homogenous reactions.

The single-electron reduction of CO_2 is highly unfavorable and occurs near -1.90 V versus normal hydrogen electrode (NHE). The lowest energy pathways to CO_2 reduction involve simultaneous multiple electron and proton transfers which are detailed below versus NHE.

$$CO_2 + e^- \rightarrow {}^{\bullet}CO_2^- \quad E^o = -1.90 \text{ V} \tag{13}$$

$$CO_2 + 2H^+ + 2e^- \rightarrow CO + H_2O \quad E^o = -0.53 \text{ V} \tag{14}$$

$$CO_2 + 2H^+ + 2e^- \rightarrow HCO_2H \quad E^o = -0.61 \text{ V} \tag{15}$$

$$CO_2 + 4H^+ + 4e^- \rightarrow HCHO + H_2O \quad E^o = -0.48 \text{ V} \tag{16}$$

$$CO_2 + 6H^+ + 6e^- \rightarrow CH_3OH + H_2O \quad E^o = -0.38 \text{ V} \tag{17}$$

$$CO_2 + 8H^+ + 8e^- \rightarrow CH_4 + H_2O \quad E^o = -0.24 \text{ V} \tag{18}$$

One of the key challenges in molecular photocatalysis is the storage of electrons to deliver to CO_2 in the presence of H^+ sources. This is in stark contrast to homogeneous semiconductor catalysts where large numbers of available electrons are often readily available in the semiconductor conduction band. However, the practical restrictions (i.e., number of reduction potentials) on the number of electrons which may be "stored" with molecular catalysts are in part responsible for the excellent selectivities of homogeneous catalysts for the formation of CO and HCO_2H. These products are at the balance between the *number* of electrons needed for reduction versus reduction potential. The selectivity for these products and the ease of

separation from one another (gas–liquid separation) has in part fueled the recent boom in molecular catalysis. Either product is highly desirable with the potential conversion into synthetic fuels via processes such as the *Fischer–Tropsch synthesis*.

A second concern in homogeneous photocatalysis is many of the catalysts and photosensitizers used are commonly soluble in organic solvents with low solubility and stability in H_2O. This has led to the common use of organic proton and electron sources and restricted available solvents to those with high solubilities for CO_2 such as DMF and H_2O. However, care must be taken when using solvents such as DMF, which have the potential to decompose to CO and HCO_2H under UV irradiation or in the presence of Lewis acids. *DMF as a solvent* in particular has led to a desire for careful background reaction measurements, *light source cutoff filters, and* ^{13}*C-labeling studies to* verify the carbon source for the products. The use of an organic electron and proton source has enabled the exploration of molecular photocatalysts, but has come with the cost of threatening practicality in generating a carbon-based waste during the reduction of CO_2 to desirable products (such as fuels) at a tremendous scale. Ideally, the electron and proton source should be derived either directly or indirectly from H_2O. To date, a single homogeneous catalyst system has emerged, which does not generate a carbon-based wasted during CO_2 reduction. The rhenium polyoxometalate-based catalyst developed by Neumann (Ettedgui et al. 2011) has demonstrated the potential for a homogeneous catalyst which undergoes a reverse water–gas shift (rWGS) reaction, as shown in Fig. 7.

This catalyst uses H_2 as a proton and electron source for the reduction of CO_2 to CO and H_2O. While this catalyst is a novel step toward practicality in terms of starting material conversion to desirable products for large-scale applications, it is limited in turnover numbers (TON, ~22) and turnover frequency (TOF, ~1.5/h) before the catalyst is rendered inactive.

The remaining catalyst examples shown in Figs. 8 and 9 will focus on systems, which use common organic amine proton and electron sources such as triethylamine (TEA) and triethanolamine (*TEOA*) in solvent quantities (Fig. 9). Table 3 summarizes the properties of these systems.

Very few catalysts have been demonstrated to operate effectively in the absence of a photosensitizer. The added demand of light absorption to CO_2 reduction processes limited catalyst variability to Re-pyridyl, Ru-pyridyl, Ir-pyridyl, and porphyrin-based complexes along with a few organic catalysts. The most well-

studied molecular catalysts for CO_2 reduction are based on rhenium bipyridyl analogues, which are highly selective for CO product formation. The first example of this catalyst was discovered in the early 1980s (Takeda et al. 2008)and has been explored as a standard for comparison as well as a common catalyst for developing multinuclear as well as semiconductor-bound novel systems. The initial *Re catalyst* (**1**) has a coordinated chlorine atom and operates for 15 turnovers in the presence of *TEOA* with a 500 W Hg lamp. Exchange of the anionic ligand $^{-}$NCS (**2**) led to a doubling of the TON while introduction of a $^{-}$CN (**3**) ligand rendered the catalyst

inactive (Takeda et al. 2008). With a lower wattage lamp (250 W), a higher TON for (**1**) was observed (TON = 27), and this number could be near doubled though the addition of tetraethylammonium chloride to give a TON of 48 (Hawecker et al. 1983). A bromine complex (**4**) was also evaluated and yielded slightly lower reactivity. Substitution on the bipyridyl ligand with phenylacetylene was found to yield substantially lower reactivities despite an enhanced absorption in the visible wavelength range (Portenkirchner et al. 2012).

Ruthenium-based photocatalysts**6** and **7** are known to give good selectivities for formate formation (Takeda et al. 2014; Boston et al. 2013) *with turnover numbers as* high as 76. **7** is also one of the only reported molecular catalysts to form MeOH during photolysis. Both the ruthenium catalysts **6** and **7** along with iridium-based catalyst **8** are effective photocatalysts in water as solvent (Yuan et al. 2011). The highest TON catalyst which operates in the absence of a photosensitizer is Ishitani's iridium-based catalyst (**9**) (Sato et al. 2013).There are examples of first-row transition metal catalyst known to function as photon-absorbing and CO_2-reducing catalysts based on porphyrin (**10** and **11**) and phenanthroline (**12**) (Behar et al. 1998; Grodkowski et al. 1997; Lehn and Ziessel 1982). The porphyrin catalysts demonstrated comparable TONs to **9** while the cobalt chloride in situ complexed with **12** gave relatively few turnovers in an early report (~3). Although few studies have focused on homogeneous organic photocatalysts, some early reports indicate oligophenyl structures can reduce CO_2 to selectively give formate albeit in modest TONs (1–4) (Matsuoka et al. 1992).

Covalently linked multinuclear photocatalysts have shown incredibly high TON values of >3,000 for a *Re–Ru*-linked polypyridyl catalyst **23** and demonstrated the use of red visible light to reduce CO_2 with a *Re–Os-linked catalyst***24** (Gholamkhass et al. 2005; Tamaki et al. 2012b, 2013a, b). These structures likely benefit from a close proximity of the photosensitizer to a CO_2 reduction catalyst to allow for efficient electron transfer. In these cases, the CO_2 reduction catalyst does not need to absorb photons, but only needs a reduction potential below that of the reduced photosensitizer. Currently, $Ru(bpy)_3$ analogues are ubiquitous covalently linked photosensitizers although osmium (**24**, TON = 1,138) and porphyrin (**25**, TON = 1)-based photosensitizers have also been reported (Schneider et al. 2011). In these systems, the selectivity among CO_2 reduction products is largely determined by the catalyst appended to the photosensitizer, whereas Re-based reduction catalyst typically gives CO selectively and Ru-based reduction catalyst typically gives HCO_2H. It is noteworthy that the highest quantum-yielding (ϕ) photocatalyst system (**23**) reached efficiencies of 45 %. This is dramatically higher than other observed good quantum yields of 8–5 % for non-covalently linked catalysts.

A diverse array of catalysts known to be active electrocatalysts for CO_2 reduction has been studied in photocatalytic systems with a variety of added photosensitizers (**38**–**44**). While Re and Ru complexes similar to those studied as covalently linked multinuclear photocatalysts have been studied, reactivity commonly decreases significantly (~twofold in many cases) when the linking tether is removed. However, these systems still typically perform an order of magnitude better with regard to TON when compared with mononuclear systems. The use of non-linked photosensitizers

has enabled the recent rapid evaluation of several noteworthy electrocatalysts in photocatalytic systems including those based on manganese (**28**) (Takeda et al. 2014), nickel (**31** and **32**) (Thoi et al. 2013), iron porphyrins (Bonin et al. 2014a), and cobalt cyclams (**32**, **35**–**37**) (Yanagida et al. 1995; Ogata et al. 1995b). Manganese complex **28** paired with ruthenium photosensitizer **6** demonstrated an unusual switch in CO_2 product selectivity from CO under electrocatalytic conditions to HCO_2H under photocatalytic conditions with a dramatic increase in TON (from 13 to 149). Perhaps one of the most important developments in these non-covalently bound systems is the recent use of $Ir(ppy)_3$ (**42**) which has been paired with electrocatalysts **31** and **33. 42** has a remarkably high-energy reduction potential (near −1.9 V vs. NHE) which allows for pairing with many electrocatalysts with higher reduction potentials than that of $Ru(bpy)_3$ photosensitizers (reduction potential near −1.1). For that case of **42** paired with **31** record TON values of 98,000 were observed under very dilute conditions. With more common concentrations, high TONs were still observed (~1,500). In this system, the photosensitizer was found to decompose over time whereas the addition of fresh **42** led to reactivity rates near that *at the start of photolysis*. **33** is a known efficient electrocatalyst which was recently paired with **42** to give good TON values >100. Interestingly, **33** was also paired with anthracene **40** to give the highest TON values observed with an organic sensitizer. It should be noted that **33** was recently shown to operate as a photocatalyst independent of a photosensitizer for 30 TON (Bonin et al. 2014b).

With the exception of Neumann's RWGS reaction catalyst, the above systems have used an organic electron and proton source. These are often present in solvent quantities as amine additives (TEA and TEOA, typically 1:5 with the listed solvent). However, several researchers have noted that addition of a second electron/proton source has resulted in substantially higher reactivities. These additional sources are often suggested to be a co-catalyst which received electrons from the stoichiometric amine reductant and delivers them efficiently to the photosensitizer or catalyst. The most commonly observed sources are ascorbic acid (**AA**), 1-benzyl-1,4-dihydronicotinamide (**BNAH**), and most recently, 1,3-dimethyl-2-phenyl-2,3-dihydro-1H-benzo[d]imidazole (**BIH**). Care must again be taken concerning the background reactions associated with **AA** which can decompose to CO. **BIH** has been shown to directly lead to a >10x increase in catalyst turnover numbers and a threefold increase in already high ϕ values (Tamaki et al. 2012b, 2013a). **BIH** has led to some of the highest quantum yields and TONs to date and will likely find utility in further studies.

Future Directions

Photocatalytic water splitting and photocatalytic carbon dioxide reduction each offer the promise of cheap and plentiful sources of energy for society's future. In addition, the transformation of carbon dioxide from a harmful waste product to usable energy source is a win/win proposition. However, the development of efficient

photocatalytic materials that make either of these processes viable on large scales has not been realized. With such a clear and potentially substantial payoff, many synthetic chemists have been attracted to this problem. In this very active field, advances are constant as the search for an ideal photocatalyst continues.

Simultaneous CO_2 and H_2S Sequestration by Electrocatalytic Conversion for Chemical Feedstock Synthesis

Nosa O. Egiebor and Jonathan Mbah

Contents

Abstract

This paper addresses the development of an innovative ionic membrane consisting of electrocatalysts and electrolyte assembly that can be used in an electrochemical cell to produce useful chemicals via simultaneous splitting of hydrogen sulfide (H_2S) and carbon dioxide (CO_2) content feedstock. The cell consists of an endurance membrane electrode assembly (MEA) material with CO_2 and H_2S feedstock and operates near 120–145 °C. Thus, a benign method of CO_2 mitigation is achieved, and at the same time useful chemicals are produced from two pollutant gases. We have successfully conducted a preliminary study in

our laboratory. The overall Gibbs energy, ΔG, of the process is (−49.27 kcal/mol), with a net energy output of about +1.06 V per mole. The instability of the cathode electrode due to the poisoning of electrode materials, corrosive aqueous media, and the chemistry nature of the electrode kinetics can be addressed by implementing electrocatalyst design scheme, which takes into consideration the location of the active ingredients and support materials of the electrocatalyst in order to enhance activity, stability, and selectivity. The aim is to research, formulate, and design anode and cathode electrocatalyst materials which are not susceptible to degradation in corrosive aqueous environment. Solid electrolytes from cesium hydrogen sulfate and from Nafion^{TM} family that conducts only hydrogen protons with added nanoscale hygroscopic oxide (silica) to maintain their integrities were studied. Operation at high pressures ensured that the membrane remained hydrated. Proper positioning of active and support materials during catalyst impregnation will eliminate any catalytic poisoning of active materials.

Introduction

Carbon dioxide (CO_2) and hydrogen sulfide (H_2S) are both greenhouse gases and pose a challenge to the modern society where environmental pollution has to be minimized to an acceptable level. CO_2 reduction over aqueous media in electrochemical cells has been reported in many literatures (Fujita 1999; Gattrell and Gupta 2006), but to date no report on simultaneous oxidation and reduction techniques for H_2S and CO_2 containing gases using solid media is available. There are so many disadvantages inherent with using aqueous media, for example, solubility issue of CO_2 with decrease in temperature is a major drawback with aqueous systems. This project tends to propose a novel technique of simultaneously splitting CO_2 and H_2S containing gases into useful chemicals via a solid membrane. Since both H_2S and CO_2 often occur together in petroleum and natural gas resources and are major by-products of integrated gasification combined cycle (IGCC) power plants, a technique that can simultaneously split both gases and at the same time produce a valuable energy fuel resource is certainly very desirable. Such a technical advancement will invariably contribute significantly to CO_2 sequestration, and toxic H_2S gas utilization for clean energy production. The concentrations of H_2S present in natural gas generally range from trace amounts to more than 80 %. Caldeira et al. (2003), while CO_2 is the main end product of fossil hydrocarbon combustion for energy. Currently, CO_2 and H_2S are separated using a double-absorber Selexol process which preferentially removes H_2S as product leaving CO_2 as a separate product stream.

Sequestration of CO_2 in geological formations includes deposition in oil and gas reservoirs, unmineable coal seams (due to seam thickness, depth, and structural integrity), and deep saline reservoirs, such as in oceans. This approach takes into consideration that many of the large emitters of CO_2 are sited near geological formations that can be tailored into storage facilities. In the case of oil and gas

reservoirs, additional revenue can be generated from enhanced oil recovery with carbon dioxide injection. Given the perspective of this program, this method will provide a low net cost as a result of the enhanced oil recovery. However, the studies are still being conducted to understand the utility of the technique for carbon dioxide sequestration and the behavior of injected CO_2 over time in these depleted oil wells. Such studies have included the determination of the extent to which the CO_2 moves within the geological formation, and what physical and chemical changes occur to the formation when CO_2 is injected (Wise et al. 2009).

The adsorption of CO_2 in coal beds to displace methane due to its higher adsorptivity than methane provides another possible technical alternative to CO_2 sequestration, but limited researches have been conducted in this area (Grimes 2005). which are not sufficient to justify this approach since sequestration capacities of these basins are yet to be quantified. Similar to the enhanced oil recovery, the recovered methane provides a value-added product stream to the CO_2 sequestration process. In comparison, the saline formations do not generate any value-added by-products but do have higher storage capacity for injected CO_2. The key issues in these programs are the safety of CO_2 storage in saline formations and perhaps potential and emerging environmental problems (Clarkson et al. 1997; Bachu and Adams 2003).

Despite the modest successes recorded by these programs, minimizing CO_2 air pollution and emission is still a major concern because the long-term effects of these methods are not yet clear. Rock layers may be weakened as a result of formation of carbonaceous acid if CO_2 happens to react with underground water. The recent recorded events of oil spillages in our high seas and oceans, worldwide, is a reminder that we ought to be cautious of the adverse effect that may proceed from the enhanced oil recovery and other nondestructive CO_2 sequestration approaches. The electrochemical approach proposed here, and described in the sections that follow, has the potential to avoid the major drawbacks associated with current approaches for carbon dioxide sequestration.

Electrochemical carbon dioxide sequestration method has also been considered by many researchers (Pérez-Rodríguez et al. 2011; Kaneco et al. 2006a). Some of the electrochemical approaches make use of aqueous media while others consider solid media. The use of electrochemical conversion to split CO_2 has shown to produce carbon monoxide and formic acid in aqueous solution in the presence of most flat metallic electrodes (Kaneco et al. 2006b). Nevertheless, it has been proven that only copper is a suitable electrode for the formation of hydrocarbons such as methane and ethylene, which can be used as fuel gases (Lee et al. 2011; Li and Oloman 2007; Chang et al. 2009). High current yields were only achieved with large overpotentials (-1.5 V vs. SCE). Some of the Faradaic yields exceeded 90 %. The primary reduction intermediate was proposed to be CO, while weakly adsorbed onto the Cu electrode, interfered with the cathodic hydrogen production reactions. The adsorbed CO was thus reduced to hydrocarbons and alcohols, with the yields increasing with more negative potentials. However, the temperature of operation must be low enough to obtain significant product efficiencies since the solubility of CO_2 decreases with increasing temperature. Owing to the freezing temperature of

water, few reports have dealt with the electrochemical reduction of CO_2 in an aqueous solution at less than 273 K. As a result of the relatively low solubility of CO_2 in aqueous solutions, methods for increasing its solubility have to be sought. A possible solution is to perform the electroreduction at high pressures or in nonaqueous solutions.

Formation of methane, methanol, CO, and formic acid has been reported by electroreduction of CO_2 with H_2. This process requires an enormous amount of overvoltage. It has been hypothesized that using hydrogen radicals instead of hydrogen molecules to react with CO_2 will circumvent this problem of overvoltage encountered. Hydrogen radicals are very reactive and can easily attack CO_2 to form methane. The use of oxygen selective membranes has also been applied to split CO_2 into C and O_2 or partial conversion to CO and $½O_2$ by noncatalytic and catalytic means (e.g., thermal, electrochemical, radiolytic, etc.), followed by subsequent removal of carbon deposits in the reactor (Bockris 2005; Toyir et al. 2001; Ordorica-Garcia et al. 2006). Reverse water gas shift and Fischer Tropsch reactions were also considered using bimetallic catalyst. In this approach, the first catalyst initiates the conversion of CO_2 to CO, and the second catalyst facilitates the conversion of CO to organic compound (Hoek et al. 1985) through Fischer-Tropsch synthesis.

It is worthy to note that electricity generation accounts for 42 % (2397.3 millions of metric tons) of the total CO_2 emissions in the USA alone excluding emissions from US territories in 2007 (Rayne 2008). The two IGCC power plants in the USA each have a capacity of 250 MW. Currently, CO_2 and H_2S are separated using a double-absorber Selexol process which preferentially removes H_2S as product leaving CO_2 as a separate product stream (Gomberg et al. 1984; Ku et al. 2005). These two by-products can subsequently be utilized as feedstock to an electrochemical cell system for useful chemical synthesis. Although the cost of electricity (COE) is less for an IGCC plant with CO_2 and H_2S cocapture compared to those IGCC plants that capture 80 % CO_2 and H_2S separately (5.48 and 6.67 US¢/kWh) respectively, the sale of methane and sulfur will eventually close this gap (Klara and Wimer 2007; Hockstad and Cook 2009). Based on the review of the available options, the chemistry provided by simultaneous splitting of H_2S and CO_2 can provide a cost-effective solution, provided the electrode kinetics can be achieved at low cost. Our starting electrochemical feedstock will be procured from CO_2 and H_2S vendors.

Electrochemical CO_2 Reduction

Aspen Plus™

Varieties of commercially available process simulators, such as Aspen Plus™, can ease the analysis of an electrochemical system. Electrochemical system may include feed preprocessors, heat exchangers, turbines, bottoming cycles, etc., all of which can be very effectively modeled in process simulation software

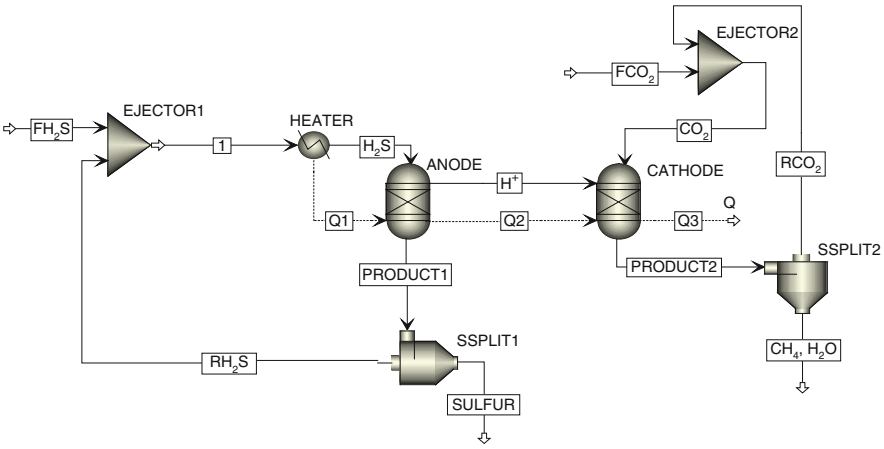

Fig. 1 Aspen Plus™ electrochemical cell model flowsheet. *Dotted lines* represent energy streams. The process involves passing H_2S through the anode compartment of the electrochemical cell to generate H^+ and electron. At the cathode compartment, CO_2 is reduced in the presence of the electron and H^+ to product

(Campanari 2001; Ersoz et al. 2006; Aspen Plus™ 2010). The concept is shown in Fig. 1. Fresh H_2S (FH2S) and unreacted H_2S (RH2S) from the anode chamber are mixed in the block called EJECTOR 1 and fed to the anode compartment where it contacts the catalytic anode and hydrogen proton selective membrane. The H_2S then split into hydrogen protons, electrons, and elemental sulfur. The sulfur flows out of the anode chamber as a low-viscosity fluid at temperature of operation (120–145 °C). The solid membrane is impermeable to the electrons which are then forced through the external circuit as a heat duty (*Q3*) via the electrode. The hydrogen protons migrate through the solid membrane as hydronium ion and at the catalytic cathode combine with the electrons and fresh CO_2 (FCO2) feed that was mixed with unreacted CO_2 (RCO2) from the block called EJECTOR 2 to form methane and water. The heat duty, *Q3*, appears as available energy which is used to drive the system since the process is highly exothermic. The overall Gibbs energy, ΔG, of the process is (−49.27 kcal/mol), with a net energy output of about +1.06 V per mole, as shown in Eq. 1, because of the favorable thermodynamics of water formation.

$$\begin{aligned} 4H_2S + CO_2 \rightarrow CH_4 + 2H_2O + 4S_{(l)}(2\text{Faradays})@\Delta G \\ = -49.27 \ \text{Kcal/mol@400 K} \end{aligned} \quad (1)$$

The outcome of the process simulation using AspenPlus™ package whose schematic is shown in Fig. 1 provides viable information on the proposed approach. One of the benefits of using the developed Aspen Plus™ model is that sensitivity analyses can be performed in an easy and time-saving manner, which helps to understand the effects of variations of the operating parameters on the

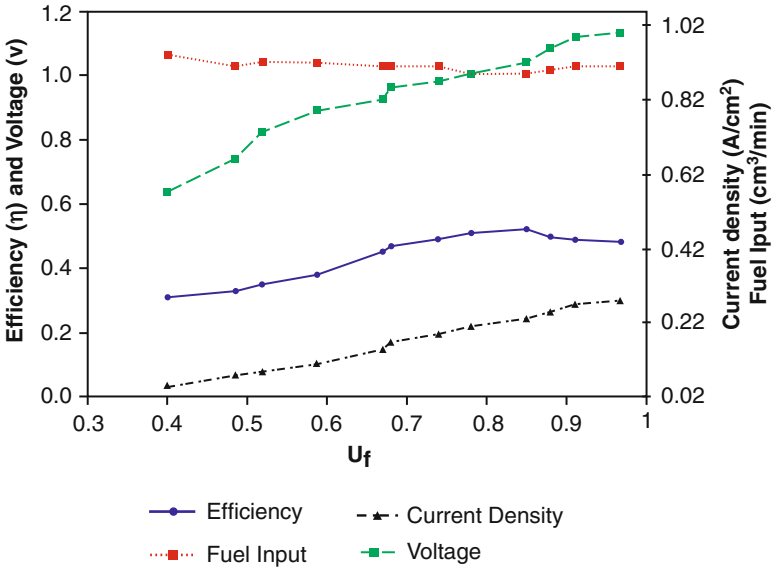

Fig. 2 Aspen Plus™ simulation: effect of fuel utilization factor (U_f) on the cell current density, cell efficiency, and fuel input for the simultaneous splitting of CO_2 and H_2S feedstock. This is based on 4:1 H_2S to C content feed

electrochemical cell's performance. Figure 2 illustrates the results of sensitivity analyses performed using Aspen Plus™. The utilization factor (U_f) is one of the most important operating parameters for most electrochemical cells and has significant effects on the cell voltage and efficiency. The utilization factor is defined as $U_f = v_{\text{H2S, consumed}}/v_{\text{H2S,equivalent}}$, where $v_{\text{H2S, consumed}}$ is the volumetric flow rate of H_2S consumed in the electrochemical reaction at the anode compartment. However, this analysis is based on 4:1 molar ratio of H_2S to C consumed. This is the preferred possible ratio for a galvanic process to proceed based on reaction Eq. 1. The electrode design will help balance the cost-effectiveness of the overall process. The effects of fuel utilization on the cell voltage, cell efficiency, current density, and required fuel input for H_2S/CO_2 splitting electrochemical cell are shown. Current density is a direct measure of the rate of electrode kinetics. If U_f is increased from 0.4 to 0.95, the cell voltage will increase because the fuel is more depleted. The current density will increase, which can be realized by increasing the CO_2 flow at the cathode, resulting in more H_2S being consumed.

Three major requirements for the success of this operation are identifiable:

1. The issue pertaining to cathodic electrode degradation needs to be resolved before meaningful progress is made.
2. Designing good electrode configurations for the cathode such that CO_2 can easily be activated and be selective to the desired end products is another issue that needs to be addressed.

3. Fabrication of an effective membrane electrode assembly (MEA) system that has good mechanical integrity, fast electron transport, and a good ionic conductivity.

Membrane Electrode Assembly

These requirements can be fulfilled by (a) considering the effect of electrocatalyst design, which considered the location of the active ingredients and support materials during electrocatalyst formulation and their composition ratios in order to enhance activity, stability, and selectivity; (b) utilizing a solid electrolyte with good ionic conductivity (Nafion@ families ~0.1 S/cm around room temperature) or cesium hydrogen sulfate, $CsHSO_4$; and (c) an innovative MEA which will consist of an anode with added nanoscale hygroscopic oxide (silica), a cathode either with or without added nanoscale hygroscopic oxide, with the solid electrolyte sandwiched between them as shown in Fig. 3. The nanosilica particles also play a role in water adsorption. When the water produced by electrochemical reaction at the cathode back-diffuses from cathode to anode, the silica, which has hygroscopic property, will adsorb the water. The water back-diffusion process also lends benefits by hydrating the membrane. As a result of the formation of strong absorption bonds between the water molecules and silica due to Van Der Waals forces, elevated temperatures cannot desorb the water adsorbed onto silica (Miyake et al. 2001). The silica at the cathode tends to retain the water which subsequently keeps the membrane from dehydrating. This self-hydrating membrane electrode assembly technique will enhance the system performance without external humidification. At our temperature of operation (120–145 °C), sulfur is a low-viscous fluid and can flow out of the electrolytic cell without hindrance.

The electrochemical system will employ solid-state electrolyte that transports only hydrogen proton or hydronium ions at operating temperature. Their ionic conductance is based on H^+ protons being transported as hydronium (H_3O^+) ions

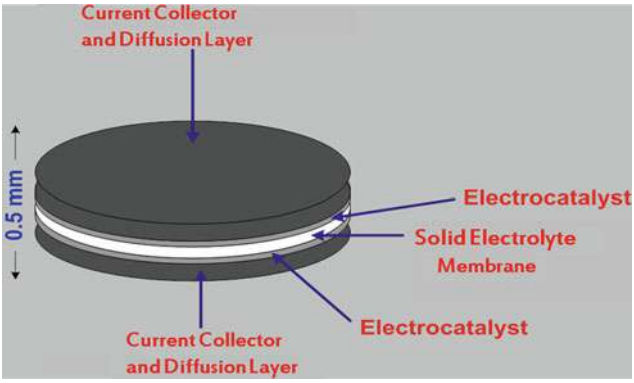

Fig. 3 Schematic of membrane electrode assembly (MEA) for CO_2 and H_2S splitting

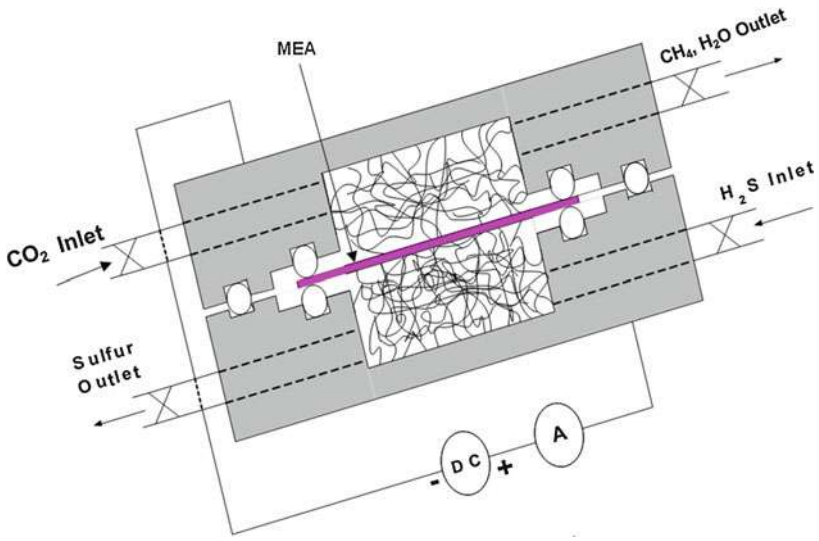

Fig. 4 Schematic of electrochemical cell

and have been tested for their good ionic conductivities. Membrane surfaces are modified with nanoscale hygroscopic oxide (silica) to prevent H_2O product from back-diffusing from cathode to anode with added advantage of keeping the membrane hydrated for easy transport of H_3O^+ ions.

The electrochemical cell schematic is shown in Fig. 4 and the experimental setup for the simultaneous splitting of H_2S and CO_2 in Fig. 5. Besides the membrane, the MEA is composed of two electrodes as electrocatalytic layers and two gas diffusion layers (GDL) made of carbon materials (see Fig. 3).

Design and Stability Study of Cathode Electrocatalysts

The electrocatalytic materials for the cathode can be selected to mimic what is obtainable in photosynthesis in plants where CO_2 is converted into organic compounds in the presence of H_2O using the energy from the sun; the hydrogen is split into its protons and electrons and used to generate chemical energy. In photosynthesis, the CO_2 molecule is initially bonded to nitrogen atoms, making reactive compounds called carbamates (Gust and Moore 1989). These less stable compounds can then be broken down, allowing the carbon to be used in the synthesis of other plant products, such as sugars and proteins.

In the electrochemical cell, the overall cell reaction potential will supply the energy that splits the CO_2 while sunlight provides the energy during photosynthesis in plants. In the electrochemical process, the electrical potential provides the driving force necessary to convert CO_2 into methane and water at the cathode compartment by using the hydrogen protons and electrons generated from H_2S split

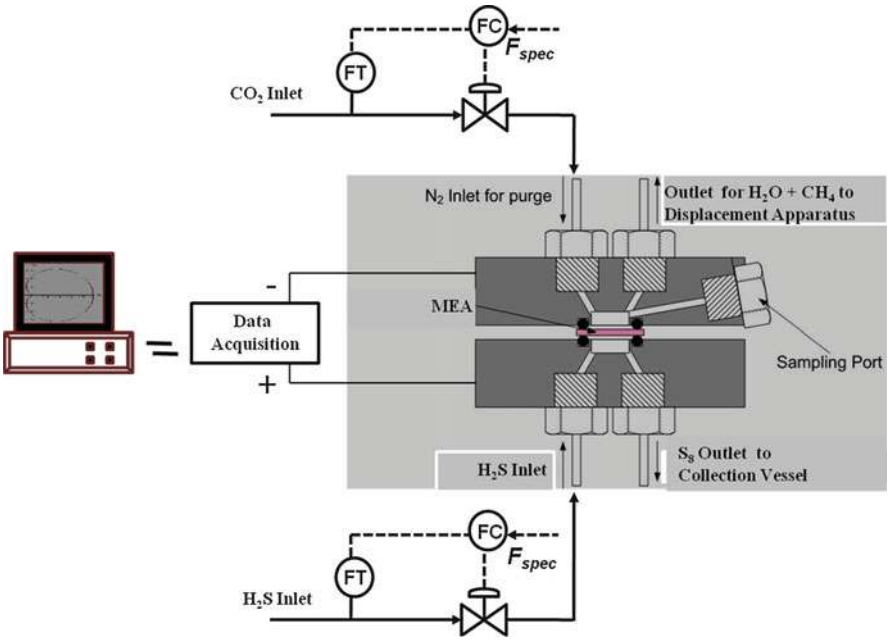

Fig. 5 Experimental setup of CO_2 and H_2S splitting system

Table 1 Postulated cathodic reaction mechanism for methane synthesis

$M_1 \rightarrow {M_1}^{x+} + xe^-$	(1)
$x\mathrm{H_2O} \rightarrow x\mathrm{H}^x + x\mathrm{OH}^-$	(2)
$xe^- + x\mathrm{H}^+ \rightarrow x\mathrm{H}^*$	(3)
$M_2 + x\mathrm{H}^* \rightarrow xM_2 - \mathrm{H}$	(4)
$\mathrm{CO_2} + xM_2 - \mathrm{H} \rightarrow \mathrm{CH_4} + 2\mathrm{H_2O} + xM_2 - \mathrm{H}$	(5)
$M_1 + M_2 + x\mathrm{H_2O} \rightarrow \mathrm{CH_4} + 2\mathrm{H_2O} + xM_2 - \mathrm{H}$	(6)

at the anode compartment in the presence of highly active bimetallic electrocatalysts (M1 and M2). The postulation is that in a first step, the catalyst enabled the CO_2 to form a reactive carbon monoxide (CO) species and oxygen atom. The catalyst's next useful step is to enable the hydrogen protons to grab the very highly reactive CO species from the CO_2 split, producing methane. The oxygen atom from the split reacts with other protons to produce H_2O. Thus CO_2 is used as a source of chemical synthesis. We have in Table 1 postulated a mechanism for CO_2 conversion to methane at the cathode as pertaining to our electrochemical synthesis.

A bimetallic catalyst (M_1 and M_2), in which one metal acts as the electron donor for the production of hydrogen radical while the other acts as a catalyst for the reduction of CO_2, was formulated using impregnation method to serve as the cathode electrocatalyst. At the cathode, metal M_1 converts the migrated hydronium

ion from the anode reaction to hydrogen with subsequent conversion to hydrogen radical. The hydrogen radical is adsorbed locally onto another metal (M_2) of known catalytic activity toward CO_2 hydrogenation. The advantage is that other intermediates formed will be reduced by the highly active hydrogen radical/metal hydride formed. Electrocatalyst M_1 will be chosen such that it can form a galvanic couple with electrocatalyst $M_{2;}$ in that case, the reaction rates would further be enhanced since the process would circumvent the need for an external electric field. Certain transition metals have these capabilities. Depending on the electrode design, the end product may be methanol or methane or other hydrocarbons. The challenge is to design a suitable electrode system that is compatible with electrolyte membrane and selective toward the production of methane and water and not susceptible to degradation in corrosive aqueous environment.

The solubility of CO_2 in water decreases with increase in temperature which implies that at the temperature of operation water produced will not be in solution with CO_2. More also, the hydration equilibrium constant is small (1.7×10^{-3}), hence CO_2 remains as molecules, given that the rate constants are 0.039 s^{-1} for the forward reaction ($CO_2 + H_2O \rightarrow H_2CO_3$) and 23 s^{-1} for the reverse reaction ($H_2CO_3 \rightarrow CO_2 + H_2O$). The water produced will be used to hydrate the membrane instead.

At the anode, the electrolytic splitting of H_2S occurs very easily since H_2S possesses a very low Gibbs energy of formation ($\Delta G = 8.9$ kcal/mol @ 145 °C), so a small amount of electrical energy can split it into elemental sulfur and hydrogen proton (Mbah et al. 2008). This initial energy demand is subsequently compensated by the overall Gibbs free energy of the process ($\Delta G = -49.27$ kcal/mol). While the primary means of splitting H_2S and CO_2 in this application appears to be electrochemical, the elevated temperatures at the membrane interface where CO_2 is adsorbed and subsequently reacts also appears to be indicative of potential thermal catalytic processes.

Cost Analysis of Electrochemical Process

Electrolytic splitting of the extracted CO_2 and H_2S can yield sulfur, methane, and water. This process is illustrated in Figs. 1 and 2. The value of the methane makes the system more profitable. The energy benefit of electrolytic splitting of the CO_2 and H_2S is shown in Eq. 1. The energy costs required to do it electrochemically are significantly low when compared to other electrochemical methods. As a result, this is potentially such a cost-effective procedure that it can have a positive influence on the cost-effectiveness of IGCC energy. This is illustrated by the conceptual economic analysis in Table 2 for IGCC energy (Krakow et al. 2006) initially developed for hydrogen production but modified herein for methane production. It considers the plant capital cost and life, the operating and maintenance costs, and the offsetting revenue from the sale of sulfur to determine the cost of methane.

The cost of $137/t of sulfur for performing the Claus process exceeds the $63/t market value of the sulfur. The $74/t difference is a penalty that operators currently

Table 2 Economic analysis of hydrogen sulfide/carbon dioxide splitting in an IGCC power plant

Power plant parameters	
IGCC Plant capacity (Gross MW)	315
On line (Days/year)	335
Coal consumption (Tons/day)	63
Coal sulfur content (%)	2.5
Electrochemical plant investments	
Apparatus to remove carbon dioxide	$ 1,350,000
Electrolyzer	$ 6,460,000
Balance of plant	$ 3,325,000
Total electrochemical plant investments	$ 11,135,000
Annual capital and O&M costs	
Annualized capital costs	$ 1,500,000
Labor	$ 525,000
Catalysts, water and other operating costs	$ 40,000
Electricity	$ 2,500,000
Total annual capital and O&M costs	$ 4,565,000
Methane production costs	
Costs to produce 1 Ton of S + 125 lb. of H_2	$ 215
Avoided cost of claus process/Ton of S	$ 137
Net production cost of 1 lb. of H_2	($ 0.63)
Net production cost of 1 lb. of CH_4 Gas	($ 0.63)
Market price of sulfur ($/LB)	$ 2.50
Market price of CH_4 ($/LB)	$ 0.08
Cost of electricity US$/kWh	($ 0.07)
Gross profit ($/LB.)	$ 1.25

pay to get rid of the hydrogen sulfide by-product gas. This penalty would be avoided by using the electrochemical/electrolytic process where the total value of the two products (sulfur and methane) exceeds the cost of the electrochemical processing. Methane costs will vary based on location and also by the quantity. The $1.25/lb. profit on the methane and sulfur increases the cost-effectiveness of IGCC energy by over $1/MWh. This is achieved without claiming any economic credit for purifying the CO_2 in the acid gas to make it more suitable for splitting.

Splitting of H_2S Over a Solid Membrane

The electrochemical system is operated near (120–145 °C) using a solid electrolyte membrane. Natural separation of the H_2S gas, CO_2, liquid sulfur, CH_4, and H_2O occurs in such a system. Hydrogen sulfide introduced at the anode compartment is electrolyzed at the surface of the solid electrolyte producing hydronium ions that pass through the electrolyte and liquid sulfur that pools at the bottom of the positive compartment from which it is withdrawn through a drain. The pool of liquid sulfur

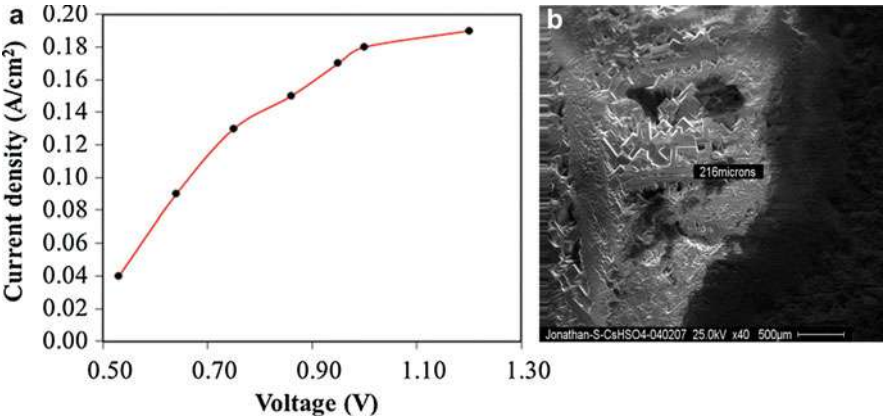

Fig. 6 (**a**) Current density versus voltage generated, (**b**) SEM image (25.0 kV × 40 500 pm) of electrolyzed pellet of $CsHSO_4$ membrane with layers of 65 wt% sulfur deposit

forms a barrier that keeps H_2S away from the drain. Figures 6a, b show the current density/voltage relationship and the resulting SEM spectrogram of electrolyzed sulfur by wt% in the electrochemical splitting of H_2S to elemental sulfur over a solid membrane using anodic electrocatalysts comprising of ruthenium (IV) oxide/ cesium hydrogen sulfate/pt black/ p-Dichlorobenzene and cathodic electrocatalyst comprising of platinum black/p-Dichlorobenzene.

The oxidation of H_2S to H^+ and sulfur ($H_2S \rightarrow 2H^+ + 2e^- + \frac{1}{8}S_8$) over a supported metal component is an important step involved in the splitting system. Most noble metal catalysts such as Pt, Pd, Ru, and Ir have high selectivity toward H_2S splitting. Noble catalysts are expensive, so augmentation is carried out by formulating metal composite using more of the less expensive materials from other groups to serve as the support materials and less of the expensive materials as the active ingredients. If dispersion of the active materials is carried out effectively during impregnation, then less quantity of more expensive materials can be utilized compared to using bulk active materials. Nevertheless, choice eletrocatalytic materials must have high density of catalytic active sites and not susceptible to poisoning.

Other potential electrocatalysts can be selected from both non-noble and noble transition metals and their bimetallic alloys and base metals. For the anode configuration, electrocatalyst precursors could consist of noble and non-noble metals of transition elements or their compounds and base metals. In some cases, main group elements and their compounds may be included. Impregnation technique is used in electrocatalyst synthesis from these precursors because it enables proper control of electrocatalyst design parameters – activity, stability, regenerability, and selectivity. These precursors include salt solutions of $CuSO_4 \cdot 5H_2O$, $RuC1_3$, H_2PtC1_6, hydrated copper chloride, hydrated zinc oxide, $Pd(NO_3)_2$, NaOH solution, $PdO{\cdot}nH_2O$, aluminum oxides, hydrated nickel chloride, iridium (III) chloride hydrate, p-Dichlorobenzene, ruthenium (IV) oxide, and hydrated cobalt chloride.

These materials have proven to possess excellent catalytic properties toward H_2S oxidation and/or CO_2 reduction. Electrocatalyst formulation using these precursors focuses on increasing the catalytic active sites and altering of the surfaces of the materials, harnessing their properties to products that have good mechanical strength at operating conditions since material integrity is an issue as discussed in the previous section. The resulted electrocatalysts after impregnation and calcinations provide the required activity, selectivity, and stability needed for both the cathode and anode reactions. It has been shown that even though copper electrode is suitable for the formation of hydrocarbons such as methane and ethylene from CO, it lacks stability. Thus, improving the stability of copper using this formulation method is desirable.

Design and Composition Ratios of Supported Electrocatalyst

Stability of the cathodic compartment is of utmost priority in this design since this is where major degradation is most prominent due to poisoning of active sites. In using impregnation techniques, it is essential to have an understanding of both chemical and physical properties of the support and the chemistry of the impregnating solution in order to control the physical properties of the finished catalyst. Loading of active metals and support materials should be varied in order to obtain optimum dosage. However, trade-off between catalyst activity and stability should be expected. Changes in selectivity can also arise from changes in intrinsic chemical activity of the active component. Typically this can be affected by use of multicomponent catalysts in which case the location of the difference components ideally should be the same.

Poisoning of the catalyst by impurities introduced with the reactants can often be minimized by placing the active material deep within the catalyst support structure, and since most catalyst supports are also good absorbents, poisons frequently can be selectively removed by such absorption before reaching the active surface. A catalyst design modification would be the deposition of a poison-resistant catalyst component close to the surface and a poison-sensitive component deep within the support. The poison resistance location of the active component becomes a critical factor in proper catalyst design. The use of electron probe microanalysis (EPMA) will provide information on the location not only of active materials but also potential catalyst poisons. Blockage of the support-pore structure is critically dependent upon the pore-size distribution of the support. Normally a correct balance of large and small pores is required; the former to aid reactant transport and the latter to provide the large surface necessary for the optimal dispersion of the active components. Porous carbon material with high activated carbon content as a support material serves this purpose. Characterization of supported catalyst species, particularly with regard to metal-support and metal-metal interactions, should be carried out possibly using temperature-programmed reduction/oxidation (TPR/O) equipment.

The techniques of catalyst preparation involves two simple steps, dispersing the active material in a liquid form and immobilizing this dispersed material as it is

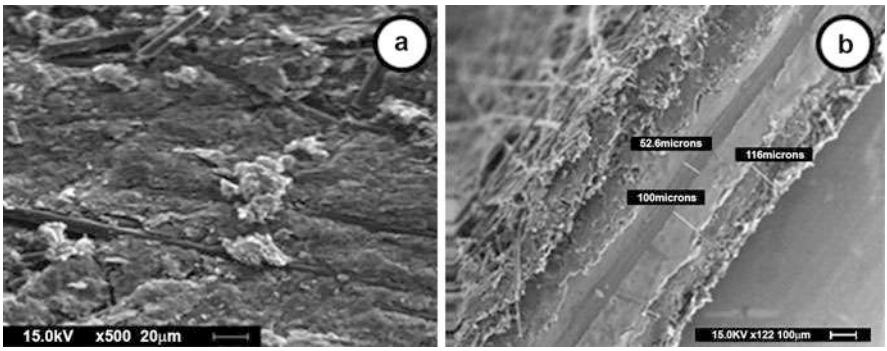

Fig. 7 (**a**) Dispersion observed for formulated cathode electrocatalyst (Cu/RuO_2) using catalyst design approach; (**b**) cross sectional view of MEA comprising of the designed electrocatalyst formulated

reconverted to an insoluble solid form. One way of doing this is to allow the material to react with the insoluble support surface. This implies that support surface should be reactive with the soluble active material. This becomes a drawback since the support material is carbon, which has peculiar and variable properties tending to form charge-transfer complexes as an electron donor, but it also can act as a weak cation exchanger by virtue of acidic surface oxide groups. Interactions between the active materials and support in terms of immobilizing the active ingredients on the support surface are either the cationic or anionic exchange with protons or hydroxyl groups on the surface. To enhance the supports cationic exchange, the carbon with γ-alumina together with bonding agents such as alumina, silica, etc. are washcoated before impregnation which then provides the necessary reactive surface for the active ingredients. In this way atomic dispersion of active ingredients is in principle possible. The proton or hydroxyl group is provided by the γ-alumina. Temperature-programmed reduction and oxidation will provide valuable guides to the thermal treatment and reduction stages of electrocatalyst preparation.

As previously mentioned, copper is a good reduction cathode electrocatalyst but suffers severely from thermal instability at elevated temperature and in corrosive environment. Stability will be improved by supporting it in a high surface material such as high-carbon porous material. Catalyst retention on support materials, regenerability, stability, activity, and selectivity is very important. Cyclic voltammetry potential sweep test should be applied to evaluate the stability of synthesized catalysts. Of equal importance is the weight lost by thermogravimetric analysis using simultaneous DSC-TGA instrument. This is very important since some materials have the tendencies to lose their integrity in the presence of sulfur and corrosive environments as was found. Furthermore, by evaluating the responses of each electrocatalytic material the catalyst loading required and the partial pressures of component gases that provide the best reactivity can easily be found.

Figure 7a is a surface morphology view of cathode electrocatalyst formulated by applying catalyst design scheme where poison-sensitive Cu component is

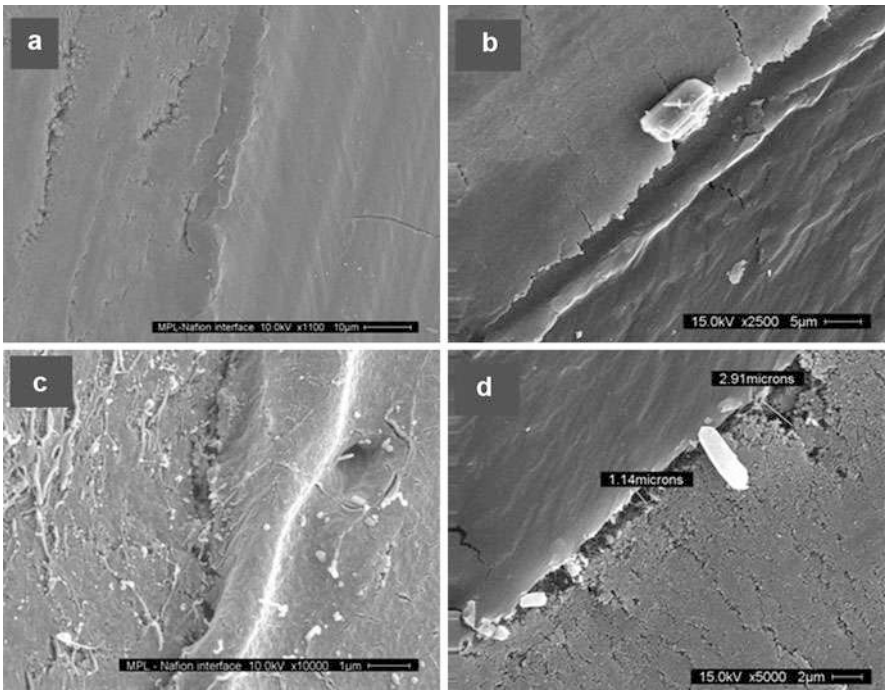

Fig. 8 (**a**) Control MEA – interface ×1100; (**b**) MEA with no catalyst design approach nterface ×2500; (**c**) a– interface ×10,000; (**d**) b – interface ×5,000

embedded deep within carbon support while poison-resistant component ruthenium (IV) oxide, RuO_2, is close to the surface. Figure 7b illustrates a typical MEA fabricated from this electrocatalyst (see also Fig. 3); the cross-sectional view was analyzed for any apparent separation or tearing of the individual layers after several cycles. The image has been annotated to indicate the approximate thickness of each of the layers of assembly, namely, Gas Diffusion Layer ∼ 116 μm; Micro Porous Layer ∼ 100 μm; Proton Exchange Layer ∼ 52.6 μm. At higher magnification, no delamination was observed in MEA fabricated using the designed electrocatalyst. The results of this investigation are summarized in Fig. 6.

Mesoporous investigation is shown in Fig. 8. Figure 8a shows the interface between the microporous (electrocatalyst) and proton exchange (Nafion) layers of an MEA which electrocatalyst layer was formulated using impregnation design approach with the noble metal-based catalyst 4 wt% (RuO_2) on the surface and 1.6 wt% active Cu embedded deep on the support (control membrane). At lower magnification of 1100×, no apparent gap or tearing of the interface was observed at 125 °C and varying cell pressures. Figure 8b depicts the same interface in the MEA which electrocatalyst layer was formulated using impregnation method but with no catalyst design approach. This image shows a more pronounced division between the two layers. This feature was very clear when we look at these membrane

microstructures at higher magnifications, 10,000×. Figure 8c shows the control membrane's interface at 10,000x magnification. A relatively smooth transition is still seen between the layers even at this magnification. In contrast, Fig. 8d shows a distinct channel dividing the two layers at half the magnification. This channel would be enough to increase the ohmic proton exchange resistance of the membrane.

This indicates that catalyst design, if monitored properly, provides good promise in eliminating cathode electrode degradation currently faced in many electrochemical applications. Different electrode/electrolyte attachments should be tested since this is a major issue in electrochemical applications that utilize solid electrolyte where delamination of membrane increases the cell ohmic resistances: as interfacial delamination width and area fraction increases, the ohmic resistance increases. Characterization of MEA may include the use of X-ray diffractometer (XRD), scanning electron microscopy (SEM), simultaneous differential calorimetry-thermogravimetric analysis (DSC-TGA), cyclic voltammeter, Quantachrome instruments (BET for specific surface, pore sizes), and electrochemical impedance spectroscopy (EIS).

Conclusion

Carbon dioxide and hydrogen sulfide are both greenhouse gases and pose a challenge to the modern society, where environmental pollution has to be minimized to an acceptable level. Since both H_2S and CO_2 often occur together in petroleum and natural gas resources, and are major by-products of integrated gasification combined cycle (IGCC) power plants, a technique that can simultaneously split both gases is desirable. The advantages offered by electrochemical approach using CO_2 and H_2S as feedstock to reduce air pollution and at the same time conduct carbon dioxide sequestration cannot be overemphasized, thereby providing a vista to the long-sought method of CO_2 mitigation. Currently, CO_2 and H_2S are separated using a double-absorber Selexol process which preferentially removes H_2S as product leaving CO_2 as a separate product stream. These two separate streams can be channeled into an electrochemical cell apparatus for production of useful chemicals. This approach is useful in the integrated gasification combined cycle power plants (IGCC), which currently extract sulfur from the process stream as hydrogen sulfide using the Claus Process along with unsequestered CO_2 stream. Our process is cost effective and overcomes the energy barrier associated with previous electrochemical processes. At the temperature range of operation (120–145 °C), sulfur is a low-viscosity liquid and can flow out of the electrolytic cell without hindrance. Although, the COE is less for an IGCC plant with CO_2 and H_2S cocapture compared to those IGCC plants that capture 80 % CO_2 and H_2S separately (5.48 and 6.67 US¢/kWh) respectively, the sale of methane and sulfur will eventually close this gap.

Future Directions

Electrochemical reduction of CO_2 into value-added chemicals using renewable energy is one approach to help address CO_2 emission as it will recycle "spent" CO_2 (carbon neutral cycle) and it provides a method to store or utilize otherwise wasted excess renewable energy from intermittent sources, both reducing our dependence on fossil fuels. Current electrolysis cells accomplish either high Faradaic yield (often >95 % selectivity) for a desired product or reasonable current density, whereas both need to be high for a commercial process.

Catalysts for the selective reduction of CO_2 into different interesting products have been developed, but catalysts that simultaneously exhibit overpotentials (e.g. <0.2 V) and current densities (e.g. >100 mA/cm^2) needed for commercial applications are still lacking. The quest for such catalysts could be aided by more fundamental studies focusing on elucidation of reaction mechanisms for distinct catalysts, an area in which reports are few. Novel catalysts have both low overpotential and high activity for CO_2 reduction reactions.

Few efforts to date have focused on the effects of electrolyte composition on electrochemical CO_2 reduction, despite the fact that electrolytes have been known to affect almost every electrochemical process. Electrolyte choice has profound effects on current density, product selectivity, and energetic efficiency in CO_2 reduction. More also, CO_2 electrolysis is much more sensitive to the structure and composition of the microporous layer. Significant strides will be made to enhance catalyst activity while reducing overpotential. Such efforts will greatly benefit from fundamental mechanistic studies, as well as modeling of new classes of catalytic materials. Fine-tuning the electrolyte composition for a given catalyst offers a further opportunity for performance enhancement. A key opportunity resides in optimization of electrode structure and/or composition.

Abstract

This chapter provides an overview on the storage technology power-to-gas for the decarbonization of all energy sectors. Other than "negative emissions" with CCS or biomass, which have clear limits in potentials, costs and environmental benefits, storage and energy conversion technologies like power-to-gas and power-to-x enable the decarbonization by neutralizing the CO_2 footprint of all energy services. Via the conversion of renewable electricity into chemical energy carriers like renewable hydrogen or renewable hydrocarbons, the existing fossil infrastructure with vast and sufficient storage and transport capacities can be used with carbon neutral renewable energy. After showing the demand for storage technologies, the technology components of power-to-gas are described, building the basis for the storage system power-to-gas itself that is described in detail, including efficiency, potential, CO_2 emissions, and costs. In conclusion, a technical pathway of decarbonization including costs is described for the industrial nation of Germany and necessary policy frameworks are derived.

Introduction

No energy system can do without storage. Storage is essential for energy security. Each energy transition needs also a storage transition. Storage will be an essential part of decarbonization worldwide. As several international summits pointed out, we need to complete decarbonization in industrialized nations by 2050. That means the exit of fossil energy carriers such as coal, oil, and natural gas. The good news is that this is actually doable: there is enough renewable energy potential, to shift completely to renewable and clean energy sources. The storage technologies also exist and are ready to be deployed. Decarbonization is possible without CCS and large-scale deployment of biomass by using vastly available wind and solar resources, transformed in biomass-like energy carriers. The technological and economical dimension of the storage technology power-to-gas in a decarbonization scenario is described in the following chapter.

The Need for a Storage Transition in Energy Transition

Storage in the Context of Energy Transition and Flexibility Options

No energy system can do without storage. Storage is essential for energy security. Each energy transition needs also a storage transition. Storage will be an essential part of decarbonization worldwide. As several international summits pointed out, we need to complete decarbonization in industrialized nations by 2050. That means the exit of fossil energy carriers such as coal, oil, and natural gas. The good news is that this is actually doable: there is enough renewable energy potential, to shift completely to renewable and clean energy sources (Sterner and Stadler 2014).

Among renewable energy technologies, wind and solar power have proven to be the most cost- and land-use-efficient technologies to harvest the energy that is in our environment. The downside is of course the intermittency of wind and solar power, but there are solutions to this:

- Flexible generation (e.g., flexible gas turbines and gas CHPs [combined heat and power])
- Flexible consumption (e.g., demand side integration)
- Network expansion
- Storage

In electricity supply, the exact matching of generation and consumption (loads) is essential for a stable supply. The chain consists of generation, transport via networks, and consumption. First of all, not all electricity from wind and solar generators must be integrated into the electricity system. It is economically not feasible to include the "last" kilowatt-hour, since some power peaks are rather high and the energy contained in those peaks is not enough to refinance the respective flexibility option.

Flexible Generation

The conventional generation capacities need to be flexibilized: fast ramping will become mandatory to include cheap wind and solar power, which does not follow any market command but is as naturally available as nature is. Fast ramping can be done by gas turbines and gas CHPs but not at the required scale by lignite coal or nuclear plants. The latter require a very high utilization rate over the years to cover their investment-intensive capital cost. Gas turbines are not capital-intensive. So both technically and economically, gas technologies offer the best "fossil" solution for backing up wind and solar. Hydropower and biomass electricity can do the same, but they are as well rather capital-intensive and limited in potential.

Flexible Demand: Demand Side Integration

Flexibilizing the power consumption is being done for demand side integration, as a combination of demand side response and demand side management, since the 1970s in the form of night heating systems and flexible tariffs. In Germany, there were state subsidies for night heating systems; in Belgium, highways were lit during the night. France shifted the major share of its heating system towards electricity. The goal in each case was to increase the utilization rate of nuclear power plants. Nowadays, demand side flexibility potentials exist at the GW scale, but they need to be market stimulated. It will be mandatory for new electricity consumers like electromobility and heat pumps. These new devices need to be connected and controlled via smart grid technologies in order to stabilize and not destabilize power network operation. The largest advantage of demand side management is the very low investment cost, since the major process is financed separately and demand side management is just an additional function. However, this potential is

also limited, since the manufacturing of products or consumer needs can be delayed by some minutes or hours, but not for days, if there is no wind and solar power for longer periods. Also, for a safe and stable network operation, a nearly 100 % availability and reliability is necessary. This availability is a challenge for demand side management in industrial applications that follow a different major function rather than the additional function demand side management.

Network Expansion
The expansion of electricity networks is another flexibility option, which is so far the most efficient integration option in terms of economy and technology, as long as a total underground cabling is not necessary. Wide area networks, like a pan European network, are therefore an essential element of future energy systems. But network expansion also has its limits: it can balance the spatial component of fluctuating wind and solar power but not the temporal component. In addition, public acceptance is not always given. The temporal balancing can only be done by storage.

Storage
Storage is needed as a flexibility option – today and tomorrow. The stability of today's system is based on stored fossil energy: coal piles, gas caverns, and so on. This functionality has to be provided also in future energy systems, since wind and solar power may be increased infinitely, due to weather conditions, still up to 80 % of the peaking power of a nation is required as backup capacity. This will be achieved by gas power plants, using the existing gas infrastructure, that offer what has been missing in the power sector: immense storage capacities.

Power-to-Gas in the Context of Energy Storage

A storage system consists of three parts:

1. Charging
2. Storing
3. Discharging

These three parts can be in one system (e.g., batteries), several parts in one system (e.g., pumped hydro), or even distributed parts over several various sectors (intersectoral energy storage, e.g., Power-to-Gas), as shown in Table 1.

These storage technologies can be classified again in different ways:

– Technology
  - Electrical
  - Electrochemical
  - Chemical
  - Mechanical
  - Thermal

Table 1 Three parts of energy storage in various applications for electricity storage

	Lithium-ion battery	Pumped hydro	Power-to-Gas
Charging	Internally fixed energy and power units	Water pumps	Electrolysis (and methanation)
Storing		Two reservoirs	Gas storage
Discharging		Water turbine	Gas turbine/vehicle/heating system

– Temporal balancing
  • Short-term storage
  • Long-term storage

Thermal energy storage is still the cheapest option to store energy and is being used widely, but it is not suitable for electricity storage, since the conversion step is "one way" from power to heat. The reconversion of heat to power is very inefficient and thus not feasible. The focus of the following part is electricity storage.

Pumped Hydro, Batteries, and Compressed Air as Short-Term Storage
Among electricity storage, pumped hydropower plants is an old, established technology that is very efficient for power storage. It is, however, a classical short-term storage technology, and its expansion is limited to geography, ecological impact in the form of land use, and public acceptance in general. The second option is batteries. Electromobility gives an impressive drive on this technology, which has been used in power plants for ages. Battery power plants are also feasible for electricity grid stabilization: they can react much faster than conventional power plants and therefore balance wind and solar in no time. In combination with renewables, stationary battery systems can take over the stability services of conventional power plants and replace them. There has been a misbelief in the past that the increase of renewables in the electricity grid is limited to 30 %. This is, from an electric engineering perspective, not true: all technologies are available to operate an electric grid even at 100 % renewables. The third option is compressed air, but compared to pumped hydro and batteries, it is not feasible and only two plants in Huntorf, Germany (60 MW charging power), and in McIntosh, USA (50 MW), are in operation worldwide. Pumped hydro and batteries offer a feasible and highly efficient short-term storage option. The drawback is the high cost for capacity and the self-discharging over time in the case of batteries. There is therefore the need for a long-term storage facility, and the gas infrastructure offers this. One standard gas cavern can fuel a gas power plant with 800 MW rated capacity for 3 months. The question remains: how can we use this infrastructure for wind and solar power? The answer is Power-to-Gas.

Power-to-Gas as Long-Term Storage and Decarbonization Technology
Power-to-Gas is a new storage technology that interlinks the power with the gas sector. It allows in the first step to split water into hydrogen and oxygen via

electrolysis and the use of renewable power. In the second step, hydrogen is combined with CO_2 to form a substitute for natural gas (SNG, synthetic natural gas), which is 100 % compatible with the natural gas infrastructure. The access for renewable energy is then given to millions of households with a gas network connection. The renewable gas (windgas, solargas) can then fuel the necessary backup gas power plants. For short-term balancing, pumped hydro and batteries offer of course much cheaper storage services with double efficiency, but when it comes to long-term storage, Power-to-Gas is the most cost-efficient option: a kilowatt-hour storage capacity costs 200–300 € for batteries and only 0.2–0.3 € for gas storage. With Power-to-Gas, a decarbonization of mobility and nonenergetic use of fossil resources in the chemical industry is possible.

A short overview of sectoral and cross-sectoral energy storage units is shown in, embedding the described different pathways and applications of Power-to-Gas within the energy system.

This promising new technology is described in the following:

Technology Components of Power-to-Gas

Power-to-Gas is an energy storage system that consists of various technologies. The systems are described in section "The Storage System Power-to-Gas" and the necessary technologies in this part. The main part of Power-to-Gas is the charging unit, which contains water electrolysis (section "Charging Technology Water Electrolysis") and optionally methanation (section "Charging Technology Methanation"). The storage and discharging unit are usually the conventional existing technology parts: salt caverns, aquifers, gas turbines, CHPs, heating units, and CNG (compressed natural gas) cars and hence not described in detail in this chapter but in the main book *Energy Storage – Demand, Technologies, Integration* at Springer-Editors (Sterner and Stadler 2014).

Chemical energy storage is the backbone of the conventional energy supply. Solid (wood & coal), liquid (crude oil), and gaseous (natural gas) energy carriers are different types of energy storage themselves. Also in the energy transition, chemical energy storage plays an important role, especially in its function as long-term storage for the electricity sector but also as a distributor of fuel for mobility and heat. This chapter will, besides the conventional storage technologies, take a deep look into the storage of renewable energies in the form of gaseous (Power-to-Gas) energy carriers.

Charging Technology Water Electrolysis

There are three different technologies available for water electrolysis, which are of technical relevance and differ in function, operating conditions, and stage of development:

– Alkaline electrolysis (AEL)
– Proton exchange membrane electrolysis (PEM)
– High temperature electrolysis of steam (HTES) or solid oxide electrolysis (SOE)

These different electrolysis technologies can be implemented as an atmospheric or a pressurized electrolysis system in various stack designs and plant peripheries, which are described in Sterner and Stadler (2014).

Alkaline Electrolysis (AEL)

The alkaline electrolysis of water is a widely proven and well-established large-scale technology. Realized sites were constructed nearby large power plants because of the continuously required power for the electrolysis unit. The largest atmospheric alkaline electrolysis unit in the world with 156 MW nominal power is situated at the Assuan retaining dam in Egypt, with a hydrogen production rate of 33,000 standard cubic meter per hour. The technology is proven and commercially available since many decades. Nevertheless, there is a need for optimization and adoption to the new requirements of fluctuating renewable energies in terms of dynamics and efficiencies.

Figure 1 shows the schematic construction and the function of an alkaline electrolysis cell.

Water circulates through both halves of the cell, which are separated by an ion-conducting membrane. Potassium hydroxide (KOH) 20–40 % by weight is added to the water to increase its conductivity. Thus, the inner resistances in the cell decrease and the conversion efficiency rises. Porous electrodes with a large surface are located on both sides near the membrane. The decomposition voltage of

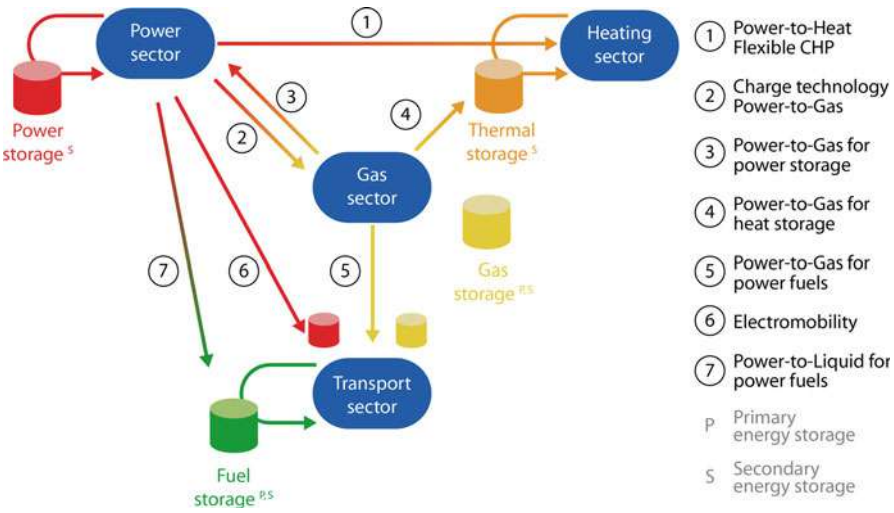

Fig. 1 Sectoral and cross-sectoral energy storage units within the energy system (Source: Sterner and Stadler 2014)

water is 1.23 V. If an ideally equal or realistically higher voltage is applied to these electrodes, the water on the side of the cathode is split into atomic hydrogen and hydroxide ions (HO^-), as described by the cathode reaction (Eq. 1).

$$2H_2O(l) + 2e^- \rightarrow H_2(g) + 2OH^- \quad (1)$$

The generated atomic hydrogen reacts to molecules, rises, and is separated from the electrolyte. At the same time, hydroxide ions pass through the membrane and react to water and atomic oxygen in the anodic reaction (Eq. 2), releasing an electron.

$$2OH^- \rightarrow {}^1\!/_2O_2(g) + H_2O(l) + 2e^- \quad (2)$$

The generated oxygen molecules are separated from the electrolyte and extracted. The consumed water has to be refilled, the electrolyte is recycled. Two electrons are required in each half of the cell for the whole reaction (Eq. 3). They are provided by the power source and transported via the closed electrical circuit.

$$H_2O(l) \rightarrow H_2(g) + {}^1\!/_2O_2(g) \quad (3)$$

The cell frame seals the cell against external influences, isolates the electrons from each other, and serves as a carrier for the membrane. The circulation of the electrolyte and hence the homogenous load distribution is ensured by the flow of rising gas bubbles at low loads. At higher loads, an active agitation has to be implemented.

Membrane Electrolysis (PEM)

The membrane electrolysis (also called Proton exchange membrane or PEM electrolysis) originates from the fuel cell technology and is based on the inverted processes of a fuel cell. It is better suited for a dynamic and pressurized operation than the alkaline electrolysis and needs less space, but to present, it has only been realized in a rather small kW-scale.

A PEM electrolysis cell (Fig. 2) consists of a proton conducting membrane, which is usually permanently fixed on both sides with the electrodes to the so-called membrane electrode assembly (MEA). A solid polymer electrolyte (SPE) like Nafion™ is coated on the electrodes. It is highly porous and accomplishes on one hand the current flow from the bipolar plates to the electrode and on the other hand the transport of water and product gases.

The bipolar plates conduct water via engraved canals to the anode and permit the withdrawal of product gases. In addition, they serve to supply a uniform current density distribution over the electrolyte.

The PEM electrolysis cell differs fundamentally from the alkaline electrolysis cell in its function. Water is supplied to the anode and split to atomic oxygen and two protons in the anode reaction (Eq. 4) with the decomposition voltage applied.

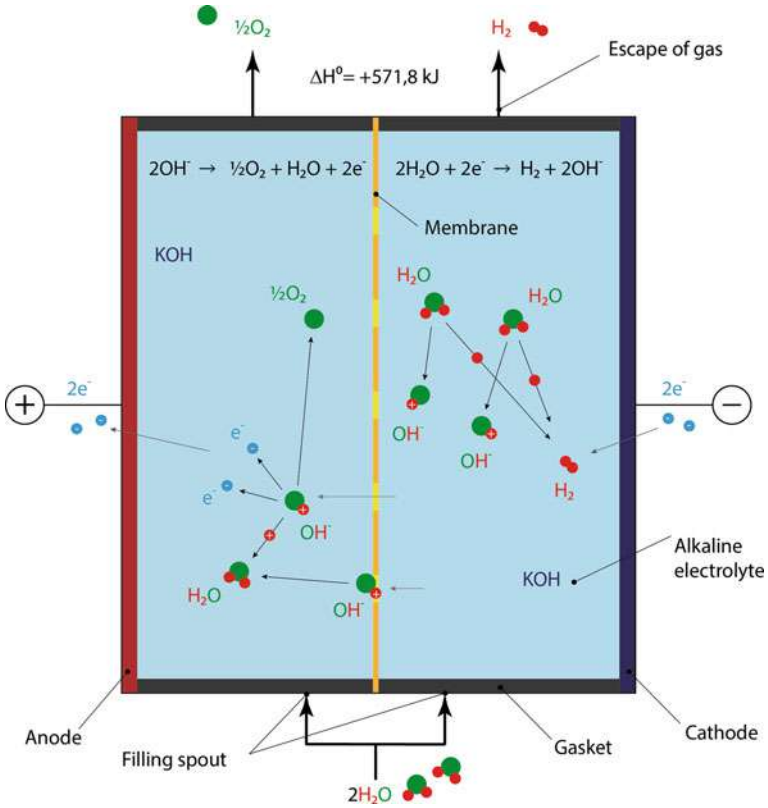

Fig. 2 Function of the alkaline electrolysis (Source: Sterner and Stadler 2014)

$$H_2O(l) \rightarrow {}^{1}/_{2}O_2(g) + 2H^+ + 2e^- \tag{4}$$

The oxygen is withdrawn whereas the protons pass through the membrane and react in the cathode reaction (Eq. 5) with two electrons to form hydrogen.

$$2H^+ + 2e^- \rightarrow H_2(g) \tag{5}$$

Hence, only the anode side is flushed with water. In theory, hydrogen is only produced in the cathode side of the cell. In reality, this side contains high humidity. Compared to the alkaline electrolysis, where partially residues have to be washed out of the electrolyte, the resulting hydrogen contains far less waste materials and has a higher purity. Therefore, the need for hydrogen purification and treatment after the cell is less in the PEM technology, but it is currently still twice as expensive as the alkaline technology.

High Temperature Electrolysis of Steam (HTES)

In the high temperature electrolysis of steam (HTES), a part of the energy for water splitting is supplied by high calorific heat in the range of 850–1,000 °C. The cell voltage can be reduced by 0.5 V to less than 1 V compared to PEM, and alkaline electrolysis and high efficiencies can be realized.

The function of the HTES is based on the reverse reaction of the solid oxide fuel cell (SOFC) (Fig. 3). Both halves of the cell are separated by an oxygen ion conducting solid electrolyte, on which the electrodes are applied on both sides.

Overheated steam is fed to the cathode and reacts with two electrons to form hydrogen and oxygen ions on the cathode side (Eq. 6). Hydrogen can be extracted, and the oxygen ions diffuse through the electrolyte to the anode, where they react to atomic oxygen, releasing two electrons (Eq. 7).

$$H_2O + 2e^- \rightarrow H_2 + O^{2-} \tag{6}$$

$$O^{2-} \rightarrow 2e^- + \tfrac{1}{2}O^{2-} \tag{7}$$

Overall reaction equation:

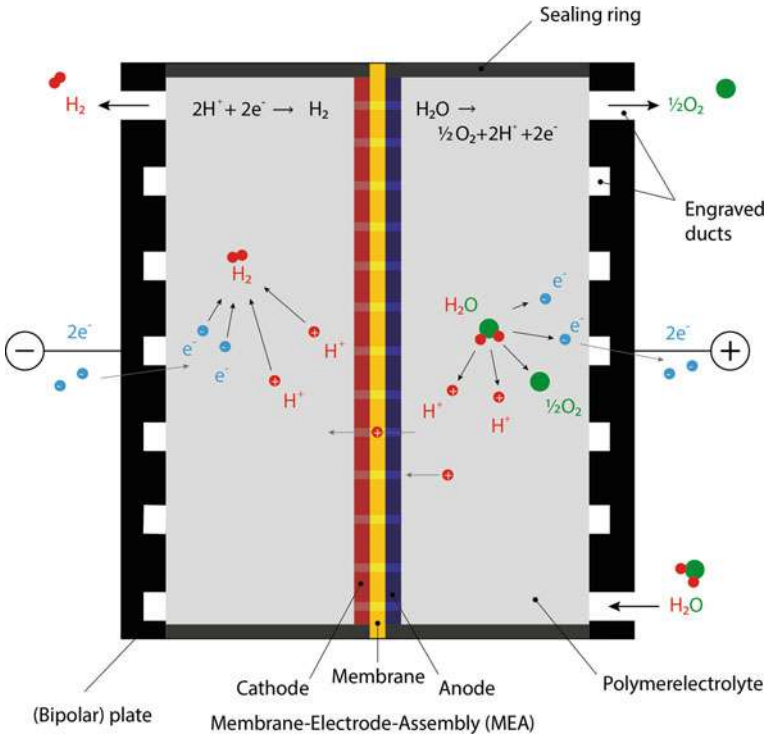

Fig. 3 Function of the membrane electrolysis (Source: Sterner and Stadler 2014)

$$H_2O \rightarrow H_2 + {}^{1}/_{2}O_2 \quad (8)$$

All of these three different approaches of electrolysis technologies have their reason and application. The AEL is the most proven one, inexpensive and well established, but needs a lot of space and has not the best efficiencies. The PEM electrolysis is efficient in conversion and space but rather expensive. The HTEL (high temperature electrolysis) is the most efficient technology, using surplus heat from other processes. However, it is also the most complex technology in terms of lifetime and technology readiness level.

Charging Technology Methanation

It is possible to transform the electrolytically produced hydrogen with the use of CO_2 to gaseous or liquid hydrocarbons. To generate methane, which is chemically the main constituent of and almost identical to natural gas, the methanation synthesis is used.

As hydrogen integration in the existing energy infrastructure is limited, further processing with an additional expenditure is appropriate. By processing hydrogen with the following technologies, it is easier to store, transport, and use it.

Chemical Versus Biological Methanation

There are two ways of methanation: the chemical and the biological way. The different parameters are described in Table 2.

The Sabatier Process

Already in 1902, the French chemist Paul Sabatier discovered the transformation of carbon dioxide to methane via a chemical synthesis. Hence, the scientist is the eponym to this chemical reaction, the "Sabatier process."

Table 2 Different parameters of the chemical and the biological methanation (Sterner and Stadler 2014)

	Chemical methanation	Biological methanation
Operating temperature in °C	200–600	40–60
Pressure in bar	5–80	1–3
Overall reaction	$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O$	
Plant size	Large plants up to more MW	kW scale (up to single digit MW scale possible)
CO_2 gas quality	High syngas quality and gas upgrading necessary; H_2 temporary storage	No requirements
Rate of production	Up to 325 m^3/h (Audi e-gas plant, Werlte)	Up to 540 l per day and liter pure culture

The industrial breakthrough of the CO-methanation succeeded during the oil crisis in the 1970s. In this period, oil prices rose sharply and through the linked price natural gas became more expensive as well. This put a burden on the economy of industrial nations, which were forced to find different solutions. Besides the expansion of nuclear energy, one approach was the production of "synthetic natural gas" (SNG) by gasifying coal to syngas and converting it via methanation to SNG. Especially brown coal was used because of its cheap price and its abundance in industrial nations. The produced gas mixture had a relatively low content of methane and needed to be upgraded before feeding it into the natural gas network.

Chemical Reactions

The chemical methanation consists of two chemical reactions that run at the same time: the methanation of carbon monoxide (CO) and the water gas shift reaction (WGSR).

CO-methanation is state of the art for decades already to gasify coal and was enhanced during the 1960s as explained before. Its chemical reaction proceeds as described by Eq. 9:

$$3H_2 + CO \rightarrow CH_4 + H_2O \qquad \Delta H_R = -206\ \mathrm{kJ/kg} \tag{9}$$

The WGSR produces water and carbon monoxide (Eq. 10):

$$H_2 + CO_2 \rightarrow CO + H_2O \qquad \Delta H_R = 41.5\ \mathrm{kJ/kg} \tag{10}$$

The resulting reaction is described in Eq. 11:

$$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O \qquad \Delta H_R = -164.5\ \mathrm{kJ/kg} \tag{11}$$

The negative sign of the molar reaction enthalpy indicates that the reaction is highly exothermic and thus sets energy free, respectively heat. A thermal management, which reliably dissipates the released energy, is necessary to provide an uninterrupted operation. To accelerate the reaction, a catalyst is used.

Operation pressure and temperature may vary according to the applied reactor concept, though general conditions of 200–300 °C and 20 bar can be assumed.

Sources of CO_2

CO_2 has to be provided as reactant gas. The following three sources are basically accessible:

1. Extraction from air
2. Fossil sources (coal power plants)
3. Renewable sources (biogas facilities)

Theoretically, any exhaust mass flow from industry or any energy supply station as well as ambient air could be used. However, the source has to fulfill the demands of a certain degree of purity as well as being able to provide the necessary quantity.

Purity is the determining factor, as, e.g., sulfur degrades the catalyst of the methanation. The CO_2 flow is mixed with hydrogen in the methanation reactor, and thus, the degree of purity has to be even higher than the CO_2 reactant gas flow.

The origin of CO_2 is relevant due to ecological reasons. Taken from a coal power plant, the plant will improve its carbon footprint, which is good on the one hand. On the other, it is contradictory to the aim of the energy transition, which implies the decrease of fossil energy carriers in favor of an increase of renewable energy carriers. Considering this, the exhaust mass flow from biogas facilities is excellently suitable. The CO_2 originates from plants, which collected it during recent years. By contrast, fossil CO_2 had been safely stored for thousands of years and thus would additionally pollute the environment. Biomass itself is a low-carbon CO_2 source as long as the associated land use is carbon neutral and does not provoke new greenhouse gas emissions by direct and indirect land-use changes. Thus, residual biomass or residues are the ideal biogenic CO_2 sources.

To separate CO_2 from air today is technically complicated and expensive. There are very good starting points at the research and development sides, which will become more attractive in future. Therefore, this is also a considerable eco-friendly source of CO_2, as it closes the carbon cycle as well.

More details on the origin and use of CO_2 are described in section "Power-to-Gas Methane."

Use of Exhaust Heat

Methanation is an exothermic reaction as described in section "The Sabatier Process." It is recommended to use the exhaust heat of the process to increase efficiency, cost-effectiveness, and improve the carbon footprint. Heat is also generated in the upstream electrolysis; hence, an overall heat management is appropriate.

Generated heat can be used for:

1. Internal process heat (purification of gas)
2. Power generation (Organic ranking cycle – ORC)
3. Integration of a heat sink (district heating)

The most obvious use is to cover the internal heat demand of the overall process, e.g., in the purification of reactant and resulting gas. However, the process heat also has the necessary temperature level to convert heat to electricity. This could be realized with the use of a conventional steam turbine or alternatively by an ORC or Kalina cycle.

However, the operating mode of the complete unit has to be considered. If the primary application of the unit is to store excessive electric energy in the gas network, the conversion of heat into electricity is counterproductive. Feeding the heat into the district heating would be an adequate solution in this case, but appropriate heat consumption throughout the whole year has to be guaranteed. If the district heating cannot continuously distribute and use the heat in summer, operational disruptions at the methanation unit could occur.

Reactor Concepts

Reactor concepts in general have to address two basic demands:

- Dissipation of heat (as explained above) to prevent hot spots
- A flexible operating method

A hot spot is a punctual overheating of the catalyst inside of the reactor. As a result, the catalyst can be deactivated or even profoundly damaged. In both cases, the operation mode is disturbed permanently.

The flexible operating mode is necessary to serve the future increase of power fluctuations in the power network, due to volatile renewable energy feed-in. This implies the operation at different levels of load. The reactor mass is critical in this context.

Fixed-Bed Reactor

In this concept, the gas usually passes through the reactor from the top to the bottom to avoid any swirling of the fixed-bed. The danger of hot spots is rather high compared to other technologies. They have to be eliminated by constant intercooling of the gas. This can be achieved by several heat exchangers placed inside the gas flow or by inserting cold reactant gas.

An advantage of this technology is its high availability and reaction time during a cool start, since only the walls of the reactor and the catalyst have to be heated to operating temperature. On the contrary, the process is very sensitive to fluctuations in its load due to a fast cooling down.

Fluidized-Bed Reactor

The fluid streams through the reactor with a relatively high velocity to swirl up the catalyst. In this way, a swirling layer with fluid-like properties is created.

The temperature distribution inside the reactor is homogenous, but the inner walls of the reactor tend to wear out with time due to the swirling layer. A low fluid flow is not able to swirl up the catalyst layer; on the other hand, when operating with high fluid flows, dwell time inside the reactor is too short and there is danger of removing particles from the catalyst. Both situations decrease the possibility of a flexible reactor operation.

Three-Phase Reactor

The reactor is filled with a fluid containing solid catalyst particles. This is also the reason for the name of the reactor: including the gaseous fluid flow, three states of matter are represented inside the reactor. The fluid is responsible for the thermal management. The main task is to dissipate generated process heat and thus to prevent hot spots. Moreover, heat can be applied in this way from outside to keep temperature on a constant level during operational interruption. However, this is only partly necessary, since the reactor mass is rather high due to a high fluid content. This allows to buffer short interruptions. A disadvantage results from the long warm-up time and therefore less flexibility.

Gas Storage Technologies

Already in the mid-nineteenth century, the construction of the gas infrastructure in Germany began – at first only for town gas – which, after the transition to natural gas in the 1970s, even in the twenty-first century is not finished. From the beginning, it was problematic to adapt the rather constant production of gas to the daily and seasonal fluctuations in the consumption. This was solved by developing gas storage facilities, at first with pressure-less gasometers via spherical gas tanks up to the underground storage with an enormous capacity, which dominates today.

In the transition from fossil to renewable energies, the development of storage technologies like Power-to-Gas congruently gains importance and will take its time, as it is still in its infancy.

Gas Holders Aboveground

The compressed gas containers explained in this section were developed for the storage of town gas. Only in individual cases they were also used for pure hydrogen. Any subsequent reference to mass storage is based on the requirements in the town gas era. Storage capacities in the future energy economy depending on renewable energies are required to be much bigger.

The first mass storage for town gas, the so-called gasometers, worked at a lower overpressure than constant pressure gasometers at a variable volume. A typical example is the liquid seal gasholder, which realized the gas sealing against the atmosphere by water. Later, telescope containers, as seen in Fig. 4, which work with the same basic principle allowed a significantly higher storage capacity.

The actual storage container was installed inside a supporting structure. After the telescope gasholder, the disk-type gasholder was established. In this technology, a piston in a cylinder created the storage volume at still low pressures.

Due to limitation to pressures insignificantly higher than ambient pressure, shortly an interest for pressure vessels emerged. In contrast to gasometers, pressure vessels operate at a constant volume but variable pressure between a minimum and a maximum value. The usable quantity of gas between these pressures is called working gas, and the quantity below the acceptable minimal pressure is called "cushion gas," while the proportion of working gas to cushion gas differs in the single pressure vessel technologies.

Spherical gas tanks, as seen in Fig. 5, allow significantly higher operational pressures and thus energy storage densities, due to their favorable geometry. This technology offers the lowest specific consumption of material for the container, which is a critical aspect, as investment costs depend on material costs in the first place (Table 3).

To date no storage technology for pure hydrogen is known.

Pipe storage facilities are gas pipelines installed in a meandering shape in the floor near the surface.

In contrast to underground storage in geological formations, these storage facilities can be installed in nearly any region. The usage of commercially available steel

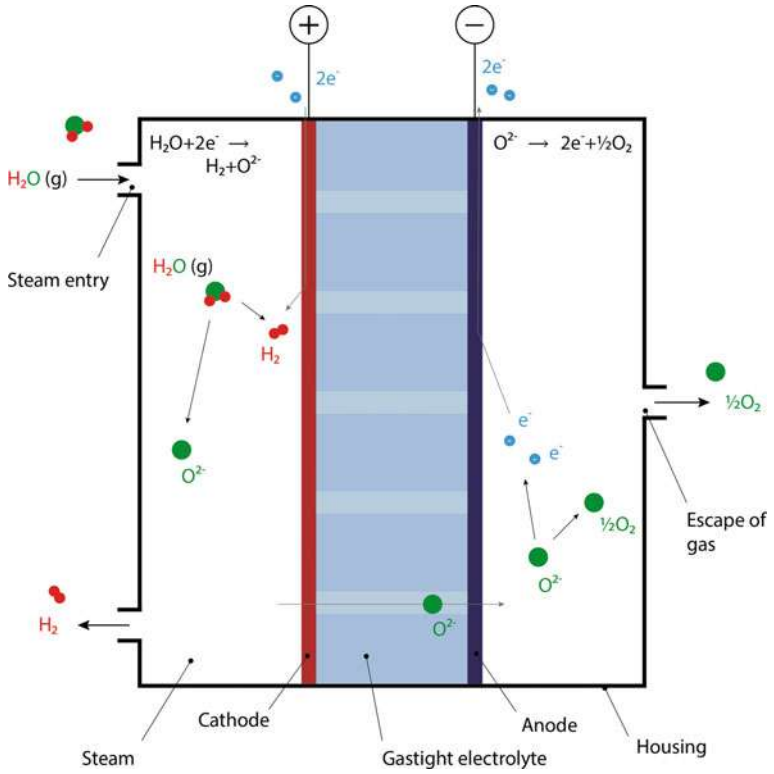

Fig. 4 Function of the high temperature electrolysis of steam (Source: Sterner and Stadler 2014)

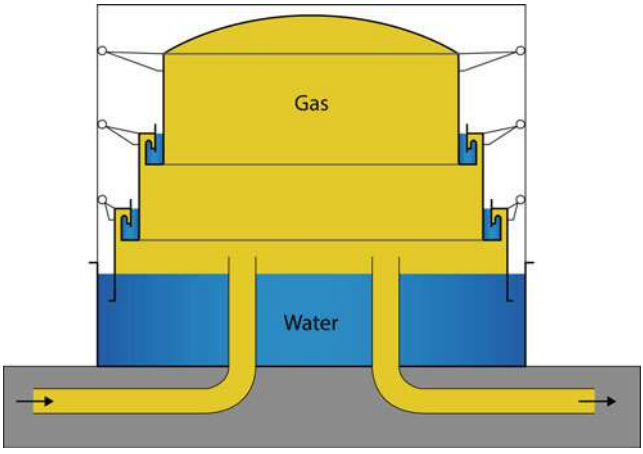

Fig. 5 Gasometer (telescope principle) (Source: Sterner and Stadler 2014)

Table 3 Typical dimensions of a spherical gas tank

Diameter of the sphere	40 m
Maximum pressure	10 bar
Storage capacity	335,000 m^2 (V_n – standard volume)

pipes allows an operation at significantly higher pressures in comparison to spherical gas tanks. The geometry of the long cylinder with a low diameter leads to a higher material consumption and thus higher specific investment costs. Therefore, also this storage technology is only used for small capacities and can only be applied to compensate minor consumption fluctuations.

Underground Gas Storage

The storage capacity of a holder aboveground is basically limited by the economically reasonable geometric volumes in combination with the desired storage pressure, whereas material costs are the predominant factor.

Big storage volumes at significantly lower area consumption can be realized in the geological underground. In addition, storage pressures of up to 200 bars and more are possible with increasing depth. As storage capacity depends on the product of volume and pressure in the first place, fundamentally bigger dimensions in capacity are possible in comparison to the storage aboveground. While the pressure vessels named above provide capacities of under one million m^3 (V_n – standard volume), the averaged capacity of German underground storage facilities is at nearly 500 million m^3 (V_n).

This is the reason why underground storage became the state-of-the-art technology for big amounts of gas.

Figure 6 shows the different types of underground storage. In the beginning, depleted deposits for hydrocarbons and porous aquifers were used as storage. Later they were complemented by artificially created salt caverns. To a low extent, porous formations and salt caverns were used for the storage of town gas, which comprises 50 % hydrogen. For many years, the storage of pure hydrogen takes place in specially equipped salt caverns.

All of the internationally installed underground gas storage facilities have in common:

1. The high safety against unintended escape of gas through the sealing rock layers of up to several hundred meters thickness – compared to the thin thickness of a few centimeters for overground containers
2. High storage capacity established by big geometric volumes and high operational pressures
3. Low surface usage overground
4. Low specific installation and maintenance costs compared to storage overground
5. Feasibility being coupled to the availability of suitable geological formations, which is a big limitation to a lot of regional cases

Fig. 6 Spherical gas tank in Gelsenkirchen (Source: Sterner and Stadler 2014)

6. Extensive positive experience in a lot of industrialized nations and therefore good conditions for the acceptance of future storage of hydrogen

Salt Caverns

Salt caverns are artificially created cavities in underground salt rock. If sufficiently big and homogenous salt rock formations are available, a drilling is sunk into the rock with a diameter of less than 1 m and sealed with a cemented steel pipe. Afterwards, the cavity is created by the so-called solution mining process. The big advantage of the further explained process is that for creating the cavern, neither an extensive tunnel has to be sunk nor a person or machine has to be transported underground. All work can be executed overground, which is a considerable advantage in costs and time compared to conventional mining.

To inject the required water for the solution process into the drilling, two concentric tubes are inserted into it at first, as seen in Fig. 7. Water is pressed through the inner tube, which dissolves the salt rock. Through the annular gap between the tubes, the evolving brine is brought overground and either used as a raw material or conducted into the sea environmentally friendly. Additionally, a protective fluid (blanket) is injected into the annular gap to prevent an uncontrolled rupture of the brine. The time-dependent spatial development of the cavern can be controlled by sonar measurements and thus applied to the requirements.

The aim is to create a cavity which effectively uses the available salt rock and which provides a safe long-term storage of gas. The unique creeping properties of salt rock make these caverns tight for gases, as long as the permitted operational pressure is maintained. Nevertheless, the creeping leads to a decreasing volume over time.

Fig. 7 Options for gas storage in the geological underground (Source: KBB UT)

As soon as the cavern obtained the required volume, tightness tests are executed, the cavern is modified for operation with gas, and the first gas is filled in. In the first step, the tightness of the drilling has to be proved – an important requirement for further approval as gas storage. Afterwards, the cavern is equipped with a casing for the exploration of gas as well as with a downhole safety valve. If the cavern head at the surface is damaged in the worst case, this valve prevents the blowout of gases from the cavern. The so-called brine removal string is inserted into the cavern and allows the displacement of the brine with the storage gas. Finally, the string is removed under pressure.

Summing up, there are sufficient technologies available for a safe and economic storage of gas.

The Storage System Power-to-Gas

The storage system Power-to-Gas (electricity to gas, PtG) is presented in this chapter. It is made out of the single conversion technologies, described in section "Technology Components of Power-to-Gas."

In general, two PtG concepts have to be differentiated based on the characteristics of their energy sources hydrogen (H_2) and methane (CH_4). Their deployment, as well as the extraction technologies used, make the main difference. In addition, there is the optional methanation stage. In the following, basic concepts of PtG are

explained. The specific application for decarbonization and some projects is presented in section "Decarbonization with Power-to-Gas."

The Beginnings of Power-to-Gas

Energy Storage Demand in Dynamic Simulations: Hydrogen and Biomass
In the course of expansion of renewable energies in Germany – mostly wind and photovoltaics – calls for energy storage grew ever louder since the early 2000s.

While it has been sufficient for a long time to consider the annual balance sheet, which is based on only one value for wind and solar power generation, dynamic simulations of a power system containing a large percentage of renewable energies have detected and revealed a large storage and balance demand. This demand could not be supplied by conventional German storage technologies, such as pumped hydro, battery power plants, or compressed air storage. Solely, caverns exclusively for hydrogen have been considered as solution (see Sauer 2006; VDE 2013). Since there is no infrastructure for hydrogen and a very limited potential for hydropower buildout, pure renewable energy systems depend on bioenergy as balancing energy.

The Combi Power Plant at the ISET Kassel, Now Fraunhofer IWES
In the 1990s, Enßin, Füller, Hahn, Rohrig, and their colleagues, at the Institute for Solar Energy Supply Technology (ISET) in Kassel, built a database for feed-in from wind turbines as part of the 250-MW measuring program. Since the early 2000s, this data has been used for wind forecasts and the construction of virtual power plant in the form of a wind turbine cluster (see Ernst et al. 2004; Ernst 2003; Enßlin et al. 1993). The project called "Combined Power Station" (see Fig. 8) resulted from their work and was able to prove that, at any point of time, power supply based on 100 % renewable energies was possible in Germany at a scale of 1–10,000, measured at the necessary energy supply and demand. To achieve this goal, wind turbines of Enercon GmbH, photovoltaic plants of Solarworld AG, and biogas plants of Schmack Biogas GmbH were combined and controlled in real time according to German load profile. Only power storage was simulated as the pump storage plant Goldisthal. That is how it was possible to rebut presumptions that purely renewable power systems were not able to provide a stable power supply (see Mackensen et al. 2008).

Reinhard Mackensen's analyzes showed that the expansion of renewable energies to the full extent would mainly be based on wind power and photovoltaics and thus require major balancing measures in the form of storage capacities or stored biomass. It is neither possible to provide these balancing measures by expanding pump storage plants nor can enough biomass be produced on the available areas (see Mackensen et al. 2008; Mackensen 2011). The core problem was to realistically upscale installed biomass and storage capacity by a factor of 10,000. One approach of the ISET was to interconnect the power and gas sector and thus be able to store wind and solar energy in the form of hydrogen in the natural gas grid. It would then

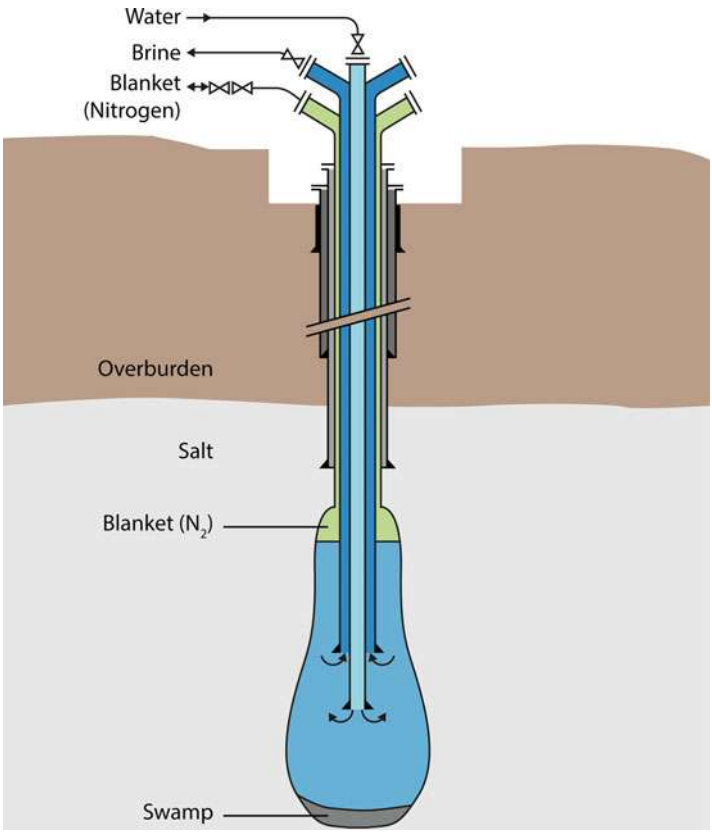

Fig. 8 The brine process – cavern creation in the salt rock (Source: KBB UT)

be possible to flexibly reconvert it into electricity via gas turbines and cogeneration plants (see WBGU 2008).

Methanol Production from CO_2 and Biomass Gasification at the ZSW Stuttgart
In the 1990s, Andreas Bandi, Thomas Weimer, Michael Specht, and their colleagues, at the Centre for Solar Energy and Hydrogen Research (ZSW) in Stuttgart, developed a synthesis to produce methanol from atmospheric CO_2 and solar energy. A small-scale pilot plant was set up, which extracts CO_2 from the air by means of adsorption and electro dialysis. It then chemically reacts the CO_2 to methanol using hydrogen from solar powered electrolysis. At this point, the technical feasibility of CO_2 recycling to produce methanol was successfully proven (see Bandi 1995; Specht 1998; Specht et al. 2000; Weimer 1996). In the 2000s, research at the ZSW concerning hydrogen and chemical energy sources focused on biomass gasification. They developed a process of their own (Absorption Enhanced Reforming Process) to produce a hydrogen-rich gas from biomass via two coupled fluidized bed reactors (see Weimer 1996; Specht et al. 2006, 2010).

The First Coupled Power and Gas Grid in the WBGU-Bioenergy Report

Until the middle of the 2000s, it became clear that the biomass potential is and will be limited. The increase in food prices in 2008 got the "food-versus-fuel debate" going and brought up the question to which degree biomass can and should be energetically used (see FAO 2008; Sachs 2008). The WBGU-Bioenergy Report shows that, while bioenergy is very well suited to balance fluctuating wind and solar energy, the necessary sustainable potential is not available. Both authors, Jürgen Schmid and Michael Sterner of the ISET Kassel, came to the conclusion that, because of its scarcity, bioenergy is best integrated into the existing natural gas grid via fermentation, gasification, and methanation (see WBGU 2008; Sterner and Schmid 2009). In this way, existing transport and storage capacities can be used and thus provide energy to all sectors via power plants, cogeneration plants, gas cars, and gas heating. In addition, it is possible on the one hand to separate CO_2 and establish an actual CO_2 sink and on the other hand to integrate fossil coal, which will last a long time, in a climate-friendly way.

In the end, this integrated energy system consisted of an electricity and a gas system, which were coupled via gas power stations and cogeneration plants on the one hand and an electrolyser, which produced hydrogen for fuel cells, on the other (see Fig. 9). Schmid and Sterner presented this system along with the combined power station at the

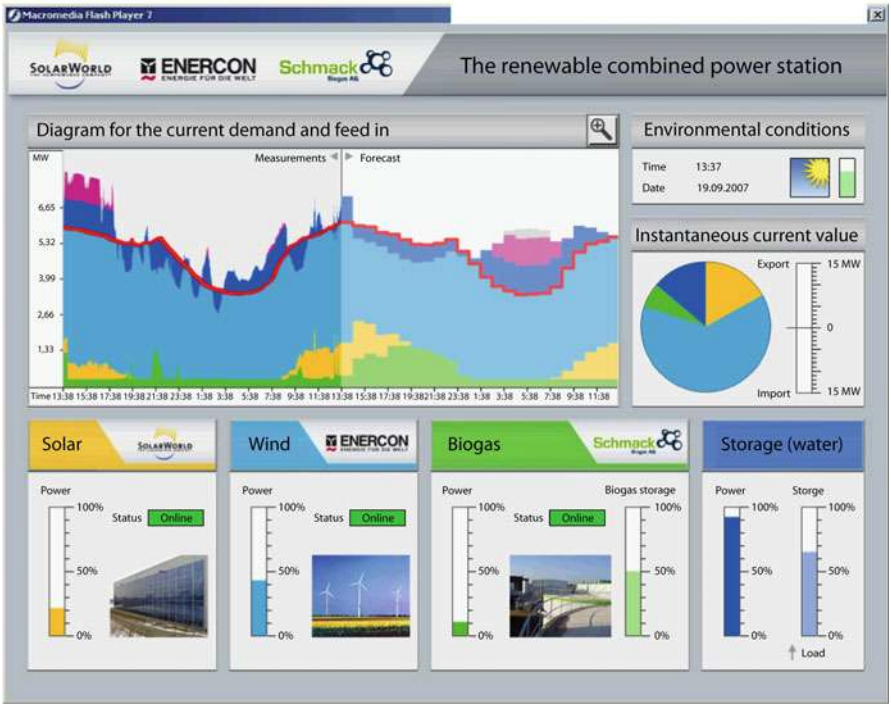

Fig. 9 Combined power station at the ISET (Source: Sterner and Stadler 2014)

16th European Biomass Conference (see Schmid and Sterner 2008; Sterner and Schmid 2008). Michael Specht and his colleagues from the ZWS Stuttgart presented their paper on chemical energy conversion of biomass (see Bandi 1995). Having the accordant background, he produced the idea to improve the possibility of integration of hydrogen into the natural gas grid by using the Sabatier reaction. As shown in Fig. 9, the syngas CO_2 from coal and biomass is used for methanation.

Patent, Studies, and Projects Concerning Power-to-Gas
At this point, both institute's preliminary work was merged together and the Power-to-Gas concept was elaborated. In 2009, this led to a patent application (see Specht et al. 2009) and a doctoral thesis on Power-to-Gas, which made the concept of chemically storing energy from wind and solar plants well known and put it into context with energy transition (see Sterner 2009). As another consequence, the first PtG plant for methanation of CO_2 in Germany was developed in Stuttgart by the order of Waldstein, the founder of SolarFuel GmbH (see Fichtner 2011; Specht et al. 2008).

In addition, different pilot projects were launched. While studies were carried out for E-On, Greenpeace Energy, and Audi AG in Kassel, hardware was refined in Stuttgart. Both activities paved the way for the realization of pilot projects and the publication of the new concept.

In energy economy, this concept was made well known by a number of associations: the research papers by the Fraunhofer IWES (formerly ISET) on which the long-term scenario of the Federal Environment Ministry (BMU) is based (see Nitsch et al. 2012), the report published by the German Advisory Council on the Environment (SRU, see SRU 2011), the Federal Environment Agency's "UBA Energy Goals 2050" (see UBA 2010), and the VDE ETG Storage Study (see VDE ETG 2012). So far, the greatest PtG project has been realized by Audi AG and fuels 1,500 vehicles with CO_2-neutral gas.

PtG Hydrogen

The storage system PtG hydrogen (PtG-H_2) uses electricity surplus from renewable energies to produce hydrogen. Hydrogen can potentially be used in several different ways, e.g., as an admixture in the natural gas grid or it can be used energetically at a different point of time and place if filled in a compressed hydrogen tube trailer. Following stages are passed through:

- Storing:
  Storing technologies
  - Alkaline electrolysis (AEL)
  - Proton exchange membrane electrolysis (PEMEL)
  - High temperature electrolysis (HTEL)
- Storage:
  Storage media
  - Gas grid

  - Cavern storage
  - Gas and oil deposits
  - Aboveground storage
- Extraction:
  Extraction technologies
  - Fuel cell
  - Gas turbine, combined cycle plant, cogeneration plant
  - Gas heating, gas hat pump, refrigeration machines
  - Fuel cell vehicles, rocket propulsion
  - Material use

Possible Plant Concepts

High-quality natural gas in Germany is composed of 96 % by volume methane, 1 vol % CO_2, 2 vol% nitrogen (N_2), and 1 vol% hydrocarbons, such as propane and butane (see Henel et al. 2013). According to the DVGW (German Technical and Scientific Association for Gas and Water), the admixture of 1.5 % hydrogen is possible. Higher blending quotas cause research needs and adjustment requirements for certain applications, such as gas turbines, porous storage, or natural gas tanks in vehicles, which are limited to 0–4 %. For this reason, PtG hydrogen storage systems differ in regard to the way hydrogen is used after electrolysis.

In this book, the use of hydrogen is distinguished between material (1) and energetic. Furthermore, energetic use can be divided into use in an infrastructure exclusively for hydrogen (2) and use in an already existing gas infrastructure (3). There is a clear presentation of how hydrogen can be used in Fig. 10.

Material Use

An industrial plant or a refinery with a great need for hydrogen can be attached directly to a PtG-H_2 plant (Fig. 11). Since most industrial applications need constant supply, the system includes hydrogen tank as buffer. Hence, requirements for PtG-H_2 systems are a location with great availability of renewable energy sources and a suitable consumer for the H_2.

> There is a great climate protection potential in the reduction of iron by applying the direct reduction process (DRP) rather than the CO_2-intensive blast furnace process. The DRP uses hydrogen to withdraw oxygen from the ore (Fe_2O_3). As a result of this reaction, there is pig iron and water. Another advantage of the DRP is that there is less than 1 % carbon in the pig iron. After the blast furnace process, up to several percent carbon has to be removed in order to meet DIN (German Institute for Standardization) norms, according to which pig iron, the staring product for steel, has to contain less than 2 % carbon.

Energetic Use via Hydrogen Infrastructure

When, in the future, a hydrogen economy has been established, it will be possible to use hydrogen directly in a hydrogen-only system (Fig. 12). Regions with already

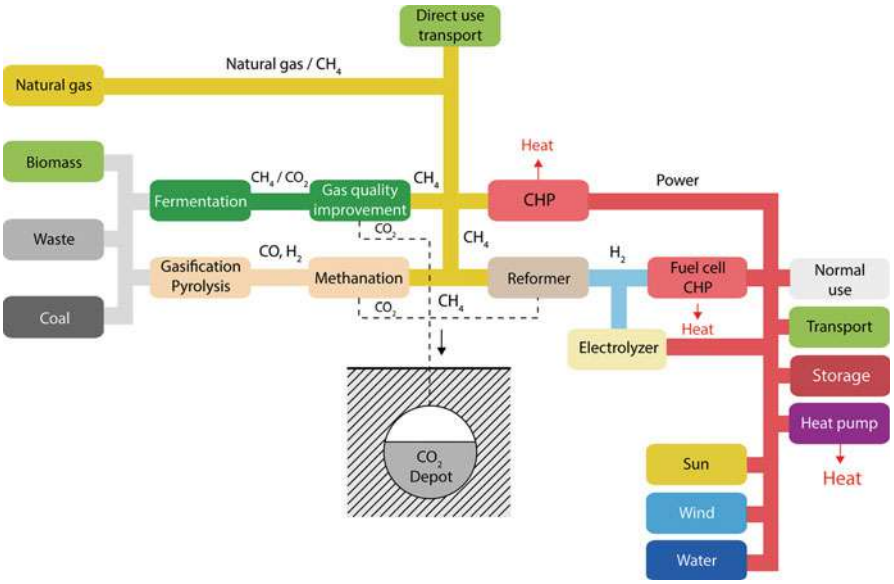

Fig. 10 Coupling of electricity and gas system via electrolysis in the WBGU Report on bioenergy (Source: WBGU 2008)

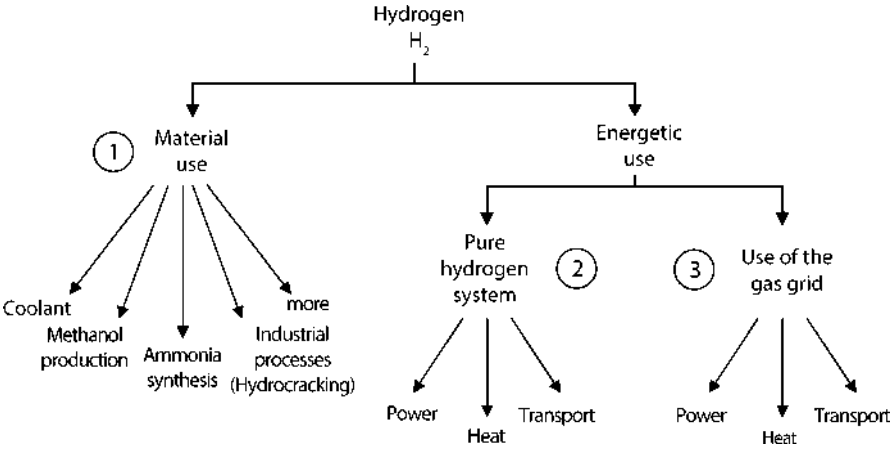

Fig. 11 Overview of the possible uses of hydrogen (Source: Sterner and Stadler 2014)

existing suitable hydrogen storage and lines are eligible starting points as well as regions with a high density of consumers in chemistry parks. This is researched in the course of the BMBF project "HYPOS" for eastern Germany, which examines wind-photovoltaic-hydrogen hybrid parks and hydrogen test fields including Germany's first hydrogen storage (see HYPOS 2014). Storage options for short-term storage are, along with hydrogen lines, aboveground H_2 tanks. Long-term

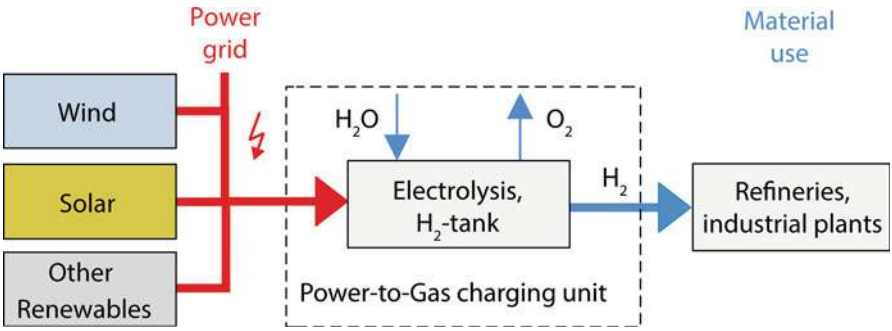

Fig. 12 Schematic representation of a PtG system for material use of hydrogen (Source: Sterner and Stadler 2014)

storage can be realized in gas caverns. Porous storage is not suitable for hydrogen storage because of microbiological hydrogen sulfide emergence, which results in corrosion.

In times of deficits due to fluctuating renewable energies, this system reconverts hydrogen to electricity via especially adapted gas turbines or fuel cells and thus acts as electricity storage. In this case, an independent hydrogen infrastructure provides seasonal balance for times of both low winds and sunshine hours.

In addition, hydrogen can be used for transport when sold at hydrogen stations or in the field of heat supply.

Realization is obstructed by high costs for the expansion of an independent hydrogen infrastructure and high prices for hydrogen extraction technologies, such as fuel cell vehicles, fuel cell cogeneration plants, and reconversion units.

Energetic Use via Admixture to Natural Gas and Use of Existing Gas Infrastructure

From today's point of view, an independent hydrogen infrastructure is only financially reasonable in some regions with a great demand for hydrogen, industrial consumers, and existing, suitable storage facilities, such as cavern storage.

Matters are different, when hydrogen is added to natural gas using the existing gas infrastructure. The gas grid is expanded over all of Germany and there are high-capacity cross-border interconnections. Furthermore, state-of-the-art consumers which only need slight adaptions to higher hydrogen percentage can be used in all energy sectors. These already existing technologies make development of new ones redundant.

The challenge here is hydrogen tolerance of specific components (Fig. 13). In this field, there are research needs and adjustment requirements to increase the technically possible blending quota of 1–2 vol% (see Henel et al. 2013).

In a PtG hydrogen storage system, surplus electricity is used for water splitting in an electrolyser (Fig. 13). In order to prepare hydrogen produced in this manner for feed-in to the gas infrastructure, it is fed to a gas storing unit including a compressor.

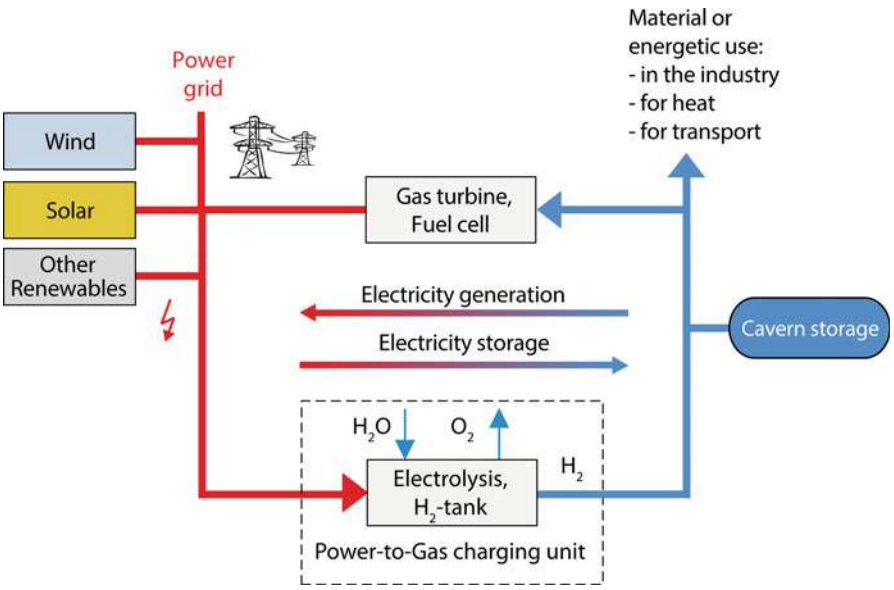

Fig. 13 Energetic use of hydrogen in a hydrogen-only infrastructure (Source: Sterner and Stadler 2014)

From that point on, usage is possible, in consideration of hydrogen tolerances shown in Fig. 22, in all kinds of ways: reconversion to electricity, heat, transport, or material use.

When used for seasonal balancing, the mixture of hydrogen and natural gas can be stored, other than pure hydrogen, in all gas storages up to a blending quota of 1 % hydrogen. Along with salt cavities, porous storage is an option. Buffering on a short-term scale is possible in aboveground gas storages. Furthermore, the gas mixture can be brought to all consumers in households, business, and industry via the gas grid. Among others, possible applications are gas engines, condensing gas boilers, gas heat pumps, gas stoves, gas tools, gas base materials, or reconversion to electricity for peak-load supply.

Power-to-Gas Methane

In addition to electrolysis, there is another storing technology, methanation, in the Power-to-Gas methane (PtG-CH_4) storage system. Hydrogen and carbon dioxide (CO_2) are reacted biologically or chemically to methane (CH_4) and water (H_2O) (see Sterner 2009).

Main advantages of this system are easier compressibility, storage, transport, and usage, due to higher energy density of methane. Disadvantages result from the additional procedural step, which needs CO_2, causes waste heat and therefore

reduces efficiency of the overall process. Among others, intelligent heat concepts can compensate for this disadvantage by using waste heat for vaporization in high temperature electrolysis (section "Efficiency, Potentials, CO_2 Emissions and Costs").

A PtG-CH_4 system can be composed of the following components:

- Storing:
  Storing technologies
  - Electrolysis
    - Alkaline electrolysis (AEL)
    - Proton exchange membrane electrolysis (PEMEL)
    - High temperature electrolysis (HTEL)
  - Methanation
    - Chemical methanation
    - Biological methanation
- Storage:
  Storage media
  - Gas grid
  - Cavern storage
  - Gas and oil deposits
  - Aboveground storage
- Extraction:
  Extraction technologies
  - Fuel cell
  - Gas turbine, combined cycle plant, cogeneration plant
  - Gas heating, gas hat pump, refrigeration machines
  - Gas vehicles, ships, airplanes
  - Material use

Possible Plant Concepts

In the field of PtG-CH_4, there are different concept categories, which are all based on the concept shown in Fig. 14 (see Sterner 2009).

Bidirectional interconnection of power and gas grid in order to store renewable energies is the general idea of Power-to-Gas (section "The Beginnings of Power-to-Gas"). Electricity surpluses power water splitting. In the process of methanation, thus produced hydrogen and CO_2 are reacted to methane. This requires one of several different possible sources of CO_2, such as Carbon Dioxide Capture and Storage (CCS), biogas plants, sewage plants, atmospheric CO_2, industrial processes, or conventional power plants. Renewable methane can be temporarily stored in gas storage or fed into the gas grid. Once there, it can be reconverted to electricity via gas turbines, cogeneration plants, etc., or be used in the heat and transport sector.

What differs between each concept from another is the CO_2 sources and how it is integrated into the process of methanation.

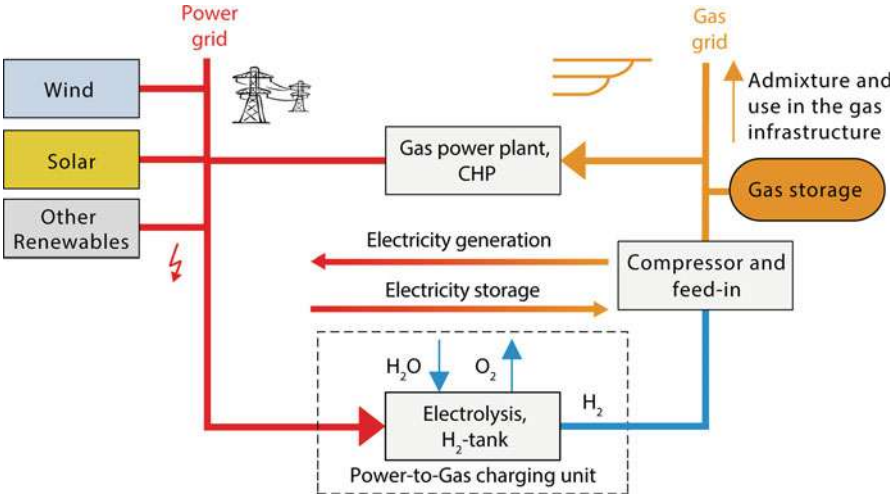

Fig. 14 Schematic representation of hydrogen use in the existing gas infrastructure (Source: Sterner and Stadler 2014)

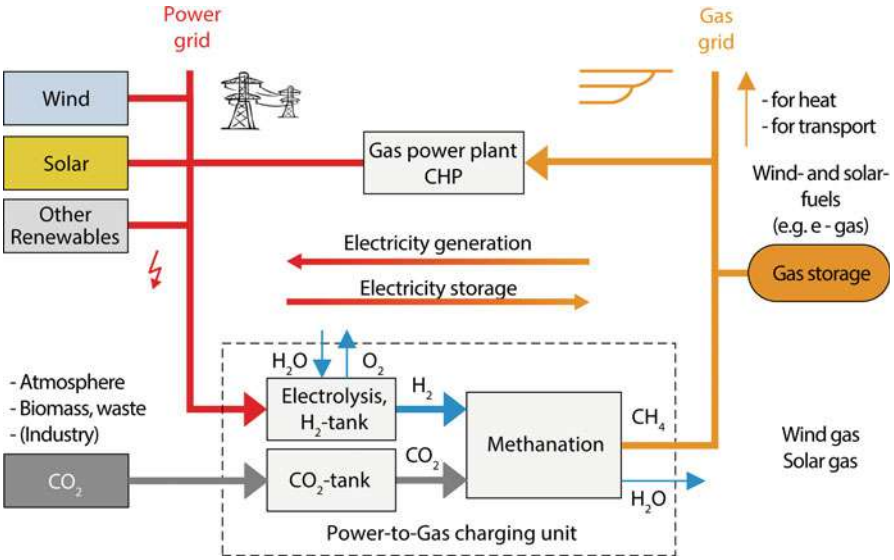

Fig. 15 Basic concept of PtG methane (Source: Sterner 2009)

Atmospheric CO_2

Methane produced with atmospheric CO_2 and renewable electricity is CO_2 neutral (Fig. 15). It is possible to decrease the content of CO_2 in the atmosphere by connecting the combustion process with a CCS system.

There are different ways to extract CO_2 from the air:

1. Adsorption
2. Absorption
3. Condensation
4. Membrane separation

Since the concentration of CO_2 in the atmosphere is only ca. 400 ppm or 0.4 ‰, every one of these processes is energy-intensive. Therefore, pure CO_2 sources should be used in order to increase efficiency and profitability of PtG plants.

This system is given its raison d'être by regions worldwide which offer a great potential of renewable energies but are far from consumers. Since air is the only source of CO_2 in these regions, this system makes it possible to use their potential and decrease their dependence on natural gas imports (see Sterner 2009).

Two of the four abovenamed extraction technologies are very energy-intensive: Condensation requires considerable cooling of the air; membrane separation requires a very high pressure to extract CO_2 from the air. These processes are standardly applied in air separation units (ASU) for industrial extraction of nitrogen, oxygen, and noble gases, such as argon (see Specht et al. 2000). From today's point of view, with respect to effort and losses, technologies based on absorption and adsorption are favored.

Absorption Process

An alkaline solution, such as sodium hydroxide (NaOH), potassium hydroxide (KOH), or calcium hydroxide ($Ca(OH)_2$), absorbs CO_2 from the air and reacts to a carbonate like sodium carbonate (Na_2CO_3). Now, an acid can dissolve CO_2 from the carbonate.

In order to restore acid and alkaline solution, an electrodialysis with bipolar membranes is carried out. In this electrochemical process, protons (H^+) and hydroxide ions (OH^-) are being separated by an electric field. These ions are produced by splitting water, which in turn is activated by a bipolar membrane.

According to tests in the laboratories of ZSW Stuttgart, absorption and electrodialysis put together require 2.28 MWh per ton CO_2 (see Bandi 1995; Specht et al. 2000). In practice, this value is higher.

Adsorption Process

The adsorption process uses a batch procedure, in which first CO_2 is adsorbed and then emitted and thus made available, when supplied with low calorific heat. Adsorption processes, such as the pressure swing adsorption (PSA), are standard in gas preparation and purification technologies. The advantage is that low temperature heat from different processes (e.g., electrolysis, CHP, possibly synthesis) can be used for desorption.

The Climeworks company produces and runs a commercially available demonstration plant capable of extracting atmospheric CO_2. One cycle takes some 6 h.

First of all, air is conducted through the adsorption chamber, where CO_2 adheres to cellulose granulate. It takes 3 h before enough CO_2 is accumulated. After another 3 h at 95 °C and reduced pressure, the desorption phase has completed the cycle. Under these conditions, it is possible to extract 99.5 % pure CO_2 from the cellulose with a vacuum pump. It is possible to extract 80 % of all CO_2 molecules from the air with this plant using a sorbent. In absolute numbers, this means 800 m^3/h air and 4 kg/d respectively 1,000 kg/a CO_2 (see Gebald et al. 2011, 2013; Wurzbacher et al. 2011).

In the future, ca. 1,000 t CO_2/a with a composition of 99.9 % CO_2, 30 ppm O_2, and 20 ppm H_2O will be achievable on a 100 m^2 area. Energy input is between 200 and 300 kWh electricity per ton CO_2 mainly for the fan and between 1,500 and 2,000 kWh/t CO_2 for low calorific heat (supply temperature: 105 °C, return temperature: 95 °C) mainly for desorption. Costs for extraction are expected to decrease in the future to some 200 €/t from today ca. 800 €/t with an expenditure of ca. 30 €/t for electricity and heat (see Gebald 2013).

This demonstration plant was installed at the beginning of 2013 and proved its suitability for daily use under different environmental conditions. It is planned to cooperate with Audi, which provides CO_2 for the PtG plant in Werlte (see Audi 2014).

CO_2 from Biogas Treatment Plants

Principle

This concept's base material for CO_2 is biomass or waste, which is being fermented in a digester. Depending on dwelling time and the kind of digester, the purified biogas can contain up to 45 % CO_2. For a lot of technical applications, the inert CO_2 is obstructive, which is why biogas is purified to natural gas quality (>96 % CH_4) prior to feed-in into the natural gas grid. For this reason, the purified biogas is called biomethane and can be stored, distributed, and used in all fields of application via gas grid. Using the existing gas infrastructure has many advantages: already existing technology can be applied and, contrarily to on-site conversion to electricity, waste heat can be used more specifically. This makes exploitation of biogas more efficient. Processes for gas separation are adsorption, absorption, chemical absorption, membrane separation, or cooling (see Beil 2008).

In combination with PtG, thus extracted very pure CO_2, which is normally blown into the atmosphere, can be used for methanation. Together with electricity surpluses and hydrogen it is reacted to methane. When there is no sufficient electricity surplus for hydrogen production or hydrogen buffers are empty, CO_2 can simply be stored and used when needed (Fig. 16).

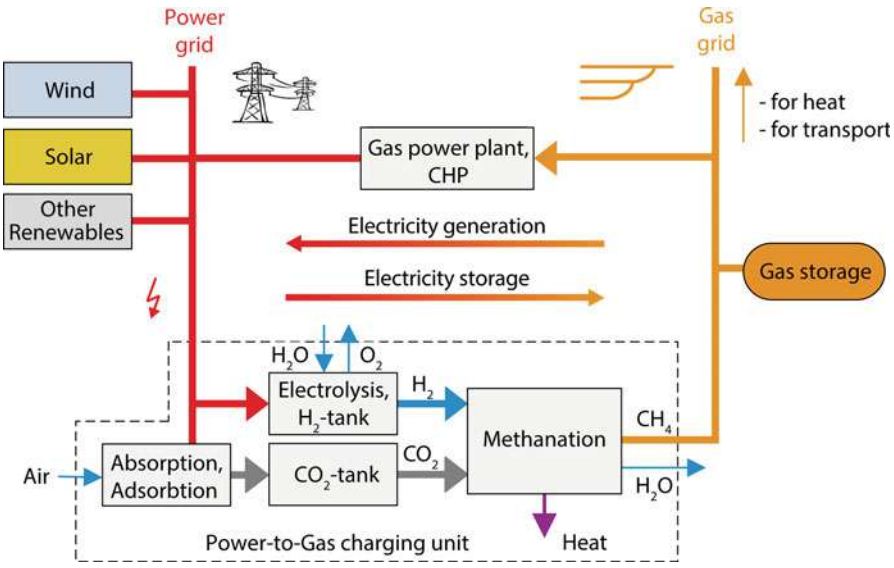

Fig. 16 PtG methane using atmospheric CO_2 (Source: Sterner 2009)

Advantages

The great advantage of coupling these processes is a more efficient use of resources and energy: in this system, waste heat produced by methanation can entirely be used for the fermentation or treatment procedures. By using CO_2, a naturally bound resource, methane production of a biogas treatment plant can almost be doubled if PtG is applied. Additionally, the climate-damaging methane slip of treatment plants can be avoided.

Biomass Gasification Variant

Instead of a digester, a gasification plant can be used for solid biomass. When supplied with heat and oxygen, carbon hydrate compounds are split into CO, H_2, H_2O, CH_4, and CO_2. This gas mixture is catalytically reacted to methane after purification and conditioning. A PtG plant can provide this process with oxygen and hydrogen and increase its gas yield by using surplus electricity.

CO_2, a Component of Gas from Biogas and Gas Purification Plants

Principle

Direct methanation of biogas or sewage gas is possible even without previous CO_2 separation (Fig. 17). Both gases consist of 50–60 % methane and 40–50 % CO_2 and small amounts of accompanying substances. This gas is conducted from the digester to methanation, where CO_2 from biogas or sewage gas and renewable hydrogen can react to high percentage methane.

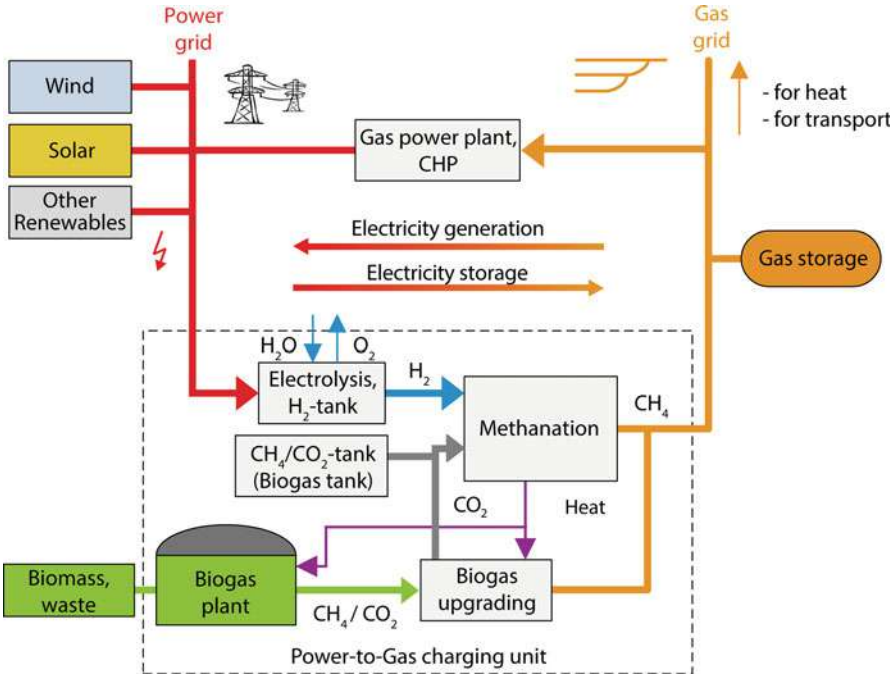

Fig. 17 PtG methane using CO_2 from biogas treatment or biomass gasification (Source: Sterner 2009)

By connecting a biogas plant to a PtG system, which also eliminates the additional energy expenditure for biogas treatment, it can produce twice as much methane.

Advantages of Biological Methanation

This process can be realized both chemically and biologically. Especially biological methanation seems suitable in this case, because the necessary bacterial strains are already contained in biogas and sewage treatment plants. Additionally, parts of the infrastructure of already existing biogas and sewage treatment plants can be used and thus save investment cost. This includes premises, electrical installations, and, if applicable, biogas or sewage gas utilization (conversion to electricity, gas grid, etc.). Especially in combination with municipal infrastructure (e.g., transport fleet), on-site PtG at a sewage treatment plant is very promising.

Along with integration into existing biogas or sewer-gas plants, another possibility is methanation in pure cultures. This has the advantage of increasing conversion rate at reduced dwelling time, because bacterial strains can be treated more specifically.

CO_2 from Flue Gas Emitted by Coal Power Stations

Principle

The main shortcoming of today's coal usage is its CO_2 emission. In the light of worldwide coal reserves, concepts for separation, sequestration, and storage (carbon capture and storage – CCS) are developed and put to the test (see Sterner 2009). It is far more realistic, to use CO_2 from coal power stations energetically or materially (carbon capture and use – CCU), rather than store it in potentially leaky formations underground. There are different processes for separating carbon dioxide from waste gases of combustion processes: In a downstream separation of waste gas after combustion, during the gasification stage before combustion for combined cycle plants using coal gasification, or during combustion in a pure oxygen atmosphere (oxyfuel combustion process, Fig. 18).

Oxyfuel Combustion Process

Since one product of water electrolysis is pure oxygen, latter process seems most attractive. If electrolysis cannot provide enough oxygen, an air separation unit can. This is more energy intensive and decreases the overall system's efficiency. Taking

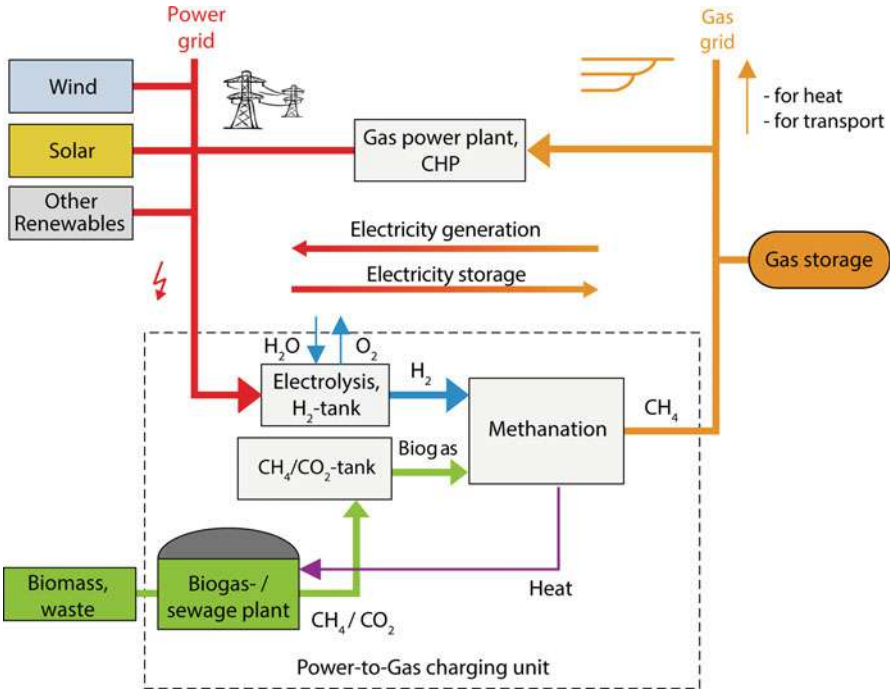

Fig. 18 PtG methane directly reacting a CH_4/CO_2 mixture from biogas or gas purification plants (Source: Sterner 2009)

everything into account, this process may still be more advantageous than energy-intensive downstream separation.

Allocation of Emissions
The allocation of CO_2 emissions is quite a challenge. On the one hand, CO_2 is disposed of by the power plant, on the other hand it is not emitted until the combustion of methane, whose production is based on renewable energies. For this reason, the concept is climate neutral at best. Clear allocation of emissions to coal power stations or gas consumers is required. Otherwise, emissions can be outsourced from the power sector to the heat and transport sector, where the emissions trading law does not apply. So-called green washing of coal power plants is to be avoided.

It is of great importance for this concept that coal power stations are not operated above their must-run limit when methanation is in progress in times of great wind and solar feed-in. In this way, energetically pointless conversion of a chemical energy source to an electrical one and following reconversion (so-called chemical short circuit) can be avoided. Renewable feed-in is mainly there to replace fossil power plants. Electrolysis must not be supplied with electrical energy by fossil power plants.

CO_2 Recycling from Gas Power Stations and Other Sources

Principle
In order to create a closed carbon cycle, the oxyfuel combustion process can be applied to combustion of thus produced methane in gas power stations. This requires spatial proximity of storing and extraction technology, because pure oxygen from electrolysis is needed for clean burning, whose only product gases are carbon dioxide and water. Thus produced CO_2 can be recycled to methane; therefore, the carbon cycle is closed, and the use of CO_2 is climate neutral.

Other Sources
Another possibility is the use of fossil CO_2 from energy-intensive industrial plants, such as steel works, paper mills, or cement plants. They supply their high energy consumption for process heat (possibility of waste heat integration) by combustion of fossil energy sources. This source of CO_2 is very favorable, because they also allow reduction of material, nonenergetic CO_2 emissions. Further sources are waste gases from engine test benches or special industrial processes.

Efficiency, Potentials, CO_2 Emissions, and Costs

Efficiency Increases Because of Integration of High Temperature Electrolysis

Irrespective of which specific process is applied to produce a specific end product, all production variants for synthetic carbon hydrates have one thing in common: while

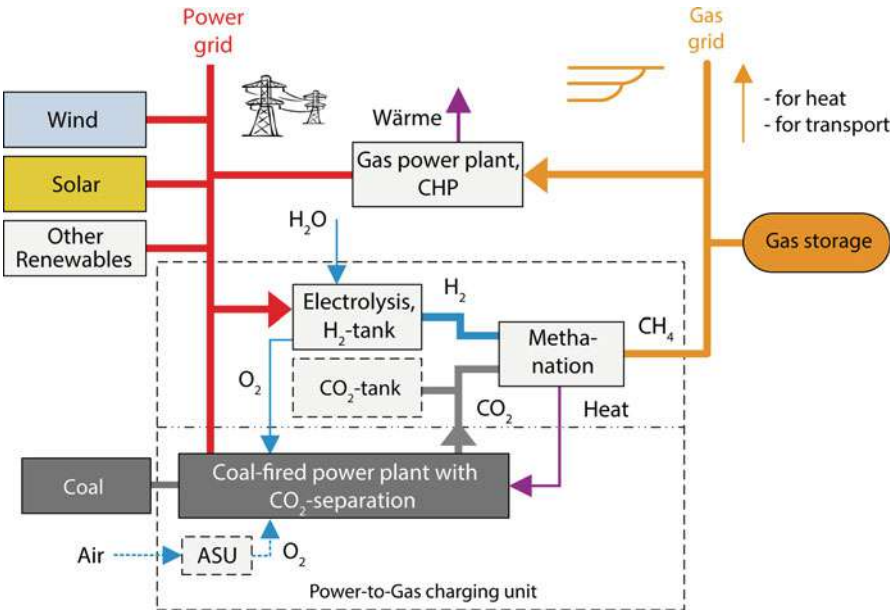

Fig. 19 PtG methane using CO_2 emitted by coal power stations via oxyfuel combustion process (Source: Sterner 2009)

production of hydrogen is an endothermic reaction at the beginning, during the exothermic synthesis of hydrogen and carbons to carbon hydrates, such as methane, methanol, gasoline, diesel, kerosene, or waxes, parts of previously supplied electrical energy are released in the form of heat.

It is this thermodynamic fundamental principle efficiency losses compared to pure hydrogen production are based upon for production of synthetic carbon hydrates. These losses can only be compensated for by reintegration of waste heat released during the process.

One way to achieve this is to vaporize feed water and supply thus produced vapor to steam electrolysis (HTEL). Now, electrical energy only has to supply the net calorific value (NCV) instead of the gross calorific value (GCV), which it has to provide for water electrolysis.

This thermodynamic saving of 16 % electrical energy by recuperating waste heat allows production of synthetic carbon hydrates with an efficiency similar to pure hydrogen production.

These two process chains are compared in Figs. 19 and 20. The thermodynamic maximum efficiency is 84 % for each one, which equals the difference between GCV and NCV of hydrogen (NCV_{H2}/GCV_{H2} – ratio). Efficiency rates expected in practice are between ca. 65 % and 79 %.

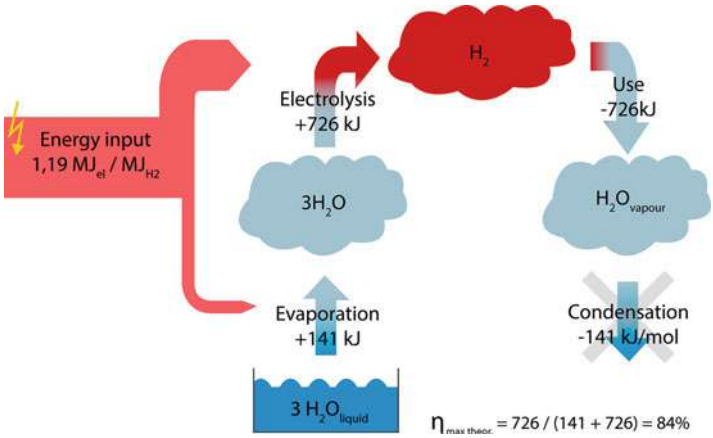

Fig. 20 High temperature electrolysis for hydrogen production from steam without recuperation of waste heat from syntheses (Source: Sterner and Stadler 2014)

Efficiency Rates of Power-to-Gas Systems

A complete PtG system contains

1. Transformer ($\eta = 90$ %)
2. Electrolyser ($\eta = 70$ %)
3. Methanation ($\eta = 82.5$ %)
4. Compression and gas storage ($\eta = 97$ %)
5. And an extraction technology, which can vary depending on the energy service

These average efficiency rates result in different overall efficiency rates (see Table 4). Efficiency of pure PtG hydrogen storage systems are some 5–12 % higher than systems with methanation, because of the missing interim step.

Potentials for Energy Storage

Other than the power grid, the gas grid offers enough transmission and storage capacity. In gas storage, there is a chemical respectively thermal storage capacity of 217 TWh with considerable potential for expansion. Thus stored gas can provide some 120 TWh electricity or 20 % of Germany's gross power consumption and fill all major gaps in renewable energy supply, if reconverted efficiently via sufficient combined cycle plants at an efficiency rate of 60 %.

For systems including methanation, this capacity is completely available. For feed-in of hydrogen, respective limits have to be considered. Assuming an average tolerance of 1–2 %, there is 2–4 TWh storage capacity for hydrogen. However, this value is purely theoretical, because it is based on the assumption that hydrogen is evenly distributed over Germany. Many gas grids' flows vary with the season. In reality, mainly hydrogen caverns are suited for hydrogen storage.

Table 4 Efficiency chains for different PtG storage systems (source: own depiction, based on (Sterner and Jentsch 2011), completed by recuperation of waste heat from synthesis for HTEL)

Path	Overall efficiency (%)	Boundary condition
Power-to-Gas		
Power to hydrogen	54–79	Compression to 200 bar (gas storage)
Power to methane	49–78	
Power to hydrogen	57–80	Compression to 80 bar (long-distance and transport lines)
Power to methane	50–78	
Power to hydrogen	64–84	No compression
Power to methane	51–79	
Power sector		
Power to hydrogen to power	34–51	Conversion to electricity via fuel cell
Power to methane to power	30–38	Combustion in combined cycle plant (60 %)
Transport sector		
Power to hydrogen to motor power	38–53	Use in fuel cell (60 %)
Power-to-gas to motor power	24–49	Reconversion via combined cycle plant and use of electric vehicle (80 %)
Power to methane to motor power	18–37	Combustion in gasoline engine (35 %)
Heat sector		
Power to methane to heat and power	43–68	CHP (45 % heat, 40 % power)
Power to methane to heat	53–84	Condensing boiler (105 %)

For comparison, pump storage plants have a storage capacity of 0.04 TWh. If, theoretically, all 42 M existing cars in Germany were electric vehicles with a capacity of 20 kWh each and on the grid at the same time, they could provide 0.42 TWh storage capacity. This calculation is realistically based on the assumption that half of the cars can be used to balance deficits. At a discharge rate of 60 GW, they could stabilize the power grid for some 7 h. Extraction of all gas storage would suffice, at the same rate, for 2,000 h or 3 months. This comparison makes clear what a huge storage potential Power-to-Gas has.

Along with storage capacity, the gas grid supplies a well expanded transport and distribution network. While typical transmission lines limit transmissions to 3.5 GW (two 380 kV three-phase systems), the long-distance trans-Europe natural gas pipeline can transport gas equal to some 70 GW.

This means the coupling of power and gas grid does not only make storage of great amounts of energy possible, it also allows their spatial separation of storing and usage of renewable methane. This is a unique selling proposition of PtG.

CO_2 Emissions of Power-to-Gas

Potential to Decrease CO_2 Emissions with Renewable Electricity Only

Two things are of importance for the climate impact of PtG storage systems: The source respectively supply of electricity and the substituted energy source.

In summary, it can be said that only renewable, CO_2-free electricity is environmentally friendly and has a decreasing effect on emissions. Gray electricity from coal or gas for hydrogen or methane production is not only energetically absurd but also causes many times over the emissions conventional hydrogen or methane do. This is revealed even by a simplistic greenhouse gas balance:

If cheap lignite electricity (1,161 g CO_2-eq./kWh) is conversed to methane at an efficiency of 60 % (1,935 g CO_2-eq./kWh) and reconverted to electricity via combined cycle plant at an efficiency of 60 %, storage electricity with 3,225 g CO_2-eq./kWh has been produced (see Table 5). This is almost eight times the amount of fossil power from natural gas.

The same applies for transport: at a thrifty consumption of 40 kWh/100 km (ca. 4 l diesel or 0.4 kWh/km) a vehicle fuelled by lignite PtG emits 774 g CO_2-eq./km, which is six times more than fossil diesel (126 g CO_2-eq./km).

In spite of this negative environmental balance, lignite electricity is in discussion to supply PtG, because it is currently the cheapest power on the market. At this point, opposing goals of economy and ecology, as discussed in section "The Need for a Storage Transition in Energy Transition", become clear.

Potential to Decrease CO_2 Emissions: Also a Question of Which Energy Source Is Substituted

The second point of climate impact of PtG is the question, in which order fossil energy sources are substituted. It is essential, if the federal government's goals are to be achieved and climate protection is to be further established, to substitute all fossil energy sources with renewable energies, renewable fuels, and energy storage in all sectors. First, the procedure of substitution should remove emission-rich energy sources, such as coal, subsequently low-emission energy sources, e.g., natural gas.

As shown in Table 5, substitution of lignite and hard coal in the power sector is the first choice from a climate protection point of view. In the first step, coal is replaced by wind, sun, and water power, and in the second step by energy storage, such as Power-to-Gas. Since PtG is only deployed in rare times of deficits of renewable energies, efficiency losses are acceptable.

Substitution of gasoline and diesel fuels makes sense, as long as they cannot be replaced by direct usage of renewable electricity in electric vehicles.

An extrapolation of the potential to decrease CO_2 emissions from one single plant to all of Germany is only possible, if surplus quantities are taken into account (section "The Storage System Power-to-Gas"). As a rule, it can be said that:

Table 5 Emissions of fossil energy sources and PtG storage systems in g CO_2-eq. per energy unit (kWh) and per energy service resp. in g CO_2-eq. per km mileage at a very moderate consumption of 40 kWh/100 km (ca. 4 l diesel/100 km); based on 100 % combustion, conversion losses included. Reference system 2010. Gray electricity mix emissions: 546 g CO_2-eq./kWh (Source: Icha 2013)

Energy source	g CO_2-eq./kWh_{th} combustible	g CO_2-eq./kWh energy service	g CO_2-eq./km mileage	Energy service
Fossil systems				
Lignite	404	1,161 ($\eta = 0.35$)		Power
Hard coal	339	902 ($\eta = 0.38$)		
Natural gas	202	411 ($\eta = 0.49$)		
Natural gas	202	224 ($\eta = 0.9$)		Heat
Heating oil	266	296 ($\eta = 0.9$)		
Diesel	266		106	Transport
Natural gas	202		81	
PtG systems (efficiency of electricity to gas: 60 %)				
Lignite – gas	1,935	3,949 ($\eta = 0.49$)		Power
Gray electricity – gas	950	1,857 ($\eta = 0.49$)		
Wind gas	33	68 ($\eta = 0.49$)		
Lignite – gas	1,935	2,050 ($\eta = 0.9$)		Heat
Gray electricity – gas	950	1,011 ($\eta = 0.9$)		
Wind gas	33	37 ($\eta = 0.9$)		
Lignite – gas	1,935		774	Transport
Gray electricity – gas	950		364	
Wind gas	33		13	

– The deployment of renewable electricity is a basic prerequisite
– The more CO_2 intensive a substituted energy source, the greater the reduction potential

Costs of PtG

Market Conditions

Hydrogen produced by steam reforming of natural gas causes production costs of 3–4 €-¢/kWh, natural gas costs 2–3 €-¢/kWh at the stock market, and gray electricity between 1 and 6 €-¢/kWh (see EEX 2014). Surplus electricity for even smaller prices is only available for a very small number of hours, which shows how difficult it is for PtG to competitively convert Power-to-Gas.

Economic Efficiency

PtG is a very young energy technology; today, it cannot be realized economically. Investment costs for new plants are between 2,500 and 5,000 €/kW; operating costs

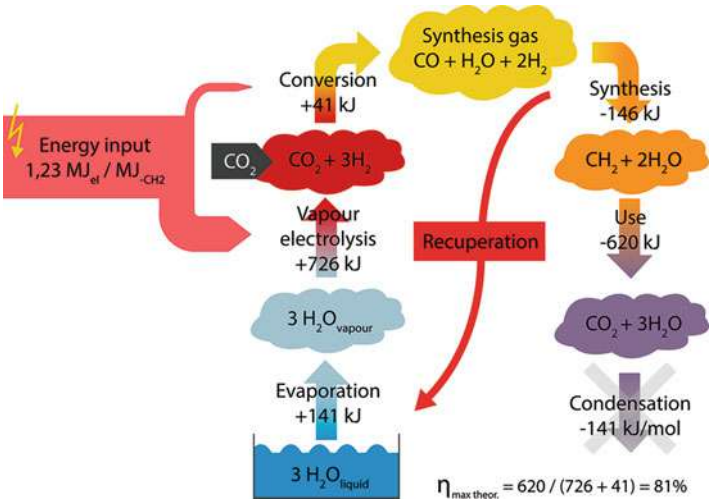

Fig. 21 High temperature electrolysis for carbon hydrate production from steam and CO_2 with recuperation of waste heat from syntheses for vaporization of water. Similar efficiency rates as pure hydrogen production (Source: Sterner and Stadler 2014)

are mainly subject to electricity prices, which vary between 0 €-¢/kWh (very rare) and 9 €-¢/kWh (average price for wind power).

Figure 21 shows results of elaborated cost calculation that were made in the course of the project "Energy Storage Concepts" for PRG hydrogen and PtG methane. These results are shown as a range from optimistic (low investment and operating costs, low interest rates, and low risk) to pessimistic expectations (high investment and operating costs, high interest rates, and high risk). All assumption can be seen in detail in Henel et al. (2013).

Economically competitive production of renewable hydrogen or methane requires more than 7,000 h electricity supply at 0 €-¢/kWh without further levies. From today's point of view, this scenario seems more than unlikely.

Only after a concept with electricity supply costs of 5 €-¢/kWh in base load operation (more than 7,000 h) has been developed, e.g., sail powered energy, it will be possible to supply hydrogen for 8–17 €-¢/kWh and methane for 13–24 €-¢/kWh. If levies for CO_2 or prices for natural gas were to increase, renewable gases could be an economical and sustainable alternative, even for higher costs.

It becomes clear that hydrogen can only be produced economically in the most optimistic case, which means almost constant electricity supply at stock market prices or below can be used. But this means that something else than surpluses of wind or solar energy are used, because they occur only very rarely and not on a constant basis. If gray electricity is used, the product gas is the same as fossil gas concerning disadvantages in the CO_2 balance and marketing. In many places in Germany, feed-in management is used to curtail surpluses. At the moment, the absolute value is within limits: in the past year, only ca. 1 ‰ of Germany's energy consumption has been curtailed.

A basic rule for PtG: only if electricity supply is mainly renewable (more than 80 %), the produced gas has the privilege to be equal to biogas. This simplifies the connection of the PtG plant to the gas grid and the gas' benchmark is increased from 2–3 €-¢/kWh (fossil natural gas) to 7–8 €-¢/kWh (bio-natural gas).

If the stored gas is reconverted to electricity via gas power station, thus generated power costs some two times more because of the complete electricity storage chain.

From today's point of view, market entry seems most likely in the field of fuels for transport or resources for the chemical industry, because the price level is higher in there than in the electricity and heat market.

Hydrogen Versus Methane

On the one hand, a PtG hydrogen storage system does not require a methanation unit and therefore saves efficiency and costs. On the other hand, costs are not assessable for the adaption of plants incompatible to hydrogen in the gas infrastructure or setting up a hydrogen infrastructure. For this reason, the exhaustion of hydrogen admixture quotas of 1–2 % including downstream methanation is favorable for long-term storage with PtG, from today's point of view. More information can be found in the gas grid development plans (see Netzentwicklungsplan Gas 2012).

Advantages and Disadvantages of Hydrogen and Methane

PtG Hydrogen

A PtG hydrogen storage system is favorable, for reasons of efficiency and costs, as long as admixture limits of hydrogen are not exceeded or hydrogen can be stored and used locally. It has to be preconceived that, for small natural gas flows, admixture limits are reached very quickly and storage has to be applied in order to level hydrogen feed-in.

Unlike for methane and natural gas, there are no comprehensive solutions suitable for the mass. While fuel cell technology is subject to research in auto industry and heat supply long since, technologies ready for the market are merely announced time and again. Furthermore, market entry is only possible, and even then merely in small quantities, if subsidized by companies or the public purse. It is also yet to be seen if fuel cells will come on top of e-mobility, conventional powertrains, electric heat pumps, and alternative renewable heating systems based on wood and sun.

When adding hydrogen to the natural gas, changing fuel properties of the gas mixture have to be taken into account. For one thing, the volumetric calorific value decreases by some 7 %, depending on the natural gas quality, if 10 % by volume hydrogen is added. This has to be compensated for by an increased quantity to be supplied, which in turn requires adaption of, for example, compressors.

The adaption of the natural gas infrastructure to higher admixture quotas is associated with the need for research and high costs.

Figure 22 shows which components are particularly affected and the existence of need for adaption and research.

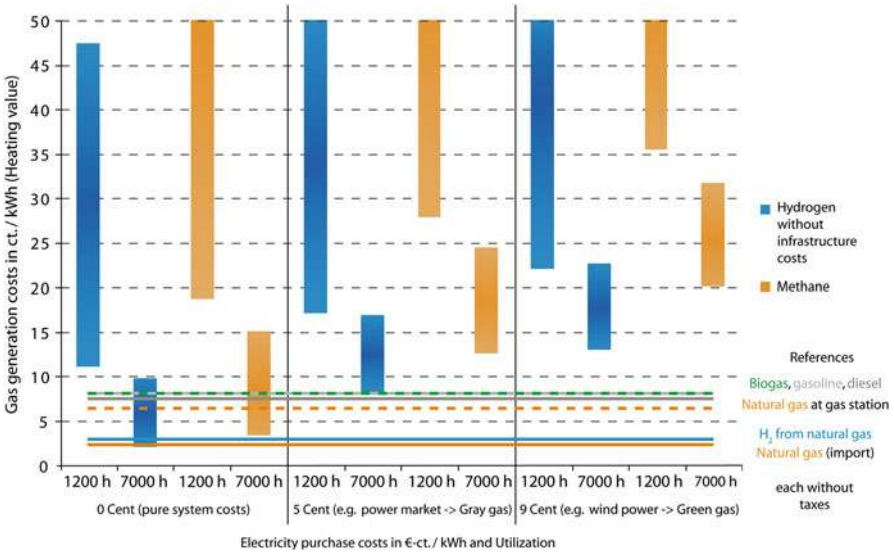

Fig. 22 Range of gas production costs in €-¢/kWh for PtG hydrogen and PtG methane for different electricity prices and full load hours in the DVGW project "Energy Storage Concepts." Hydrogen paths are represented in blue, methane in orange, each in a range from optimistic to pessimistic. Electricity supply is plotted from 0 €-¢/kWh (plant costs only) over an average value for stock market prices (5 €-¢/kWh) to electricity supply by a wind power plant (9 €-¢/kWh), each for different periods of use and utilization time (the year has 8,760 h). Reference costs for gases and fuels made with fossil and biogenic energy are depicted as dashed lines (Source: adapted from Henel et al. (2013))

In the transport sector, it has to be taken into account that natural gas must not contain more than 2 % by volume hydrogen, because higher concentrations may cause embrittlement of steel tanks in CNG vehicles. But also for reconversion to electricity, high shares of H_2 are problematic: gas turbines are only operational, as specified by the manufacturer, for admixture quotas between 1 % and 3 % by volume, because of changing combustion characteristics (increased flame velocity, different temperature, etc.). For this reason, even cogeneration plants which are, according to manufacturer's data, hydrogen-tolerant up to 25 % are in practice operated with only 15 %.

In general, it is assumed that the admixture limit for hydrogen in the natural gas grid is 1–1.5 %. High local feed-in of hydrogen may cause problems if the natural gas load flow is low, because limits are exceeded locally. Additionally, there are some industrial gas applications, which use gas as "flaming tool" (e.g., drying in the porcelain and glass industry). Fluctuating gas quality can have a strong influence on the product quality (see Henel et al. 2013).

Since conditions and requirements in long-distance and distribution gas grids vary strongly both locally and regionally, each possibility for the feed-in of the additive gas hydrogen has to be checked individually.

According to the FNB's (long-distance grid operators) gas grid development plans, increasing the admixture limit from today's 1–1.5 % to 10 % requires the replacement of all compressors, which costs 3.6 Bio. € in the long-distance grid alone (see Netzentwicklungsplan Gas 2012).

Advantages and disadvantages of feed-in of hydrogen into the gas grid versus PtG methane are compared in Fig. 23 and Table 6.

PtG Methane

The storage system PtG methane has certain advantages compared to the hydrogen system and other long-term storage systems but also disadvantages.

The systems advantages are obvious. It is possible to integrate renewable methane in today's energy infrastructure without any problem, since it has the same quality, it can fully replace natural gas ("replacement gas"). Unlike hydrogen, the use of renewable methane is uncritical regardless of admixture quotas for gas turbines, porous storage, distribution lines, seals, and applications, such as combustion engines or gas stoves.

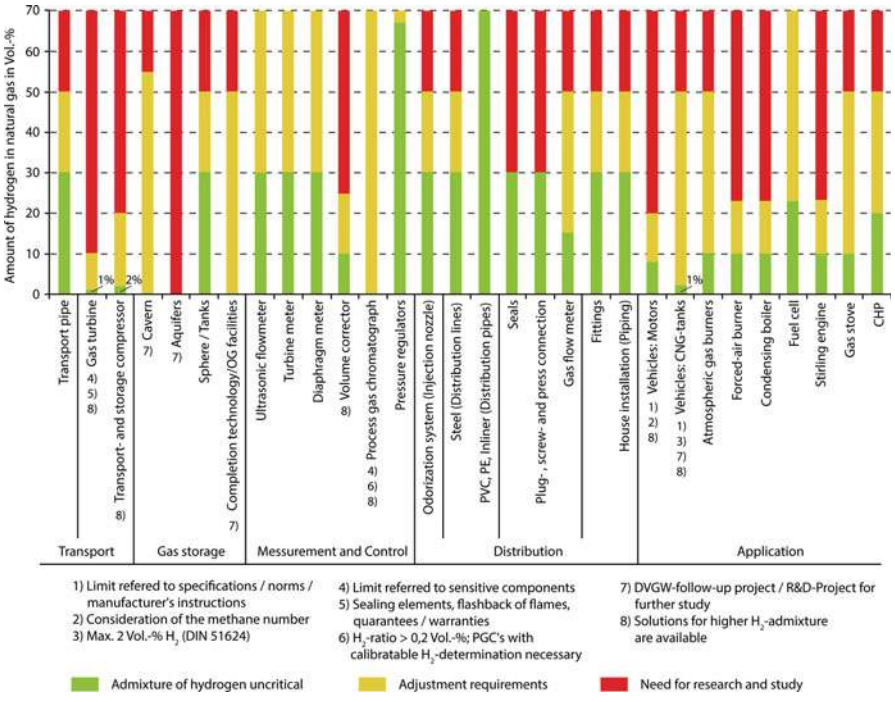

Fig. 23 Hydrogen tolerance of specific components of the gas infrastructure (Source: Henel et al. 2013)

Table 6 Advantages and disadvantages of a PtG storage system with hydrogen and methane

	Hydrogen		Methane	
	Advantages	Disadvantages	Advantages	Disadvantages
Efficiency				
Storing technology	54–84 %		Equal	49–79 %
Storage	Equal		Equal	
Extraction technology	Equal			
Feed-in into the gas grid	Equal	Additive gas: today's admixture limit 1–1.5 %; max. 2 % by Volume	Replacement gas: no limit	
Infrastructure		Largely nonexistent, no affordable and fully developed application technology	Existing infrastructure including application technologies, usable to the full extent	
Transport				
Storage				
Application				
Material demand, climate impact, and plant operation	Independent of CO_2, therefore more flexible siting (except for usage of atmospheric CO_2 for methanation)	Additional hydrogen storage necessary for fluctuating load flow of natural gas	Possible CO_2 sink if operated in CCS mode	Necessity of a CO_2 source, continuous methanation is based on upstream hydrogen production
Energy density (specific calorific value at 0 °C and 1.013 bar or space requirement for storage)		3.0 kWh/m³	10.0 kWh/m³ Three times more, smaller storage system possible	
Transformation costs	Cheaper than methane up to the admixture limit	Storing: Electricity – H_2 Storage Extraction: H_2 – electricity Transport, storage		Only storing and additional methanation and CO_2 supply versus hydrogen

Furthermore, there exists already a large and widely distributed infrastructure for energy transport, storage, and application technology. This means there are well-established state-of-the-art applications in every energy sector and in the chemical industry.

Another advantage is the higher volumetric energy density of methane compared to hydrogen, which makes smaller storage systems possible and saves cost and space. With reference to one standard cubic meter, the calorific value of methane is 3.3 times that of hydrogen.

The cost situation of this storage system requires a differentiated review. Up to the admixture limit of hydrogen, a system without methanation is more economical, because they operate without CO_2 supply and methanation units. As soon as that limit is reached, it is more cost-efficient to store renewable energy in the form of methane instead of adapting the German infrastructure to a higher admixture quota of hydrogen.

A disadvantage of PtG methane is its need for CO_2 supply. Efficiency losses of the overall process reflect the additional expenditure. But, on the other hand, the extraction and storage of atmospheric CO_2 is a possibility to reduce its concentration in the air by the energy system itself and in the long run, CO_2 extraction from air might become a necessity in fighting global climate change anyway and therefore cheaply available. In any way, it is important to operate PtG with a closed carbon cycle.

Decarbonization with Power-to-Gas

So far, the necessity for energy storage and the physical, economical, and ecological parameters of the technology of Power-to-Gas have been described in detail. Now, a brief outlook on the potential for decarbonization with Power-to-Gas is given in the context of the energy transition in Germany and more over is given.

Technical Pathway of Decarbonization

As seen, PtG can be very useful for the decarbonization of electricity and heat: It offers the required long-term storage for weeks of no wind and solar energy at reasonable cost and is a supplement/addition to biomass, geothermal energy, and solar energy for decarbonizing heating and cooling systems. The access is also given for mobility: although electric vehicles will be the most efficient way of using wind and solar power, their range is limited. Long-distance mobility, lorries, ships, and airplanes still demand energy carriers with high energy density. These can be hydrogen or SNG from Power-to-Gas or even wind kerosene or wind diesel from Power-to-Liquid. Biofuels will have their share also in heavy duty applications like tractors, but their potential is limited and not sufficient to cover all high energy density fuel demand (Sterner and Schmid 2009). A possible pathway towards decarbonization of the whole energy sector is given in Fig. 24.

Power-to-Gas or Power-to-X will also be required to decarbonize the chemical industry. This sector is also using large amounts of fossil fuels like oil and gas in a nonenergetic way. To decarbonize industrialized nations not only by 80 % (2 °C goal) but by 95 % (1.5 °C goal), Power-to-X will become a requirement, since there

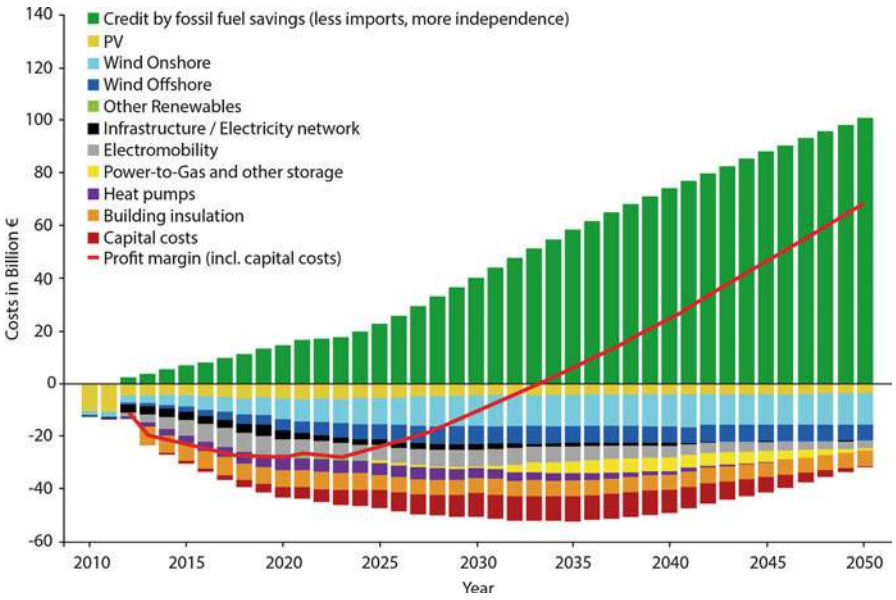

Fig. 24 Energy transition scenario for all energy sectors in Germany until 2050 – costs and savings in Mio. €/a (Source: Gerhardt et al. 2014)

are no other technologies left that can technically do this. As mentioned, biomass does not have the potential but chemical products from wind and solar do.

Costs of Decarbonization with Power-to-Gas

So technically, the energy transition and decarbonization is doable. And it is also feasibly regarding costs: wind and solar show generation costs below 10 €-cts/kWh and are therefore less expensive than new coal, gas, or nuclear power generation. What is missing is the cost for storage and balancing. The EU imports fossil energy carriers worth 400 Bio. € each year. If this money would be saved by the implementation of locally available renewable energy, it could refinance the necessary expensive infrastructure for networks and storage. There are calculations for Germany, that show a macroeconomic return of invest rate of 4–7 %, if a moderate increase of fossil fuels prices are assumed (see Fig. 25 and Gerhardt et al. (2014)).

Necessary Policy Framework

What is then left for decision makers in the EU and worldwide? First of all, remove subsidies for fossil energy. Second, a must for the energy transition is the interlinkage of electricity, gas, heat, and transport sectors. The technical possibilities are given and should be used (Fig. 26).

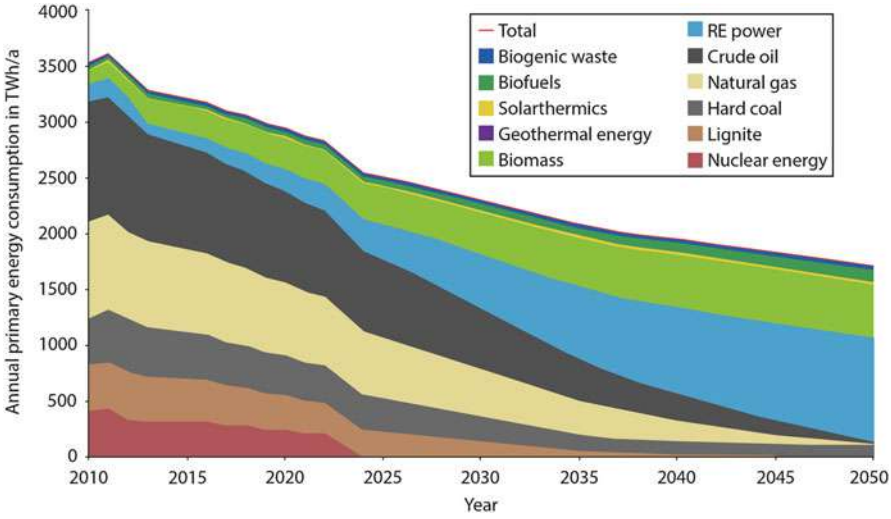

Fig. 25 Energy transition scenario for all energy sectors in Germany until 2050 – primary energy sources and demand in TWh/a (Source: Gerhardt et al. 2014)

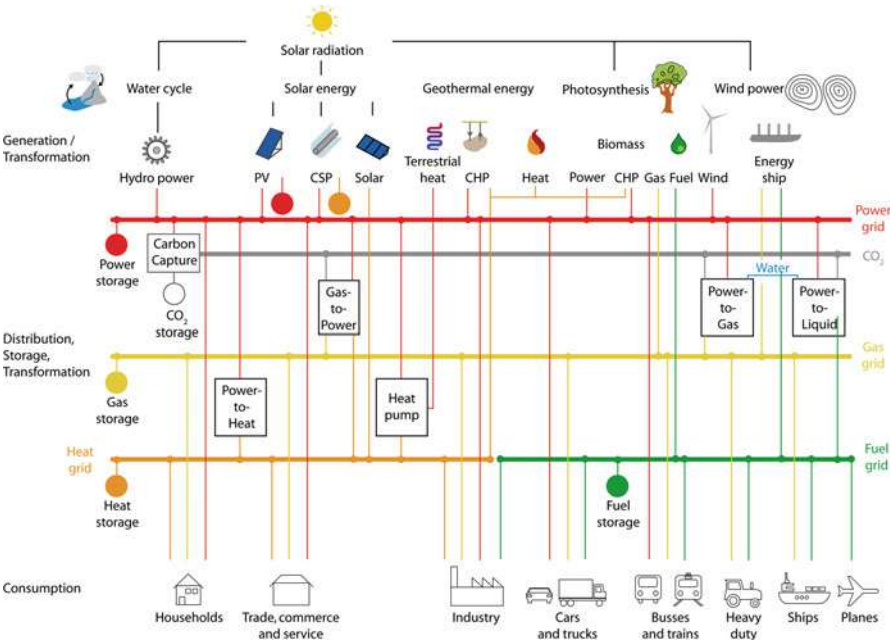

Fig. 26 Technical pathways of the decarbonization of energy sectors, mobility, and chemical industry via renewable energy and interlinked energy storage and transport infrastructure and Power-to-Gas/Heat/Fuels at the heart of the system (Source: Sterner and Stadler 2014)

Energy markets should be merged via energy storage and energy transmission. Power-to-Gas and Power-to-X are essential technologies that save costs by using existing storage and transmission infrastructure. Storage technologies should be developed in Europe to create jobs and values in the EU with these complex system technologies that would be needed worldwide at some point of time in future. But without framework conditions, we would not see a large-scale development of storage that is needed to bring costs down by mass production. To reduce import dependence, it is helpful to build up strategic "renewable reserves." The still cost-intensive technologies like storage or electromobility should be cross-financed by CO_2 funds, fossil fuel savings, and cheap renewables. To enable this transition, market barriers have to be removed. That includes better access of storage and renewables to control power markets, the avoiding of double taxing, and the implementation of limited tax exemptions. The storage problem is solved technically and global markets are ahead, but in history, no new energy technology did its way to the market without official support. Another requirement is the mandatory use of renewable power for storage, electromobility, and heat pumps. Otherwise, with fossil power, these new technology do not have the desired impact on climate change.

And last but not least: policy makers need to explain to people the need of this energy transition due to climate change, import dependency, and depleting fossil resources in an open, transparent, and decisive way. We can find nice technical, eco-friendly solutions that are economic, but if we don't convince society, we would implement decarbonization. Besides an energy transition, there is therefore also a strong need for the transition of storage and the transition of consciousness and awareness.

Concluding Remark

The chapter shows that BioCCS (Biomass and CCS) is not the only option to reach the 1.5 °C climate target and that storage systems are ready for decarbonization of all sectors

Changes in the Future

- Cost updates will be implemented.
- Eventually emission reduction scenarios will be integrated.

Reduction of Greenhouse Gas Emissions by Catalytic Processes

Gabriele Centi and Siglinda Perathoner

Contents

Abstract

Catalytic technologies for the abatement of greenhouse gases (GHGs) can effectively limit the increasing tropospheric concentration of GHGs and reduce their contribution to global warming. After introducing the general possible applications of catalytic technologies for GHG abatement, two specific cases are discussed: (1) reduction of anthropogenic emissions of non-CO_2 GHGs (N_2O and CH_4) and (2) reduction or conversion of CO_2.

W.-Y. Chen et al. (eds.), *Handbook of Climate Change Mitigation and Adaptation*,
DOI 10.1007/978-3-319-14409-2_49

Combustion is one of the main options for controlling methane emissions. The use of catalytic combustion may yield economic benefits, due to the usually low concentration of methane in its emissions, and avoid the formation of by-products in traces like formaldehyde, which may be more harmful than methane itself. The types of catalysts, mechanism of action, and reactor options (regenerative catalytic combustion, reverse flow catalytic combustion, and catalytic combustion using a rotating concentrator) are discussed.

The catalytic control of N_2O emissions shows different specificities, because different types of emission sources are present. The catalytic abatement or reuse of N_2O from industrial emissions (particularly adipic and nitric acid production), the treatment of emissions from power plants or waste combustion, the alternatives of catalytic decomposition or reduction, and the role of the other gas components (O_2, NO_x, SO_x) are analyzed.

The problem of the catalytic conversion of fluorocarbons is also briefly discussed.

The case of carbon dioxide is different because, in this case, the issue is the development of cost- and energy-effective catalytic routes for its conversion to usable products. There are many catalytic routes for using CO_2 as a building block in organic syntheses to obtain valuable chemicals and materials. Attention has focused recently on the catalytic conversion of carbon dioxide to fuels. In this case as well, different options exist, such as hydrogenation to form oxygenates (e.g., methanol) and/or hydrocarbons, dry reforming with methane, reverse water gas shift, or, in a longer-term perspective, different methods using solar energy directly or indirectly (via bioconversion). Limitations and possible advantages of these different options are analyzed.

Introduction

The control of GHG emissions from anthropogenic sources is becoming a global challenge. In addition to regions such as Europe at the forefront of measures to reduce GHG emissions, there is a global trend to adopt advanced environmental political measures to reduce GHG emissions. EU leaders agreed on 23 October 2014 the domestic 2030 GHG reduction target of at least 40 % compared to 1990, following the roadmap on GHG emissions approved from the European Parliament for their reduction to 80 % with respect to 1990. On 11 November 2014, a historic US-China Joint Announcement on Climate Change reported that the USA and China joined the European Union in committing to new limits on GHG emissions. These three economic powerhouses emit about as much each year as the rest of the world combined, so their commitments have important implications for the world's ability to stay within its carbon budget. The USA will reduce GHG emissions 26–28 % from 2005 levels by 2025. China announced its intent to peak carbon dioxide emissions around 2030 (around ten billion metric tons per year, with respect to emissions leveling off between 2030 and 2040 at approximately 12–14 billion metric tons per year) and to strive to peak earlier by reducing carbon emissions per unit of GDP by

40–45 % from 2005 levels by 2020. The Cop 20 (UN climate change) conference (Lima, 1–12 December 2014) for the first time commits all countries – including developing nations – to cutting GHG emissions.

The IPCC Fifth Assessment Report, finalized in November 2014 (Pachauri and Meyer 2014), showed how the "warming of the climate system is unequivocal" and "continued emission of greenhouse gases will cause further warming and long-lasting changes in all components of the climate system, increasing the likelihood of severe, pervasive and irreversible impacts for people and ecosystems." The report also remarked that "without additional mitigation efforts beyond those in place today, and even with adaptation, warming by the end of the twenty-first century will lead to high to very high risk of severe, widespread, and irreversible impacts globally (high confidence)."

The implementation of the decisions taken at a political level coincides with the scientific indications deriving from the cited IPCC report that it is necessary to accelerate the measurer to reduce GHG emissions. Catalytic technologies offer effective cost-basis solutions for their control (Centi et al. 1999, 2003a). The "Technology Roadmap on Energy and GHG Reductions in the Chemical Industry via Catalytic Processes," prepared recently by the IEA and the ICCA in collaboration with Dechema (IEA 2013), evidences the role of catalysis to meet the objectives of GHG reduction in the chemical industry, with a potential impact on the reduction of energy intensity by 20–40 % as a whole by 2050. In absolute terms, such improvements could save as much as 13 EJ and 1 Gton of CO_2-eq. per year by 2050 versus a "business-as-usual" scenario. The white paper "Available and emerging technologies for reducing greenhouse gas emissions from the petroleum refining industry" prepared by US EPA (2010) shows the role of catalysis in reducing GHG emissions in refinery industry, one of the highest industrial consumers of energy.

Although catalysis has been associated traditionally to chemical production and refinery, except for the relevant cases of catalytic converters for mobile sources and DeNOx systems for the reduction of NOx emissions from stationary sources, catalytic technologies for GHG emissions have a broader area of applications, as discussed in this chapter. By including the potential role of converting CO_2 as a way to trade on a worldwide scale renewable energy (presented later), the potential is of several Gton CO_2-eq. Catalytic technologies have thus the potential, although still underestimated, to be one of the pillars to reach the political goals to reduce GHG emissions.

We may distinguish between direct and indirect roles of catalytic technologies in contributing to climate change goals. The direct role is associated to catalytic technologies for the conversion of GHG, either for direct conversion to not harmful products (e.g., conversion of N_2O to N_2) or having lower GWP (e.g., conversion of CH_4 to CO_2) or for reutilization of GHG (e.g., N_2O utilization as selective oxidation or utilization of CO_2 as raw material). In the latter case, it is important to distinguish when the utilization leads to an effective reduction of GHG impact on a LCA basis. For example, the reaction of CO_2 with high-energy molecules such as epoxides to form carbonate needs to account the impact on GHG of forming the epoxide but also the positive impact of producing an alternative material to those based on fossil fuels.

Therefore, the impact is not relative to utilization only of CO_2 as raw material but to the associated effect on LCA bases. It is possible to indicate an effectiveness factor (EF) to the various routes for reducing GHG emissions, for example, for carbon dioxide. Sequestration and storage (CSS) has an average EF value of around 0.5, because it is necessary to consider the energy necessary to capture and store CO_2. On the contrary, several of the routes for chemical utilization of CO_2 have an EF value higher than one, for the benefit in substituting other materials starting from fossil fuels only (Centi and Perathoner 2014; De Falco et al. 2013). When renewable energy is utilized in the process of converting CO_2 to valuable fuels, EF may be even larger than a decade on a timescale of 20 years. It is thus necessary to account this EF value in estimating the impact of the different routes of utilization of GHG and not only the direct amount of GHG utilized as raw material.

The indirect role of catalytic technologies in contributing to climate change goals is related to various aspects, from the role of catalysis to produce biofuels having lower GHG impact (on LCA bases) with respect to the equivalent fossil fuel-based ones to the role of catalysis in developing new production routes having a better efficiency of using raw materials and energy (Centi and Perathoner 2014). There are additional aspects more difficult to estimate in terms of positive impact on climate change goals. For example, enabling a new competitive catalytic route to produce polyurethane foams (using CO_2 as one of the feedstocks), in addition to a specific benefit (compared to production of conventional polyether polyols, the production of polyols with 20 wt% CO_2 allows for GHG reductions of 11–19 % as shown by von der Assen and Bardow 2014), allows further benefits related to the utilization of the foam to insulate buildings. We limit discussion here, however, to only routes related to the direct role of catalytic technologies in contributing to climate change goals.

A further necessary preliminary differentiation is between technologies for converting non-CO_2 greenhouse gases (NCGG) and those related to utilization of carbon dioxide (CO_2), due to the different types of sources and problems to address. In fact, NCGGs have typically a GWP (over a 20-year time horizon) significantly larger than CO_2, which is conventionally put equal to one: 72 for CH_4, 289 for N_2O, to values ranging from 3000 to over 16,000 for hydrofluorocarbon depending on the specific structure. The emissions of NCGGs are lower of those CO_2: in 2010, the sum of NCGG emissions was about 15 Gton CO_2-eq. with respect to about 35 Gton CO_2-eq. emissions of CO_2 from fossil fuel exploitation plus land use change (Montzka et al. 2011). On the average, NCGGs contribute to about 35–45 % of total climate forcing from all LLGHGs (range represents direct forcing to the sum of direct and indirect forcing). Climate or radiative forcing is the time-dependent responses of the warming influence. Cut NCGG emissions could substantially lessen future climate forcing, with additional ancillary benefits that include reduced costs for climate mitigation relative to CO_2-only approaches, improvements in air and water quality, reduced acid deposition, and decreased eutrophication of aquatic ecosystems (Montzka et al. 2011).

There is a tendency to increase NCGG emissions, for example, due to the increase of shale gas production (CH_4) and biofuels (N_2O, due to the larger use of fertilizers in monocultures).

Short Introduction to Catalytic Concepts, Materials, and Technologies

The reduction of GHG emissions by catalytic processes belongs to the general area often referred to as environmental catalysis or catalysis for environment protection, which is part of the broader area of catalysis for sustainable industrial production (Cavani et al. 2009). The largest part of catalytic technologies in this field is based on solid catalysts, because cost, pressure drop, effectiveness in a wide range of experimental conditions, low sensitivity to deactivation, and ease of management and handling are the critical aspects for these applications. Solid (heterogeneous) catalysts offer advantages over homogenous catalysts from these points of view and for this reason predominantly used in the area of environmental catalysis.

The term "solid or heterogeneous catalyst" indicates a material having one or both of the following characteristics:

- Increases the reaction rate (moles converted per unit time) of a chemical reaction, thus enhancing the conversion of a reagent, that is, the moles of a reactant converted with respect to inlet moles of the reactant
- Changes favorably the reaction rate of one reaction with respect to competing reactions, thus enhancing the selectivity, that is, the fraction of moles of the reagent(s) converted to the desired product

The catalyst itself does not undergo any permanent change, although it participates in the reaction mechanism providing an alternative reaction pathway, which modifies the energy associated with the pathways of reaction (activation energies of formation of reaction intermediates). However, the thermodynamics of the reaction (e.g., the net reaction enthalpy and free energy) do not change. The catalyst thus changes the kinetics, not the thermodynamics, of the reaction.

A catalyst may undergo a progressive modification with time, leading to an alteration of the catalytic behavior (usually associated with a loss in catalytic performance, that is, catalyst deactivation), even if formally the catalyst is not modified in the catalytic cycle. This is a consequence of chemical reaction and/or of external factors (e.g., other components of the feed, the reaction temperature, etc.). The three properties that characterize a catalyst are (1) activity, (2) selectivity, and (3) stability (i.e., no deactivation). However, there are a number of other aspects equally important for the choice of the catalyst, such as its texture (porosity) and shape, its macro- and microstructure, and its mechanical strength properties.

In defining the activity of the catalyst, differentiation must be made between the following aspects:

- *Intrinsic activity*, that is, the rate of reaction not affected by mass or heat transfer limitations (see below), which may refer to total weight or volume of the catalyst or to the amount of the active phase or component; the units of measure are moles per time and per mass or volume.

- *Effective activity*, that is, the measured rate of reaction (effective activity depends on the conditions of testing, because it can be influenced by mass or heat transfer limitations); the units of measure are the same as for intrinsic activity. The ratio between effective and intrinsic activity defines the effectiveness factor (η) of the catalyst.
- *Catalyst performances* and specifically the following quantities:
  1. *Conversion*: the ratio between the molar flow of reactant converted with respect to the inlet molar flow of the same reactant.
  2. *Selectivity*: the ratio between molar product flows at the outlet of the reactor with respect to the inlet molar flow of the reactant.
  3. *Yield*: the conversion multiplied by the selectivity.
  4. *Productivity*: the ratio between molar product flows at the outlet of the reactor and catalyst weight or volume. The units of measure are the same as those for the reaction rate, but the two concepts should not be confused.

Conversion, selectivity, and productivity depend on the integrated change in the reaction rate(s) along the reactor. Therefore, these parameters (often indicated as global activity parameters) are not intrinsic characteristics of the catalyst. When more than one reactant is present, conversion, yield, and selectivity should refer to the limiting reactant, that is, the reactant that may limit (also considering reaction stoichiometry) the conversion. However, these parameters (conversion, yield, and selectivity) also can refer to other reactants, and it is therefore a good practice to indicate the reference reactant.

While all these terms depend on the reaction conditions (reaction temperature and reactant composition), conversion, selectivity, yield, and productivity also depend on the type of reactor and space velocity (total volumetric flow of the reactants divided by the volume of the catalyst). The inverse of the space velocity is defined as the contact time, that is, the time required by the flow of reactants to fill the volume occupied by the catalyst. Sometimes, the space velocity refers to the apparent volume of the catalyst, that is, the total volume of the catalyst (this volume depends on the grain size and packing of the pellets) and sometimes to the specific catalyst volume, that is, considering the void fraction of the catalytic bed. For this reason, it is preferable to refer not to the catalyst volume but to the mass of catalyst. In this case, the units of measure of the space velocity (indicated also as space–time) are $g_{cat}s_{cat}mol^{-1}$, that is, the inverse of the units of measure of the reaction rate, although the two concepts are different. In gas–solid catalytic reactions, the space velocity is often defined as GHSV (gas hourly space velocity), which is exactly the same definition as that of space velocity, but the time unit is hours instead of seconds. In liquid–solid reactions, the equivalent definition is LHSV (liquid hourly space velocity).

In the discussed applications, the reactant(s) is typically present in one or more different phases (gas and/or liquid) with respect to the solid catalyst. The reactant (s) should thus diffuse to the catalyst surface before reacting. The reactant(s) diffuses across the boundary gas or liquid layer that surrounds the solid catalyst body (pellet, layer, or film) and diffuses inside the catalyst pore volume. These two steps are referred to below as external and internal diffusion. Often in environmental

applications, the rate of these steps is slower than the rate of the chemical reaction (s) occurring at the catalyst surface, and therefore the rate of the overall process becomes controlled by the mass transfer. Gradients in concentration through the boundary fluid layer and throughout the catalyst pore volume develop.

The heat transfer to or from the catalyst surface (due to the heat generated or consumed by the reaction) can also determine temperature gradients within the catalyst pellet or layer and through the fluid boundary layer. The magnitude of the effect depends on the effectiveness of internal and external heat transfer, which is a function of the rate of heat generation/consumption, the solid characteristics, and the fluidodynamics of the system.

The presence of thermal or concentration gradients influences considerably selectivity, activity, and/or stability. Therefore, proper reactor design integrated with catalyst design is critical to improving performances. Different types of reactors are used commercially in these reactions. The choice depends on various factors, such as the catalyst characteristics, mass and heat transfer limitations, scale-up, fluidodynamic and flow regimes, pressure drop, liquid holdup, etc. However, often there is a contrast between optimal conditions for efficient multiphase contact, high catalyst effectiveness and wetting efficiency, and low fouling/attrition and pressure drop. In these cases, new types of reactors based on structured catalysts are an attractive alternative to conventional reactors, due to low-pressure drop, the absence of a need for catalyst separation, and the large geometrical surface area.

Structured catalysts offer an efficient multiphase contact and minimize the influence on the reaction rate and selectivity of the reagents' diffusion and products' back-diffusion. They also offer some additional advantages: easy catalyst separation and handling, minimization of contamination of the solution by the catalyst, safer operation, improved heat supply and removal, and easier scale-up and technology manageability. The latter characteristics of the structured catalysts often are the critical factors for the selection of these technologies in environmental protection applications. Four main types of macrostructured catalysts can be distinguished: (1) monoliths, (2) foams, (3) cloths, and (4) membranes.

The main classes of catalysts used for the reduction of GHG emissions are metals (noble and not noble metals, typically supported), oxides (typically multicomponent metal oxides in the bulk or support form), and solid acids (clays, mixed oxides, and, in particular, ordered metal oxides: zeolite and mesoporous materials). Solid catalysts come in a multitude of forms and can be loose particles or small particles on a support. The support can be a porous powder, such as aluminum oxide particles, or a large monolithic structure, such as the ceramics used in some applications. The choice depends on many requirements, but the critical ones are the type of reaction and relative reaction conditions and the choice of the reactor to use. Industrial catalysts are generally shaped bodies of various forms, for example, rings, spheres, tablets, and pellets. Monolithic-type catalysts, similar to those in automobile catalytic converters, are also used.

The production of heterogeneous catalysts entails numerous physical and chemical steps. The conditions in each step have a decisive influence on the catalyst properties. Catalysts must therefore be manufactured under precisely defined and

carefully controlled conditions, including the control of the level of the impurities in raw materials, which may have a dramatic effect on the performances. Depending on their structure and method of production, solid catalysts can be divided into three main groups: (1) bulk catalysts, (2) supported catalysts, and (3) ordered porous structure catalysts.

Bulk catalysts are used when the active components are cheap, there are no specific diffusional limitations on the reaction rate under industrial relevant conditions, and other specific requirements (e.g., density and mechanical resistance for fluid-bed reactor applications) are absent. Supported catalysts are the class of catalysts most used industrially. They are used under the following circumstances:

- When expensive active components such as noble metals are employed and there is the need for their effective dispersion over a support that also provides the stabilization of these metal nanoparticles against their sintering
- When a modification of the properties of an oxide by supporting it over another oxide is necessary
- When the density of the catalyst and its mechanical properties are not suited for the specific reactor operation, as well as in other cases

The most common class of ordered porous structure catalysts are zeolites, but there are many more examples, from ordered mesoporous materials (e.g., mesoporous silica such as SBA-15 and MCM-41) to other class of inorganic or inorganic–organic hybrid materials. Zeolites are microporous crystalline solids with well-defined structures. Generally, they contain silicon, aluminum, and oxygen in their framework and cations, water, and/or other molecules within their pores. Many occur naturally as minerals, but the most used commercially are synthetic one due to their better reproducibility.

A defining feature of zeolites is that their frameworks are made up of four connected networks of atoms. These tetrahedra can then link together by their corners to form a rich variety of beautiful structures. The framework structure may contain linked cages, cavities, or channels, which are of the right size to allow small molecules to enter – that is, the limiting pore sizes are roughly between 3 and 10 Å in diameter. There are nearly 200 different types of framework structures prepared and identified, but the theoretical number is much larger. Zeolites have the ability to act as catalysts for chemical reactions taking place within the internal cavities.

Reduction of NCGG Emissions

Methane (CH_4)

Methane is the second most important long-lived GHG. Approximately 40 % of methane is emitted into the atmosphere by natural sources (e.g., wetlands and termites), and about 60 % comes from human activities (about 400 Mt/y) by different sources (Fig. 1).

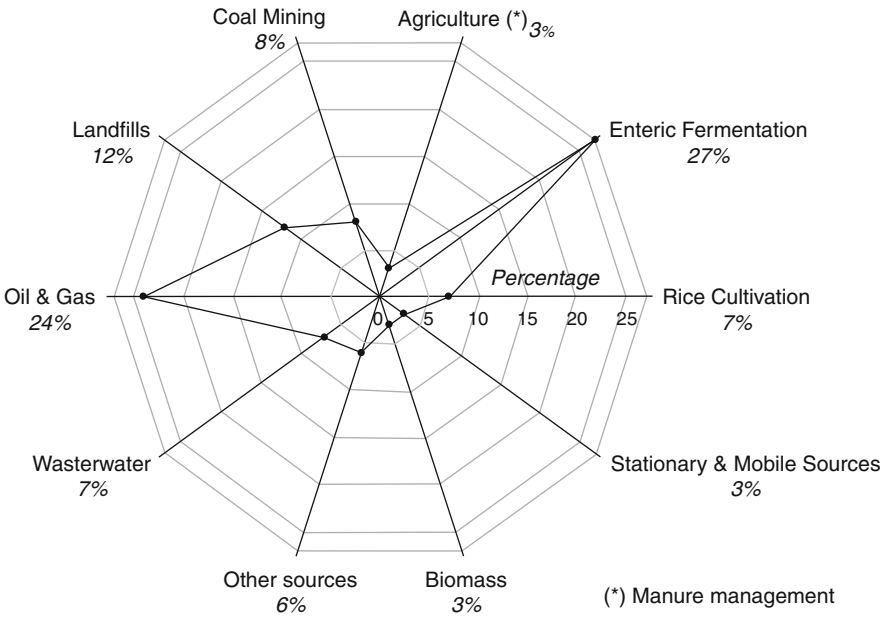

Fig. 1 Estimated global anthropogenic methane emissions by source, 2015

Atmospheric methane reached a new high of about 1,824 ppb in 2013, due to increased emissions from anthropogenic sources. Around half of methane emissions from anthropogenic activities derive from sewage disposal, rice cultivation, livestock, and burning of biomass. The remaining part is associated with production, transport and use of natural gas, coal mining, and disposal of solid waste. A considerable part of the methane emitted is converted to CO_2 and water in the troposphere by reaction with hydroxyl radicals, around 500 Mt/y. The total methane removed annually in all sinks is estimated to be about 600 Mton/year, but a large amount uncertainly exists in the balance of methane emissions. The current role of methane in global warming is large, contributing 1.0 W m^{-2} out of the net total 2.29 W m^{-2} of radiative forcing (Pachauri and Meyer 2014). The expected increase in shale gas production will further increase impact on climate changes, because the carbon footprint of shale gas (on average, integrated over 20 years) is higher than that of conventional natural gas and coal (about 51 gC per MJ with respect to about 38 and about 30, respectively).

Methane emissions from the oil and gas industry derive mainly from the venting of unused gas during oil production, the use of natural gas to purge or to operate pipeline equipment, and leakage from the gas distribution system. It is estimated that these emissions will nearly double in two decades (due to the increase in gas production and pipeline transport) unless abatement measures are taken. Coal measures contain methane, which will be released by mining. The methane is removed by drainage of the coal measures before and during mining; the rest is

removed in the ventilation air while mining is taking place. Drainage gas is high in methane concentration and can be used directly to generate electricity. The emissions associated to production and transport of coal is expected to increase in the future from the current value of about 22–33 Mton/year by year 2020 unless actions are taken.

A major source of methane emissions is the anaerobic decomposition of solid wastes in landfills, although the amount generated depends upon the method of dumping and on the composition of the waste and therefore vary considerably from country to country. It is expected that methane emissions from solid waste disposal will increase from the current 32–62 Mton/year by year 2025. Other anthropogenic sources of methane include sewage treatment, rice growing, livestock, and biomass burning. The large majority of these emissions are associated to developing countries. Methane emissions from sewage treatment are expected to increase from current 35 Mton/year value to 58 Mton/year, while those deriving from rice growing have leveled off in the last two decades. Livestock (mainly enteric fermentation in ruminants) contributes an estimated 49 Mton/year of methane emissions, but significant is also contribution from the anaerobic decomposition of manure. Biomass burning gives rise to direct emissions of methane, but has also the negative impact of reducing the ability of the soil to act as a sink. An increase of about 20–25 % of these emissions is estimated in two decades.

The increase in methane emissions should be contrasted by introducing highly efficient technologies to limit the emissions that can be reduced, because only a part of the global emissions of methane can be effectively controlled. The complexity of the problem derives from the very broad range of situations and type of emissions, e.g., various methodologies should be used and integrated.

It is possible to distinguish between two main types of sources: (i) confined, e.g., the gas is physically contained and can be managed with industrial process units, and (ii) diffused, e.g., methane is produced over a large land or aqueous area. The strategies for mitigation of the two cases are different (Stolaroff et al. 2012). For the latter case of diffuse sources, three general strategies of mitigation have been developed: suppressing methanogenesis, biocovers, and caps. The latter may be related to catalytic technologies, differently from the first two methodologies, although the first deals on enzymatic catalysis that however is not covered here. Caps are a typical method for controlling landfill emissions, being the land or manure ponds covered with an impermeable layer (a plastic sheet or layer of clay) and an array of wells and pipes to collect the gas then treated as discussed later. An alternative possibility is to use materials, such as liquid solvents and nanoporous zeolites, which can capture effectively the fugitive methane emissions (Kim et al. 2013). The methane stream produced during the regeneration of these capture materials can be then treated as discussed below.

Table 1 reports examples of typical concentrations of CH_4 in some relevant cases of methane sources. Concentrated streams (above about 40 %) can be used as chemical feedstocks, with syngas, methanol, and carbon black production among the main possibilities (but requiring typically further treatments to purify the gas and concentrate above about 95 %). In the concentration range 30–60 %, different

Table 1 Examples of typical concentrations of CH_4 in relevant cases of methane sources (Adapted from (Stolaroff et al. 2012))

Source	Methane concentration, vol fraction
Arctic air (current reference free air)	2–8 ppm (1.8 ppm)
Swine feeding or dairy milking ventilation air	10–300 ppm
Enclosed manure storage headspace	140–28,000 ppm (2.8 %)
US landfill, at surface	<500 ppm by regulation
Fugitive methane emissions at shale gas production wells	10–1000 ppm
Coal mine VAM	0.1–1 % typical, <1 % by regulation
Anaerobic digester gas	35–65 %
Landfill drainage gas	40–60 % at peak production
Coal postmining drainage gas	30–95 %
Coal premining drainage gas	60–95 %
Natural gas, at wellhead	75–99 %, typical

technologies are applied to coal mine drainage gas, landfill gas, and gas from anaerobic digesters. For lower concentrations, catalytic combustion is the main option, with commercial units able to handle methane concentrations as low as 0.1 % (1000 ppm). Bioreactors may be used to treat ppm and ppb (parts per billion) concentrations of methane, or alternatively very dilute methane streams can be used as air in combustion processes. Not yet developed, but a potentially interesting possibility, is the use of photocatalytic semiconductors such as TiO_2 to oxidize methane in the presence of sunlight. A modification of titania is required to activate methane.

Combustion is one of the main options in controlling methane emissions. The utilization of this methane, besides to contribute to the reduction of GHG impact, may be an opportunity in some cases for a sustainable energy source (Karakurt et al. 2011), as proposed for VAM (about 70 % of the methane emitted from coalmines). In general, however, incentives to mitigate VAM (carbon market or other regulatory drivers) are necessary to generate revenue from energy production. Some cost-effective solutions, as thermal reverse flow reactors (discussed later), may have a payback period of 3–6 years at a relatively modest carbon price (about $10/t-$CO_2$-eq.) (Stolaroff et al. 2012).

Due to the usually low concentration of methane in these emissions, the use of catalytic combustion is necessary and may avoid the formation of traces of harmful by-products like formaldehyde. Note that the combustion reduces the overall GWP of emissions, but produces CO_2 and water (combustion converts 1 kg of methane with a GWP of 21–2.75 kg of carbon dioxide with a GWP of 1 and 2.25 kg water). An additional benefit derives from the use of the heat of combustion in steam raising or electricity production, because it avoids the use of fuels for these purposes.

Autothermal methane combustion requires that methane concentration in the feed should be around 0.6–1.0 %. For lower concentration, the extra addition of fuel is necessary to sustain combustion. Using catalytic combustion, besides the much lower reaction and light-off temperature necessary for operations, different reactor/

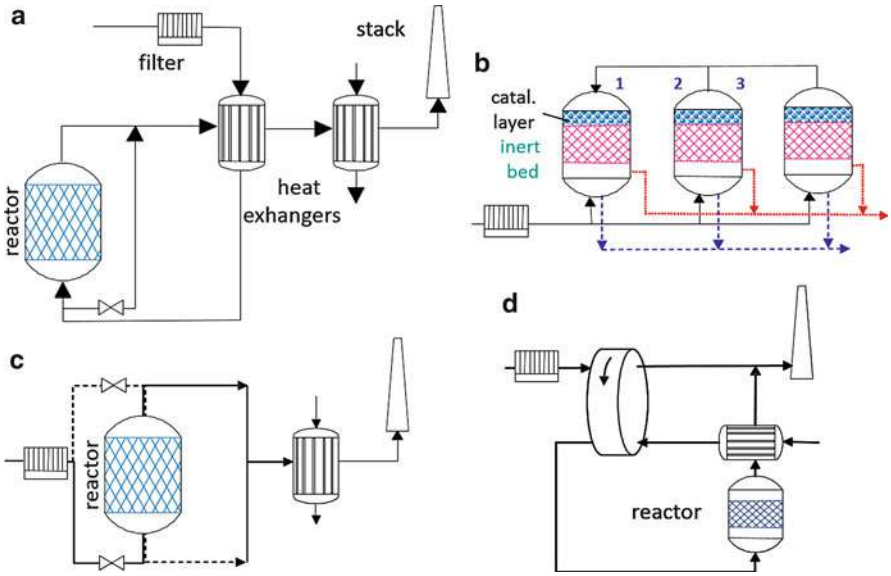

Fig. 2 Different reactor/process options for catalytic combustion of methane in diluted emissions: (**a**) recuperative catalytic combustion, (**b**) regenerative catalytic combustion, (**c**) reverse flow catalytic combustion, and (**d**) catalytic combustion using a rotating concentrator

process options are possible to operate it autothermally by using much lower methane concentrations in the feed:

- Regenerative catalytic combustion
- Reverse flow catalytic combustion
- Catalytic combustion using a rotating concentrator

Figure 2 shows the schematic flow sheet of the different options. Recuperative catalytic combustion (A) is the conventional option in which the reactor inlet is preheated from the reactor outlet and an eventual further heat exchanger allows further recovery of the heat before sending the gas to the stack. The regenerative catalytic combustion (B) allows better heat recovery efficiency and thus autothermal operations with lower methane concentrations. It involves cyclic operations: the ceramic layer preheats the gas to light-off temperature and the off-gas heats the ceramic layer of another reactor, while the third is under purging. When the ceramic layer has lost the capacity of gas preheating, the second reactor starts operations. The operations then continue in a cyclic way. Efficiency in heat recovery passes from about 70–75 % (case A) to 90–95 % (case B), but fixed costs are higher.

The reverse flow catalytic combustion (C) involves a periodical switch of the feed introduction from the bottom to the top of the reactor and vice versa. Fixed costs are lower than in case B, which heat recovery efficiency remains good. However, problems related to thermal shock and deactivation of the catalyst can occur.

Table 2 Fields of application of catalytic technologies for methane combustion (especially emissions containing diluted CH_4 concentration) and potential reduction of methane emissions which could be attained using catalytic combustion

Source		Emissions potentially reduced, Mt/y
Oil and gas supply chain	Fugitive emissions Process vents and flares	6–10
Coal mining	Underground ventilation and drainage	10–15
Shale gas production	Up- (well) and mid- (processing) stream	6–15
Solid waste	Landfill gas capture	4–8
Sewage treatment	Emissions from anaerobic digestion	7–12
Agricultural livestocks	Emissions from anaerobic digestion	3–5

The catalytic combustion using a rotating concentrator (D) may be applied also to very low methane concentrations. It is based on the concept of a rotating adsorption/desorption system. The part exposed to (cold) emissions adsorbs methane from the feed, while on the other part of the rotating element, the desorption of methane is induced by exposition to a hot air feed producing a concentrated stream which can be then sent to a catalytic combustor. The limit of the approach is given from the difficulty to find suitable adsorption materials, which can efficiently capture methane from the main stream in the presence of the typical, other gas-phase components (like water vapor). Other reactor options for the catalytic combustion of methane not shown in Fig. 2 include catalytic fluidized bed reactor, microchannel reactor, and catalytic membrane reactor (Wang et al. 2013), but these options are valuable mainly for concentrated streams of methane.

Catalytic combustion offers thus several opportunities to improve the economics in diluted methane emission control, although higher in fixed costs with respect to flame combustion. Some examples of possible specific applications are shown in Table 2 with also an indication of the potential reduction of methane emissions, which could be attained using catalytic combustion. As commented before, some economic incentives or regulatory drivers are necessary for the wider utilization of these technologies. Consequently, only for some specific application, such as coalmine methane (Özgen et al. 2011), commercial technologies are available. In general, catalysts should be further developed especially regarding their sensitivity to poisoning, being this one of the major problems in the treatment of the emissions, and low-temperature activity.

Table 2 evidences that coal mining is one of the main sources to control for methane. Coal measures contain methane, which will be released by mining (Özgen et al. 2011). The methane is removed by drainage of the coal measures before and during mining; the rest is removed in the ventilation air (VAM) while mining is taking place. Drainage gas is high in methane concentration (from 20 % to 90 %, depending on mine) and therefore can be used directly to generate electricity. VAM,

which carries around 70 % of the emissions, contains instead a very low CH_4 concentration (Table 1). Catalytic combustion using supported noble metals can be successfully employed to destroy all of the dilute emissions. The same technology could be applied to control methane fugitive emissions, process vents, and flares in the oil and gas supply chain.

CH_4 emissions from shale gas production are becoming a major issue of concern. Large emissions averaging 1.1 kton CH_4/y per well were observed (Caulton et al. 2014). The fraction of methane that is emitted ranges 0.6–7.7 % of the lifetime production of a well and 0.07–10 % emitted during "downstream" transmission, storage, and distribution to consumers (Weber and Clavin 2012). To note, a recent study (Alvarez et al. 2012) showed that the immediate net radiative forcing for natural gas use is worse than for coal (when used to generate electricity), if total CH_4 emissions are greater than approximately 3.2 % of production. Table 1 shows that fugitive methane emissions at wells for shale gas production are on the average more diluted than VAM. It would be thus necessary to develop improved (catalytic) technologies to utilize these low concentrations (around 200 ppm), in which development opens also a new range of applications (animal feedlots and manure storage), including the possible potential utilization for unconfined sources, Arctic or otherwise. A requisite is the development of efficient capture systems for methane, operating around room temperature or below (e.g., for Artic). Porous covalent–organic materials (Xiang and Cao 2013) are one of the interesting options to investigate further.

Disposal of solid waste on land is another significant source of methane. Given appropriate conditions, solid waste decomposes anaerobically with production of methane, which can be captured with existing technologies (low permeability barriers around the waste and capture of gas and leachate). Landfill gas can be burned, but the addition of fuel may be necessary because of its low quality. In this case, catalytic combustion is potentially preferable, although specific tailoring of catalyst characteristics may be necessary due to the possible presence of a number of poisoning elements. It is also possible to upgrade the gas so that it can be used as a substitute for natural gas, using the catalytic technologies commonly employed in the natural gas industry, although this option can be expensive. A third possibility is to use landfill gas for direct electricity generation with gas turbines. Gas cleanup using conventional catalytic technologies may be however necessary. Therefore, the basic catalytic technologies and knowledge are already available, but they must be adapted to the quality of the specific landfill gas. In addition, downsizing of the technology is necessary, because in most applications, small, compact, modular, and automatic equipment is required.

Sewage arises from both domestic and industrial sources, especially from the food processing, pulp/paper making, and chemical industries. In developed countries, most municipal and industrial wastewater is collected and treated in an integrated sewage system, in which an aerobic degradation step minimizes CH_4 emissions. In developing countries, integrated systems are not common, and thus collection of the gas from existing disposal sites and catalytic combustion is a feasible, cost-effective solution.

A special case may be considered, the conversion of residual methane in the emissions from NGVs (natural gas vehicles). Although the very limited diffusion of these vehicles do not allow to indicate this source as a major issue of methane emissions, the expected increase of these vehicles due to their lower environmental impact may determine a more serious problem in the future. In Germany, for example, Audi's e-gas plant, first announced in May 2011, is a first industrial step to push the conversion of CO_2 to methane using excess electrical energy produced during night by windmills and use this methane to fuel cars. The facility will generate enough e-gas to power 1,500 new Audi A3 Sportback TCNG vehicles for 9,320 miles every year. "Power-to-gas" (P2G) is the name given to an energy process and storage technology, which allows renewable electricity to be "stored" and distributed as chemical energy in the form of a gaseous fuel (methane), for which already an extended network of distribution and storage (e.g., in salt caverns) is available.

Although NG-fueled vehicles (NGV) are presented as a very clean solution, methane is not totally converted and emitted from the car, in the absence of suitable catalysts. The current legislation, Euro 6 in Europe, for example, puts limits for total hydrocarbons (THC) but does not differentiate, as in the past, non-methane hydrocarbon emissions (NMHC). It is necessary to use catalysts with a quite high content of noble metals (platinum, rhodium, and palladium, particularly the latter), around 2–4 g/L (from 4 to 10 times higher than conventional) to convert the THC emissions composed by more than 90 % of NMHC for NGV. In addition, the high presence of oxygen in the emissions does not allow converting NOx in the absence of a specific additional catalyst able to operate in lean-burn conditions, as for diesel vehicles emissions.

Lean-burn NGVs equipped with catalysts are commercially available in buses and other fleet service vehicles. Characteristics required for a catalyst for methane conversion in lean-burn NGVs are the following:

- Low light-off temperature (200–300 °C or below) at space velocities of 50,000 h^{-1} or above
- High efficiency using low methane concentrations (below 1000 ppm) and high oxygen concentrations (the air to fuel ratio in lean-burn engines is typically in the 20–27 range and thus residual oxygen in exhaust gases may be 8 % or higher)
- Stability (thermal and hydrothermal) in the presence of about 8 % O_2 and similar water concentration in the feed
- Resistance to deactivation by sulfur (low concentrations of sulfur compounds are present as impurities in the feed)

Pd-based catalysts show the best performances under the conditions outlined above, but are very sensitive to poisoning by H_2O and SO_2 (the latter as little as 1 ppm SO_x in the exhaust vehicle gases) which shifts the light-off curve to temperatures about 200 °C higher. Furthermore, high Pd loadings in the catalysts are necessary. The performances of the catalysts are thus still not satisfactory, and further improvements are necessary.

Three directions of research may be identified to improve performances:

- Identification of the reaction mechanism of methane activation as a tool to design improved catalysts
- Identification of the deactivation mechanism to identify how to prepare more resistant catalysts
- Development of alternative supports for palladium which may improve activity or stability

Supported noble metal catalysts are used in the largest part of commercial applications of methane combustion, especially when temperature of operation may be limited due to low methane concentrations in the stream. A large effort has been made in literature to find alternative catalysts not containing noble metals, like supported transition metals (e.g., CuO/alumina), spinel, and perovskite materials. They may find application when the presence of other components in the feed gives rise to deactivation of the noble metal catalysts, but usually the light-off temperature is around 500 °C or above and thus too high for the conversion of diluted methane containing emissions.

Often the choice of non-noble metal containing catalysts is motivated from the supposed lower cost of the catalyst. Structured type catalysts such as monoliths should be generally used in catalytic combustion. The cost of the active component (noble metal or other) in a monolith is typically only a fraction of the overall costs (10–30 %). If a non-noble metal catalyst has a reaction rate 50 % lower with respect to that of a noble metal catalyst, for example (often is even less), and a cost per active phase mass which is about a quarter of that of noble metal, the total cost of the monolith catalyst in order to have the same conversion is higher. The process cost (fixed + variable) is higher, if the reaction temperature should be 50 °C or higher with respect to the case of using noble metal-based catalysts. In conclusion, non-noble metal catalysts for methane conversion should be considered when (i) the rate of reaction is comparable, (ii) deactivation phenomena may dominate the behavior, or (iii) activity is not an issue due to the high temperatures of operations (e.g., using high methane concentrations).

Palladium is usually the most active noble metal in methane combustion. The resistance of palladium to thermal and hydrothermal sintering is also better than that of platinum, but its behavior in the presence of poisons such as sulfur-containing pollutants or lead is worse. Either supported Pd catalysts or Pd–zeolite catalysts are used in diluted methane combustion.

Some new direction is proposed. Gorte and collaborators (Cargnello et al. 2012) have developed nanomaterial that catalyzes methane combustion 30 times better than existing catalysts and at lower temperatures. Existing catalysts are usually composed of Pd nanoparticles deposited on oxides such as CeO_2, while Gorte and collaborators (Cargnello et al. 2012) use 1.8 nm Pd nanoparticles surrounded by a protective shell of 3 nm CeO_2 crystallites as their catalysts. Such small particles usually sinter together when heated, reducing catalyst activity, while the core–shell structure of these new catalysts (prepared by a self-assembly techniques) avoids

(or greatly limit) this sintering. However, it is still necessary to demonstrate the use of these catalysts in real applications.

The mechanism of low-temperature methane oxidation on supported Pd samples should be not generalized, because it depends on the specific catalyst. However, a typical mechanism is the following (Liu et al. 2012). The rate-determining step is the dissociative chemisorption of CH_4 on a site pair consisting of adjacent Pd surface vacancies and surface Pd–O species. The negative water effect is due to the inhibition of the formation of Pd–O species which block the water desorption during recombination of the surface hydroxyl groups. The stronger Pd–O bonds in small Pd–O clusters or incompletely oxidized PdO_x crystallites can lead to a lower surface density of vacancies and thus to lower methane oxidation turnover numbers. The mechanism of deactivation at temperatures below 450 °C is attributed to a water/hydroxyl inhibition effect (Schwartz et al. 2012). Hydroxyl accumulation occurs on the oxide supports during catalytic methane combustion, hindering oxygen exchange with the oxide support playing a relevant role in catalyst activity.

Nitrous Oxide (N_2O)

N_2O global emissions from natural sources (soils, oceans, and atmospheric chemistry) account for about 13 Mton N_2O per year, while those from anthropogenic activities about 7–8 Mton N_2O per year. The latter derives for about 50 % from agricultural practices (including use of fertilizers) and the remaining from various main sources: fuel and waste combustion (especially combustion of industrial N-containing waste in fluidized bed reactors), transport (this contribution is increasing much faster than the others), polluted surface water and wastewater (sewage) treatment plants, chemical production (nitric acid production and use), and biomass combustion (van Ham et al. 2000).

Control of N_2O emissions from agriculture is difficult to implement in a short term, due to the different types of diffuse sources and the limited number of existing options for the control. However, it is possible to utilize nitrification inhibitors to reduce nitrous oxide emissions. In general, global food system (fertilizers, manure, grazing animals, resides treatment, and waste) is a main source of N_2O, estimated at 4.1–4.4 Tg N_2O-N for 2010 (Oenema et al. 2014). Lowering this impact is possible by various (non-catalytic) mitigation strategies, such as improved crop and animal production, better manure management, improved food utilization, and lowering the animal-derived protein in human diets (Oenema et al. 2014). However, all these are long-term strategies.

The transport sector (mobile sources) is expected to increase rapidly in relevance especially with the expansion in the use of diesel and lean-burn engines. Their contribution was doubled in the last decade and was about 0.142 Tg N_2O-N/y in 2010 with the majority (≈55 %) of emissions resulting from catalytic emission control systems of light-duty vehicles (Wallington and Wiesen 2014). It is unlikely that N_2O emissions will be regulated, with attention being given to other priorities (NO_x, particulate). However, improvements in the emission control systems of

light-duty vehicles will reduce the emissions of N_2O from global transportation to about 0.108 Tg N_2O-N/y by 2030 (Wallington and Wiesen 2014).

N_2O from (uncontrolled) biomass combustion, being also widespread, cannot be reduced in short term. N_2O emissions that can be reduced in the short term are associated with chemical production, energy industry, waste combustion, and sewage treatment. The better premise for an economic and efficient reduction strategy is to eliminate N_2O in localized and large sources, such as from some chemical industry processes and from stationary combustion processes. Emissions from chemical industry mainly apply to adipic and nitric acid production plants, but significant emissions of N_2O are also present in plants for the production of caprolactam, glyoxal, and acrylonitrile and in general in all processes using nitric acid as oxidizing agent or involving ammonia oxidation (Lee et al. 2011).

The impact can be significant, even if in some countries voluntary actions have already significantly reduced nitrous oxide emissions. In China, however, industrial N_2O emissions grew by some 37-fold from 5.07 to 174 Gg (N_2O), with total accumulated emissions of 1.26 Tg from 1990 to 2012. The projected emissions are expected to continue growing rapidly from 174 to 561 Gg in 2020 under current policies and assuming no additional mitigation measures (Li et al. 2014). The total accumulated mitigation potential for this forecast period is about 1.54 Tg, the equivalent of reducing all the 2011 greenhouse gases from Australia or halocarbon ozone-depleting substances from China. Adipic acid production is the major industrial emission source and contributes nearly 80 % of the industrial N_2O emissions, e.g., about 96.2 % of the industrial mitigation potential.

Adipic acid production differs from the other cases, because N_2O concentration in the tail gas is quite high (typically 20–40 %). A number of adipic acid producers have voluntarily introduced technologies to reduce N_2O emissions, which passed from about 0.6 Mton/year in 1994 to about 0.1 Mton/year in 2000. Due to the exothermicity of the decomposition of N_2O to N_2 and O_2 (a feed containing 20 % N_2O would increase the adiabatic temperature of a reactor of more than 500 °C), activity of the N_2O decomposition catalyst is not a real critical issue for the effectiveness of the technology, but rather its stability. A number of different catalysts are active using high N_2O concentrations. The catalysts employed are based on noble (Rh) or non-noble (Cu, Co) transition metals supported on a structured matrix such as zeolites or hydrotalcites deposited on monoliths. However, the same kind of catalysts do not show enough activity when applied to the treatment of streams containing low concentration of N_2O (typically below 1 %) (Pérez-Ramírez et al. 2003; Sobolev and Pirutko 2013; Centi et al. 2003b).

When N_2O is present in high concentrations in the effluents, besides catalytic decomposition, other options are also possible, such as the recovery and use of N_2O as valuable reactant (see later, Solutia–Boreskov process) (Parmon et al. 2005). Thermal (non-catalytic) decomposition is also an effective possibility. However, most of N_2O emissions, which may be treated by catalytic technologies, are characterized from N_2O concentrations below about 1 % (Fig. 3). Furthermore, tail gas

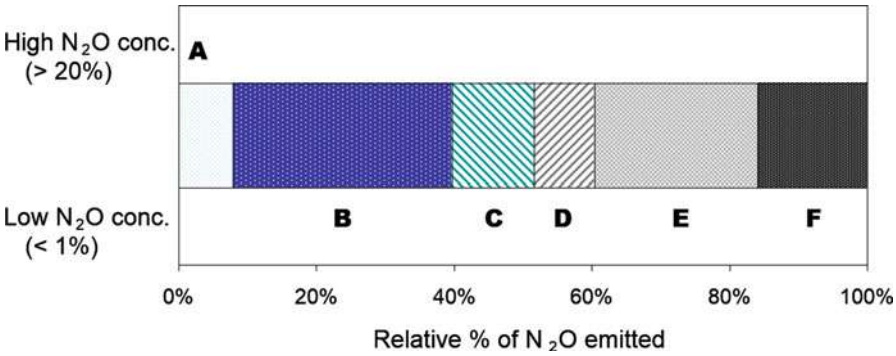

Fig. 3 Relative % of N_2O anthropogenic emissions, which may be treated by catalytic technologies: (**a**) adipic acid plants. (**b**) Nitric acid production. (**c**) HNO_3 use (no SO_2 in emissions). (**d**) HNO_3 use (the presence of SO_2 in the emissions). (**e**) Sludge and industrial waste combustion (fluidized bed combustion). (**f**) Municipal incinerators

differs in terms of temperature and composition (especially the presence of inhibitors for the catalyst such as O_2, H_2O, SO_2, and NO_x).

In Fig. 3, emissions derived from nitric acid use in chemical processes are differentiated between those containing and not containing SO_2, because N_2O abatement technologies may be different in the two cases (as discussed in the following sections). Figure 3 distinguishes also emissions having high (above 20 % v/v) or low (below 1 % v/v) concentrations of N_2O, because this also determines different N_2O abatement technologies. It may be further differentiated between emissions at low temperature (typically below 200 °C) (cases A–D) and emissions characterized by high temperatures (above 300 °C) (cases E–F), because in the former, catalysts active at low temperature are required for economic operations, similarly to what is discussed in the case of methane conversion.

For adipic acid plants, an interesting alternative to the N_2O catalytic or thermal abatement is the reuse of N_2O, which is a valuable chemical in some oxidation reactions of industrial interest such as the hydroxylation of (substituted) benzene to (substituted) phenol (Parmon et al. 2005). The relatively high cost of synthesis of N_2O (e.g., by ammonia selective oxidation) has prevented its practical application, but its recovery from industrial emissions can be economically interesting and avoids at the same time N_2O emissions.

This is the basic idea of the Solutia–Boreskov AlphOx process (Parmon et al. 2005; Notte 2000) to reuse nitrous oxide emissions from adipic acid plants, instead of eliminating them through catalytic decomposition. The process uses N_2O, formed as a by-product in the adipic acid process, to hydroxylate benzene to phenol on Fe-containing ZSM-5 catalysts. Phenol, after hydrogenation to cyclohexanone, is introduced in the adipic acid process thus closing the cycle. Figure 4 outlines the reaction scheme and reports a model of the reaction inside the zeolite channels of the catalyst. The key features of the process are the very high selectivity in benzene to phenol (over 98 %) and reuse of N_2O which eliminates the cost of its abatement

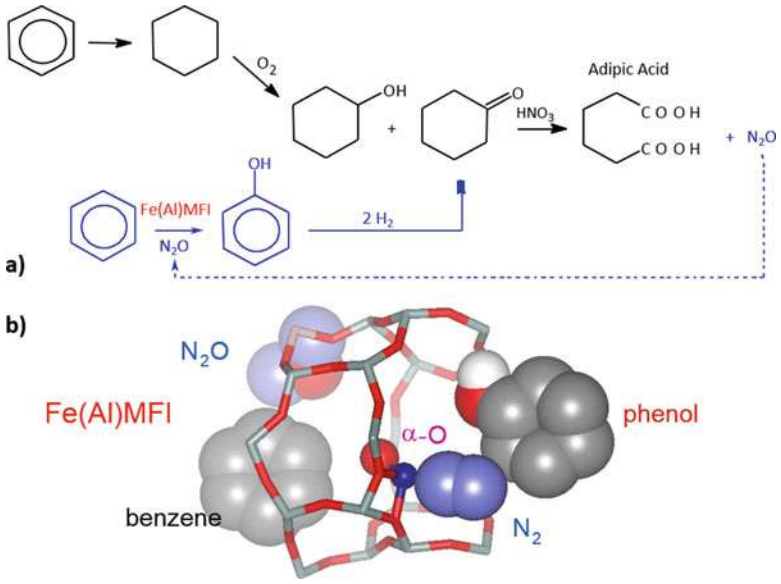

Fig. 4 Outline of the reaction network in the AlphOx process of recovery/reuse of N_2O in adipic acid production (**a**) and model of the reaction occurring at the active sites of Fe-containing MFI catalyst (**b**) (Modified from (Centi et al. 2005))

(although a purification step is necessary) and allows higher plant productivity, reduction of costs, and decrease in hydrogen consumption. The deactivation rate, however, still requires improvement.

This AlphOx process has been successfully tested in a pilot plant facility erected by Solutia in its adipic acid plant in Pensacola (USA). However, the process has not passed on commercial scale. Fe(Al)–MFI catalysts are used in the reaction of benzene hydroxylation with N_2O. No other classes of catalysts have been reported in the literature having comparable performances to Fe–MFI catalysts, although other Fe-zeolites also have been shown to be active in the reaction (Hensen et al. 2005; Centi et al. 2005). The proposed model of the reaction occurring at the active sites of Fe-containing MFI catalyst (Centi et al. 2005, 2006) is reported in Fig. 4b. The reason of the specific behavior, in addition to the stabilization of specific configurations for iron ions, is related to the large repulsive interaction of benzene with zeolite framework that can be greatly reduced when forming C–O bond (Yang et al. 2013). The otherwise repulsive adsorption on iron sites derives thus from the specific constrains induced from the zeolite cage. Adsorbents have nearly no migrations for proton-transfer steps to form phenol.

Due to the interest of N_2O as reactant, the possibility of its recovery is interesting also from emissions where it is present in low concentrations (below 1 %). A possibility of selective recovery is given by modified zeolites, which can selectively trap N_2O in the 25–80 °C temperature range, which is that of interest for a process of recovery of N_2O from a nitric acid plant. Ba-exchanged ZSM-5 zeolites, in

particular, show the best performances (Centi et al. 2000). Ba^{2+} due to its large ionic radius and electronic configuration creates a large local electrostatic field within the cavities of the zeolite and probably the enhanced adsorption behavior and the difference with respect to other analogous alkali and alkaline-earth elements can be attributed to this effect.

N_2O forms as a side product of ammonia oxidation in the synthesis of nitric acid (concentration 50–65 %) (Keller 2011), produced in large amounts worldwide (over 130 plants in Western Europe providing a total yearly capacity of approximately 22 million tons of 100 wt% nitric acid), which is being used to synthesize nitrogen fertilizers like ammonium nitrate and super phosphates, but also as reacting agent for the production of adipic acid and other chemicals. N_2O emissions from nitric acid plants can range from about 2–20 kg per ton of HNO_3 or up to 3,500 ppm concentration in the tail gas, depending on the nitric acid process and plant operating conditions. The process of nitric acid can be schematically differentiated in three main blocks:

- Catalytic oxidation of ammonia with air into nitric oxide
- Oxidation of nitric oxide into nitrogen dioxide
- Absorption of nitrogen dioxide in water to produce nitric acid

N_2O forms only in the first stage (ammonia combustion), but passes unchanged through the remaining parts of the plant and is emitted in the tail gases. Pt–Rh gauzes (typically 90 % Pt and 10 % Rh) are used for the ammonia oxidation. The selectivity to N_2O in this process depends on the reaction temperature (reaction temperatures below 1000 °C favor N_2O formation with respect to NO). Low linear velocities (below about 1 m/s) may also favor the secondary reaction of N_2O formation by reaction of NH_3 and NO in the gas phase. Although selectivity to N_2O is typically lower than 2 % in current plants, inhomogeneous flow distributions in the combustion chamber and aged catalysts may increase N_2O formation. Typical N_2O concentration in the tail gases ranges from 500 to 1,500 ppm. Depending on the burner design and reactor configuration, the kg N_2O produced per ton 100 % HNO_3 may vary from 2 (new plants) to 5–6 (usual value) up to 20 for the oldest plants.

In new nitric acid plants, N_2O emissions may be reduced by a better reactor design, improved geometry of Pt–Rh gauzes, or even using alternative (oxide-based) catalysts. Using extended chambers in the ammonia oxidation reactor, it is also possible to minimize N_2O formation, because upon increasing the residence time by 1–2 s in the reactor down to Pt–Rh gauzes, thermal decomposition of N_2O occurs resulting in a nitrous oxide level of about 200 ppm (from 50 % to 70 % abatement) in the tail gas. This technology was developed by Norsk Hydro. It suffers high capital costs and limited applicability to retrofit.

An alternative is the in-process use of a catalyst for selective decomposition of N_2O formed during ammonia oxidation (Fig. 5, position 1) (Pérez-Ramírez et al. 2003; Kapteijn et al. 1996). The catalyst can be introduced behind the Pt–Rh gauze pack and the recovery unit for the noble metals lost from the Pt–Rh catalyst, in substitution of the inert Raschig rings used as support for the Pt–Rh gauze. The main

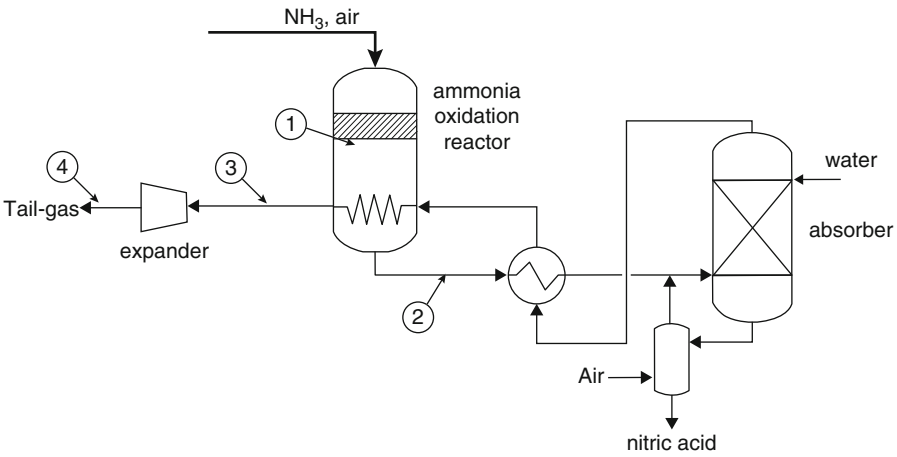

Fig. 5 Simplified flowsheet of a nitric acid plant with the indication of the potential locations of catalytic N_2O abatement systems (DeN_2O). See text regarding the description of "positions in the flow sheet"

problems in development of these in-process N_2O decomposition catalysts are associated to the necessity of minimizing possible NO decomposition and developing high hydrothermal and chemical stability related to the high temperatures of operations. This solution was proposed by BASF using first Cu–Zn–Al spinel catalysts and then CuO/Al_2O_3 in the shape of small pellets, which were also installed in two commercial plants in Ludwigshafen (Germany) and Antwerp (Belgium). A stable activity for 3 years and minimal NO decomposition (<0.5 %) were reported. N_2O decomposition efficiencies higher than 80 % were reported. However, a problem may arise from the possible loss of copper, because when it contaminates nitric acid used for fertilizers' production, severe safety problems can occur (copper catalyzes ammonium nitrate decomposition). Instead of decomposing N_2O to N_2 and O_2, it is preferable to oxidize N_2O to NO, because this solution would improve HNO_3 productivity. This reaction is endothermic, and although thermodynamically favorable, the equilibrium constant is very low at the ammonia oxidation reactor conditions.

An alternative to in-process location of the N_2O abatement catalyst (inside the ammonia oxidation reactor) is to put it downstream to the reactor (Fig. 5, position 2) in line with the absorption column. Iron-loaded zeolites with MFI or BEA structure have been proposed by Krupp UhDe to be used for this application. However, hydrothermal stability of these materials is unclear, taking into account the high steam content of emissions (typical 13 % vol.) and high temperature (above 500 °C). This location of the DeN_2O technology interferes with heat exchange series (simplified in Fig. 5), and therefore the advantage of simpler revamping of existing plants with respect to in-process solution is unclear.

In terms of simpler revamping of existing nitric acid plants, it is preferable to position the DeN_2O unit in the tail gas train upstream of the tail gas expander

(position 3 in Fig. 5). This configuration offers the great advantage of not influencing the heart of the nitric acid plant, i.e., the ammonia burner and the absorber, and therefore of greater flexibility in terms of reaction temperature with respect to previous options. Being present less space constraints on the volume of the catalytic bed, higher levels of N_2O removal (higher than 95 %) are possible. The decoupling of the DeN_2O unit from the ammonia burner is important, because the stop of the unit (e.g., to change the deactivated catalyst) may be independent on the main process operations. The tail gas leaves the absorber at temperatures close to room temperature, but then passes various heat recovery stages before reaching the expander where pressure decreases typically from 3 to 13 bar to near to 1 bar recovering energy. Depending on the exact position of the DeN_2O unit in the tail gas train, the temperature ranges from 250 °C to 500 °C. In modern nitric acid plants, the typical NOx concentration is around 0.02–0.04 %, N_2O concentration about 0.01–0.02 %, O_2 concentration about 2–3 %, and H_2O concentration at 0.5–1.0 %. Values may change depending on the nitric acid plant technology (low or high pressure, mono- or dual pressure).

Two catalytic options are possible to convert N_2O:

- Catalytic decomposition
- Selective catalytic reduction by adding a selective reductant for N_2O

Direct catalytic decomposition of N_2O without adding a reducing agent is the preferable option, if catalysts having suitable activity under realistic conditions of feed composition and space velocities can be found. Transition metals like Cu, Co, and Ni and noble metals (Pt, Rh, Pd) supported on oxides such as Al_2O_3, TiO_2, ZrO_2, and CeO_2 or mixed oxides (ZrO_2–Al_2O_3, ZrO_2–CeO_2, perovskites, Mg–Al hydrotalcites) are active in N_2O decomposition but generally very sensitive to the presence of other gases in the feed (O_2, NO_x, H_2O) which cause severe deactivation. N_2O decomposition process may be located also downstream of the tail gas expander before the stack (position 4 in Fig. 5). The main advantage of this solution is that this end-of-pipe technology does not require modifications in the tail gas expander in existing plants and is thus the simplest solution for revamping existing processes. However, temperature of the emissions is low (200–300 °C), and thus preheating is required. Furthermore, pressure is also lower (about one bar vs. 4–10 bar in the case of positioning before the tail gas expander). The increase of the pressure increases the reaction rate.

N_2O concentration in tail gases of nitric acid plants is too low to have autothermal operations. Therefore, if the temperature of the emissions is below the temperature necessary for achieving the necessary N_2O conversion in the catalytic decomposition reactor, the preheating of the stream, usually through a separate furnace, is necessary. Instead of using the fuel gas only for external heating of the tail gas in a furnace, it is preferable to add it directly to the feed and use both to in situ heating of the gas stream (due to its combustion) and as selective reductant for N_2O, when a suitable catalyst can be found. An economic estimation of the two competitive technologies, based on a temperature of 430 °C for decomposition operations and 380 °C for

selective reduction operations (by adding 0.2 % propane to the feed in the latter case) and a conversion of N_2O of 90 % or above in both cases, indicates nearly equal operating costs, but an advantage of the selective reduction technology in terms of fixed costs.

Ethane or propane are an interesting reductant for this purpose (Hevia and Perez-Ramirez 2008; Centi and Vazzana 1999), because they are inexpensive hydrocarbons, much more reactive than methane and preferable to ammonia, because it does not have the problems of safety, side pollution, and formation of deposits (ammonium bisulphate) of the latter. The main problem in searching for a catalyst able to reduce N_2O by ethane or propane in the presence of oxygen is that the catalyst reactivity toward propane oxidation to carbon oxides by O_2 must be lower than the catalyst activity in the reaction of alkane with N_2O (or atomic oxygen produced by N_2O dissociation). The largest majority of the catalysts active for N_2O decomposition are not promoted or are even deactivated in comparing the reactivity in N_2O decomposition (in the presence of O_2) with that observed when the alkane is also co-fed.

Propene, propane, ethane, methane, and ammonia have been used as the reductants. Criteria to consider in their evaluation are (i) de-N_2O activity and operation temperature; (ii) hydrocarbon utilization, i.e., the selectivity to react with N_2O in O_2 excess; (iii) emission of CO and CO_2; (iv) sensitivity to NO and NH_3; and (v) cost. Propene, due to the higher cost, is not a suitable reductant. Methane requires reaction temperatures higher than ethane and propane (about 100–150 °C higher), with the latter allowing the lowest reaction temperatures. Ammonia has a comparable activity of propane as reducing agent, but the cost is higher. Propane and ethane are the preferable reducing agent, but propane has the advantage of slightly lower reaction temperatures and especially an easier storage, although carbon efficiency is lower with respect to ethane.

The N_2O abatement unit can be located downstream of the tail gas expander (position 4 in Fig. 5). This *end-of-pipe* unit does not require modifications of the tail gas expander in the existing plant (therefore, may be well suited for revamping of existing plants), but due to the low temperature (typically below 250–300 °C), the gas must be preheated. Selective catalytic reduction seems the only feasible solution from the economic point of view in this case. Using propane as reductant and Fe–ZSM-5 catalysts, the efficiency for the reduction of N_2O could be better than 70 %. A start-up in-line burner is required to start the reaction and to correct for fluctuations in the tail- as flow and composition, while tail gas preheating is made using the heat generated in the catalytic reactor.

The evaluation of the different options to reduce N_2O emissions in nitric acid plants depends on several factors, which may vary from case to case, including regulations on emissions or incentives on lower emissions. The cost of N_2O abatement (per ton of CO_2 equivalent) is in the 0.2–3.0 € range, a cost which appears compatible with polities for the reduction of greenhouse gas emissions. Two main distinctions, which should be made in the selection of the preferable de-N_2O technology, are whether or not the technology should be applied to existing nitric acid plants and if in process gas (with respect to tail gas N_2O abatement) N_2O

decomposition is feasible. Catalytic N_2O decomposition directly after the ammonia oxidation catalyst in the converter is the less expensive option, but the loss of NO and the catalyst lifetimes are the crucial factors.

For new nitric acid plants, catalytic decomposition of N_2O upstream of the expander (with a cost in the 0.3–0.5 € per ton CO_2-eq.) is often preferable, but the plant should be designed in such a way that the temperature before the expander is around 500 °C to avoid sufficiently high reaction rates for the decomposition. In existing nitric acid plants, the temperature before the expander is too low and often no space in the ammonia oxidation reactor for catalyst placement is present. SCR upstream of the tail gas expander or downstream when space constraints do not allow location of the unit appears to be the preferable solution, although the cost is higher (in the 0.5–1.0 € per ton CO_2-eq.). However, if SCR of N_2O can be combined with elimination of also NO_x, the SCR technology will gain attractiveness.

Combined N_2O–NO_x removal from the emissions of nitric acid plants is an interesting opportunity, because NO_x emissions of a nitric acid plant range from 100 to 2000 ppm, with an average of 200 to 500 ppm. In order to comply with emission targets, a DeNOx SCR unit is used. Typically, ammonia is used as the reductant and supported vanadium oxide as the catalysts. The DeNOx unit is generally located upstream the expander in the tail gases of the plant, but N_2O emissions are not reduced from the conventional NH_3–DeNOx technology.

A less studied case of N_2O emissions is that of N_2O emissions from waste (industrial or municipal) combustion. N_2O forms in relatively high amounts (0.1–0.6 %), when combustion temperatures are lower than 1000 °C (e.g., using fluidized bed combustors). Temperature of the emissions is typically above 300 °C, but often SO_2 is present in the emissions, together with O_2, CO_2, CO, NO, N_2, H_2O, and other minor compounds. Ashes are also typically present. Deactivation of the catalyst is a main issue. N_2O decomposition catalysts typically deactivate quite fast in the reaction conditions of the emissions from waste combustion. Fe–ZSM-5 catalysts show good performances in the SCR of N_2O with propane, also in the presence of SO_2 in the feed (Centi and Vazzana 1999).

Fluorocarbons

Differently from methane and nitrous oxide, fluorocarbons, which include hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF6), are generated exclusively by anthropogenic activities. Current atmospheric concentrations of these gases are small relative to other greenhouse gases, but their GWP is quite high. Halocarbons that contain chlorine and bromine, being implicated in depletion of the ozone layer, are controlled by the Montreal Protocol and its amendments. The uncertainly in the estimations of the emissions of fluorocarbons is high, due to unpredictable developments in the mix of substitutes for CFCs and halons, the presence of a mix of applications, lag times, etc. HFCs and PFCs have been introduced as alternatives to ozone-depleting substances (e.g., HFC-134a

($C_2H_2F_4$) is a substitute for CFC-12 (CCl_2F_2)), and thus their emissions are expected to increase dramatically in the coming years. IPCC evaluations (Pachauri and Meyer 2014) is that the replacement of CFCs and HCFCs, which are both ozone depleters and greenhouse gases, with HFCs (emissions of which are regulated under the Kyoto Protocol) is not expected to produce a runaway greenhouse effect. The effect of the fluorocarbons will remain constant or will decline over the coming century, both in absolute terms and relative to the other greenhouse gases.

Fluorocarbons are used in a variety of industrial processes, including the manufacture of semiconductors (plasma etching and cleaning tool chambers), refrigeration, and fire protection. There are also some emissions during their manufacture. For example, HFC-23 is emitted during the production of HCFC-22. PFCs are emitted during the aluminum smelting process (during primary aluminum production, CF_4 and C_2F_6 are emitted as by-products of the smelting process). Sulfur hexafluoride is mainly used in the electric power industry as a gas for electrical insulation, current interruption, and arc quenching in the transmission and distribution of electricity, because of its inertness and dielectric properties. SF_6 is used extensively in circuit breakers, gas-insulated substations, and switchgear. Other industrial applications include use in magnesium melting operations and as a gas tracer.

These emissions probably will decrease in the future, based on a voluntary program of the aluminum and magnesium industries, semiconductor manufacturers, HCFC-22 producers, and the electric power industry. In several cases, the fluorocarbons will be recovered from the emissions using conventional adsorbents and then reused, when possible. However, in some cases, their destruction will be necessary, but thermal incineration is expensive, and special care must be adopted to avoid the formation of harmful products, corrosion problems, etc.

There are limited studies on the catalytic conversion of fluorocarbons to inert chemicals, although a large number of studies deal with the catalytic conversion of CFCs to fluorocarbons as a consequence of the Montreal Protocol to find alternatives to CFCs responsible for the depletion of the ozone layer (Ertl et al. 1999; Manzer and Nappa 2001). Supported metal catalysts (Pd on alumina or carbon), AlF_3, and other oxides are active in the hydrodechlorination of CFCs to HFCs. In particular, the CCl_2F_2 (CFC-12) conversion to CH_2F_2 (HFC-32) has been studied (Yu et al. 2006), but the higher strength of the C–F bond makes the selective catalytic hydrodefluorination of fluorocarbons to form inert hydrocarbons (which then can be combusted safely) more difficult to realize. Some of the emerging ideas (Perutz 2008; Schwartsburd et al. 2014; Whittlesey and Peris 2014; Ahrens et al. 2013; Reade et al. 2009; Sabater et al. 2013) are difficult or costly to implement on an industrial scale, but some have a promising potential, although still to be fully demonstrated. Methane is formed with selectivities ca. 50 % as a side product in CFC-12 hydrodechlorination on supported Pd catalysts. The selectivity can be increased by tuning the operating conditions and catalyst composition. New homogeneous catalysts, based on silylium-carborane or ruthenium *N*-heterocyclic carbene (NHC) complexes, have been shown to be able to break the carbon–fluorine bond at room temperature. They were reported as highly promising for an effective disposal

of these pollutants, but the effective applicability to practical problems has to be demonstrated.

A different possibility is catalytic steam reforming for the effective destruction of halocarbons using nickel-based catalysts (Menini et al. 2000). The process has been demonstrated with conversion levels higher than 99.99 % for chlorocarbons (trichloroethane, trichloroethylene, perchloroethylene) but can be adapted to treat fluorocarbons. The process was found to be economically attractive over thermal incineration and catalytic combustion. Furthermore, in comparison with thermal combustion, catalytic combustion avoids the formation of harmful by-products in traces.

Catalytic Conversion of CO_2

The use of catalytic technologies for the reduction of CO_2 emissions is a different case from those discussed regarding methane and nitrous oxide emissions, due to the higher volume of emissions, different characteristics of the source, and different requirements for its transformation. In particular, while N_2O after transformation to an inert gas such as N_2 and CH_4 after conversion to CO_2 having about 30 times lower GWP can be emitted to the atmosphere, the problem with CO_2 is different. The possible options for CO_2 are the following:

- Recovery and storage underground or under the sea (CSS)
- Reaction with inorganic solids to form inorganic carbonate (disposed or eventually used as materials)
- Conversion to chemicals or fuels which are reused

Catalysis plays a central role in the third option. Large amounts of carbon dioxide, often already concentrated as side stream of many processes or CSS plants, are available at zero or even negative cost due to carbon taxes. There is thus increasing research attention on chemical, biological, and physical uses of CO_2 (Centi and Perathoner 2009, 2014; Aresta and Dibenedetto 2007; Sakakura et al. 2007; Schaefer et al. 2010; Darensbourg 2007; Dorner et al. 2010; Quadrelli et al. 2011; Aresta 2010). An emerging possibility as regards the use of the conversion of CO_2 to higher-energy products as a way to introduce renewable energy in the chemical production value chain (Quadrelli et al. 2011) is commented in a more detail below. This opportunity will also allow creating a worldwide base marked to trade and exchange renewable energy through the conversion of CO_2 to liquid fuels (Barbato et al. 2014), in order to enable a smooth and effective transition from current (largely based on liquid fuels) to the future energy system based on renewable (perennial) energy. The potential of this route is thus quite large, with a potential contribution in saving CO_2-eq. emissions of several Gtons.

Often the discussion on mitigation of GHG effect has been limited to consider long-term sequestration of CO_2, for example, CSS or mineralization, supposing that a short cycle time means that carbon is returned to the atmosphere quickly. However,

when renewable energy is introduced in the cycle of CO_2 to fuel conversion (thus storing renewable energy in the form of chemical energy), a short cycle time (e.g., when CO_2 is converted to methanol using the H_2 produced with renewable energy sources and then methanol is used as fuel) means that in every cycle, there is a minus delta in carbon emissions deriving from the substitution of fossil fuels with less carbon-intensive sources. On a certain timescale (e.g., 20 years), the long-term sequestration of CO_2 impacts once, while for short time cycles there is a cumulative effect. The exact value derives from a LCA analysis, but on average, the effect is at least one order magnitude higher in short time cycles with respect to long-term sequestration.

Carbon dioxide, in addition, is an excellent carbon source (Centi and Perathoner 2014), particularly when combined with the incorporation of renewable energy in CO_2 transformation. Recycle of CO_2 and incorporation of renewable energy in the production process will be between the driving elements reshaping the future of chemical production (Perathoner and Centi 2014a, b; Lanzafame et al. 2014a). In a longer term, a distributed conversion of CO_2 to chemicals/fuels will be possible by the development of artificial leaf-type devices, in which the development is raising interest (Bensaid et al. 2012). There is thus a progressive movement to a kind of CO_2 circular economy, which is schematically outlined in Fig. 6. Current economy is largely based on the use of fossil fuels, but as already at the stage of transformation of fossil fuels to the energy products or the raw materials used for chemical production, nearly half of the original energy content is lost in the form of CO_2, as indicatively shown in Fig. 6 (Ampelli et al. 2015). Various other losses are further present in downstream processes, before the utilization of the energy or chemical products. Even in the process of production of biofuels, large amounts of CO_2 are

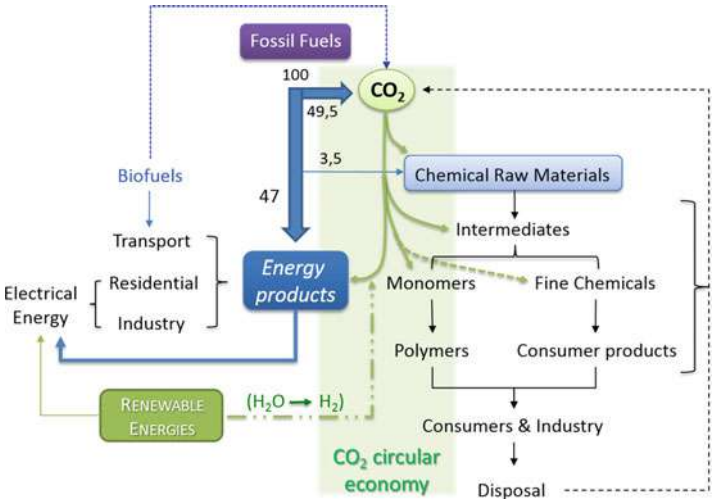

Fig. 6 Simplified model of CO_2 circular economy and its impact on chemical and energy value chain (Modified from (Ampelli et al. 2015))

formed (e.g., approx. 1 t CO_2 per ton of ethanol). Through the (re)use of CO_2, it is possible to rebalance this economy, allowing a more effective use of renewable energy (including a lower impact on environment and a better carbon footprint for biofuels), providing new raw materials for chemical production and especially preserving the actual value chain. The latter is a very important element because it allows to minimize the costs of transformation to new sustainable production system.

Although a number of organic syntheses using carbon dioxide are known, only a few were applied in industry, the main processes being the syntheses of urea and its derivatives and the production of organic carbonates, where phosgene ($COCl_2$) is increasingly being replaced by CO_2 as the C1 building unit. CO_2 is also used in the electrochemical Kolbe–Schmitt process for the production of salicylic acid. CO_2 is used industrially for fertilization in greenhouses and increasingly in photobioreactors (for breeding algae and microalgae), in enhanced gas or oil recovery processes and in refrigerant applications. All these uses account for about 110 Mtons/year, e.g., for less than 1 % of the worldwide carbon dioxide emissions. Although other industrial uses outlined below are still quite limited currently, this is a dynamic field with many emerging industrial initiatives. The concise technology roadmap outlined in Fig. 7 introduces the expected scenario for industrial utilization of CO_2 based on the analysis of the state of the art, including recent trends in patents (Ampelli et al. 2015). In a short-to-medium-term perspective, CO_2 utilization will continue its progression especially in areas that are technologically more advanced (e.g., CO_2-containing polymers, CO_2 hydrogenation). The use of CO_2 conversion to exploit

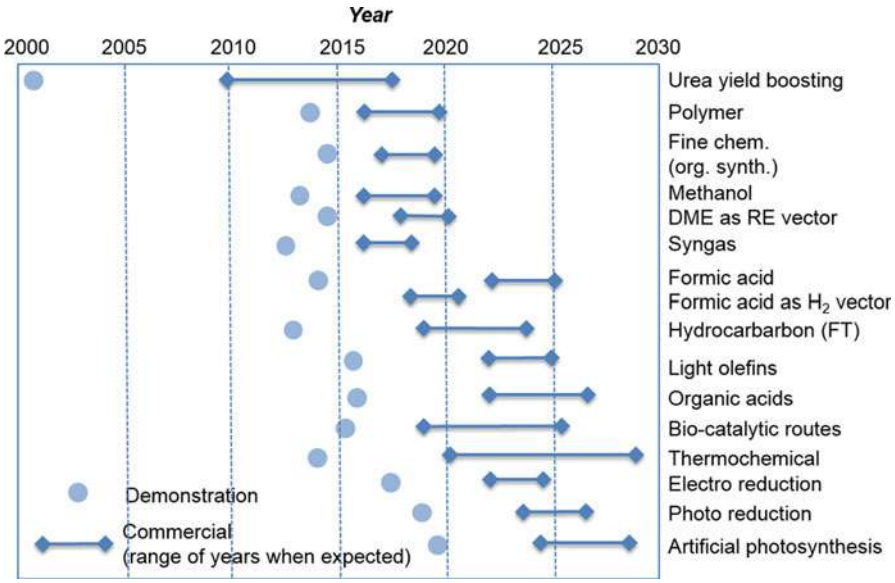

Fig. 7 Estimated technology roadmap for commercialization of CO_2 reuse paths (Modified from (Ampelli et al. 2015))

unused renewable energy resources or to mitigate instabilities on the grid (related to the discontinuous production of energy by renewable sources; chemical conversion is a way to store and distribute energy) will play a future relevant role.

In the long term, CO_2 utilization will become a key element of sustainable low-carbon economy in chemical and energy companies, combined with curbing consumption (Centi and Perathoner 2014; Perathoner and Centi 2014a). CO_2 will become especially a strategic molecule for the progressive introduction of renewable energy resources into the chemical and energy chain (Perathoner and Centi 2014a), thus helping to lessen fossil fuel consumption (expected to decrease by >30 % by year 2030). CO_2 utilization will become an important component of the strategy portfolio necessary for curbing CO_2 emissions (with an estimated potential impact of gigatons equivalent CO_2 emissions, similar or even superior to the impact of CCS and biofuels, but with lower cost for society (Barbato et al. 2014)). CO_2 utilization will thus be at the heart of strategies for sustainable chemical, energy, and process industries and for a resource and energy efficiency development.

Four main routes are predominantly investigated:

- Carboxylic acids and derivatives, e.g., novel CO_2-based routes to products essentially for the chemical market
- Alcohols, ethers, and hydrocarbons, e.g., CO_2 conversion to already well-established products for the chemical and energy market
- Organic carbonates and other monomers for CO_2-based plastics
- Urea and derivate, e.g., novel alternative or more sustainable (phosgene-free) routes to well-established chemical products

Figure 8 reports an overview of the different possible catalytic conversions of CO_2 to industrially relevant chemical products or components for fuels. Most of these routes are still not commercial, apart from urea and some organic carbonate. Their expected industrial application is summarized in Fig. 7. Some of them, such as acetic and acrylic acid or vinyl acetate from CO_2, are attracting, but the results are still far from the possible application.

Many valuable chemicals can be also produced by CO_2 fixation using homogeneous catalysis: lactones, pyrones, oxazolidinone, imidazolidinone, quinazoline, etc. Although interesting, the market for these products is quite limited, and thus the impact of these synthesis on the global carbon dioxide emissions is nearly negligible. CO_2, coordinated to metal centers, may be inserted into various metal–element bonds to give rise to various reactions, such as (i) C–C bond formation to produce acids, esters, lactones, and pyrones; (ii) C–N bond formation with production of carbamates and isocyanates; and (iii) C–O bond formation for the synthesis of linear or cyclic carbonates and poly(carbonates).

Some interesting examples of recent new routes for activating CO_2 using homogeneous catalysts are listed below:

- Hydrosilanes used to convert CO_2 into methane or methanol using zirconium phenoxide borane complexes or *N*-heterocyclic carbenes as catalysts

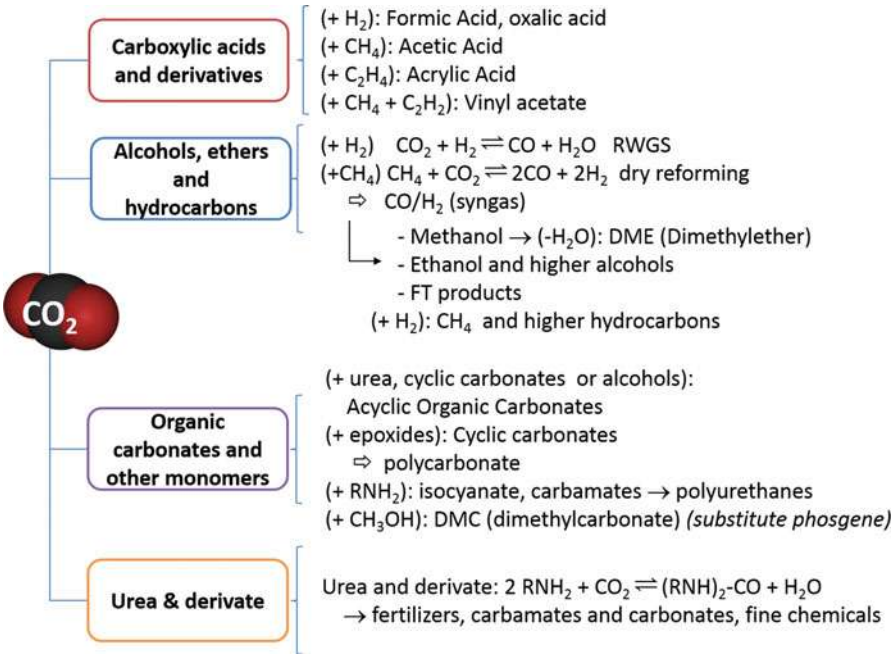

Fig. 8 Overview of the different possible catalytic conversions of CO_2 to industrially relevant chemical products or components for fuels

- Borane reduction of CO_2 to form boryl formats using nickel diphosphine complexes as catalysts
- Frustrated Lewis pairs for homogeneous hydrogenation of CO_2
- Nonmetal-mediated homogeneous hydrogenation of CO_2 to CH_3OH
- Indirect conversion of CO_2 to methanol based on the use of Ru pincer complexes as catalysts for the hydrogenation of carbonates, carbamates, and formats

Also in the area of the use of CO_2 in organic synthesis, a number of recent breakthroughs have been discovered. For example, in the area of carboxylation, the catalytic hydrocarboxylation of styrene and the copper-catalyzed hydrocarboxylation of alkynes using CO_2 in the presence of a hydrosilane may be cited. These reactions open new interesting perspectives for organic synthesis, but all these cases refer to low-volume productions.

Electrocatalysis is offering new possibilities, either to produce small organic molecules to be used in conjunction or integrated with solar devices (for artificial leaf-type systems) or as a valuable synthetic procedure. The number of new discoveries after years of stagnation is remarkable. There is the need to go beyond the conventional metal-type electrodes operating in liquid phase. Gas-phase or liquid-phase operations in the presence of molecular catalysts (such as pyridinium ions) are two promising directions to form either methanol or even long-chain alcohols, but

scientific effort in these areas is still too limited. The use of nonconventional electrolytes, such as ionic liquids, is another attractive direction. New electrocatalysts are also recently discovered, for example, a nanoporous silver electrocatalyst that is able to reduce CO_2 to carbon monoxide with approximately 92 % selectivity at a rate over 3000 times higher than its polycrystalline counterpart under moderate overpotentials (<0.50 V). Electrocatalytic carbonylation on novel catalysts (MOF) is another interesting possibility relevant for organic syntheses.

On short term, the following two are the catalytic routes with the higher potential impact to reduce the CO_2 emissions:

- The use of CO_2 to produce monomers for advanced material polymers, e.g., CO_2-containing polymers such as polycarbonate
- The hydrogenation of CO_2 to produce synthesis gas (syngas, a mixture of carbon monoxide and hydrogen) which can be subsequently transformed to compounds for energy/chemical market: (i) via Fischer–Tropsch process, a set of chemical reactions that convert syngas into liquid hydrocarbons, or (ii) via methanol/DME (dimethyl ether)

CO_2 Use to Produce Monomers for Advanced Materials Polymers

The incorporation of carbon dioxide into polymers is an active area of research for the interesting perspectives of application (Darensbourg 2007; Fukuoka et al. 2010). Examples are the synthesis of polycarbonates, polypyrones, lactone intermediates, and polyurethanes. There are various industrial initiatives in this sector, among which the production of polyols for polyurethane (Bayer) and the production of polypropylene carbonate (BASF and Novomer Inc.) (Centi et al. 2013).

Asahi Kasei Corporation was the first to succeed in industrializing the production of an aromatic polycarbonate (PC) using CO_2 as a starting material (Fukuoka et al. 2010). The carbonate group of PC links directly to the residual aromatic groups of the bisphenol. Until Asahi Kasei's new process was developed, all of carbonate groups of PC in the world were derived from CO as starting material. Furthermore, more than about 90 % of PC has been produced by the so-called phosgene process (phosgene is highly toxic and corrosive and derives from the reaction of CO with Cl_2), which besides safety issues, gives rise to a PC containing Cl impurities and large amounts of wastewater. The new CO_2-based process uses a safer reactant and contributes to reduce carbon dioxide emissions but also produces a higher quality PC and has a lower impact on the environment. Regardless of the many advantages, the higher cost of production has still significantly hindered the market introduction of this process.

The novel green Asahi Kasei process is based on the condensation of DPC and BPA in a melt-polymerization process including a pre-polymerization step (Fig. 9). The process is clean, producing valuable ethylene glycol as the by-product. The starting material is ethylene oxide (EO) (Step 1). The by-product of ethylene oxide manufacture, CO_2, is itself consumed in the process (173 t per 1000 t of BPC);

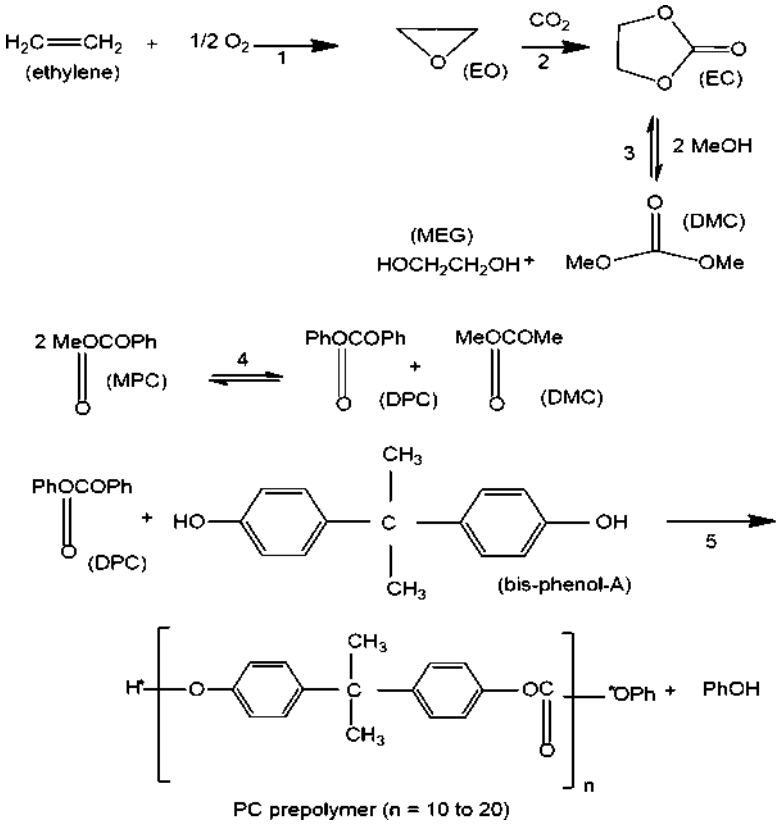

Fig. 9 Asahi Kasei process for polycarbonates

ethylene oxide is converted into ethylene carbonate (EC) by reaction with CO_2 (Step 2). Step 3 is the conversion of EC into DMC by reaction with methanol and the production of high purity monoethylene glycol (MEG).

Bayer has developed a process for polyether carbonates polyols (PPP) from CO_2 up to pilot/demo plant. The PPP resulting from the copolymerization of CO_2 with a starter molecule (mono-, di-, and polyols; alkoxylated oligomers of glycols) and an alkylene oxide are characterized by low molecular weight and terminal OH functionalities, available for further reaction with isocyanate to lead to urethane groups (Fig. 10). A key scientific breakthrough allowing industrialization of CO_2 polymerization to PPP was the development of a catalyst that is sufficiently stable and active under the process conditions (90 °C, 10 bar of CO_2), such as double metal cyanide catalyst.

Novomer has proposed a new catalytic process for the industrial production of aliphatic polycarbonates by reaction of CO_2 with epoxides. In particular, they have developed novel catalytic processes for the reaction of carbon dioxide with propene oxide or ethylene oxide to produce polypropylene carbonate and polyethylene

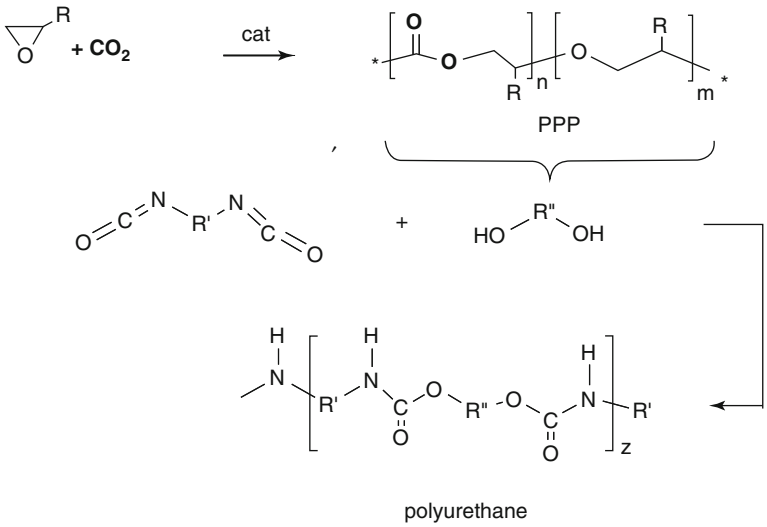

Fig. 10 Schematized Bayer route to polyurethane from the polyether polycarbonate polyols (PPP)

carbonate, respectively. Applications of these polymers range from packaging, coatings to electronics, and barrier layers. The processes, however, are not still on a commercial production scale (demonstration at an about 2 m^3 scale). The polymer has different properties – it can be hard, soft, transparent, or opaque – based on the type of epoxide used, and it is biodegradable.

There are other possible monomers for polymers produced using CO_2 in the step syntheses, directly or indirectly. Urea can be used as a "reactive CO_2" in the synthesis of carbamates and then carbonates.

$$H_2N - CO - NH_2 + ROH \rightarrow H_2N - CO - OR + NH_3 \quad (1)$$

$$H_2N - CO - OR + ROH \rightarrow RO - CO - OR + NH_3 \quad (2)$$

The separation/purification cost of the carbonate decreases with increasing number of carbon atoms in the chain of the alcohol. Hence, this technology is better suited for the synthesis of carbonates of higher alcohols. Urea has been used for the synthesis of cyclic carbonates by reaction with diols. The released ammonia can be recovered and recycled. The transesterification reaction can be used to convert one carbonate into another (Eq. 3). However, the alcohol coproduct must be recycled or have a market comparable to that of carbonates.

$$(RO)_2CO + 2R'OH \rightarrow (R'O)_2CO + 2ROH \quad (3)$$

Diphenyl carbonate is commercially produced by this way, using efficient catalysts, which have been recently developed, such as Cp_2TiCl_2, Pb and Zn double oxide, and V, Nb, and Ta.

Isocyanates are also industrially relevant compounds with applications in several fields, as starting materials for pesticides, dyes, detergents, and adhesives, as well as in the manufacture of resins and rubbery plastics. Furthermore, diisocyanates are the primary feedstock for the production of polyurethanes, with a global market of almost 5 Mtons/year. The direct synthesis of isocyanates from amines and CO_2 (Eq. 4) is a challenging task which requires to deoxygenate the cumulene bonds of CO_2; some Ti(IV) and U(V) organometallic complexes are capable of promoting such a transformation.

$$RNH_2 + CO_2 \leftrightharpoons RNCO + H_2O \tag{4}$$

New catalysts in combination with ionic liquids show promising results (Heyn et al. 2014).

CO_2 Hydrogenation

A main route of conversion of carbon dioxide is the hydrogenation to produce syngas, alcohols such as methanol or ether such as dimethyl ether, or hydrocarbons. The availability of renewable H_2 and/or renewable sources of energy is the critical element for this route. The alternative is to use methane as the source of H_2 in the so-called dry reforming reaction. This is an endothermic reaction occurring at high temperature and may be combined with the steam reforming (also the endothermic reaction between methane and water, to optimize the CO/H_2 ratio) and with the partial methane oxidation (an exothermic reaction between methane and O_2) in the so-called tri-reforming process. After this first step of formation of syngas (CO/H_2) different established routes are possible to produce chemicals or clean fuels. The alternative is to produce CO by breaking the C–O bond in carbon dioxide. This requires high reaction temperatures (>2000 °C), but the process could be assisted by redox metal oxides which reduce the temperature of operations to a range (around 1000 °C) compatible with concentrated solar furnaces. An alternative is the use of a photocatalytic or photoelectrocatalytic systems to convert directly CO_2 and H_2O at near room temperature using solar light.

Between the carboxylic acids, which can be obtained by hydrogenation of CO_2, formic acid is the more interesting. This reaction has been proposed as the basis for a "formic acid" economy, being possible to use formic acid in fuel cells (to store and transport H_2) and as chemical. However, formic acid has problems of toxicity and storage. Methanol economy (Olah et al. 2009a, b), which could be also based on CO_2 hydrogenation, has stronger fundaments.

Formic acid is the simpler chemical produced by hydrogenation of CO_2 and that requires less hydrogen:

$$CO_2 + H_2 \leftrightharpoons HCOOH \tag{5}$$

A consortium was formed within EPSRC (Engineering and Physical Sciences Research Council) activities in the UK to investigate formic acid synthesis from CO_2 and its use including as feedstock for fuel cells. A renewed interest on this reaction is also present in Japan after a significant improvement in the understanding of the active form of the catalyst and rate-determining step to convert CO_2 into formic acid using water as a green solvent. There is an active research on the synthesis of formic acid particularly using homogeneous catalysts. New opportunities have been also offered from ionic liquids.

Formate could be reduced to formic acid also in mild hydrothermal conditions using iron nanoparticles as the reductant and Ni as a catalyst. CO_2 may be also directly reduced in the presence of iron nanoparticles under mild hydrothermal conditions to form formic and acetic acid. Both these possibilities, however, still appear far from the application.

The enzyme formate dehydrogenase can be also used to convert CO_2 to formic acid. It may be also encapsulated in biomimetic hydroxyapatite–polysaccharide capsules to promote stability and operations (broader temperature and pH range). However, productivity should be improved.

Electroreduction of CO_2 (ERC) is the method used by the company Mantra up to pilot scale for producing formic acid. The reduction of CO_2 in methanol-based electrolyte (limited CO_2 solubility in water is an issue) gives rise to formic acid and CO using Zn particle-pressed electrodes, while the addition of Cu_2O particles to this electrode leads to the formation of also methane and ethylene. At high CO_2 pressure (to increase productivity) using Cu electrode and MeOH as electrolyte, the reduction products were formed in the order of CO, methane, formic acid, and ethylene. The use of microfluidic techniques to build microscale electrochemical reactors is identified to be highly promising to increase the electrochemical performance (Lu et al. 2014).

Formic acid, together with other products such as methanol, formaldehyde, and minor amounts of hydrocarbons (CH_4, ethylene), is the main product obtained in the photocatalytic reduction of CO_2 in water (Das and Wan Daud 2014). The recovery of the products in the photocatalytic reduction of CO_2 is energy-intensive and particularly critical due to the low productivity. To promote visible light activity, sensitizers could be used, but stability is still low. In the photoelectrochemical reduction of CO_2 at p-InP electrode, formic acid and carbon monoxide form by reaction of CO_2 with a photogenerated electron at the semiconductor surface. The $^{\bullet}CO_2^-$ adsorbed anion radical formed may react with a further electron and a proton to give either adsorbed CO or $HCOO^-$, but when copper particles are present in solution, methane and ethylene were also detected.

The coupling of two $^{\bullet}CO_2^-$ anion radicals formed by the addition of one electron to CO_2 can give rise to oxalate ion, particularly in some nonaqueous electrolyte. Oxalic acid is used as industrial cleanser especially to scour rust off metals. A dinuclear Cu^{I} complex that is oxidized in air by CO_2 rather than O_2 was discovered recently. The product is a tetranuclear Cu^{II} complex containing two bridging CO_2-derived oxalate groups. Treatment of the Cu^{II}–oxalate complex in acetonitrile with a soluble lithium salt results in quantitative precipitation of lithium

oxalate. The Cu^{II} complex can then be electrochemically reduced nearly quantitatively at a relatively accessible potential, regenerating the initial dinuclear Cu^{I} compound.

The direct synthesis of acetic acid by reaction of CO_2 with methane is potentially a very attractive reaction alternative to current method by methanol carbonylation (e.g., using CO). The methanol carboxylation (e.g., using CO_2) forms dimethyl carbonate (DMC), but acetic acid could be produced from the reaction of CO_2 and methane, using two powerful and widely available greenhouse gases:

$$CO_2 + CH_4 \rightarrow CH_3COOH \tag{6}$$

However, current results are still far from the possible application. Another attractive reaction is the carboxylation of alkenes with CO_2 using transition elements in a low oxidation state (Fe^0, Mo^0, Ni^0, and Rh^I) as catalysts. This reaction has been recently revisited for its potential for obtaining acrylic acid derivatives. The development of efficient catalysts is required to favor the acrylic acid or acrylate release. An alternative synthetic approach to acrylates is based on the formation of alkyl esters of acrylic acids' alkyl esters. The reaction involves a preformed Pd–COOMe moiety as a system for the insertion of ethene and propene into the Pd–C bond, followed by acrylate elimination. Actual data, however, are quite far from those necessary for the process to be in competition with the commercial process involving the selective (multistep) catalytic oxidation of propene.

The production of alcohols (methanol in particular or its products of dehydration dimethyl ether (DME)) or hydrocarbons (especially Fischer–Tropsch (FT) products) is actually the more interested route to hydrogenate CO_2 (Quadrelli et al. 2011). Pilot plant experimentation is available as well as stable catalysts. The possibility of commercialization is highly dependent on the need to use CO_2 as raw materials (e.g., due to carbon taxes) and the availability of H_2 sources from renewable or other nonfossil fuel (e.g., nuclear plants) energy sources.

Methanol is one of the most important commodity chemicals as it is used as a raw material in several intermediate chemicals and end uses. Methanol is commercially produced from synthesis gas (CO/H_2), but the presence of small amounts of CO_2 in the feed accelerates the reaction. However, pure CO_2 feed or even larger CO_2/CO ratios instead inhibit the reaction rate, essentially due to the poisoning effect of the water formed from the reverse water–gas shift (RWGS) reaction:

$$CO_2 + H_2 \leftrightharpoons CO + H_2O \tag{7}$$

The critical aspect for a process using a CO_2–H_2 feed is to improve current syngas–methanol catalysts in terms of both low-temperature activity and water tolerance. Current catalysts are based on Cu–Zn oxides containing various additives (ZrO_2, Ga_2O_3, and SiO_2) in addition to alumina (Behrens 2014). The best productivities were obtained with Ga_2O_3, but within the same support, the productivity to methanol was linearly dependent on the metallic copper surface area, as found in syngas to methanol reaction. Ga_2O_3 allows improving the specific activity for

methanol synthesis, while Al_2O_3, ZrO_2, or SiO_2 improves the dispersion of copper particles and the stability.

Due to the strong water inhibition, a new process for methanol from CO_2 should include also a continuous removal of water from the reactor. Possible solutions are the catalytic distillation and the use of inorganic water permselective membranes. The latter is a preferred solution, although no specific results have been reported in literature. Suitable and recoverable membranes are those based on hydrophilic nanopore zeolite (NaA) films over a ceramic tubular support and developed for pervaporation of water–ethanol solutions.

A new interesting area of development is based on the nonmetal-mediated homogeneous hydrogenation of CO_2 to methanol at low pressures (1–2 atm) using frustrated Lewis pairs (FLP). In FLP, the steric environment imposed on the donor and acceptor atoms by the substituents prevents a strong donor–acceptor interaction.

High faradaic efficiencies (up to 90 % and 96 % with 465 and 365 nm radiation, respectively) in the selective conversion of CO_2 to methanol at a p-GaP semiconductor electrode with a homogeneous pyridinium ion catalyst and an applied potential of about −0.2 to 0.3 eV have been reported (Barton et al. 2008). Quantum efficiencies were between 1 % and 10 %, but an inverse relationship between methanol formation and current density was observed. This indicates from the practical point of view that only very diluted solutions of methanol in water could be obtained, and thus the energy to recover methanol is greater than the advantage of using solar energy.

Ethanol is less toxic and a better intermediate for chemicals with respect to methanol, although its low-cost production by sugar fermentation makes less attractive its synthesis by CO_2 hydrogenation. The selective ethanol synthesis from CO_2 using supported $Rh_{10}Se/TiO_2$ catalysts is known for a long time. At 300–350 °C, a rate of ethanol formation from CO_2–H_2 of about $2–4 \cdot 10^{-3}$ mol/h · g_{cat} with a selectivity to ethanol in the 70–85 % range has been observed. The alternative routes are (i) to add centers (such as K^+) able to promote the C–C bond formation to catalysts for the synthesis of methanol from CO_2 and (ii) use homogeneous catalysts able to give the methanol homologation with CO_2–H_2 such as bimetallic ruthenium–cobalt carbonyl complexes. Both routes, studied around the years 1995–2000, were only partially successful and no longer explored recently.

Dimethyl ether (DME) is a clean and economical alternative fuel (high cetane number, but low boiling point). There are also several technology developments recently for selective production of olefins, especially propylene either from methanol or from DME. DME synthesis from CO_2–H_2 should be considered as an extension of methanol synthesis to shift the equilibrium by using hybrid catalysts.

$$2CH_3OH \leftrightharpoons CH_3OCH_3 + H_2O \tag{8}$$

Catalysts used are thus a combination of a catalyst for methanol synthesis from CO_2–H_2 and an acid catalyst, typically zeolite.

Higher alcohols (>C2) are valuable chemicals, solvents, and additives for fuels, but few data are available regarding their possible synthesis from CO_2.

Cyanobacteria (*Synechococcus elongatus PCC7942*) have been recently genetically modified (strain SA579) to consume carbon dioxide in a set of steps to produce a mixture of isobutyraldehyde (primarily) and isobutanol. The engineered strain remained active for 8 days and produced isobutyraldehyde at a higher rate than those reported for ethanol, hydrogen, or lipid production by cyanobacteria or algae.

A different approach is by electrocatalysis (Centi and Perathoner 2004, 2009, 2010). Using novel electrocatalysts based on metal particles carbon nanotubes and gas-phase operations, it is possible to form isopropanol as the main product, together with other alcohols (methanol, ethanol) and hydrocarbons (up to C8–C9). The rate of formation is roughly comparable to that of biocatalysis, but with the advantage in the case of electrocatalysis that the products form in the gas phase and are thus easily recovered. The electron and protons necessary to reduce the CO_2 electrocatalytically have to be supplied from water photoelectrolysis on the photo-anode side of a photoelectrocatalytic device, but the full apparatus has not been tested yet.

CO_2 hydrogenation to methane is the well-known Sabatier reaction. It proceeds in the presence of a Ni-based catalyst:

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O \tag{9}$$

On this reaction, indicated with the acronym P2G, there is strong R&D effort, particularly in Germany, in relation to the local storage of excess electrical energy (by wind) and the production of methane for automotive use (Audi e-gas process). A 6-MW P2G, located in the Lower Saxony city of Wertle, started the operations in 2013. Being methane as gas, storage and distribution are more difficult than that with methanol (even considering the large pipeline net; there are also issues of purity for introduction in the pipeline system), and chemical use is quite difficult, if not passing through syngas (but then direct production of syngas from CO_2 would be preferable).

Interest on this reaction also arises for the possibility to generate O_2 and fuels on Mars and for applications such as propellant production on Mars or air revitalization in the space habitat. Microchannel designs offer advantages for a compact reactor with excellent thermal control. A Ru–TiO_2-based catalyst was used for the microchannel reactor.

The Sabatier reaction can be viewed as the combination of CO methanation and RWGS reaction. Therefore, catalysts active in these reactions are also active on CO_2 methanation. The conversion of CO_2 in Sabatier reaction could be increased using a water permselective membrane. Using a membrane reactor integrated with a water vapor permselective membrane, the conversion was increased about 18 % in comparison to the case without the membrane.

From the application perspective, more interesting is the production of higher hydrocarbons via the Fischer–Tropsch (FT) synthesis (Davis and Occelli 2009). This reaction typically uses synthesis gas, e.g., CO/H_2 mixtures, as the raw materials, but a number of recent studies have been dedicated to the effect of CO_2 on FT synthesis. CO_2 can be activated by suitable promoter(s) for hydrocarbon synthesis at low temperature. Low K content is suitable for increasing hydrocarbon yield. The Fe

catalysts promoted by Zn and Cu have higher CO and CO_2 conversion and decreased CH_4 selectivity. FT synthesis could be useful to produce hydrocarbons from CO_2-rich syngas as those produced from biomass. In general, there is increased carbon utilization in FT synthesis using CO_2-rich syngas feeds.

A modification of the FT catalysts allows obtaining good selectivities to light alkenes and thus to use this process also to make chemicals. About 85 % selectivity to alkene in the C_2–C_4 fraction (about 40 % of the whole hydrocarbon fraction) could be obtained. There are problems of catalyst stability, however. Hydrocarbons may be obtained via conversion of methanol/DME on multifunctional catalysts instead of the FT mechanism. On Fe–Zn–Zr/HY catalyst, it is possible to maximize the selectivity to isoC4. The use of CO_2 instead of CO increases the formation of isoalkanes (iC_4 and iC_5). The selective synthesis of ethylene by electrocatalytic reduction of CO_2 has been also shown using copper electrodes. Up to 33 % faradaic efficiency to ethylene was observed with low amounts of methane (about 4 %).

Urea and Derivate

The industrial synthesis of urea from carbon dioxide and ammonia is one of the most important examples of the large-scale production processes where carbon dioxide is utilized as a raw material. The worldwide urea production is over 120 Mtons/year, being used as fertilizer and as monomer for the manufacture of thermosetting polymers/plastics, such as melamine and urea–formaldehyde resins. Urea is also used as an auxiliary material in the petroleum and pharmaceutical industries. Although urea synthesis is commercially made from already many years, still there is the need of improvements, particularly regarding the increase of carbon dioxide conversion and heat recovery, the minimization of the environmental impact, and the introduction of catalysts to optimize the process variables.

Urea boosting indicates the capture of an external current of fossil CO_2 for urea production in an integrated ammonia–urea manufacturing plant and the use of natural gas as a feedstock in the reforming process to produce CO_2 and NH_3. When natural gas is used as feedstock, an excess of NH_3 is produced. An external source of CO_2 can be delivered via pipeline to the urea plant and reacted with surplus ammonia to form urea. This solution gives various types of GHG emission mitigation action:

1. Feedstock switch (avoidance of the emission of a fossil CO_2 current through its capture and utilization as input for urea production)
2. Thermal energy savings (thermal energy savings through the reduction of fossil fuel combustion needed to produce the CO_2 input for urea production)

Disubstituted ureas are useful chemical intermediates in the synthesis of pharmaceuticals, agricultural chemicals, and in dye chemistry. They are also used as antioxidants in gasoline and additives in plastics. As an alternative to their synthesis by phosgenation or oxidative carbonylation, they can be synthesized by the reaction

of CO_2 with primary amines, with different catalytic systems. Basic ionic liquid (1-*N*-butyl-3-methylimidazolium hydroxide ([BMIM]OH)) could be also used as the catalyst.

The interaction of CO_2 with several N-nucleophiles (e.g., amines) has a great synthetic relevance as it is a key step toward the formation of N–C bonds, when the carbamic acids generated in situ react with electrophiles such as organic halides or alcohols (Eqs. 10 and 11), to obtain carbamates RHN–C(=O)OR′, R, and R′ = alkyl or aryl. The utilization of CO_2 for the synthesis of these derivatives is a safer alternative to toxic phosgene.

$$R_1R_2NH + CO_2 + R_3X + \text{Base} \rightarrow R_1R_2N - C(=O)OR_3 + HX(\text{Base}) \quad (10)$$

$$RNH_2 + CO_2 + R'OH \rightarrow RNH - C(=O)OR' + H_2O \quad (11)$$

Carbamates find a wide application in the chemical, pharmaceutical, and agrochemical industries, with a market of several Mtons/year.

Organic Carbonates

Linear and cyclic carbonates are industrially relevant chemicals, which incorporate CO_2 via catalytic routes. The most relevant chemicals are the following: dimethyl carbonate (DMC), diphenyl carbonate (DPC), ethylene carbonate (EC), and styrene carbonate (SC). The latter is useful intermediates for polycarbonate production, while DMC, EC, and propylene carbonate (PC) are widely used as nontoxic aprotic polar solvents and as electrolytes in Li-ion batteries. Moreover, linear carbonates are important alkylating and carbonylating agents (Sakakura et al. 2007). DMC is of interest as an additive to diesel fuel, increasing the octane number and reducing the particulate emissions from engines. Current DMC worldwide production is about 0.5 million tons/year, but if DMC will be used as gasoline additive, its market would reach the Mtons/year.

Traditional routes for the industrial production of linear carbonates, especially DMC, utilize either phosgene or carbon monoxide, causing problems due to toxicity or corrosion. The synthesis of linear carbonates by means of urea or cyclic carbonates, as well as by direct one-step CO_2 reaction with alcohols, is much safer and cleaner than other processes, although thermodynamically unfavorable.

The alcoholysis of urea has the potential to be integrated with a urea plant for optimizing ammonia recycling. The use of catalytic distillation can intensify the process. The formation of several side products, which results in poor selectivity, is one of the major drawbacks of using this reaction. The indirect transesterification route represents a method for achieving high purity in DMC and DPC production. The economic advantage of this method mainly relies on (i) reactant costs; (ii) enhancement of catalyst productivity, separation, and recycling; and (iii) higher conversion by a drift in thermodynamic constraints. The advantage of the direct reaction is that it does not depend on the demand and supply balance of the

coproducts formed in the indirect routes (ammonia or glycols). The key issue to advance this green process and related engineering will be either a proper choice of more stable, active, and selective catalytic systems or a new approach to eliminate water by pervaporation or separation technology with mesoporous silica, polyimide–silica, and polyimide–titania hybrid membranes.

Oxiranes and oxetanes undergo cycloaddition with CO_2 to give five- and six-membered cyclic carbonates. This synthesis is selective, but homo- and copolymerization can also take place. Synthesis of five-membered carbonates occurs by oxidative carboxylation of alkenes. In the presence of CO_2, the dehydration of 1,2-diols gives cyclic carbonates. A wide range of catalysts recently developed for the synthesis of cyclic carbonates from CO_2 and oxiranes can be classified as follows: (i) alkali metal halides (KCl, KI, LiBr, etc.), (ii) ammonium or phosphonium salts, (iii) metal *salen* complexes, and (iv) solid or immobilized catalysts (in particular, amine-functionalized silica catalysts) to facilitate recovery and recycling without affecting activity. Recently, the carboxylation of oxiranes was carried out in ionic liquids (i.e., imidazolium salts) as solvents and/or catalysts, resulting in deep effects on the reaction rate and product selectivity.

The oxidative carboxylation of carbon double bonds into five-membered cyclic carbonates has been tested on alkenes such as ethene, propene, and styrene, using different catalysts. This oxidative methodology has a great potential, starting from cheap and easily available reagents and would be inherently safer due to the presence of CO_2.

Cyclic carbonates are widely used as high-boiling point aprotic polar solvents, electrolytes in secondary batteries, precursors for polycarbonates and polyurethanes, and intermediates in the production of fine chemicals and pharmaceuticals (Fig. 11).

CO_2 in Reforming Reactions and as Selective Oxidant

Syngas, e.g., a mixture of CO/H_2, is one of the major petrochemical building blocks and is commercially produced by hydrocarbon (mainly methane) steam reforming, partial oxidation, or a combination of the two processes. An alternative route is to produce syngas by reforming methane with carbon dioxide. This process is indicated as “dry” reforming, in contrast to “wet” reforming by steam. Combination of “dry” and “wet” reforming and/or partial oxidation is instead indicated as “mixed” reforming.

$$CH_4 + CO_2 \leftrightharpoons 2CO + 2H_2 \tag{12}$$

$$CH_4 + H_2O \leftrightharpoons CO + 3H_2 \tag{13}$$

The CO/H_2 ratio produced in the dry reforming is 1, but the RWGS reaction occurs simultaneously, and thus the effective ratio is less than 1 and the CO_2 conversion greater than that of methane. The CO/H_2 ratio is appropriated for FT synthesis of alkanes (which requires a ratio between 0.5 and 1) and alkenes (ratio 0.5). This is a

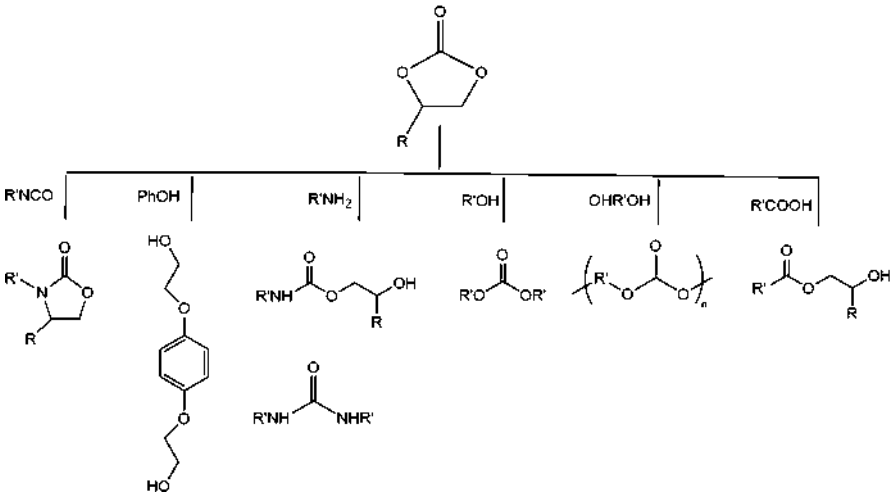

Fig. 11 Applications of cyclic carbonates in organic synthesis

clear advantage over the conventional production of syngas for FT reaction, which uses a combination of steam reforming and partial oxidation.

A further great advantage is that often CO_2 is present together with methane in natural gas deposits. Therefore, using dry reforming at or near wellhead coupled to FT would produce liquid hydrocarbons that are easy to transport from remote areas (stranded gas). The additional potential advantage is that the process converts two of the principal gases responsible for greenhouse effect. It should be remarked, however, that CO_2 is typically reintroduced in the well to increase the deposit exploitation. Biogas upgrading is another target application for dry reforming.

The dry reforming is a strong endothermic reaction and requires temperatures above 700 °C to have reasonable conversions. A key problem is how to supply the energy needed to sustain the reaction, which under industrial conditions is limited from this rate of heat transfer. A typical reactor configuration is to use packed tubes directly placed inside the furnace. Advances in this area regard mainly the reactor design to improve efficiency of this heat transfer.

In principle, catalysts that are active for steam reforming also work for dry reforming. However, since the steam-to-carbon ratio is lower for dry (or mixed) reforming than for steam reforming, the risk of carbon formation is considerably higher. As a result, research efforts have focused on catalysts, which show high activity to synthesis gas formation and are resistant to coking, thus displaying stable long-term operation. Especially the rare earth elements (in particular La and Ce) have been identified as suitable candidates for enhancing catalyst performance.

An important factor for catalyst reactivity and stability lies in the catalyst's resistance to carbon deposits, which could lead to active site blocking. Apart from directly altering the metal's properties by additives, an alternative route is to use a support, which suppresses carbon deposition. This can be achieved with so-called

oxy-transporters, such as ZrO_2 or CeO_2, which are capable of oxidizing deposited carbon. Additionally, because of their oxygen-conducting properties, these supports can actively participate in the catalytic reaction by oxidizing or reducing reaction intermediates.

Carbon is one of the principal mechanisms of catalyst deactivation, even if it should be considered that in dry reforming with respect to steam reforming, the carbon is more easily oxidized. Carbon derives from two main reactions:

$$\text{Methane decomposition} : CH_4 \rightarrow C(s) + 2H_2 \tag{14}$$

$$\text{CO disproportionation} : 2CO \rightarrow C(s) + CO_2 \tag{15}$$

To design a catalyst to be active and stable, it is necessary to consider both thermodynamic and kinetic aspects. The first aspect requires to optimize the key process variables, but within the constraints of economic feasibility. For example, low methane concentrations minimize Eq. 12 but also inhibit the main reforming reaction. For this reason, typical reaction conditions are those in which carbon formation is thermodynamically feasible. Therefore, it has to operate to minimize reactions 10 from the kinetic point of view. On Ni-based catalysts, carbon formation is minimized by adding small amounts of an alkali metal to the catalyst. Doping with MoO_3 also reduces the carbon formation. A special case is the carbon deposition inhibition by "controlled passivation" of the catalyst surface (noble metal) by sulfur, the basis for the Haldor Topsøe A/S SPARG process.

Sintering is a further important aspect determining the lifetime of the catalyst. The stability of nickel-based catalysts can be enhanced by addition of basic and rare earth metal-oxide promoters.

The tri-reforming process is a synergetic combination of endothermic CO_2 reforming (Eq. 11), steam reforming (Eq. 12), and exothermic partial oxidation of CH_4 (Eqs. 18 and 19) in a single reactor for effective production of industrially useful syngas (Song 2006):

$$CH_4 + CO_2 \rightarrow 2CO + 2H_2 \tag{16}$$

$$CH_4 + H_2O \rightarrow CO + 3H_2 \tag{17}$$

$$CH_4 + ½O_2 \rightarrow CO + 2H_2 \tag{18}$$

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O \tag{19}$$

Tri-reforming cannot only produce synthesis gas ($CO + H_2$) with desired H_2/CO ratios (1.5–2.0) but also could eliminate carbon formation, which is usually a serious problem in the CO_2 reforming of CH_4. These two advantages have been demonstrated by tri-reforming of CH_4. A fixed-bed flow reactor operating at 850 °C with supported nickel catalysts was used.

An area of emerging interest, particularly in patents, is the use of nonthermal plasma (NTP) to activate both CO_2 and CH_4 and produce syngas under quite mild

conditions. Plasma, i.e., ionized gas, is usually sustained in electrical discharges by the application of electric fields. The energy is transferred, in the first instance, to free electrons. It is subsequently distributed through collisions to the feedstock molecules (CO_2 and CH_4) and their decomposition products. The sum of all possible excitation mechanisms leads to the key aspect of NTP: the injected energy is not equally distributed across all the species and their degrees of freedom. In particular, heating of the gas can remain low (due to the large mass difference between the colliding electron and molecule), while certain molecular vibrations are highly excited. The latter will promote bond breaking and dissociation. It is possible to obtain up to 90 % energy efficiency in plasma chemical reduction of pure CO_2 (in the absence of CH_4) into CO. In the CO_2 reforming with methane, conversions typically lower than 50 % were obtained, in combination with catalysts such as supported Pd catalysts, nickel ferrite nanoparticles, and Ni-based supported catalysts. However, conventional-type catalysts have been used. The challenge is to develop specific catalysts tailored to operate optimally in synergy with the high reactive species present in the plasma.

The dissociation of CO_2 on catalyst surface could produce active oxygen species. Some heterogeneous chemical reactions can benefit from using CO_2 as a mild oxidant or as a selective source of "oxygen" atoms. Oxidative dehydrogenation (ODH) of alkanes is a relevant example. With respect to ODH with oxygen, the use of CO_2 allows forming CO as by-product and a better control of the heat of reaction but requires more severe reaction conditions:

$$C_nH_{2n+2} + CO_2 \rightarrow C_nH_{2n} + CO + H_2O \tag{20}$$

Ethane ODH is the most interesting application, for both the interest in producing ethylene, the need of high temperatures in ethane dehydrogenation due to thermodynamic limitations, and the low selectivities observed in ODH with oxygen. An ethylene yield of about 55 % at relatively mild reaction temperatures (650 °C) could be obtained using Cr_2O_3/SiO_2 catalysts modified by some acidic and basic oxides.

ODH of propane to propylene was also extensively studied. The equilibrium conversion of C_3H_8 in the presence of CO_2 is much higher than that without CO_2. The catalysts studied for this reaction were also mainly based on Cr.

Another relevant case of using CO_2 as a mild oxidant is the conversion of ethylbenzene to styrene. Styrene is an important monomer required for the production of polystyrene and copolymer blends. It is currently produced by the dehydrogenation of ethylbenzene over iron oxide catalysts (Fe_2O_3–K_2O–CeO_2 with additives) in the presence of large excess steam. This reaction suffers of many drawbacks, but the addition of CO_2 promotes the reaction. KRICT (Korea Research Institute of Chemical Technology) developed a novel process for dehydrogenation of ethylbenzene to produce styrene using carbon dioxide as soft oxidant, so-called KRICT-DECSO process. The dehydrogenation catalyst employed comprises oxygen-deficient iron oxide and many promoters with transition metal oxides. Chon International Co. developed SODECO$_2$ (Styrene from Oxidative Dehydrogenation via CO_2) technology based on KRICT studies. A Fe_2O_3–V_2O_5 supported on

Al_2O_3–ZrO_2 and doped with Mn (activity promoter), Mo and Sb (stability promoter), Ca and Mg (structural stabilizer) is used as the catalyst.

Also the liquid-phase air oxidation of p-xylene to terephthalic acid (PTA) (a large-scale chemical) using commercial Co/Mn/Br catalysts and acetic acid as the solvent (reaction temperature 195 °C) could be promoted by adding CO_2. Introduction of CO_2 in the O_2 feed increases both the yield and selectivity toward PTA, with also an increase of the product quality. This effect is more marketable when the catalyst is modified with an alkali and/or transition metal additives. The effect is probably related to the formation of a peroxocarbonate species [$CO_4^{=}$] which either participate in the selective oxidation or simple acts as reservoir to enhance the amount of dissolved oxygen in solution, improving the oxidation effectiveness.

The promotion effect of CO_2 on both activity and selectivity is also present in the liquid oxidation of other alkylaromatics, for example, in p-toluic acid oxidation to PTA, in ethylbenzene oxidation to acetophenone and benzoic acid, and in the oxidation of p-methylanisole.

CO_2 modifies the selectivity also in gas-phase oxidation. Using iron and molybdenum containing zeolite, the introduction of CO_2 in the feed increases both the conversion and the selectivity in the gas-phase selective oxidation of toluene, xylenes, and ethylbenzene to the corresponding aldehydes and acids.

CO_2 may thus have multiple roles in catalytic industrial processes. It is an interesting feedstock and a green solvent (supercritical CO_2) but may also have other uses. It may act as modifier of the catalytic behavior, it allows safer reaction conditions (as ballast to avoid explosive mixtures), it may be used to modify the properties of solvents (CO_2-expanded solvents (Subramaniam 2010)) and particularly O_2 solubility, it can tune and control the surface properties (oxidation state), and it can reduce the formation of carbonaceous species.

CO_2 Utilization in Biocatalytic Routes and to Reduce Impact of Bioprocesses

There are several emerging biocatalytic industrial routes for CO_2 valorization. Evonik is developing a CO_2-based acetone fermentation process using industrial waste gas streams that contain carbon monoxide (CO) and hydrogen (H_2) in addition to CO_2. They use genetically modified acetogens, e.g., bacteria strains (*Clostridium ljungdahlii*, *C. carboxidivorans*, and *C. aceticum*) that are able to utilize CO_2. The stage of development is the successful acetone production and the scale-up from flask into lab fermenter.

Bio-succinic acid from glucose and CO_2 is another interesting product derived from engineering strategies. At least five groups are developing (semi)commercial plants for bio-succinic acid. Bioamber is starting a facility in Pomacle, France, with an annual capacity of 2000 tons. Their process uses an *Escherichia coli* strain developed specifically to produce succinic acid, with wheat-derived glucose currently being used as the substrate. DSM (now Sabic) is also actively investigating the production of bio-succinic acid. In early 2008, DSM formed a partnership with

France's Roquette Frères to develop bio-succinic acid, and the two companies have been supplying kilo-scale samples for over a year from a pilot plant at Roquette's site (Lestrem, France). Myriant is building a commercial-scale facility in Louisiana using *E. coli* and unrefined sugar as a feedstock. BASF linked up with Purac subsidiary CSM is planning to produce bio-succinic acid using a BASF-developed bacterial strain (*Basfia succiniciproducens*) and glycerine or glucose as a feedstock. Finally, Mitsubishi Chem. Co. has also developed its own process for making bio-succinic acid from biomass.

Another interesting metabolic pathway is the production of longer-chain alcohols from CO_2. Mitsubishi Chemical Holdings Corporation is developing the original results of UCLA researchers on CO_2 conversion, in particular, for the production of butanol and hexanol by applying genetic manipulation techniques to modify algae. Liao at UCLA developed engineered bacteria to convert CO_2 into alcohols, in particular, genetically modified *E. coli* bacteria to produce various alcohols and modified cyanobacterium to produce isobutanol (Zhang et al. 2008). Using a nonnatural metabolic engineering approach, the branched-chain amino acid pathways are extended to produce abiotic longer-chain keto acids and alcohols by engineering the chain elongation activity of 2-isopropylmalate synthase and altering the substrate specificity of downstream enzymes through rational protein design.

An interesting possibility for CO_2 valorization is through syngas fermentation. Although industrial developments are still on the use of syngas (CO/H_2) rather than CO_2, the modification of the path could lead to direct use of CO_2. It is known that CODH from *C. thermoaceticum* (a Ni- and Fe-containing metalloenzyme) catalyzes the reversible oxidation of CO to CO_2. It is possible to couple this enzyme with a semiconductor such as TiO_2, which produces the electrons necessary for the reduction. A hybrid enzyme–nanoparticle system was used to achieve an efficient CO_2 to CO reduction using visible light as the energy source. In a different approach, several purple non-sulfur bacteria were used to convert CO to H_2 in a process similar to the WGS reaction. An alternative possibility is represented from coupling syngas fermentation to a plasma approach to convert CO_2 to CO or CH_4/CO_2 mixtures (e.g., deriving from biogas) to a mixture, which may be treated by syngas fermentation processes, which are at a semicommercial level. There are several microorganisms which can produce fuels and chemicals by syngas fermentation. These microorganisms are mostly known as acetogens including *C. ljungdahlii*, *C. autoethanogenum*, *Eurobacterium limosum*, etc. (Henstra et al. 2007). Most use the Wood–Ljungdahl pathway. The fermentation of syngas to ethanol by *C. ljungdahlii* was developed into a commercial process that combines biomass gasification, syngas fermentation, and distillation of ethanol from the reactor effluent. LanzaTech process of CO fermentation is currently applied on a 0.4 Ml demonstration facility (Shanghai, China) using steel mill off-gas from a working steel mill. INEOS Bio also began in 2011 the construction of their first commercial-scale plant, the Indian River BioEnergy Center in Florida.

The integration of CO_2 valorization routes in the frame of production schemes of biorefineries/biofactories (Perathoner and Centi 2014a; Lanzafame et al. 2014b) is a necessary direction to reduce the carbon footprint and environment impact of these

productions and increase their added value as well. Some of the possible routes have been discussed above, but further are possible in developing integrated solar biorefineries schemes (Lanzafame et al. 2014b), e.g., in production schemes integrating the use of waste and CO_2 to enhance the production and also through the use of solar light, for example, to convert CO_2 to valuable products such as methanol.

Introduction of Renewable Energy in the Chemical Production Chain Through CO_2 Utilization

An indirect, but relevant, way to address GHG emissions is to improve efficiency of use of resource and energy in production processes. Increasing the use of renewable resources is between the relevant goals for this objective, but the direct use of renewable energy is not effective, for example, in chemical industry, for two main reasons:

1. Most of renewable energy sources produce electrical energy, which accounts for only a small fraction (10–15 % typically) of the energy input in the actual chemical production.
2. These renewable energy sources are discontinuous, while a continuous input is necessary in process and chemical industries.

The most effective way is to produce raw materials (utilized in process industry) from the conversion of CO_2 utilizing renewable energy in the conversion process. The concept is exemplified in Fig. 12. The reaction of CO_2 catalytic hydrogenation to methanol with renewable H_2 is a possibility which has the potential to be used:

- As chemical, which may be introduced directly in the chemical production chain or after the eventual conversion to other building blocks for petrochemistry (light olefins, e.g., (Capoferri et al. 2011)); also note that these are products already in large use (drop-in products) and do not require large investments for their use differently from novel chemicals.
- As liquid energy carrier, which can be easily stored and distributed, bypassing the issue on renewable energy production intermittency and enabling the possibility to use unexploited remote sources or excess of renewable energy production; both these are current relevant targets for R&D in the area of renewable energy.

With respect to bio-routes, CO_2 utilization paths are not in opposition but in integration to move to a low-carbon economy, as commented in the previous section. Realizing a sustainable, resource-efficient, and low-carbon economy requires integrating in the chemical production chain other forms of renewable energy than those associated to the use of biomass.

Preliminary studies (Barbato et al. 2014; Perathoner and Centi 2014a) evidence how this is an economically feasible route. The concept of using reaction of CO_2 conversion to methanol to trade renewable energy (after incorporation in a suitable liquid chemical such as methanol) allows to exploit remote production of energy

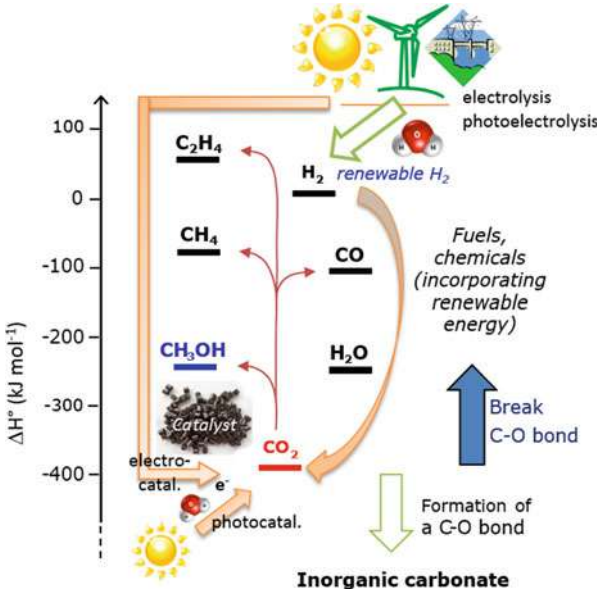

Fig. 12 Energy scale in some of the products of CO_2 conversion, with illustration of the different routes by which renewable energy could be introduced in the carbon dioxide molecule to produce fuels or chemicals

(by hydropower, solar, etc.), which otherwise cannot be utilized, thus promoting the transition to a new low-carbon economy. The technology can be considered nearly ready for commercialization, although scale-up aspects in electrolyzers have to be solved and improvements in CO_2 conversion catalysts and in stability of the electrolyzers, particularly under high-pressure operations, would be necessary. In a longer term (approximately 15 years), it will be possible to reduce the number of steps, realizing inverse fuel cells or directly solar fuels cells.

Future Directions

The effect of GHGs on global warming is becoming a problem of increasing relevance (Li et al. 2014), and there is thus an increasing need to find new and improved solutions to limit the anthropogenic emission of methane, nitrous oxides, and carbon dioxide, while for other very powerful greenhouse gases, such as fluorocarbons, some mitigation strategies are already in place.

This short overview on the reduction of greenhouse gas emissions by catalytic processes has demonstrated how these technologies can be an effective possibility for limiting the increasing tropospheric concentration of GHGs and reducing their contribution to global warming, but the more extensive use of these technologies depends on the environmental regulations that will be adopted to control GHG emissions from the variety of possible sources.

Catalytic technologies should be useful in the (1) reduction of anthropogenic emissions of non-CO_2 GHG (mainly N_2O and CH_4) and (2) reduction or conversion of CO_2. In the latter case, it was shown how a problem may be converted (reducing

CO_2 emissions) to an opportunity for more sustainable and innovative chemical and energy processes.

The challenge for methane and nitrous oxide control by catalytic technologies is the development of more active catalysts at low temperature in the presence of the other typical components of the emissions. Control of the characteristics of the support is a key step toward this objective of low-temperature activity.

Several opportunities exist for the conversion of carbon dioxide to chemicals, particularly polymers or organic intermediates. However, the challenge is the possibilities of the conversion to fuels, because the market for chemicals is two orders of magnitude lower with respect to that for fuels. It was shown how this path has a large potential, several Gtons of CO_2 eq., and is as a relevant pillar of the strategies to move to a low-carbon economy, as well as for the future of sustainable chemical production.

The requisites for these objectives are to (i) minimize as much as possible the consumption of hydrogen (or hydrogen sources), (ii) produce fuels that can be easily stored and transported, and (iii) use renewable energy sources. From this perspective, the preferable option is to produce liquid fuels using solar energy to produce the protons and electrons necessary for the reaction of CO_2 reduction. Integration between CO_2 use and bioeconomy, for example, in developing integrated solar biorefineries, is another relevant aspect to reach above objectives.

The conversion of CO_2 to methanol or syngas is already at a pilot plant scale and may thus be commercially implemented. The economy of the process will strongly depend on the value (or negative value) of CO_2 and the availability (and cost) of energy and hydrogen. These aspects will greatly depend on a number of variables.

Hydrogenation of CO_2 to form fuels is the most investigated area. By coupling conventional methanol process to RWGS, it is possible to feed even pure CO_2 to produce methanol. This reaction scheme has been implemented at a pilot plant level, and results are quite encouraging. A further step would be to use multifunctional catalysts to directly produce DME, which is a preferable energy carrier.

Hydrogenation of carbon dioxide to hydrocarbons is possible, but requires much higher consumption of H_2. Conversion of CO_2 to other oxygenates such as ethanol and DME is attractive, but further development of the catalysts is necessary. There is great interest in the conversion of carbon dioxide to formic acid, but a complicating factor is the availability of efficient technologies to use formic acid as energy carrier, as well as the toxic character of formic acid.

Dry reforming of methane with CO_2 is a known technology. Tri-reforming is an extension of the concept to operate autothermically and with the advantage of not requiring a pure CO_2 stream to operate. Pilot plant studies have shown stability of operations (using noble metals supported on MgO) for over 7000 h, although larger-scale demonstration could be necessary.

There are also various processes at an earlier stage, particularly biological and photo-/electrocatalytic processes, which need to be studied representing the future in medium to long term. Therefore, the area of carbon dioxide conversion to fuels and chemicals is a very active R&D sector and represents a challenging possibility for companies to develop complementary strategies to CCS to reduce greenhouse gas emissions.

Abstract

A future of renewable energy as a primary source for the world's energy society can no longer be ignored. As fossil fuel supplies diminish and the cost of atomic energy continues to rise, while there is no safe and well-documented solution to the deposition of nuclear waste, renewable energy can step in to provide feasible alternatives to energy demands. Renewables do pose significant challenges especially in addressing the fluctuating power supply that is inherent in their nature. Robust, integrated solutions using available, mature technologies have proven to be the solution to the challenges that wind and solar energy causes. Denmark has in the past and continues to be a leader in integrated renewable energy solutions. By 2014, Denmark with its 5.65 million inhabitants still was on the world top 10 list measured by accumulated wind power capacity; 39 % of the electricity came from the wind. In particular, the use of combined heat and power systems and the implementation of district heating have proven successful for Denmark and can be transferred elsewhere. This chapter seeks to explore questions surrounding the implementation of sustainable integrated solutions very concretely in relation to energy in general and renewable energy in particular.

Introduction

Increasing populations, urbanization, and sustained economic growth have resulted in strong rise of the demand for energy services, not least in the developing countries. Also growing concerns over climate change and the environmental impact of fossil fuels are causing many nations and communities to seek low-emission options.

Rapid technological progress has made renewable energy increasingly viable and cost-effective while contributing to security of energy supply. Worldwide, over 100 GW of new renewable energy capacity has been added every year from 2011to 2014, which is the equivalent to the total installed generation capacity of Brazil. Renewable energy has contributed with more than half of net capacity of the global power sector since 2011, which means that more new renewable energy capacity is being installed than new capacity in fossil and atomic energy combined. In China, 2013 marked the first time that new renewable electricity capacity surpassed new fossil fuel and atomic energy additions while solar deployment outpaced wind for the first time IRENA (2014).

Global investment in renewable generating capacity has increased fivefold 2004–2014 and has exceeded investment in new fossil-based power generation capacity. The rapid expansion in deployment is stepped up by declining costs of renewable energy technologies. Renewable energy is often competitive with conventional power at utility scale, and while this becomes more widely recognized, markets will expand; due to mass production and increased competitions, costs are expected to fall further. Furthermore renewable energy increases energy supply security, diversifies national energy mixes, mitigates the impact of price fluctuations, and reduces impact of geopolitical risks.

Especially in the face of climate change and resource scarcity, the world's energy system is on the verge of a major transformation. In order to massively reduce CO_2 emissions, there is a need to build a new energy system that is based on a greatly expanded use of renewable energies. It is almost certain that in 20 or 30 years the world will have a very different energy system from the one that currently exists.

In discussions of climate change, it is frequently stated that it is urgent to reduce CO_2 emissions by 40 % below what were 1990 levels by the year 2020 and further still to 95 % by 2050. The technological building blocks for the transition to a sustainable energy future already exist in the form of hydropower, decentralized cogeneration plants, wind turbines, large and small biogas plants, geothermal energy, several types of solar energy, and numerous types of biomass for energy purposes. The primary task, therefore, is to integrate the various forms of renewable energy, sometimes in combination with natural gas, in order to achieve the maximum utilization of renewable energy sources and supplies (Fig. 1).

The necessity to combine and integrate technologies is the reality of renewable energy since no single renewable energy source can sufficiently stand alone. A comprehensive future conversion to renewable energy requires mobilization of all forms of renewable energy installations, including both large and small plants. It is not enough to base development on technologies which are currently the cheapest, as this could lead to a unilateral deployment of large wind turbines in particular. Electricity generation from renewable energy sources, especially solar and wind, has a fluctuating nature. As these sources will be more and more integrated into existing power grids in large quantities, the fluctuations will become a main technical challenge. While the share of wind and solar energy on power grids increases, electric utilities must find solutions of balancing large amounts of the fluctuating

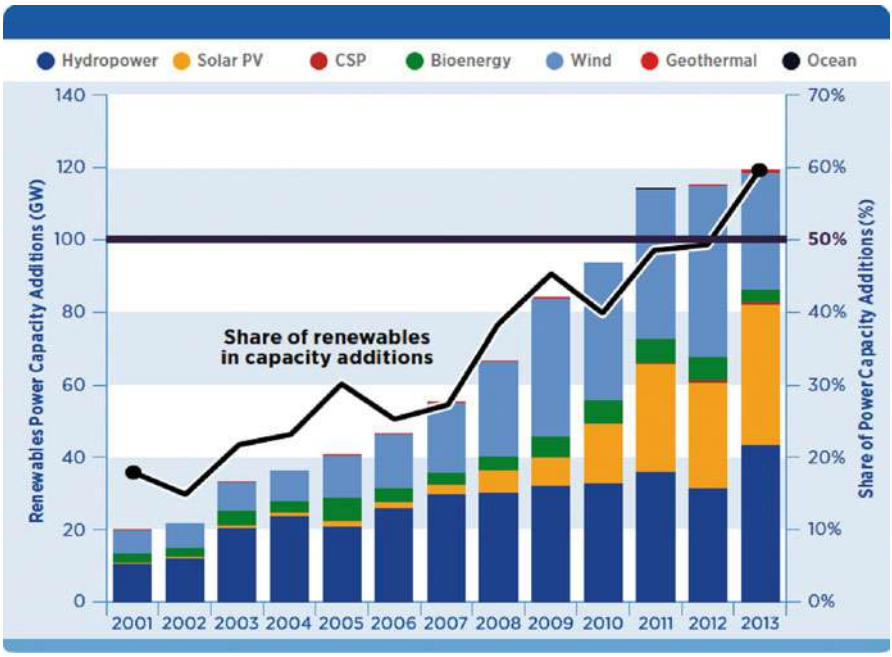

Fig. 1 Annual renewables capacity addition by technology (2001–2013) (Source: IRENA database)

renewables, in order to maintain grid balance and stability according to technical and regulatory tolerances (Fig. 2).

A persistent global attachment to the dominant fossil fuel-based energy system has limited the development of combined fluctuating solar and wind energies into coherent, autonomous systems. One consequence of this is that renewable energies, when generated in excess, remain unutilized or even wasted. Wind turbines in regions with high shares of wind energy may periodically be shut down when they produce too much power. Similarly, when combined heat and power (CHP) production coincides with excess wind energy, a surplus power capacity may occur. These problems will become increasingly frequent as more wind turbines feed power into the grid and more CHP systems are utilized. Electric boilers have proved to be a low-cost solution to capture excess energy, by using excess wind power in fuel-efficient combined heat and power systems.

A lack of balance between supply and demand of power means that there may periodically be an increasing problem of excess power from the combined supply from wind turbines, solar power, and CHP. The problem, however, needs not to exist but is caused by lack of political management and coordination.

"Renewables Global Futures Report 2013 (REN21)" registers six different types of measures within technology and operation for balancing fluctuating energy production and distribution.

Rank	State category SOLAR	P, W/c	State category WIND	P, W/c

Fig. 2 2014 global ranking of cumulative installed power (P) and Watt per capita (W/c) of wind and solar power in 48 nations. Exclusion of installed power waiting for grid connection (SolarSuperState Association)

Controlled Curtailment of Renewables

"Curtailment" is the prevailing strategy by many utilities to deal with excess amounts of wind power during periods of insufficient demand or uncurtailable generation from especially combined heat and power stations, CHP, with a commitment to supply of heating. In Denmark the share of CHP in electricity generation is up to 60 % which makes curtailment obsolete when electric boilers and heat pumps are installed and can use some of the excess power. In 2014, Denmark averaged about 39 % of its power generation from wind, with much higher peaks during some time periods, including a historic peak of 127 % of total national power demand at midnight on 22 December 2013 (Fig. 3).

Demand Response

"Demand response" covers a range of actions by utilities and the consumers to reduce power demand at specific times. It includes contracted load curtailment that is controllable by the utility within pre-established parameters and can also include time-of-use-based market prices to influence consumption decisions. Demand

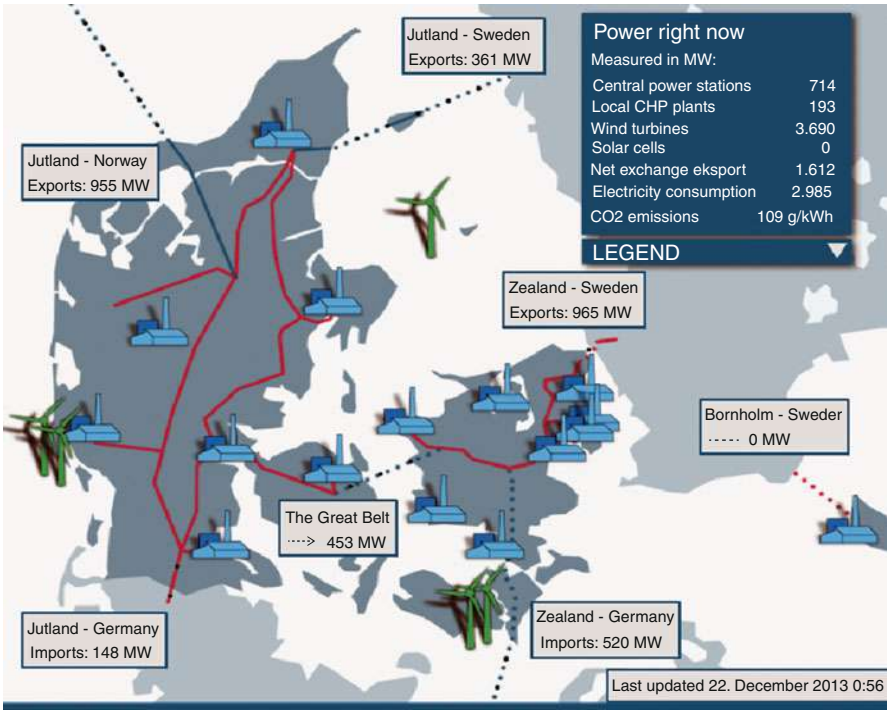

Fig. 3 Power right now – power production, exports and imports of energy in Denmark, 22 December 2013 (energinet.dk)

response in the chemical and metals industries can be integrated with process engineering as well as hydrogen production and water desalination, examples of which can be seen in China as derivatives of non-grid-connected wind power. Other examples are water pumping, air conditioning, and freezing, which can offer options for shifting demand when integrated with storage solutions.

Gas Turbines and Gas Motors (Peaking and Non-peaking)

Natural gas can be seen as a bridging fuel toward high-renewable shares. Advanced gas motors at CHP stations have electrical efficiencies around 44 % and included heating more than 90 %. They find a growing need for balancing grids, particularly for complementing wind power. Even if most gas engine CHP stations that exist today were not planned nor designed to operate on a variable regime, daily ramping up and down does not create lowering lifetimes and increasing maintenance costs. In Denmark up to 60 % of the electricity used to come from combined heat and power. CHP stations below 10 MW electrical capacity mostly are gas engines that are especially suited for power balancing.

Strengthened Transmission Capacity and Interconnection

Stronger transmission capacity is an important means to balance power flows and variable sources within a region, as well as to deliver renewable generation from remote locations. Some countries bury underground transmission to achieve a more robust grid at weather extremes and stronger balancing capability while mitigating social acceptance. In Denmark nearly all distribution up to 10 kV is already in underground cables and big share of new transmission will also be buried underground.

Also stronger two-way cross-border interconnections to transfer renewable power generated in one country to neighboring countries are increasing, not least in Northwestern Europe. However, with increased simultaneous amounts of fluctuating power from solar and wind, countries in the same region will try to export their excess power to each other. Asian countries are discussing an "Asian super grid," while in Europe the "Desertec" was envisioned to one-way transfer of especially solar power from Sahara to Europe.

Energy Storage

From a grid stability perspective, different storage technologies are suited for different balancing time frames, ranging from seconds to minutes, minutes to hours, and even to days or weeks. As seasonal storage from summer to winter or from windy to calm seasons, huge hot water covered ponds up to 90 °C are emerging in Denmark with its high share of district heating. Postponing combustion of

Fig. 4 Energy autonomous house in Freiberg, Germany. Gray battery electricity storage box and its own car charging station (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

biomass (straw, wood chips, pellets) can be considered as a cheap and reliable season-to-season storage solution where solar and wind energy is the primary sources of supply while stored biomass is the primary backup fuel. Hydropower is a traditional form of large-scale energy storage on power grids, in the form of both conventional and pumped hydro. Grid-tied battery storage has made inroads and shows promise for the future both in the form of container size battery storage stations and distributed batteries at the millions of end users that have acquired residential photovoltaic installation. At the consumer level the self-supply ratio can be doubled from 30 % to over 60 %. In Germany household battery systems and controllers connected to domestic PV installations are commercialized products that are offered by several suppliers (Fig. 4).

Beyond hydro and batteries, concentrated solar thermal power (CSP) plants also offer storage capabilities. Currently operating CSP plants typically have 4–8 h of thermal storage that allows evening and morning peak period operation.

Ramping and Cycling of Conventional Plants

Conventional hydropower plants are routinely used to ramp and cycle. For other types of conventional power plants, however, ramping and cycling on a daily or hourly basis can reduce equipment lifetime and cause higher maintenance costs and stability of emission equipment.

Atomic power plants are primarily built for covering base loads and are not designed for cycles on a daily or even less than hourly basis which is needed to follow rapid changes in the supply of wind and solar electricity production. Denmark

early decided not to deploy atomic energy and therefore with over one third of the electricity by 2014 coming from wind power does not have the challenge to integrate technologies with conflicting operational modes. For backup capacity, the many gas engine-based CHP stations that allow start-ups within a few minutes are available and high-capacity, two-way cross-border power interconnections to Sweden, Norway, Germany, and Holland. Thus, centralized grids are still being developed to facilitate large-scale wind farms, including offshore wind along with large capacities of electricity-based electric boilers and heat pumps and new applications of fluctuating power together with strong interconnections to neighboring countries. Distributed generation will not necessarily seem like a revolution of the energy system as a whole but an evolution of current systems.

Appropriate forms of public management and control of supply seems best to solve problems associated with fluctuating and intermittent power production. What is required are political solutions with incentives for the wise use of this so-called surplus power to avoid selling it at very low prices, especially to neighboring countries, and the establishment of major new transmission lines and integrated systems to match with supply peaks when solar and winds are strong.

The various renewable forms of energy (solar, wind, biomass, etc.) can provide an alternative to fossil fuels when they are used in combination with one another. None of the renewable energy forms are capable of covering the need for electricity, heat, and transportation if they are used alone. There must be, however, a multiform effort involving many kinds of supply systems, energy storage, and saving mechanisms, as well as appropriate user-management strategies.

The constant expansion of renewable energy not only provides realistic potential but ultimately could lead to an end of the combustion of fossil fuels. The economic risks associated with investments in new conventional power plants will grow significantly, especially with increased uncertainties of fossil fuel prices in the future. Not least will be the growing risk of low utilization as their annual production is being marginalized by increased use of decentralized renewable energy forms.

Renewable energies will have the key role in the global push toward a CO_2-neutral future of energy production. Due to their in-principle unlimited potential, in comparison to the current global energy regime, they are treated in this chapter as the primary source of supply for meeting the future demand for electricity, heating, and mobility, irrespective of their intermittent character. In areas with high shares of wind or solar availability, these energies will more and more be seen as a base load that periodically covers the supply of power of 100 % and often more. Overall, a picture of power systems of the future emerges as a complex combination of on-site, minigrid, and centralized grid levels, with renewables and natural gas generation and energy storage at all levels and with all levels coordinated and interacting, according to a range of requirements for cost, reliability, flexibility, and service.

Because biomass functions as an ideal long-term storage solution, due to its limited availability, it is necessary that it be reserved for combustion in combined heat and power stations with efficiencies of 85 % or more. Their primary function is for balancing by upregulation when solar and wind energy cannot cover the demand loads.

Besides an electricity grid, in the future energy structure with extensive pipe networks for district heating and cooling will have ancillary functions. Due to their low efficiencies of 45 % or less, conventional condensation power stations will not have an appreciable role to play.

Some regions and even countries already have relatively high shares of fluctuating power supply. In 2014, Denmark saw 39 % of its demand for electricity from wind turbines, which by 2020 will grow to approximately 50 %. During periods of low peak power demand and high wind speeds, wind power can currently fully cover the consumption of electricity; at the local level, the share of wind power may even be 400 % of actual consumption. Interregional compensation with strong power line connections to neighboring countries plays an important role for upregulation and downregulation; it may be a short-term solution, however, as the present importers of excess power most likely in the future will be less interested in buying power as the deployment of fluctuating forms of renewable energy will only increase in neighboring countries as well. The reality is that new outlets for periodical overcapacities will be required locally.

There are solutions for providing a balanced energy supply from fluctuating renewable energy sources such as the use of biomass in combined heat and power (CHP) plants with embedded heat storage or locally variable operation of the CHP plant based on end users' demands, generation of hydrogen or synthetic gas from excess renewable electricity for injection into the natural gas grid (absorption on-demand), and centralized "smart grid" for charging increasing numbers of electric vehicles and appliances.

Since the first wind turbines were introduced in the 1980s, there has been much discussion and controversy about the level of variability from renewable energy sources that power grids are/will be able to support and integrate cost-effectively. The crucial issue of this debate is the percentage of a technical "upper limit" to integration, with conservative numbers such as 10 % or 20 % often cited. Practical experiences in Nordfriesland in northern Germany, the Jylland peninsular in Denmark, and other regions with similarly high shares of especially wind power demonstrate the potential to reach significantly higher shares with appropriate use of the various balancing measures.

In the pioneering regions, up to 100 % shares of variable renewables can be accommodated at the annual basis and peaks of 400 % compared to the actual demand for electricity without negative impact on power quality. As there are plans in the regions mentioned to even double the share of fluctuating power by 2025, further restructuring of the power system, also with the incorporation of non-grid-connected energy solution, which is being developed especially in China, may increase shares of variable renewable energies even more gradually leading to 100% renewable energy supply solutions.

Electricity storage will be an essential part of the integrated systems that see power supply, mobility, heating, and cooling as a whole together with existing possibilities such as demand-side management. These systems should be affordable, sustainable, and efficient.

By 2014, there exist many different energy storage systems, but only a few are functional and commercially available. Moreover, these technologies need to be compared by their investment volume, their losses, and their potential for centralized and decentralized applications. The storage solutions have to be discussed by their limits, environmental effects, geographical requirements, application focus, investment complexity, and efficiency. Furthermore, storage technologies have to be optimized in terms of size and capacity, responding time and flexibility, as well as their cost-effectiveness.

Worldwide, their role is still limited, but with the expected significantly increased use of intermittent and fluctuating energy forms, structural aspects including CHP connected to district heating and cooling are indispensable. The supplies of water, electricity, gas, heat, and energy for transportation have in common the fact that they are all daily necessities for domestic consumers, as well as for industry and public sector institutions. Therefore, it is the case in many countries that the same company, often a municipal-owned entity, may have supplied all these services for several decades, a process which has generally worked to everyone's satisfaction.

The following chapters will focus on increased applications of various forms of renewable energy and solutions for power-balancing technologies with references to pioneering countries that are already facing the need for new kinds of power management and its opportunities. Besides storage technologies, power production in combination with heating and cooling will be discussed as especially important ancillary solutions.

A Brief History of Energy Transition in Denmark

Denmark is internationally well known for its wind industry and the high share of electricity that is obtained from wind power. District heating, coupled with combined heat and power (CHP), may, however, in the long term prove to be even more important (Fig. 5). This transition represents the single most important initiative to reduce CO_2 emissions in Denmark. Moreover, the construction of CHP plants that already by 2001 supplied up to 60 % of electricity and 70 % of the demand for heat has created the necessary infrastructure to gradually transition entirely to renewable energy.

By 2007, 43 % of the 36 TWh of electricity used in Denmark came from independent power producers (IPPs) consisting of wind power operators and local, consumer-owner district heating companies. As a consequence, the central power utilities (owned by Vattenfall and DONG Energy) had their share of the electricity market reduced to little over 50 % of the domestic demand. The transition primarily took place in a 10-year period since 1990. Coincidently this is the amount of time it takes to build one nuclear power plant, or the equivalent of 1,200 MWel. Denmark has not and is not planning to build atomic power plants; this controversial source of supply was ultimately withdrawn from national energy plans in 1985.

Denmark has succeeded in stabilizing its primary energy supply during 30 years of economic growth. During this time, CHP plants and renewable energy

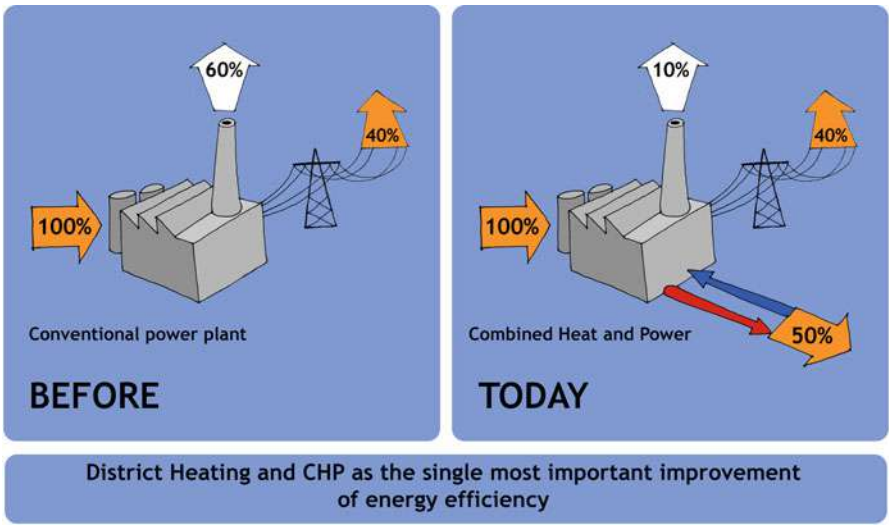

Fig. 5 It took 10 years to dramatically shift almost half of the power production from inefficient, centralized fossil fuel power supply to local, municipal, or consumer-owned companies. In conventional power plants, the loss is 60 % or more, whereas CHP may have efficiencies of 90 % (Anna Krenz/Nordic Folkecenter for Renewable Energy)

technologies were introduced extensively and supported by the state. In the period 1975–2000, fuel consumption for space heating was reduced by 30 %. In the same period, an almost 100 % oil-based primary energy supply in the year 1975 decreased to 40 % by means of diversification. The fuels used were a mixture of oil, coal, natural gas, and renewable energy Maegaard (2009).

During the whole period, the national gross energy consumption had a level of around 20 million tons of oil equivalents (TOE). The combination of energy conservation and district heating based on CHP was the most important single factor in improving overall energy efficiency. Insulation of buildings contributed to a 12 % decreased heat demand from 1975 to 2000, while at the same time the heated areas increased by 46 %. District heating increased by over 50 %, while CHP plants replaced conventional condensing power plants, which, during the 25-year period, decreased the consumption for heating per square meter by half. Approximately 40 % of this decrease was attributable to the implementation of new building codes that were important for the energy conservation that resulted from improved energy efficiencies and new CHP for the balance. Since 1980 permission has not been given to build new conventional condensing power stations, only for CHP with supply of district heating as main location factor. Coal was not accepted as fuel for new CHP stations built since 1990 Danish Energy Agency (2010).

During the 1990s, many hundreds of decentralized Danish CHP plants in sizes of 0.5 MWel to double-digit MWel capacity were mostly built in connection with district heating systems in towns and villages as small as 150 households. The

CHP plants contain one or more CHP units, peak load boilers, and heat storage systems. The CHP units are either engines, gas turbines, or in some cases steam turbines or combined cycle plants (Fig. 6).

Support for CHP has a long tradition in Denmark. In the past it has been mainly focused on the development of district heating based on large centralized or smaller decentralized plants. Bioenergy CHP is supported primarily by energy tax exemption. New installation on natural gas-based CHP is no longer promoted and has to face a highly complex energy taxation system.

Based on an energy agreement in the Danish Parliament in 2012, Denmark has set the target to reach an energy supply system based on 100 % renewable energy up to 2050 (Fig. 7). CHP with bioenergy has an important role to play. CHP in industries and greenhouses shall be promoted as well.

With a share of CHP in total power production of about 60 %, Denmark has the most developed CHP system in the European Union and in the world as such. With changing focus to the expansion of renewable energy, support for CHP has shifted to bioenergy which has been designated to take the role of coal, while natural gas CHP is not promoted anymore. There exist, however, still relevant potentials to switch from boiler firing to CHP in industry, housing, commercial companies, and public institutes situated in areas without district heat supply. Key proposal in Denmark is to take an active CHP expansion policy that the CHP electricity produced could be increased by 10 % up to 2030.

For some years it has been judged that Danish potential for installing cogeneration output is largely being exploited that the socioeconomic potential of cogeneration was found to be limited. Since 2012, new technologies and a change to the rest of the energy system may alter the picture in respect of both theoretical and economic potential.

The planned increase of wind power to 50 % share in total power production up to 2020 needs a further development of flexible backup capacities of fuel-based power production. Contrary to previous analysis, there is a need for growing CHP electric capacities. The additional amounts of wind power should not replace CHP electricity but the remaining production of condensing electricity, which covered still 26 % in 2011. Regarding Denmark's political objective of reaching a 100 % share of renewable energy in electricity and heat supply up to 2035, the state Energy Agency has carried out a study with four scenarios designed to reach the 100 % renewable energy target. The biomass scenario with a relative high share of bioenergy had the lowest total cost; also the cost of electricity grid construction measures had been taken into consideration.

With a growing share of bioenergy in heat production, either in district heating or individual housing with biomethane distributed over the existing natural gas grid, solid biomass and waste gasification offer the opportunity to replace the conventional steam turbine CHP plants with their relative low electric efficiency by high-efficiency CHP based on gas engines or combined cycle gas turbines.

The replacement of old low-efficiency coal-fired CHP by modern technologies with biogas, biomethane, gasified solid bioenergy, and waste could increase the electricity capacity and supply from CHP by an estimated 20–30 %. In the

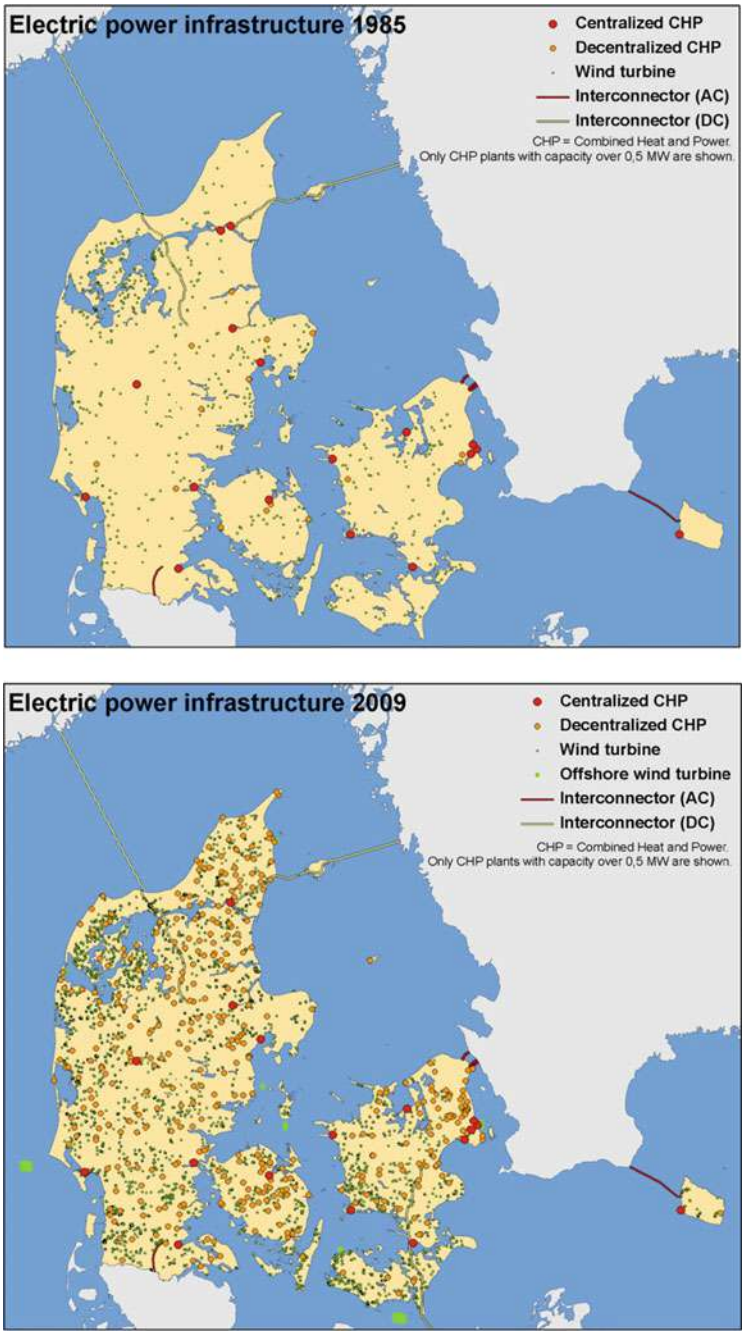

Fig. 6 (continued)

Government's targets	Results of „Our Future Energy" in 2020
100% renewable energy in 2050	A reduction of the total consumption of fossil fuels by 26% from 2010-2020 is a major leap towards total phasing-out of fossil fuels and the conversion to 100% renewable energy
100% renewable energy in electricity and heat supply by 2035	On track towards the target in 2035 by cutting consumption of fossil fuels for electricity and heat supply by 50% from 2010 to 2020
Coal phased-out in 2030	A large contribution to the target as coal consumption is reduced by 65% in 2020 in relation to today
Oil-fired boilers phased-out by 2030	Halving the number of oil-fired boilers in 2020 in relation to 2010 and a good start towards the effort to be done from 2020 to 2030
Half of electricity consumption supplied by wind in 2020	The share of wind power in electricity consumption will be 52% in 2020

Fig. 7 Danish Government Energy Plan of 22 March 2012

meantime, micro CHP systems are available on the market which offers good economic results for the users, and, combined with heat pumps, they additionally can contribute to a flexible smart electricity supply system. In the industry additional CHP potentials should be reconsidered by a revision of the energy taxation system and some financial incentives to switch from boiler fired process heat production to CHP.

Fluctuating Sources of Energy

The Consequences of Fluctuating Power Supply

On days with both a high demand for heat and high winds, combined heat and power plants, CHPs, and wind turbines together sometimes feed more power into the grid than needed by power consumers. On such occasions, the CHPs are not operating to cover a need for power but to supply heat through district heating systems, while the production of electricity can be seen as residual. Wind turbines deliver their electricity production to the grid in accordance to the prevailing wind speeds (Fig. 8).

Together, CHP plants and fluctuating wind and solar feed their production into the same grid. The early application of solar and wind to an existing power grid can be balanced without special problems. Once the share of wind energyexceeds 20 % or more, however, initiatives have to be taken. With 20 % of wind power at the annual basis, there will be hours and even days when wind power production can fully cover the actual need for power. In regions with a high concentration of wind power, they

Fig. 6 In 1985, Denmark's 14 central power stations and a small number of windmills covered the production of electricity in Denmark. By 2009, power production was decentralized with approximately 3,000 windmills and more than 700 CHP units over 0.5 MWel. Together, wind power and small CHP periodically can deliver 60 % of the annual demand for electricity (Danish Energy Agency)

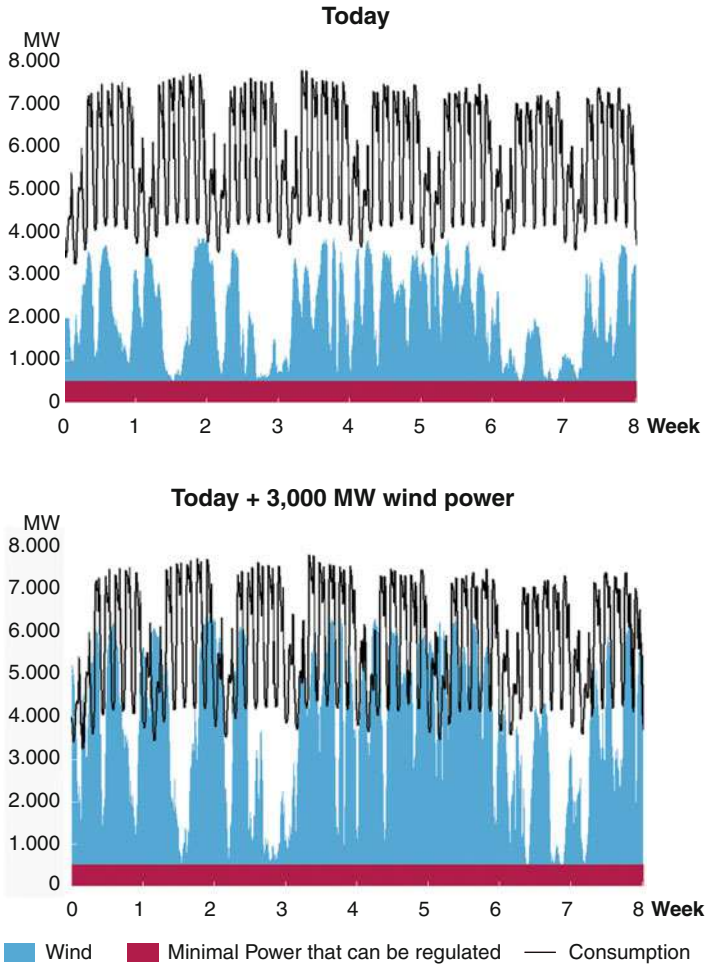

Fig. 8 Consumption of power and production of wind power during the first 8 weeks of 2007 (*left*); same consumption with the integration of 3,000 MW additional wind power (*right*). Security of supply should be maintained and the value of wind power should be maximized ecologically and economically (Danish District Heating Association)

can deliver most of the base load for power, but also periodically when wind speeds are high, they can even produce up to 400 % of actual power needs (Fig. 9). The structural and technological challenges involved in a transition from fossil fuels and atomic energy to renewable energy are obvious, considering that some countries have plans of 50 % wind and solar in their supply of power. In Denmark by 2020 wind energy will supply half of the demand for electricity Energy Policy Report (2013).

As an example of current fluctuating power management, on 2 January 2015, which was a windy day, out of total installed capacity of 5,000 MW of wind power in

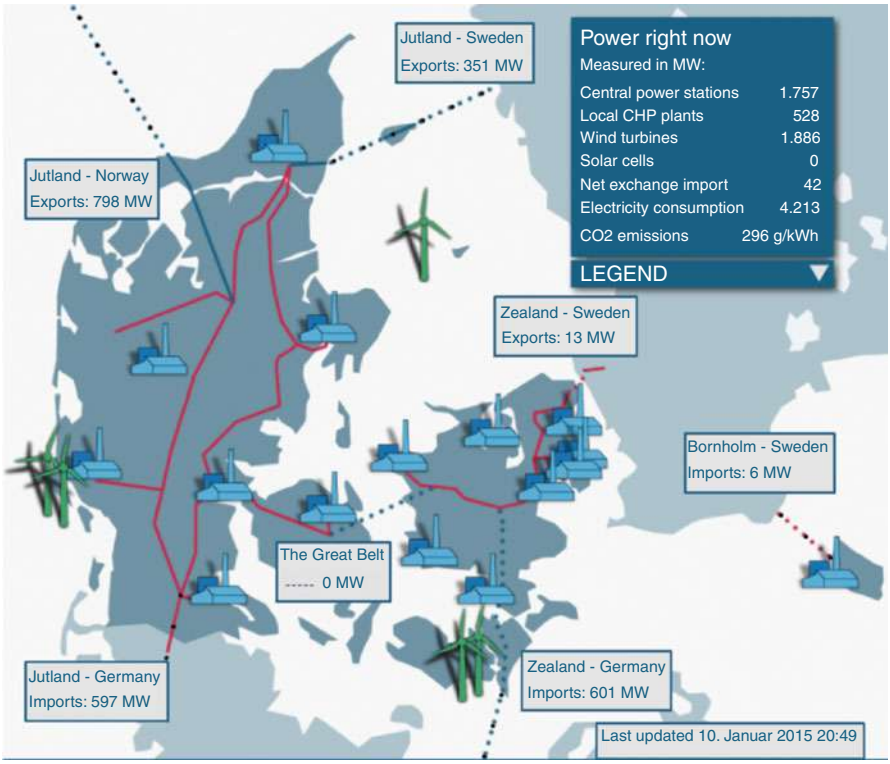

Fig. 9 "Power right now" from the system responsible state company, Energinet.dk. When high wind velocities were available in the evening on 10 January 2015, the wind turbine capacity of approx. 5,000 MW potentially should have been able to deliver the total demand of 4,213 MW. Wind turbines at the moment in question supply 1,886 MW only. There are various reasons. Many automatically stop when they are beyond cutout wind speeds; the demand for heating forces the CHP stations to operate at a minimum level, while strong wind over most of Northwestern Europe can cause negative electricity prices that encourage the wind turbine operators to curtail production

Denmark, 1,700 MW was sold at low or negative prices to Norway and Sweden, while simultaneously wind turbines of 1,200 MW capacity were simply stopped. The nationally unused power of 2,900 MW (58 % of total available capacity) could have delivered electricity and power-to-heat to consumers in Denmark, substituting fossil energy sources such as coal or natural gas, which at the same time delivered 1,700 MWel capacity into the CHP-based networks. The existing power system in Denmark by 2014 was not adapted to match big power capacities that allow it to absorb sufficient amounts of excess power from wind. Therefore, significant part of it was not utilized, stored, or commercialized in a rational manner. While the capacity for usage of excess power is lower than the wind power production peaks, the surplus is either sold to neighboring countries bringing no income or rather economic losses. Stopping windmills is the sign of an irrational approach to

wind energy. Denmark, like other countries, annually installs more and more wind power capacity, but is in the end not sufficiently considering the development of the total energy system to allow proper use of the produced energy. The challenge is to design and apply smart energy system concepts, which can absorb the excess power and balance different fluctuating renewable energy sources. Denmark is facing problems that other countries still have ahead; however, solutions have to be given high priority.

Some measures that can be taken to maintain a balance between supply and demand include:

- Store the electricity for use in periods with insufficient solar and wind.
- Temporarily stop the operation of some wind turbines.
- Export power to neighboring countries.
- Encourage demand-side power consumption.
- Find new applications of fluctuating electricity for industrial purposes and in the heating/cooling sector.

Special focus will be made at the use of fluctuating power in the heating/cooling sector and the infrastructural changes that it requires. Storage of electricity will be discussed separately, whereas discontinued operation of windmills is considered non-acceptable during periods when fossil fuels are being combusted. Export of power to neighboring countries involves heavy investments in long-distance transmission lines and is not a long-term realistic solution; period with high wind speeds is a transborder phenomenon and neighboring countries are often expanding their wind power capacity as well. With tariff differentiation and smart grids, industrial consumers and households may be encouraged as well to change the pattern of their electricity use by operating special machinery, using their washing machines at night, and charging-discharging future electric cars at periods according to the power supply situation (Fig. 10).

Experiences, however, indicate that changes of consumer behavior have their limits. Electric car owners, for instance, may prefer the benefit of leaving their home in the morning with a fully charged car instead of earning a few cents per kWh for delivering excess electricity to their utility company during peak consumption periods.

Supply and demand on windy days can be balanced with simple solutions such that excess wind and solar power can be used in electric boilers and heat pumps at combined heat and power stations. In the case of Denmark, with its many hundreds of CHP stations, it is possible to stop gas engines at periods when the wind and solar power is sufficient for both the actual supply of power and heat and hot water-based cooling. As the CHP stations already have large hot water storagetanks, additional excess power can be stored for some days of hot water supply with no electricity to water conversion loss.

As an example, the gas-based cogeneration in Denmark from around 600 decentralized CHP plants and more than 170 industrial auto producers can be stopped and started within minutes so that they match ideally with the fluctuating renewable energy supply. Conversely, conventional fossil fuel and in particular

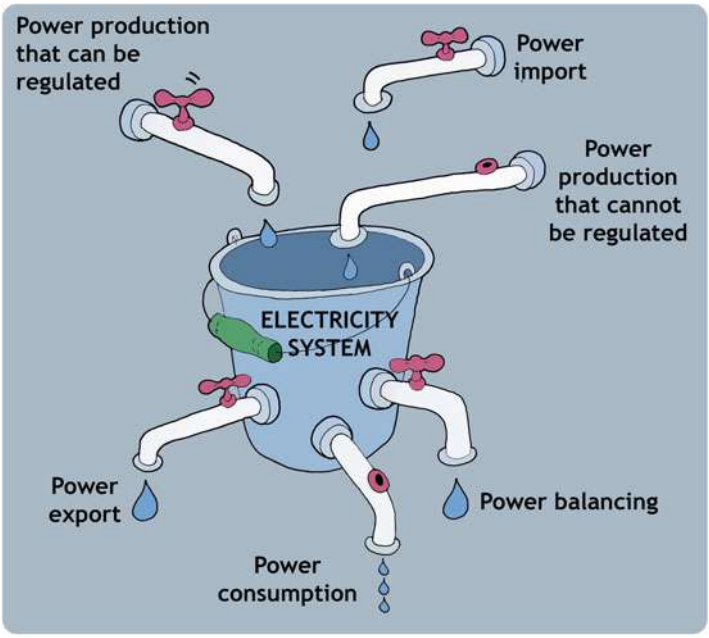

Fig. 10 An electrical system based on fluctuating sources – unlike conventional supply of energy that can be regulated – needs to be balanced according to the consumption. District heating stations with CHP plants can support by converting excess electricity to hot water that can cover the actual demand or stored for later use (Nordic Folkecenter for Renewable Energy)

atomic energy power plants have basic constraints in terms of curtailment and may need several hours or even a day for adjustment.

A decentralized power supply system will only work to further create a more robust power structure against national blackouts. Energinet.dk, the national enterprise responsible for Denmark's power system, announced to divide up the national supply system in cells with each 50,000–100,000 consumers in primarily self-supplying cells based on local wind and CHP to take advantage of the decentralized and diversified structure.

With its high share of wind electricity (in 2014, 39 %, and by 2020, 50 %) Denmark is the first country that experienced problems related to big amounts of fluctuating renewable energy supplies and, therefore, is especially focused for the quantification of the challenge (Lund 2010).

The challenge for the system operator is already and will increasingly continue in the future to further optimize the available resources even more. While Europe as a whole has 11 % of the efficient CHP in the energy system, the share in Denmark is the world's highest at about 60 %, which at the same time represents not only the problem mentioned but also its solution. Therefore, already existing challenges and solutions as they can be observed in Denmark will throughout the chapter be presented as examples of reference.

In principle, the experiences and solutions in the case of Denmark are generally transferrable and will hold true in other countries and regions as well. It should be mentioned that one of the authors of the chapter is a resident in a municipality of 46,000 inhabitants that since 1992 has basically received its supplies of heating and power from various local renewable forms.

It is often claimed in the media that with the expansion of wind energy, periods of a surplus of wind energy will become more and more frequent and contribute to instability in the power system. It is, however, as impossible to determine whether the wind or whether the heat-generated power causes the excess power as it is to separate cream from coffee. By combining and integrating CHPs with electric boilers, heat pumps, and hot water storage in combination with fluctuating energy forms of wind and solar, it will be possible to have much higher shares of solar and wind in the energy structure as a whole, without causing instability in the power system. With further integration of the mobility sector using cars with batteries and smart grids, additional possibilities of handling fluctuating power will become available.

Integration of fluctuating power production with the heating sector will gradually allow significantly higher future shares of wind and solar energy in the system because in a temperate climate, the demand for heat exceeds the need for electricity by a factor of 3 or so. With increased use of hot water for cooling when applying adsorption heat pumps that are driven by hot water, not only does it become realistic for more temperate climate regions, but a more general application is feasible when combining fluctuating power supply from solar and wind with local CHP. Thus, the need for heating, and cooling with hot water and adsorption chillers at the point of consumption, may become the largest single outlet for the disposal of power fluctuations from solar and wind. Furthermore, this can be achieved with low initial investments especially when a district heating/cooling network is already available. Building of new district heating structures will at the same time create the needed flexibility for the management of a 100 % renewable energy supply and is an affordable, highly efficient, and well-developed solution with a mature technology.

Following a decision by the EU Commission, the use of wind power for heat has become an attractive alternative. Previously, heavy taxation prior to 2007 did not make the excess energy economical. While excess electricity sometimes was sold at the spot market for €0.01 per kWh or less, it will at any time (when used for heating) have a value equivalent to the fuel that it replaces, €0.04–0.12 per kWh.

Technologies for Up- and Downregulation

Solar and wind cannot alone ensure a continuous supply of electricity. In a future supply scenario dominated by fluctuating energy forms based in full on renewables, three typical situations may occur to meet the actual demand for electricity:

(a) Solar and wind produce too much power; downregulation is required and some of the excess power can be converted, stored, or exported.
(b) Solar and wind produce too little power; upregulation is required and the stored energy will be used and power imported.
(c) Solar and wind produce no power; storageable supply and import is required and will cover the total demand.

Wind and photovoltaic (PV) power are cornerstones in future integrated renewable energy supply structures. They are, however, fluctuating which causes a need for adaptation by consumers and backup from other supply solutions or storage (Fig. 11).

With wind and solar as the primary sources of energy, biomass that is easy and cheap to store will be the ideal backup fuel (Fig. 12). On the other side, biomass should not be combusted when wind and solar is sufficient (Fig. 14). Environmentally and economically, the conversion of excess wind power for the local district heating supply and in their hot water reservoirs will have the per kWh value of the substituted combustible fuel (Fig. 13). Thus, it becomes an optimal solution instead of exporting the excess power to neighboring countries, sometimes at low or even negative spot market prices (Fig. 15).

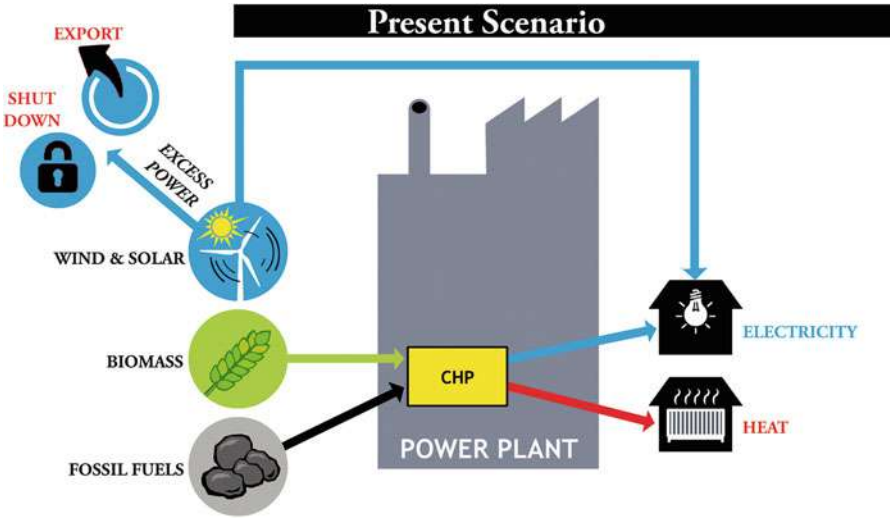

Fig. 11 Traditional CHP facility that combusts fossil fuel and/or biomass. The heat production is supplied to the heat consumers and the electricity to the grid. The power is supplied without considering to which extent wind power is available. The demand of heat must be satisfied and therefore the CHP is given priority to feed power into the grid. On windy days, excess power from wind is either exported or wind turbines are stopped. With increased fluctuating power capacity, excess power will appear more and more frequently (Anna Krenz/Nordic Folkecenter for Renewable Energy)

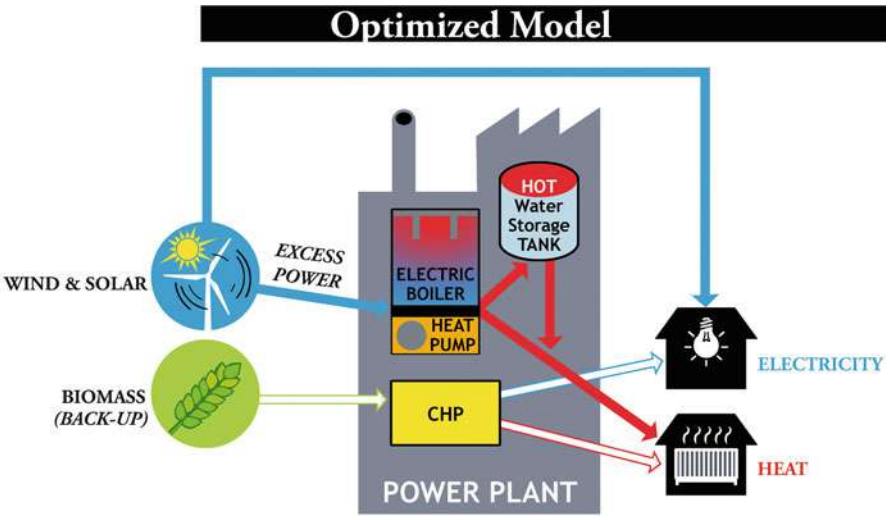

Fig. 12 In the alternative scenario, the solar and wind energy finds two kinds of applications: an electric boiler and heat pump have been installed in the CHP station. It will still be able to supply electric power into the grid when fluctuating power is not sufficiently available to fully cover the demand for heat. However, on days with strong wind and/or solar, excess power is fed into the electric boiler (or heat pump) at the CHP station. Now wind and/or solar power has the potential to cover the demand for heat as well and the CHP engine or turbine can be stopped. Thus combustible fuels can be saved (Anna Krenz/Nordic Folkecenter for Renewable Energy)

Energy Storage

A number of storage solutions are available. They are of very different character regarding technology, medium, and cost. Flexibility and response time are important requirements that the various types of energy storage will meet differently to match satisfactorily with the integrated supply of power, heat, and cooling.

A storage solution that converts the residual power from wind and solar may be chemical, gravity, heat, compression, etc. and suitable for either conversion back to electricity or heating/cooling. The need of storage may be for seconds, minutes, hours, or a few days. Seasonal storage is well developed for hot water but is rare for large-scale electricity storage (Fig. 15).

Electrolysis has been around for many decades and is widely used for the production of oxygen and hydrogen in the chemical industry, paper industry, hospitals, and for welding. For energy storage, hydrogen is still at the early stage of development. Initial costs are high due to prohibitive pressure and diffusion of hydrogen, while conventional gas storage equipment is not suitable. Losses of conversion in the process from electricity back to electricity may be 65–80 % accumulated by losses in rectifier, electrolyzer, compression, transmission, and the fuel cell.

*Compressed Air Storage for Energy*has been in operational use for several years in the USA and Germany. Excess fluctuating electricity is used for the compression

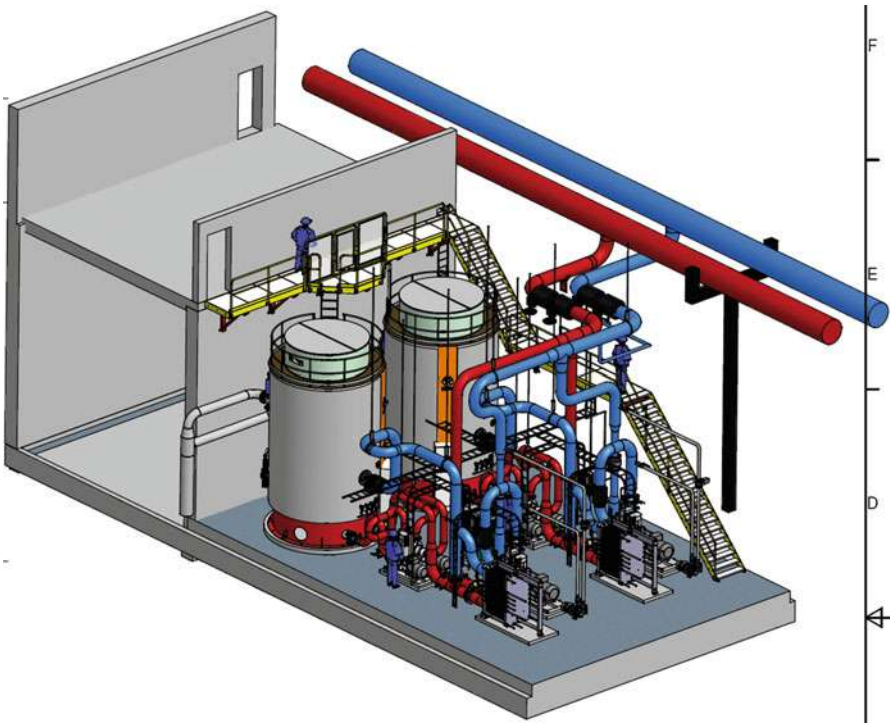

Fig. 13 A new scale of downregulation: 80 MW electric boiler that in March 2015 will start operation at the central power station to use excess wind power. The heat will be supplied to the city of Aarhus (Aarhus Municipality)

of atmospheric air into deep underground caverns of a type similar to natural gas storages. At the time of consumption, the process is reversed and the air drives a conventional-type turbine that instead of natural gas or steam uses compressed air. The turbine is connected to the generator. During compression, heat is produced while the reversal process occurs with decompression and the air expands so that the system can deliver cooling. The electric efficiency is around 50 %; the overall efficiency can be improved in case the heating and cooling potential is utilized.

Batteries for storage of electricity are widely used for many applications. For electric cars, a new generation of lithium batteries is being developed in many industrialized countries; they are expected gradually to be available for large-scale storages as well. For the hundreds of thousands of stand-alone PV installations in the developing countries, conventional car and truck batteries are used as well as batteries designed for frequent deep discharging and recharging. For regional and national supply structures, such batteries will have a limited application.

Water-pumped storages are installed in many countries to compensate for fluctuations in the demand for power. Pump storages have dual purposes. At times of downregulation, water is pumped from the lower to the higher reservoir; the process

Fig. 14 Biomass from agriculture and forests is a limited resource. Dry biomass is ideal for long-term and seasonal storage of energy when solar and wind energy is not available (Preben Maegaard/ Nordic Folkecenter for Renewable Energy)

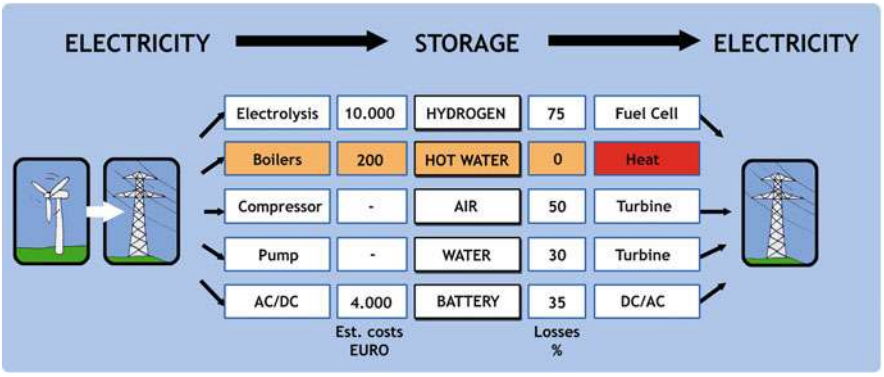

Fig. 15 Storage of electricity (Nordic Folkecenter for Renewable Energy)

is reversed for upregulation. Pumps/motors and turbines/generators are often of multimegawatt capacity. They match well with atomic power stations with constant power output. At nighttime and other off-peak periods, water is pumped to a higher-level reservoir and available for typical morning power peak periods. Their general application is limited by the topography; in Europe, most potential sites for pump storage have already been developed.

Other storage solutions can be mentioned as well. Molten salt is used for concentrated solar power storage. It can be used alone or combined with wind energy in utility size installations of 50 MW or larger as it is being demonstrated in southern Spain and in the USA (Fig. 16). With operational temperatures up to 400 °C, the storage medium can produce steam for conventional steam turbines

Fig. 16 The 150 MW Andasol solar power station (*Top*) is a commercial parabolic trough solar thermal power plant, located in Aldeire, Granada, Spain. The Andasol plant uses tanks of molten salt to store solar energy so that it can continue generating electricity even when the sun is not shining (BSMPS). (*Bottom*) Molten salt secondary battery (FIAMM SoNick) (Rudolf Simon)

combined with production of electricity. The process heat can be distributed by a district heating network for heating and for cooling by adsorption chillers. Flywheels with integrated motor/generation are one of many other forms of storage technologies that will be relevant in integrated energy systems (Boston Consulting Group 2010).

Special focus in this chapter will be made at hot water storage at temperatures below 100 °C at atmospheric pressure in insulated tanks made of steel or concrete. Hot water storage within this temperature range is not suitable for electricity production.

Considering that the amount of energy needed for space heating in temperate climate is about three times higher than the energy need for electricity, hot water supply and storage based on solar and wind peaks can find large-scale applications by replacing oil, natural gas, and coal for heating purposes and for cooling by adsorption chillers. In Denmark, several hundred hot water reservoirs are installed at local CHP; sizes range from 10 m^3 for short-term storage up to 200,000 m^3 for seasonal storage. The dimensioning criterium is mostly to cover the CHP station's need for supply to the district heating network during low peak power periods and weekends.

Compared to the earlier mentioned storage solutions, hot water storage involves an especially low initial investment. Compared to batteries and hydrogen for storage, the investment may be more than 90 % lower. In pumped storage, air compression, and flywheels, the conversion losses range between 30 % and 50 %, however, with initial costs significantly lower than with the hydrogen/fuel cell option.

Average investments per kW in new power generation based on fossil fuel and renewable energy are shown as well in the table. It will be seen that initial investment in the electric boilers for downregulation combined with decentralized natural gas CHP for upregulation (€900 per kW together) is less than investment costs of conventional fossil fuel power stations and significantly lower than atomic power where costs of long-term storage of radioactive waste have to be added. One objective to the preferred solution may be that costs of a district heating network should be added. Based on experiences of numerous installations in Denmark, the investment in a new district heating network is often similar to the costs of the CHP station that it is connected to (Fig. 17).

In case that conversion from electricity to hot water is made by an electric boiler, the conversion factor is 1:1. When conversion is by compression heat pumps, the conversion factor is significantly better and may be 1:2 up to 1:6 depending on the heat source available for the heat pump. A heat pump costs 5–8 times more than electric boilers in initial investment; therefore the annual hours of operation for heat pumps must be 3,000–5,000 h per year, whereas electric boilers will be profitable with much fewer operational hours per year.

District heating and cooling, CHP, and fluctuating energy forms from solar and wind energycan be combined and integrated to create truly autonomous systems. Pioneering projects demonstrate that a decentralized heat and power system using biomass and wind energy can be cost-effective and pave the way for a sustainable

Technology	STORAGE / Est. EUR/kW

energy supply. It has been demonstrated as well that conventional fossil fuel-based power production from big centralized power plants can be phased out with improved safety of supply and prevention of climate changes (Fig. 18).

The transition from a few large-scale centralized, fossil fuel-based power stations to thousands of wind turbines, solar installations for heat and electricity, and combined heat and power stations using biomass or natural gas will be a technological and structural challenge. As it was seen in Denmark, the shift to renewables takes some decades using a mix of conventional and renewable energy technologies. Denmark in 2013 had around 6,000 MW of centralized power plants, 2,500 MW independent combined heat and power, and 4,800 MW wind power that will increase to 6,000 MW or more by 2020. With more and more decentralized CO_2 neutral capacity, the centralized plants are being modified to combust biomass fuels (wood pellets and wood chips) (Figs. 19 and 20). Several units that used to burn coal have been phased out. The transition to renewable energy forms will stabilize consumer energy prices and fulfill international climate commitments.

A smart energy system strategy implies the development and integration of a wide range of supply and end-use technologies, markets, and control systems, including electric boilers and heat pumps in distributed generation, electric vehicles, mechanical and electrochemical storage systems, flexible demand mechanisms, and more.

According to *Coherent Energy and Environmental System Analysis* (*CEESA*) (Aalborg 2011), approximately 20–25 % of wind power on the grid can be integrated without significant changes to the energy system. With more than 20–25 % of wind

Fig. 18 Viborg CHP plant (*Top*) using natural gas turbine for the production of heat and electricity. The hot water storage is seen to the right of the turbine hall. The city of Odense (*Bottom*) with its 165,000 inhabitants was a pioneer within large urban CHP resulting in low heating costs. Fuels for the supply of steam to the turbines are straw, household waste, and natural gas (Preben Maegaard/ Nordic Folkecenter for Renewable Energy)

power, the analysis points to installation of large heat pumps in district heating plants in combination with the heat storages as the next needed step in integrating the heating and power systems. With wind power levels above 40–45 %, the transport sector also needs to be integrated with the electricity system. Integration with the transport sector will be a significant challenge in the coming years. Electric vehicles can be important in this integration, as they provide flexibility on the demand side. Exceeding 50–60 % fluctuation renewable energy in the system electrolysis becomes important as really large capacity.

Wind Energy and Its Role in Power Production

By the end of June 2014, the accumulated installed wind power capacity in the world had reached 318 GW. Within less than a decade, a historic change has occurred to the wind power development of China. Takeoff for wind power in China was 2005. Five years later, in 2010, China became a country with the largest annual newly added installed capacity in the world. In 2013, the newly added wind-power installed capacity of China reached 16,000 MW, and the accumulated installed capacity of China reached 91,000 MW. Wind power generation output of China was 135 TWh, which made wind power the third biggest source of supply in China in the wake of thermal power and hydropower.

Being fluctuating power this in itself will cause a total restructuring of the whole energy sector. This most certainly will lead to the integration of the sectors for power,

heating, and mobility. Each represents about one third of the total national energy consumption and will gradually eliminate the use of oil and coal.

The problems associated to this have gradually emerged along with the increase of the percentage of wind power in the total electric power consumption. Comprehensive projects and programs for the development of new applications of renewable energy have been launched. The Chinese government has also made efforts and attempts in the development process of wind power to match with the new situation.

For many years, the efforts have been to explore exploring new concepts with renewable energy development to achieve high efficiency and low cost in the utilization of renewable energy resources at a large scale. Wind energy and other new energy resources are, however, by nature leading to significant fluctuations of their electric output. This is bringing very big challenges to the utilization of electric power which calls for innovation and new advanced concepts in various countries, including China.

In this process, professor Gu Weidong, Nanjing University, has conducted a Chinese national "973" research program and put forward the pioneering non-grid-connected development model (Fig. 21). He proposes that a smart grid system based on the non-grid-connected coordinated power supply of multiple and new energy resources should be set up. This new system succeeds in making power grid more flexible and intelligent, i.e., transforming high-energy-consuming industries into new intelligent loads which can carry out peak regulation for power-grid facilities (Maegaard 2010).

The theory has sparked a new field for the worldwide multiple application of large-scale wind and solar power for the manufacturing of basic industrial products and services for which there will a big demand in a post-fossil-fuel age as well. These research fields are unprecedented worldwide and open up for new ways of integrating very huge quantities of fluctuating power.

Examples of innovative use of solar and wind energy include:

- Large-scale non-grid-connected wind-power seawater desalination
- Large-scale direct wind-power hydrogen and oxygen production

Fig. 21 Water desalination based on non-grid-connected wind power is one of the technologies pioneered by Prof. Gu Weidong, Nanjing University, within the "973" research program (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

- Nonferrous metallurgical industry
- Salt-chemical chlorine-alkali industry
- Wind/methane power-to-gas integration
- Wind/nickel-ferrite alloy smelting
- Wind/hydrogen reduction iron-making
- Pure-oxygen converter steel-making

Wind energy will be a cornerstone in future supply of electricity. Worldwide, wind energy capacity by end of June 2014 reached 336,000 MW, out of which 18,000 MW new capacity was added in the first half of that year.

Onshore wind power is fast approaching grid parity in terms of cost per kWh. Technical innovation and series production make onshore wind the cheapest source of new electricity in a range of markets in China, Germany, Italy, Spain, and the UK and has already attained parity in Brazil and Denmark.

Electricity from onshore wind energy is already significantly cheaper than new atomic energy with the British *Hinckley Point C* as a reference for 2014 and would also be cost competitive with natural gas and coal globally if health and environmental costs were included in prices. In 2014, the Danish Energy Agency informed that onshore wind was the cheapest of all new power producing technologies. Most of wind energy's competitiveness has been driven by the strong pace of technological development among the largest turbine manufacturers. Growth in the scale of the wind market has encouraged competition, driving down costs. The capital costs of wind turbines have also declined.

The wind energy sector in 2013 employed 834,000 persons worldwide and is expected for the first time to offer one million jobs a few years later. The *World Wind Energy Association* (WWEA) expects global wind power capacity to reach 500,000 MW by 2016 and that total global wind power capacity of around one million MW is possible by the year 2020, according to its *World Wind Energy Report 2013* (Fig. 22).

In 2013, for the first time in contemporary wind energy development, there was a decline of annual new installed capacity of wind power, as some countries leading within wind energy did not maintain their traditional policies in favour of renewable energy. In this regard, the Chinese and the Danish governments have set up positive examples for the world and will have special attention in this chapter as both countries have set ambitious targets (Figs. 23, 24, and 25).

The onshore wind resources available in most countries exceed the demand for electricity several times. An assessment by country for Europe indicates that utilization of a limited share of the wind resources available is sufficient to cover all present and future needs for power. To mention a few examples in the largest economy in Europe, Germany, onshore wind in principle can deliver seven times more than the total demand for electricity. For Sweden, Denmark, and the UK it will be factors of 40, 20, and 10, respectively (Fig. 26).

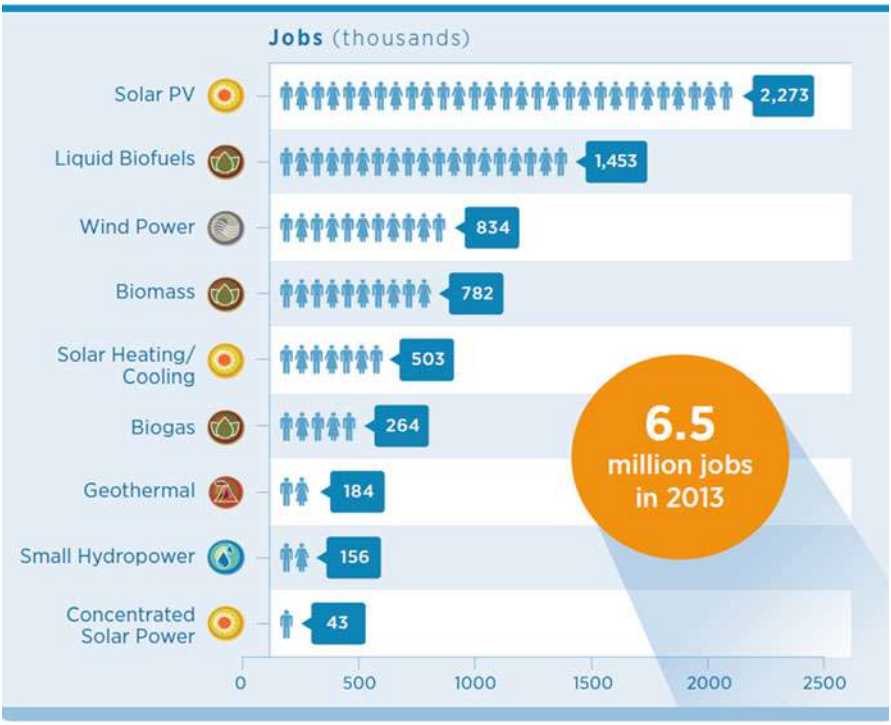

Fig. 22 Employment in thousands of persons in 2013 within various renewable energy sectors (Source: IRENA 2014)

Wind Energy Development in Denmark

Contemporary wind technology was born and came of age in Denmark. In the 1980s Denmark began to implement wind power at a commercial level and a dynamic production and implementation process evolved, resulting in the creation of a new industry.

Wind power during days with strong wind and low peak power consumption sometimes covers more than the total need for electricity in Denmark, while normal power quality standards are maintained. The wind power of Denmark accounted for 39 % in 2014 of its total electric power consumption of 36 TWh. The percentage is planned to reach 50 % by 2020. Further growth is expected from 5,000 MW of wind power in 2014 to 20,000 MW. This means that wind power within a decade or so will cover much more than the demand for electricity in 2014 (Fig. 27).

Even though wind power in Denmark was close to a standstill from 2002 to 2009, Denmark by 2014 was still the leading wind power country on a power percentage and per capita basis. By middle of 2014, 4,855 MW of wind capacity was installed in Denmark; with a population of 5.65 million, this is equivalent to 859 W per person

Fig. 23 The top 15 countries worldwide in terms of installed wind energy capacity by June 2014 (World Wind Energy Association, WWEA)

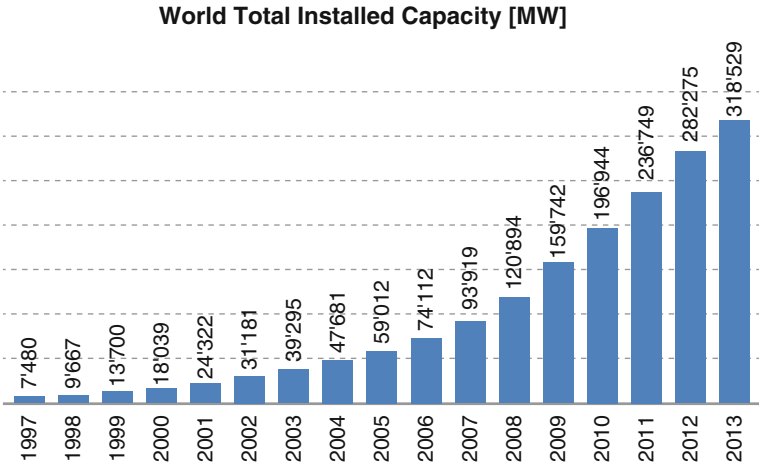

Fig. 24 World total installed capacity 1998–2013 (World Wind Energy Association, WWEA)

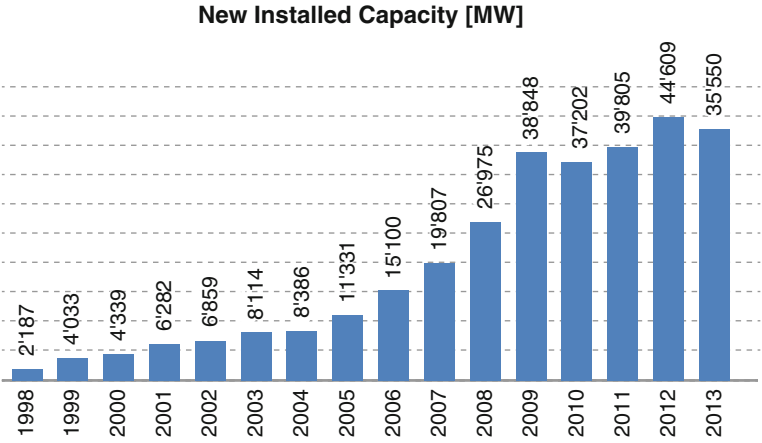

Fig. 25 New annually installed wind energy capacity 1998–2013 (World Wind Energy Association, WWEA)

(Fig. 28). As an extreme, the peninsular of Thy in Denmark with its 46,000 inhabitants, the 219 wind turbines' capacity of 125 MW results in 2,700 W per person, sufficient for 80 % of the demand for electricity coming from the wind. In Germany by middle of 2014, there were 36,488 MW and 82 million people, resulting in 445 W per person. On the other side, the UK, which has especially rich resources of wind, by middle of 2014 had 11,180 MW, meaning with a population of 64 million, 174 W per person. Even with 6 years of wind energy moratorium, Denmark has, by the middle of 2014, still obtained the number ten position on the world wind top 15 list.

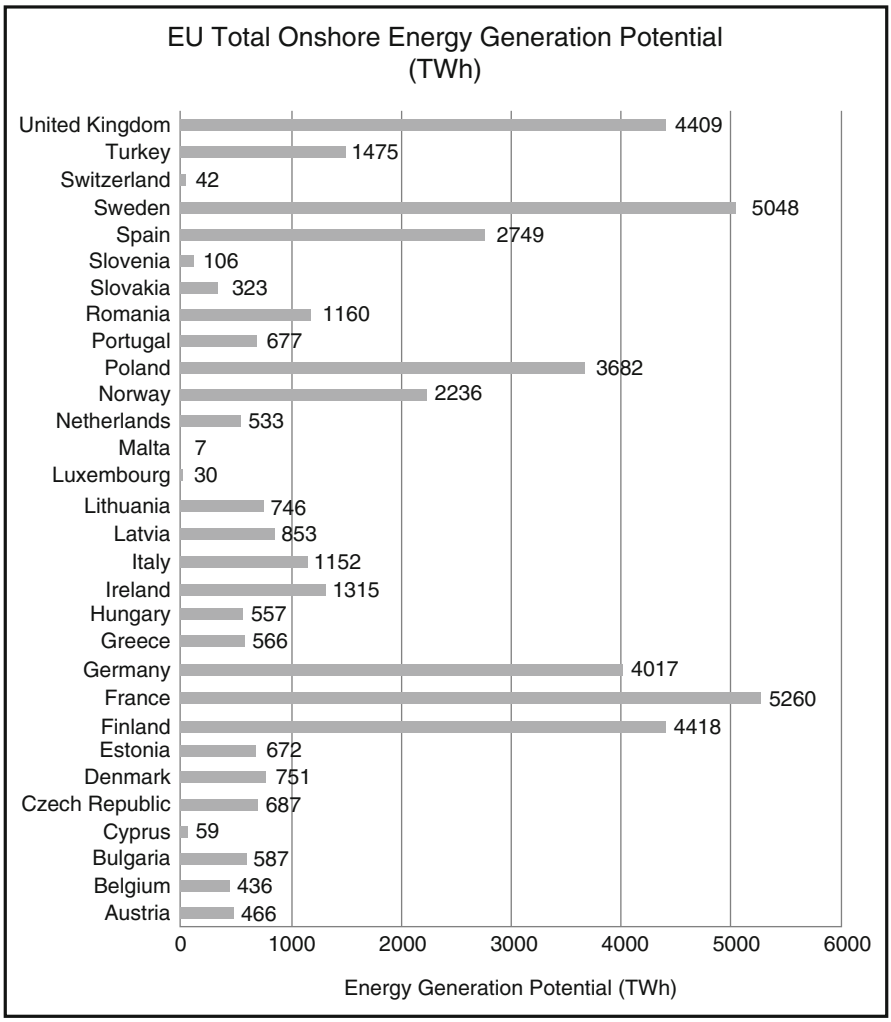

Fig. 26 EU total onshore energy generation potential (WWEA, World Wind Resource Assessment Report, 2014)

In the meantime, 2012 new targets have been set for wind energy in Denmark. The wind energy policy in 2014 consisted of targets that will be reached by 2020–2022 through the installation of 1,000 MW offshore wind farms, with one in the North Sea of 400 MW and another of 600 MW (called Kriegers Flak) in the Baltic Sea. Each 100 MW of new offshore wind power capacity will add some 1 % to wind energy's share of electricity in Denmark. Furthermore till 2020, 500 MW nearshore and 1,800 MW of onshore wind power will be installed while there will be repowering of some hundred MW of existing wind turbines. New multi-MW size offshore wind turbines will have capacity factors of 0.45–0.50, while onshore

Fig. 27 (*Left*) 25 KW solid wind of the new household wind turbine generation for single families and farms. Production: 40,000–80,000 kWh per year. (*Right*) Envision 3 MW wind turbine prototype during testing in Thyborøn, Denmark. Engineering and design by a Chinese company's R&D division in Denmark (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

Year	2010	2011	2012	2013	2014*
Installed wind capacity (MW)	3,752	3,927	4,162	4,792	4,855
Electricity generated (TWh)	7.81	9.77	10.27	11.12	9.30
Wind power share in domestic electricity supply (%)	20.2	28.0	33.7	32.2	40.8

Fig. 28 Key figures for wind power in Denmark (energinet.dk/Danish Energy Agency)

capacity factor ranges between 35 % and 42 % on wind rich locations. With the newly decided offshore and onshore capacity, the adaptation of the entire power system to balancing the fluctuating energy forms is more urgent in Denmark than other countries (Maegaard et al. 2013).

Wind energy share of electricity demand in Denmark 2007 to 2030:

- **2007: 18 %**
- **2010: 25 %**
- **2013: 33 %**
- **2014: 39 % = 5,000 MW**

Type of wind power	Year/period	Installed capacity, MW	Costs/kWh/€-cents
Existing	End of 2011	3900	5-9
Offshore, Anholt	2013/14	400	14 (50 000 full load hours)
Onshore	2012-2020	1800	7,5 (22 000 full load hours)
Near shore (up to 3 km)	2013-2020	500	10,5 ?
Offshore	2017-2020	1000	12-15 (50 000 full load hours)
Community owned	*2012-2020*	-	*5-8*
TOTAL		6,600 MW	

Fig. 29 Electricity costs in Denmark by type of wind power (Danish Ministry of Energy, press release)

- **2020: 50 %**
- **2030: 150 % ? = 20,000 MW**

Denmark does not have a coherent feed-in tariff scheme. Biogas finds one solution, onshore wind a second that may be quite different from offshore. For PV household, small wind power, and mini CHP up to 6 kW installed capacity, net metering principle is the rule. The tariff for wind energy in Denmark depends on several variables: which year the turbine went into operation, how many full-load hours they already delivered, and whether they are offshore or onshore. The tariff comprises a market power price element, power-balance compensation, and a government subsidy.

New onshore wind turbines receive as a general rule a price premium of €0.03 per kWh for 22,000 full-load hours, which leads a total remuneration of €0.7 per kWh. In comparison, the most recent offshore wind farm, Anholt with 400 MW, 2013/2014, was installed by the central utility DONG Energy. A tendering process guarantees a price of €0.14 per kWh for 50,000 full-load hours, making offshore wind power at least two times more expensive than when placed onshore (Fig. 29).

The Ownership Model Behind Two Decades of Success

Nontechnical aspects are also of importance for a successful transition to renewable energy supply. The absence of financial investors made the wind sector in Denmark unique at an early stage compared to other countries. At the turn of the century, around 150,000 households were co-owners of a local windmill. The ownership model rather than the technology and tariff schemes were substantial for the success of wind energy in Denmark. It was the key factor behind the high public acceptance that wind power projects enjoyed during that time. It also enabled a much faster deployment, since large numbers of people were involved in the sector that provided the necessary goodwill (Fig. 30).

In 1992, the role of cooperatives shrank due to a change in planning procedures. In 1998, due to liberalization in the sector, the ownership model changed dramatically. The residential criteria for ownership were abolished and everyone was allowed to own any amount of windmills as they could get, building permission for anywhere in the country. The takeover bids began, resulting in a dramatic decrease in public involvement. As a result, in 2009 about 50,000 households

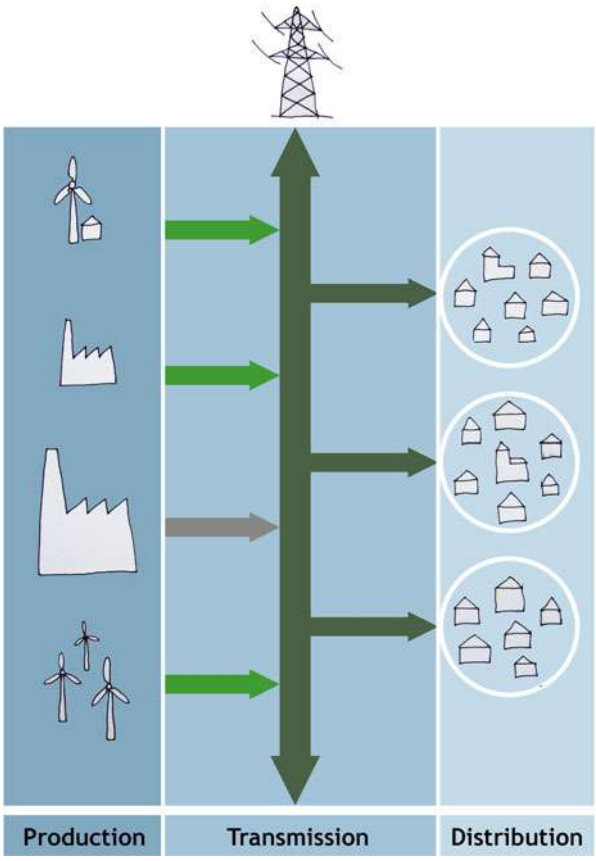

Fig. 30 Legislation in 2004 in Denmark resulted in separation of production of power, transmission, and distribution (Nordic Folkecenter for Renewable Energy)

were co-owners of windmills compared to 150,000 a decade earlier (Maegaard 2012).

Consequently, the attitude toward wind power suffered a reversal. The erection of a windmill often became a local drama and resulted in bitter conflicts that lead to long delays or cancellations. In 2008, a wind turbine neighbor compensation scheme was introduced that also caused local conflicts. The solution seems to be to "normalize" the wind energy sector so that wind power like district heating, CHP, and power distribution changed from investment to public supply, with municipalities and consumer-owned local companies as the future wind power owners. This would make wind power even more significantly cheaper.

Denmark already has hundreds of consumer-owned local energy supply companies for combined heat and power, district heating, and power distribution. New organizational structures and nonprofit ownership models to the direct benefit of the involved municipalities may prove to be the most realistic long-term solution for community wind power as well to again make it locally acceptable.

Integration of the Energy Supply by Public Ownership

Renewable energy is still young; technology and tariff problems have found reasonable solutions; however, generally acceptable organizational structures for decentralized ownership for the common good as well are part of the transition process.

The ownership and operation of large wind turbines for community supply should be a service provided by local public authorities as for CHP, supply of water, central district heating, public transport, and other parts of public infrastructure. It is the lesson from the past 100 years of practice that the state should promote public regulation in favor of local and collective ownership of basic public services, such as energy. This approach is in line with the protection and promotion of the common good in most democratic societies. Considering the size of order and complexity of the transition to 100 % renewable energy-based energy system, and its urgency, it is only realistic for public administrations to undertake this task.

The common good approach will make wind power a part of the public planning with expropriation of the necessary areas for wind turbines, as it is done with power pylons, waterworks, and similar areas of public interest. It is already standard practice to provide monetary compensation when areas are being designated for the common good. This would be a decisive contribution for attaining local acceptance and making wind energy more competitive. In Denmark, it could lead to a 30 % or more cost reduction, more than can be expected from improved technologies.

In several countries, new legislation mandates utility companies to buy electricity from renewable energy installations at a price determined by the government that is guaranteed for a period of 10–20 years. Such laws, based on guaranteed and differentiated feed-in tariffs, FIT, are used in the most successful wind energy countries. This would be a serious incentive for municipalities as well to actively be a part of the development of CHP combined with renewable energy either through municipal companies or existing and eventually new local renewable supply companies that can supply a full renewable energy package including wind power.

By making the establishment and operation of large wind turbines the responsibility of public supply companies, there would be significant savings due to cheaper sites for wind turbines, saved repowering fees, and cheaper long-term financing. Wind energy would then be more attractive for individual municipalities as well as at a national level and improve supply security, guaranty steady energy prices, and fulfill international agreements concerning CO_2 reduction as well.

Combined Heat and Power (CHP) and Its General Application

Cogeneration/CHP is the second cornerstone in future self-sustaining supply structures. CHP is the simultaneous production of electricity and heating/cooling from the same fuel which more than doubles traditional conversion efficiencies. This chapter focused on two aspects of CHP: its higher overall fuel efficiency and the important

role for power balancing in future energy systems with high shares of fluctuating power from wind and solar energy due to its generally local character with proximity to the places of consumption.

As a whole, the European Union generates 11 % of its electricity using cogeneration. However, there is large difference in the member states with variations of the share of CHP between 2 % and 60 %. The four countries with the Europe's most intensive cogeneration shares are Denmark, Latvia, Finland, and the Netherlands. The Danish CHP share varies from 43 % to 60 % with the lower share generated in years when export to neighboring countries of coal-based electricity from conventional power stations is high (Fig. 31).

Other European countries are also making efforts to increase their overall energy efficiency by increased use of CHP. Over 50 % of Germany's total electricity demand could be provided through cogeneration. Germany has set a target to double its electricity supply from cogeneration from 12.5 % of the country's demand to 25 % by 2020. Due to the advantages of combining the fluctuating renewable energy forms with CHP, Germany's ambitious wind and solar energy programs will not be in conflict with an increased share of CHP. On the contrary, with an extensive

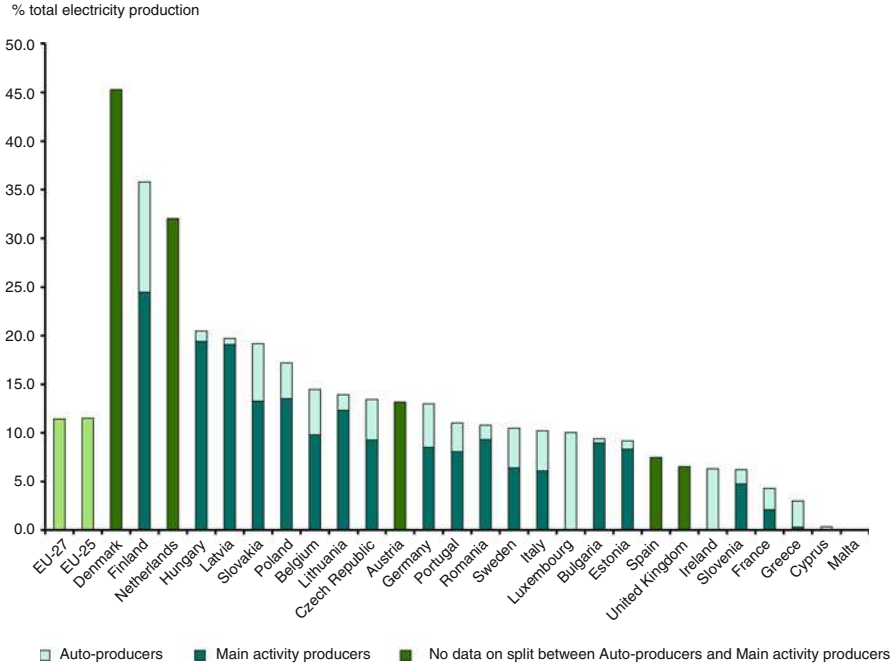

Fig. 31 Share of combined heat and power in gross electricity production in 2009. The share of electricity from combined heat and power in total gross electricity production in the EU-27 was 11.2 % in 2011, but 11.4 % in 2009, a growth from 2008 of 0.4 % and from 2005 of just 0.3 % points. CHP has seen modest progress in increasing the share of CHP in EU electricity generation (Eurostat, energy statistics)

increase of hot water-based district heating and cooling and the technologies properly integrated with electric boilers, heat pumps, and hot water storage, the CHP stations will pave the way so that significantly more solar and wind power can be installed in Germany. With high shares of wind power, some of it will, at periods with high wind, be available for the supply of heat. This will lead the way to 100 % renewable energy in the largest European economy. Using well-proven already existing technologies, investments per MW of new installed capacity of electricity and heating will be in the same size of order as conventional fossil fuel-based investments for similar power capacity.

Conventional power generation is based on burning fuel to produce steam. It is the pressure of steam that turns turbines and generates power in an inherently inefficient process. Because of a basic principle of physics in practice, a maximum of 40–45 % of the energy of the original fuel is converted to electricity. The European average is 35 % and the world average 30 % meaning that conventional condensation power plants represent an outdated technology.

Cogeneration, in contrast, recovers the heat for useful purposes. With efficiencies up to 90 % or higher, CHP is the ideal means of generating heat and electric power; at the same time from the same consumption of gas, oil, or biomass, it can double the supply of energy compared to conventional power generation (Fig. 32).

The favorable environmental implications of cogeneration stem not only from its inherent efficiency but also from its decentralized character. Because it is impractical to transport heat over long distances, cogeneration equipment must be located physically close to its heat application. A number of environmental benefits flow from this fact: power is generated close to its consumer, significantly reducing

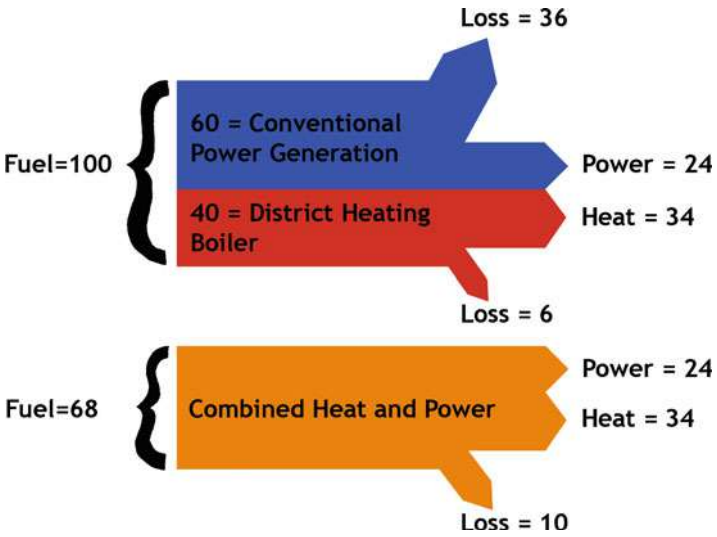

Fig. 32 For the same supply of heat and power, with the conventional solution with separated heat and power production, the consumption of fuel is 47 % higher (Nordic Folkecenter for Renewable Energy)

Fig. 33 Faaborg CHP plant (*left*) with its location close to the town center. It can supply its 7,000 inhabitants. The circular center building is for the hot water storage (*right*) (Jane Kruse/Nordic Folkecenter for Renewable Energy)

transmission losses and the need for distribution equipment. Cogeneration plants are usually smaller and owned and operated by smaller and more localized consumer companies than conventional power plants. Cogeneration is at the heart of district heating and cooling systems (Fig. 33).

Cogeneration units can be manufactured in series, similar to how truck and tractors are, which leads to low unit costs, while each individual conventional power station is unique so that similar cost reductions cannot be expected.

Due to international policies to reduce emissions of greenhouse gases, governments, municipalities, owners, and operators of industrial and commercial facilities are actively seeking ways to use energy more efficiently. Especially important is cogeneration that is the key technology in future integrated energy systems based on CO_2-neutral energy forms, solar, wind and biomass, to maintain continuous supply of electricity, cooling, and heating.

Combining a cogeneration plant with an adsorption refrigeration system for air conditioning and other needs for cooling allows utilization of seasonal excess heat. The hot water from the cogeneration plant can serve as drive energy for an adsorption chiller. Around 70 % of the thermal output of the cogeneration plant is thereby converted to chilled water. As the hot water replaces electricity for cooling needs, a well-balanced system with low losses can be designed. In this way, the year-round capacity utilization and the overall efficiency of the cogeneration plant can be increased significantly.

Cogeneration Technology

A typical cogeneration system consists of a gas engine, steam turbine, or gas turbine that drives an electrical generator. Heat exchangers recover the engine's cooling water, exhaust gas, lubrication oil, turbocharger, etc. to produce hot water.

An emerging technology that provides additional possibilities for cogeneration is the fuel cell. A fuel cell converts hydrogen or other fuels to electricity without combustion. Heat is also produced. Most fuel cells use natural gas (composed mainly of methane) as the source of hydrogen. Solid oxide fuel cells may be a potential source for cogeneration, due to the high temperature heat generated by their operation and high electrical efficiency of around 60 %.

Cogeneration Units

Cogeneration plants are the modules for combined production of electricity and heat.

CHP is characterized by:

- Low investment costs
- High efficiency rate, on average 85–90 %, of which electricity is 35–44 %
- Process automatic control
- 40,000 h of operation between major overhauls
- Rapid installation of 6 months or less
- Meets international emission standards

Main parts of a cogeneration unit are:

1. Internal combustion engine
2. Engine support frame
3. Alternator
4. Electricity control cabinet
5. Engine cooling system with heat exchangers for connection to the heating and cooling system

A CHP module including all components can be factory built on a frame or in a container ready for transport and installation. It can be designed for operating on natural gas, plant oil, biogas, or mixtures of gas. Its compact construction includes all the components of the CHP system, it can also contain additional facilities as heat pumps and electric boiler to match well with fluctuating energy forms like wind and solar (Fig. 34).

A CHP module can be built to industrial standards and meet the requirements of various national energy authorities. The modularized design ensures use of compatible technical components. Trouble-free and rapid commissioning of district heating stations and biogas plant using CHP is possible by using standardized equipment. Building time of conventional power stations may take 4–8 years. In contrast, CHP stations may be planned, installed, and commissioned between 4 and 8 months. The CHP module has already been tested and is ready to be connected when it is delivered. Only the cables and pipes for electricity and the heat supply must be connected as well as the source of fuel that can be natural gas,

Fig. 34 Ancillary equipment in a CHP station: the exhaust heat exchangers (*left*) convert the exhaust heat from the gas engines to hot water. The absorption heat pump (*right*) upgrades 20–40 °C water for use in district heating (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

oil, biogas, and other gases. Consequently, the production of electricity and heat can begin within a short period of time.

Cogeneration Applications

Cogeneration systems have been designed and built for many different applications. Large-scale systems can be built on-site as a plant to supply a city or industry with district heating or steam. Cogeneration systems are also available to small-scale users of electricity. Small-scale packaged or "modular" systems are being manufactured for commercial and light industrial applications and in agriculture using biogas. Modular cogeneration systems, such as energy boxes, are compact and can in the future be manufactured like automobiles and other mass-produced equipment. These systems range in size from 6 kWel and up to several MWel capacities. It is usually best to size the systems to meet the hot water and heating needs. They can be operated continuously or only during peak load hours to benefit from peak demand tariffs. Cogeneration is inherently more energy efficient than using separate power and heat generating sources, making it an effective antipollution strategy.

Manufacturers of gas engines include GE Jenbacher, Caterpillar, Perkins, MWM, Scania, Cummins, Rolls-Royce, Wärtsilä, MTU, MAN, Yanmar, Kubota, and several other engine builders (Fig. 35). Engines can have spark plug ignition, which is the most common. Some have 4–10 % oil injection for compression ignition. The modern high-speed gas engine has higher efficiency (44 %) than gas turbines. The gas engines are intensively used in transcontinental compressor stations with proven long-time trouble-free operation without service and major overhauls. Most of the gas engines are based on a diesel engine platform that is converted.

Germany in particular uses a significant amount of small-size CHP that are based on natural gas, biogas, diesel oil, pure plant oil (PPO), wood pellets, or other fuels (Figs. 36 and 37). In the city of Freiburg, Germany, often described as Europe's renewable

Fig. 35 Snedsted CHP (*left*) with GE Jenbacher V20 3,500 KWel gas motor. Farm CHP (*right*) with MAN V12 375 kWel motor using biogas (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

Fig. 37 Three types of small-size CHP. The Ecopower using natural gas (*left*), the Sunmachine wood pellet-fueled Stirling CHP, and small farm CHP using biogas (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

energy capital, a small CHP campaign for 1,000 CHP units was launched. They will be installed in Freiburg's old buildings in city quarters. Freiburg already has 55 % of its electricity coming from CHP consisting of a 40 MWel natural gas CHP of a chemical company and some CHP in public and family houses. The additional potential for CHP in Freiburg is more than 5,000 multifamily buildings and other buildings.

The CHP plants in Denmark already have considerable experience in optimizing their electricity production against the triple tariff which has existed since the early 1990s. Consequently, the plant operators know how to organize the production of the CHP units in order to optimize their income. Meanwhile, Denmark had a process of replacing such pricing conditions by market prices. Consequently, new methodologies and tools for the optimization of the daily operation of small CHP plants are needed. The new markets include upregulation and downregulation which meets short-term imbalances mostly caused by increased use of fluctuating and intermittent supply from solar and wind energy.

Case Study: CHP in Skagen, Denmark

District heating systems have a long history in Denmark – the very first system was established in the beginning of the 1900s in the city of Frederiksberg. Other cities followed the example and today there are about 500 district heating plants in the country, covering over 60 % of Denmark's demand for space and water heating.

Skagen Varmeværk started operating in 1964 with 535 cooperative society members. Today Skagen Varmeværk is responsible for operating district heating for the town of Skagen, the most northern town in Jutland, with 8,400 inhabitants. The Wärtsilä CHP plant (3 × W28SG) is equipped with efficient heat exchangers that reach total efficiencies of above 90 %. After some years of operation, the engines were upgraded to give a higher output and improved performance. In addition to its own production, a municipal waste incineration plant and a nearby industry are delivering heat to the common Skagen district heating network (Fig. 38).

Fig. 38 CHP power plant in Skagen (Jane Kruse/Nordic Folkecenter for Renewable Energy)

Table 1 Fact sheet – Skagen CHP power plant

3 × Wärtsilä gas engines	3 × 4.6 MWel/19.4 MWth
4 × Gas hot water boilers	46 MWth
1 × Electrical hot water boiler	11 MWth
Heat import from the waste incineration plant	Max. 6 MWth
Heat import from the neighboring industrial plant	Max. 6 MWth
Heat storage capacity/hot water accumulator	600 MWhth

The plant not only produces heat for the city and power for the distribution system operator but also actively participates in the Danish electricity regulating and primary reserve/frequency balancing markets. To handle these simultaneous production requirements effectively, very flexible operation, short start-up, and shutdown capability, as well as operator alertness, are essential. Besides the gas engines and in order to secure the production, the plant is equipped with hot water boilers operating on natural gas and prepared for the possible use of bio-oils and fuel oils, an electrical boiler operating in parallel with the gas engines and with heat storage accumulator. All these units allow very flexible and environmentally friendly operation (Table 1).

Heating of Communities

District Heating Networks

District heating systems are networks that supply hot water that is produced centrally, in one or several locations, to heating and cooling customers. Two-way pipes are used to distribute the hot water at a temperature of 60–90 °C that is returned at 30–50 °C after consumption.

The countries with the strongest growth in CHP capacity also had the strongest growth in district heating capacity. Operators that construct new district heating schemes often consider application of CHP a rational and viable solution or CHP may be a requirement by the local or national energy authorities as it improves energy efficiency significantly and makes it easier to meet CO_2emission reductions.

The same policies that have created a high penetration of district heating in Scandinavia have also created a high share of CHP with hot water storage connected to the district heating systems. This as well paves the way for increased use of the fluctuating energy from solar and wind leading to 100 % renewable energy. Presently, power peaks coming from wind and solar can be balanced in the local CHP stations as gas engines can respond within seconds or minutes to the variations in the productions of wind and power. In the long term, solar and wind can often cover power base load needs and at periods with maximum supply of solar and wind power, the fluctuating energy forms may even periodically cover both the need for electricity and the need for heating. This saves natural gas or biomass that will be available as backup fuel when solar and wind is not sufficient.

While some countries have opened up for decentralized energy structures with numerous operators and a diversity of energy drivers, the relatively low penetration of CHP in district heat production in, for instance, France, is an example of the obstacles decentralized producers face when entering an electricity market that is dominated by monopolies or oligopolies.

In practice, it is feasible for an ambitious national policy to reach, as in Finland, an almost 80 % share of district heating produced in combined production. The Finnish example shows that this can be reached by a diversified fuel input without depending on a single fuel type. In the future, the integration of large quantities of solar and wind can become included as well. Well-planned district heating and CHP offer an important potential for increased energy efficiency in the energy sector.

In Denmark, district heat is supplied by some 500 district heating companies and accounts for more than 60 % of Denmark's heat demand, compared to levels of 30 % in 1980. Most of the companies produce and supply the heat, but some purchase heat from the central power plants. The average consumer connection rate in district heating areas is 82 % and is still increasing. The district heating network supplies heat to large consumers, apartment blocks, offices, institutions, and to single-family houses. Danish district heating companies are owned either by the municipalities, particularly in the major cities, or by local consumer cooperatives (Fig. 39).

Between 43 % and 60 % of the electricity generation is from CHP, compared to just fewer than 20 % in 1980. Twelve of the 14 central power stations in Denmark deliver all or part of their excess heat to a district heating network. Nearly all large-scale power plants are located close to major cities. This and the fact that 80 % of the population lives in urban areas allowed the high shares of combined development of district heating and CHP. The first steps in the development of CHP were taken in Aarhus, Odense, and Aalborg, which are the second, third, and fourth largest cities in Denmark, respectively.

In 1904, the first CHP plant was commissioned, supplying heat and electricity to a hospital. By the mid-1930s, the Copenhagen district heating network was well established, even though heating was to a large extent still provided by small individual coal-fired boilers. The first plant specifically designed for CHP was commissioned in 1934. The heat planning legislation, initiated in 1979, aimed to increase the share of cogeneration in the district heating supply system and to promote use of natural gas. Through the heat plan, the cities and towns were divided into areas suitable for district heating and areas more suited for individual supply of natural gas. The heat plan shielded district heating from interfuel competition from natural gas and electric heating. The majority of district heating loops are owned by the inhabitants of the community (Fig. 40). This gives control to the residents and ensures that energy is distributed to the communities at the lowest possible prices. If

Fig. 40 Example of a district heating network (*left*). Vorupoer CHP (*right*) has two Jenbacher natural gas motors, each of 900 kWel. The electrical efficiency is 42 %. It serves 200 households, local business, and institutions with heat. The electricity is delivered to the public grid. The chimney is decorated by a local artist. In the background are two hot water storagetanks. The CHP and heating network is owned by the local consumers in a not-for-profit company. The staff consists of one person, a technician. In 2010 the plant was presented in the film documentary "The 4th Revolution" as an example of best practice (Jane Kruse/Nordic Folkecenter for Renewable Energy)

profits are made, they are given back to the energy consumers in the form of lower heating costs in the succeeding year.

Major cities have city-wide district heating systems where almost all of the heat (95–98 %) is produced in large coal-fired or gas-fired CHP plants and waste incineration plants, with a number of oil-fired or gas-fired heat-only boilers for peak load and emergency. Since the early 1980s, no new power plants have got permission for commissioning unless provided with the ability to use CHP and to supply heat to the district heating networks (Fig. 41). This was motivated by security of supply and environmental concerns encouraging energy efficiency. Construction of new electricity-generating capacity must be justified by the need for new heat-production capacity (Fig. 42).

In addition to the large-scale CHP and district heating units, a large number of small-scale CHP plants exist. Most of the plants range between capacities of 0.5–5 MW and supply heat to small communities and institutional buildings. Often, the plants consist of more than one CHP gas engine unit. Small-scale CHP plants, which are not connected to a district heating network, rarely exceed an electric capacity of 1 MW. Small-scale CHP plants are laid out to cover at least 90 % of the local heat demand.

The national power system responsible will purchase the electricity from all types of producers (Fig. 43). The electricity generated is sold to the public grid. The fuels used in small-scale CHP are natural gas and, to a lesser extent, biogas and other biomass (Fig. 44). In connection with the presentation of the Energy 2000 plan in 1990, a more ambitious program for small-scale CHP was put forward. To accelerate the establishment of small-scale CHP, a state subsidy was introduced in 1992 for power production from waste incineration, natural gas, and renewables. The subsidy originally amounted to €0.014 per kWh. With an implementation period of less than 10 years, the development of small-scale CHP peaked in the late 1990s. The capacity

was sufficient to produce 25 % of the national demand for power. About 80 % of the installed capacity is based on natural gas engines. Sixteen percent are gas turbines and 4 % are biogas-fired engines. Most of the installed gas engines have an electric capacity in the range of 0.5–6 MWel, whereas gas turbine units typically range in capacity from 5 to 25 MWel.

The electricity from CHPs is fed into the national grid. The feed-in tariffs for CHP were based on a three-tier tariff system, with tariffs reflecting electricity demand patterns (low, medium, and peak tariff periods). After liberalization of the electricity sector, market principles were applied like in the other Nordic countries.

Industrial CHP is used in industries with high demand for process heat, especially the petrochemical, wood, malt, and paper industries. The food industry and greenhouses can also use low-pressure steam or hot water from CHPs. To illustrate the variety of applications, the national railway company gets hot water for cleaning its passenger trains from a medium-size CHP at the maintenance facility. In 2000, electricity production from industrial CHP was about 8 % of total power generation.

Technology for Decentralized District Heating

As mentioned earlier, the preferred CHP technology predominantly has been gas-powered engines. Stationary natural gas engines used in combined heat and power applications boast a factor 4 reduction in CO_2emission compared with conventionally generated thermal coal power for same produced power and individual supply of heat.

This is because:

1. The heat can be used if the system is placed in the community increasing the total efficiency of the system to over 85 % compared with the best thermal coal condensing power plant at around 45 % electrical efficiency.
2. Natural gas has a tenth of the SOx, half of the NOx, and a third of the CO_2 produced compared to the emission by the combustion of coal. The cost of removal of these pollutants in a coal-generation plant is significant.
3. The cost to install a gas engine is around 40 % lower per kWel installed than that of a coal plant and even cheaper if removal of the emissions from coal is included. Additionally, gas-fired engines can be installed in 6 months as opposed to 4–8 years for a thermal coal plant.
4. Gas engines are manufactured in series and are cheap, while central power plants are one-of-a-kind technology. The gas engines can be installed in existing or new buildings without any noise or visual impact for the neighborhood.

With these benefits, it became possible for local district heating companies owned by municipalities or consumers to build their own CHPs and offer cheaper heat to households. This became the primary driving force which encouraged a rapid change to local CHPs.

Natural gas used in a CHP is not renewable but local CHP creates the basis for a decentralized energy structure that later with modest investments can be changed to local renewable energy sources. Stationary gas engines can run on a variety of fuels which can be tailored to local fuel availability.

These local supply sources can be:

- Biodiesel
- Plant oil
- Biogas
- Gasified biomass
- Landfill gas
- Solar thermal installations
- Wind heat and power (WHP)

If these alternate fuel sources are not available, natural gas can be used as a transitional fuel, while the community determines which fuel can be utilized in the future. In essence, district heating with CHP provides the initial framework toward a renewable energy power and heat system.

Summarizing the Advantages of Local CHP

Advantages of community-based CHP units are significant, the main benefits being:

1. Reliability: Gas engines can be used where reliability is of the utmost importance. Typically these gas engines are installed in transcontinental gas compressor stations, drilling rigs, offshore oil platforms, and villages not served by the national power grid.
2. Community Autonomy: Having local CHP provides the local community with autonomy giving the "power to the people." This enables the community to ensure that the electricity is produced in an appropriate manner.
3. The Ability to Incorporate Renewable Energy in the Future: Having CHP with district heating opens opportunities to incorporate large shares of renewable energy in the form of biogas, solar thermal heating, wind for heat, biomass gasification, plant oil-based fuels, and combustion of locally grown biomass.
4. Scalability and Flexibility: Local CHP is scalable and flexile to operate. This makes it easy to increase capacity in the future and matches well with the incorporation of wind and solar power in the supply system.
5. High Efficiency: Medium-size stationary gas CHP units boast an electrical efficiency of around 44 %, and with heat recovery of the jacket water, exhaust, lube oil, and turbocharger, they can achieve an overall efficiency of over 85 % (power 44 % plus heat 43–48 %).
6. Cost-Effective Heat and Power: With high total efficiencies and two energy products from the same fuel source, cost of power and heat can be reduced. As an example, in 2007, Denmark according to Eurostat had the fifth lowest power prices (without taxes) for GWh consumers in Europe with Sweden, Norway, France, and Finland, all countries with old hydro and/or atomic energy, being lower.

Combining CHP and Wind, in Summary

On days with a high demand for heat combined with high wind, CHPs and wind turbines, as mentioned earlier, together periodically feed more power into the grid than needed by the consumers. The challenge for the system operator in some countries is already and will in the future be even more to optimize the available resources. While Europe as a whole has 11 % of the efficient combined heat and power (CHP) in the energy system, the share in Denmark is 43–60 %, the world's highest, which at the same time represents not only the problem mentioned but also its solution.

The combined high CHP and wind power production causes a potentially major problem in the power sector. However, supply and demand can be balanced by feeding on windy days the excess wind power into electric boilers and heat pumps at the combined heat and power stations, which makes 100 % renewable energy supply of heat and power realistic. The electric boilers and heat pumps make it possible to

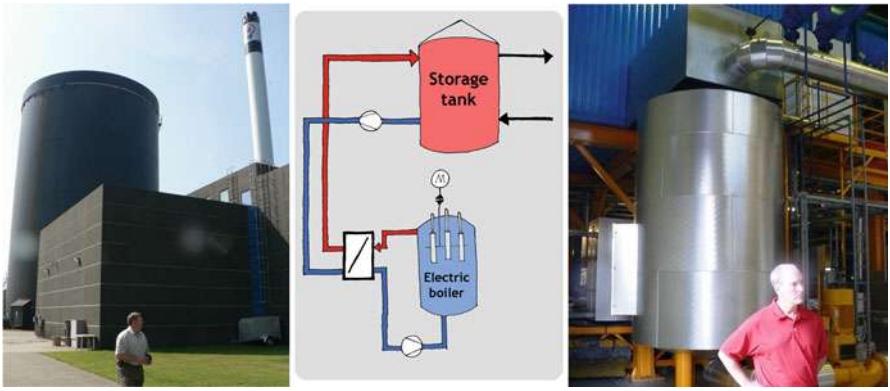

Fig. 45 Principle of downregulation using excess wind power at a CHP plant with 10,000 consumers. Storage for 2 days of heat supply (*left*) in Grindsted; 20 MW electric boiler (*right*) (Nordic Folkecenter for Renewable Energy)

stop the natural gas and biomass-fueled CHP units at periods with excess wind and solar energy. With increased renewable energy shares in the future, more and more often the fluctuating solar and wind energy will be sufficient to satisfy both the need for power and heat (Fig. 45).

Compared to other uses and storage of excess power, electric boilers and heat pumps cause no conversion loss. Heat pumps even boost the excess production of power by a factor of 2–6 depending on the energy source available. For the heat pumps, a low-quality source may be atmospheric air, soil, and water from the sea or rivers, which will result in a relatively low efficiency, while geothermal heat, air ventilated from buildings and industries, and other types of potential heat sources up to 40 °C will result in high efficiencies in the heat pumps. As they require substantial investments, the operation of heat pumps using excess wind and solar power for balancing the grid by downregulation should result in yearly operation of 3,000 h or more. This amount of excess power will in a more distant future be available at medium peak periods. As fluctuating solar and wind will always cause short-term high peaks, electric boilers will due to their low initial investment be the preferred solution to utilize the high peaks of solar and wind energy.

Therefore, it is not a relevant discussion whether electric boilers or heat pumps should be preferred. In the early stage of using fluctuating solar and wind in the heating system, electric boilers will be optimal, while increased amounts of fluctuating power will pave the way for heat pumps to convert the medium peak electricity into district heating while the electric boilers will take the high peaks (Fig. 46).

Like the transition from fossil fuels to renewable energy forms leads to zero emission, the modern power balancing is an integrated part of the change of the energy system. The natural gas-based cogeneration in district heating stations and the industrial autoproducers can be adjusted within seconds or minutes and ideally match the fluctuating renewable energy supply.

Fig. 46 Three sizes and types of electric boilers for power downregulation: 20 MW, 10 kV (*left*); 3,300 kW, 400 V (*middle*); and 45 kW, 400 V (*right*) (Nordic Folkecenter for Renewable Energy)

New taxation rules can make it economically beneficial to use fluctuating wind electricity for district heating according to a decision by the EU Commission. While excess electricity sometimes is being sold at the spot market for €0.01 per kWh or even at negative prices, it will at any time when used for heating have a value equivalent to the fuel that it replaces or €0.04–0.12 per kWh depending on the type of fuel and taxation.

Case Study: Thy, the Municipality of Thisted

In the Thy peninsular with its 46,000 inhabitants, the 219 windmills and other renewables cover 100 % of the annual need for electricity. The local energy production has become an important source of income. "In Thy people prefer to use renewable energy. That is the essence of the Thy model where people, economics and technology come together to create clean carbon neutral energy" (Thisted Municipality).

On days with strong wind, the wind turbines may even produce four times more than the actual consumption and the power quality still lives up to the highest standards. The local utility, Thy-Mors Energi, has demonstrated real-time management of such big quantities of wind energy to visitors from all parts of the world.

In the towns and villages in Thy, people get their heating from hot water pipelines in the streets. It is environmentally and economically the best solution to use the excess wind power for the actual supply and storage in the big hot water reservoirs of the local district heating suppliers instead of exporting the surplus power to neighboring countries sometimes at low-spot market prices (Fig. 47).

A new municipal energy foundation plans to own further windmills. In 2010, 80 MW of new capacity was in the planning process. The income of the discussed foundation may be up to €7 million per year earmarked for local energy initiatives which secures acceptance of the wind power and illustrates the benefits of change from investor policy to local supply (Table 2).

Fig. 47 (*Left*) Thisted combined heat and power for a town of 25,000 residents. Fuels used include household waste, straw, wood, solar thermal, and geothermal. (*Middle*) 6 MWel steam turbine. (*Right*) trucks discharge waste (Jane Kruse/Nordic Folkecenter for Renewable Energy)

Table 2 Thisted Municipality fact sheet for 2012

Electricity
Power production: 365 GWh Power consumption: 322 GWh Share of natural gas: 33 GWh (12 % of produced electricity available for "export")
100 % of power consumption was produced fossil-free: Wind: 297 GWh Waste: 20 GWh Biogas: 9 GWh Solar: 6 GWh Fossil-free total: 332 GWh Power consumption: 322 GWh (3 % surplus of produced electricity available for "export")
92 % of power consumption came from local windmills: Number of windmills: 219 Capacity: 113 MW Production: 297 GWh Power consumption: 322 GWh (92 % from wind)
Renewable energy total
84 % of energy consumption (heat and power) was fossil-free: Fossil-free production: 642 GWh Heating and power, total: 762 GWh

For the last 35 years, farmers, industry, utilities, and cooperatives in Thy have invested in and used renewable energy resources such as:

- Biomass for district heating
- Biogas, small and large CHP
- Geothermal heat
- Concentrated solar heating
- CHP waste incineration
- Wind power
- Wind energy management
- CHP and wind heat and power (WHP)

The further development of wind power will make it the primary source of electricity and heating, WHP. With an estimated 80 MW new additional wind power, peaks will be more frequent. The strong local support is crucial and is obtained by local ownership of windmills and biogas plants by several farmers. All the CHP plants and the district heating are not-for-profit consumer owned. Local surplus of wind electricity will in the future be used in combined heating and power plants and periodically replace natural gas and biomass. Biomass will function as backup storage when wind and solar energy is not sufficient to cover the need for electricity and heating. Solid and liquid biomass is easy and cheap to store. Biomass will only be used when solar and wind is not sufficient to cover the needs for heat and power.

In the peninsular of Thy, the local community owns/installs/operates the green power producing infrastructure; therefore the benefits from the infrastructure are reaped by the community. Local pollution and CO_2 reduction, job creation, business development, economic diversification, and skill building are of general interest for the community. Once a community has experience with community power, that skill can be transferred to other communities.

In 2007, the Thisted Municipality received the prestigious European Solar Prize. At the award ceremony in Berlin, mayor Erik Hove Olesen stated: "I am very proud and grateful that we today receive this award. Not us as authorities have the honour. Our 46,000 citizens, the energy centre, and our 1,700 local companies made the change. The many windmill owners, the farmers that have biogas plants and the community utilities, they have together made Thy self-sufficient with energy."

Case Study: Ringkøbing District Heating, Denmark

Ringkøbing Fjernvarmeværk, the Ringkøbing district heating, is an example of a successful integration of CHP (gas engine and gas turbine), solar thermal, electric boiler, natural gas boilers, and hot water storage making it an independent, attractive, and reliable source of cheap fossil-free heating with a high level service across the district heating consumers and with a remarkable ability to evolve following changing targets of sustainable energy supply since 60 years.

Ringkøbing Fjernvarmeværk is a private consumer-owned cooperative established in 1963. In the beginning the Ringkøbing plant was an oil-fired plant, and in 1980, following higher demand for heat, another coal-fired plant was built in Rindum (Fig. 48).

In 1989, the Ringkøbing plant converted from oil to a CHP with natural gas. A gas turbine of the Ruston Tornado class was installed with an output of 6.2 MWel and 12.5 MWth. In addition, two boilers were installed with a total power of 18 MWth.

In 1993, the Rindum plant also converted from coal to a CHP with natural gas. There a gas turbine of Siemens-Ruston Typhoon class was installed, and by the end of 2002, it was replaced by a Wärtsilä gas engine 20V34SG with an output of 8.8 MWel and 10.5 MWth (it produces almost twice as much electrical power as the

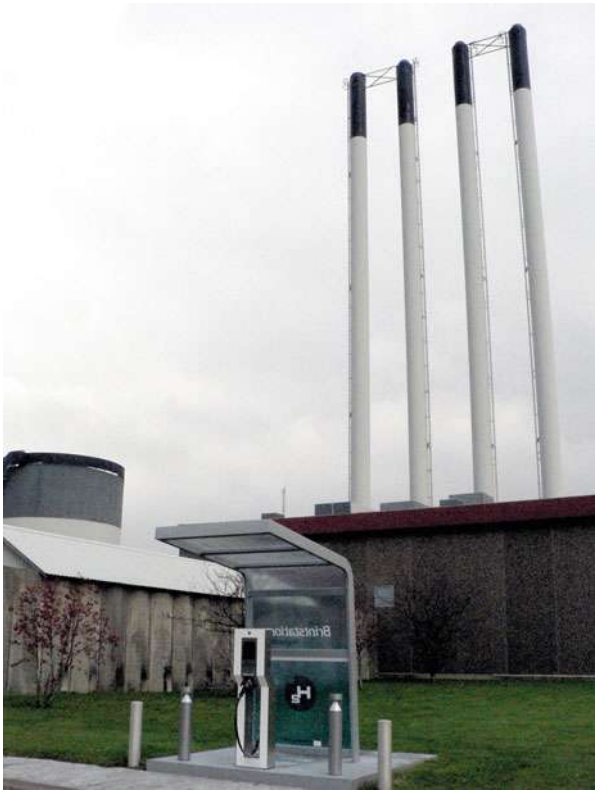

Fig. 48 The combined heat and power station in Rindum, Ringkøbing (Jane Kruse/ Nordic Folkecenter for Renewable Energy)

Table 3 Main specifications of CHP unit at the Rindum power plant

Heat capacity (total)	9,680 KWth
Electrical capacity (total)	7,861 kWel
Technology	Lean-burn gas engine
No. of units	1
Manufacturer	Wärtsilä
Type of fuel	Natural gas
Year of construction	2001
Investment	3.2 M EUR

replaced engine) and two gas/oil boilers were installed with a total power of 20 MWth (Table 3).

The electrical efficiency of the gas turbine was 27 %, while the efficiency of the Wärtsilä 20-cylinder gas engine is almost 44 %. The spark-ignited lean burn engine delivers heat to the town's 3,500 consumers and electricity to the local utility company RAH.

The operator was faced with tough environmental demands from the authorities to reduce the NO_X emissions from the gas turbine, in addition to which a major overhaul was scheduled for the gas turbine. The high total efficiency of the plant

Fig. 49 *Left*: Ringkøbing Fjernvarmeværk's power plant. To the right, hot water storage tank, in the background there are solar thermal panels; *Right*: Ringkøbing solar heating panels (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

gives the owner maximum security in an open market where fuel and power prices are volatile. The cost of heat production from the Rindum plant has been reduced by 20 % compared with continuing operation of the gas turbine.

In 2010, the Rindum plant furthermore installed an electric boiler with power of 12 MW during periods of power from surplus production from wind turbines, converting electricity into cheap district heating.

In keeping with the focus on renewable clean energy, in 2010, a solar heating plant "Sol 1" of 15,000 m^2 was built. By that time, it was the world's second largest solar plant, with a maximum power of 11 MWth when weather conditions were optimal. Four years later, in 2014, the solar heating plant was extended by a further solar heating system, "Sol 2" of 15,000 m^2 (Fig. 49). Both plants currently supply around 14 % of the total district heating to Ringkøbing. The district heating pipeline network delivers heat to approximately 4,200 consumers.

Ringkøbing Fjernvarmeværk sets its goals following the Energy 2020 Plan, for the municipality to become self-sufficient in energy by 2020, and changing from gas to renewable energy supply considering various alternative solutions such as more solar heating, heat pumps, biomass, biogas, and geothermal energy.

Renewable Energy Sources for Integrated Systems

Focus: Biogas, Energy Source with Potential

Biogas will be an important component in the future combined and integrated energy systems. It can be produced where organic waste is available. Resources that basically are without value for other purposes can be digested – often in combination with energy crops to increase the yield. Biogas digesters are a well-developed technology and available in many varieties and sizes. Family-size biogas plants in developing countries may treat the dung from a few cattle, while big, advanced biogas plants can handle several hundred tons of slurry per day.

Anaerobic digestion (AD) involves the breakdown of organic waste by bacteria in oxygen-free environment. It is commonly used as a waste-treatment process but also produces a methane-rich biogas with 50–70 % being methane and the rest CO_2 and small quantities of other trace elements. Biogas can be used to generate heat and electricity.

AD equipment in a biogas plant consists, in simple terms, of an air-tight heated digester tank, a gasholder to store biogas, a gas-burning engine/generator, and a CHP unit if electricity is to be produced. The organic waste is fermented in the digester at temperatures between 25 °C and 55 °C.

The fermentation process is in itself unlike composting not able to produce heat. The rate of breakdown depends on the nature of the waste and the operating temperature. Biogas has a calorific value typically between 50 % and 70 % that of natural gas and can be combusted directly in modified natural gas boilers or used to run internal combustion engines. Apart from biogas, the process also produces a residue that may be separated into liquid and solid components. The liquid fraction can be used as a fertilizer and the solid element may be used as a soil conditioner or further processed to produce higher value organic compost.

Biogas has several applications of use: for direct combustion in boilers, for combustion in gas engines, and for transport. When upgraded by removal of CO_2, biogas can be fed into existing natural gas network. Compared to solar and wind power, biogas is fairly easy and cheap to store and can periodically fill the gap when solar and wind is not sufficient. When applying the Sabatier catalytic process, hydrogen will react with the CO_2 component in the biogas and it will have the same properties as natural gas.

Deployment of Biogas: Denmark as a Case Study

According to the Danish Energy Strategy 2050, biogas will play an essential role in the process of limiting and finally being independent of fossil fuels in Denmark. Biogas has the potential to balance fluctuating power generated from renewable energy sources like wind and solar by cogeneration. Also, produced biomethane can replace natural gas in the grid, reducing the country's dependence on imports of oil. As for the use of biogas for transportation, unlike in other countries, Denmark is in favor of electric vehicles and has rather limited infrastructure for gas vehicles. However, public and heavy transport is of increasing interest for more and more municipalities (Fig. 50).

Compared to its size, Denmark has the second biggest number of farms in the EU and the highest amounts of livestock per holding.

Production of biogas in Denmark can offer a solution to the manure problem the country is facing and support the development toward the goal of use 50 % of the raw manure for biogas production (as stated in the Government "Green Growth" program of 2009) and at the same time improve Denmark's energetic independence of oil, natural gas, or coal, offering a substitute to fossil fuels. Other advantages of biogas production are the reduction of evaporation in the atmosphere of methane and

Fig. 50 Farm biogas plant of the ComBiogas type during the inauguration. Through a network of pipes the slurry is pumped from the farms for digestion and returned back for spreading as fertilizer over the fields. The biogas is piped to the nearest CHP station (Jane Kruse/Nordic Folkecenter for Renewable Energy)

laughing gas from manure as well as transition of nitrogen in the manure to more accessible fertilizer for the crops.

By 2014, there were approximately 150 biogas plants in Denmark, producing 4.2 PJ of energy annually. In centralized biogas plants, heat is used in internal process and in district heating networks, based on two models:

- CHP unit is integrated in the biogas plant and then heat is sold to a district heating company.
- Biogas plant sells and transports biogas to a district heating CHP plant.

In the farm plants heat is used in internal process and in:

- District heating networks (when possible)
- Heating of houses, or stables, or other buildings on-site while surplus heat is ventilated to the atmosphere

The first biogas plants in Denmark were established in the 1970s; however, the development increased in the period of 1999 to 2003, doubling the number of plants from about 30 to 60. By 2003, total production of biogas accounted for 0.8 TWh_{el}. Since that time, the development of biogas production has been steadily but slowly increasing. In 2012, total production of biogas reached

1.14 GWh_{el}/a and 1.19 TWh_{el} in 2013. It is estimated that the production may increase to 2.77 TWh_{el} by 2020.

In 2012, the largest biogas plant in Denmark, and one of the biggest in the world, is the Maabjerg BioEnergy plant producing approximately 5MWel, followed by Lemvig plant of 2 MW while delivering biogas for other applications as well.

Historical Overview of Biogas Development

Biogas was first introduced in Denmark in the late 1970s. The first plants were by present standards rather primitive and built at farms by dedicated and enthusiastic individuals searching for alternatives to the fossil oil that was being imported from the Middle East. As a consequence of the precarious situation in 1974, the energy policy of Denmark became for almost three decades a concerted effort uniting normally divided parties in broad consensus with the primary purpose to reduce the dependency on oil.

In 1977, oil covered 95 % of the total energy consumption of Denmark. Twenty-five years later oil represents only 40 % of the energy consumption of 20 million TOE/year, followed by 36 % in 2012. In the meantime, there came significant improvements in energy efficiency combined with increased use of renewable energy sources and extensive application of central and decentral cogeneration solutions being the main elements in the energy policy. The result is energy consumption at nearly the same levels as in the 1980s.

The long-term benefits of the policy in 2010 were a renewable energy sector employing 30,000 people and an annual export value of €6 billion with around 75 % coming from the windmill industry. Further, Denmark is one of the first European countries which is targeting a complete independency from fossil fuels by 2050. The transition is supported by policies like the new Energy Agreement reached in March 2012, containing energy initiatives and large investments in renewable energy and energy efficiency that by 2020 approximately 50 % of electricity consumption should be delivered from wind power, and more than 35 % of final energy consumption should be supplied from renewable energy sources. Hardly any other countries have achieved similar industrial benefits by restructuring the energy sector Biogas in Denmark (2014).

In the early 1970s, renewable energy equipment based on wind, solar radiation, biomass, and similar natural resources could not be imported from abroad in the form of well-tested, documented, and reliable equipment. At the local-level teams of voluntary development, groups consisting of engineers, blacksmiths, farmers, architects, and others with practical skills were organized to invent concepts and build biogas plant prototypes that were installed and tested under real-life conditions.

Throughout the following decade, a broad variety of experiments and concepts emerged at the noncommercial level as a result of this bottom-up research and development process that is historically unique. Undoubtedly the success and efficiency also by conventional professional standards was significant, furthered by principles of local cooperation. Absence of patents and other forms of protection

of rights allowed exchange of knowledge between inventors, coordinators, potential consumers, and manufacturers. Experience and knowledge was exchanged at the informal level but also more systematically transferred in manuals and seminars organized by the emerging renewable energy organizations satisfying the need for best practice solutions. Around 1980, the first regular commercial initiatives of manufacturing and marketing of renewable energy equipment within wind power, solar thermal panels, wood stoves, and biogas installations were demonstrated. Apart from energy planners and a few physicists, professionals from universities in general did not see the development of the renewable energies as an earnest and promising effort by that time. However, the following development proved the opposite.

Origins of Three Farm Biogas Concepts

Biogas was initially used only for individual farms. Its specific development grew out of the process described above involving a broad variety of concepts and experiments. Especially three parallel development lines contributed to advance the technology:

(a) The first one came as a result of a state financed research and development program named Cooperation for Technological Development of Biogas Plants (STUB), initiated in 1978, that set up three extremely different digester concepts. None of which, however, became of commercial relevance. The aim was to combine theoretical skills, prototype building, capacity building at the farms, deployment of biogas in agriculture, and setting the standards for future biogas plants. Within the project, a number of reports mostly based on experiences and measurements from the prototypes were published.
(b) The second biogas development team, Højbogaard, was the combined efforts of a progressive farmer and the local blacksmith. They quickly obtained high gas yields from well-designed digesters in different versions made from steel plate and concrete by systematically investigating the biological process. Under the trade name of Bigadan, in 1982 they became suppliers of a scaled-up version for some of the first community biogas plants in Denmark. Today, Bigadan operates on large-scale biogas plants.
(c) The third significant biogas development initiative grew out from an effort of mobilizing the local human and technological potential in the region of Thy in northwestern Denmark. Funding from UNESCO made it possible quite early in the biogas implementation phase in 1977 to invite a few international biogas experts with proven knowledge and experiences within a new technology. It became an early and concrete example of international technology transfer within renewable energy, however, in the form of South-North cooperation.

This opportunity allowed consultancy and technology transfer from experts like Ram Bux Singh from India, former leader of the Gobar Gas Research Institute. He had the authority to set important standards in the early development process in

terms of valuable technology inputs by encouraging farmers in the region and stressing that comprehensive application of biogas was a long-term learning process and not merely a matter of hardware.

Materials and Technology in Biogas Construction

The suppliers of biogas plants in Germany and other countries are primarily using concrete digesters, whereas almost all biogas plants in Denmark manufactured are from steel plate. Concrete was also used in Denmark in the 1980s for digester tanks made from concrete prefabricated sections originally developed for liquid manure storage tank.

These tanks had a large diameter in comparison to the height (ratio 3:1) providing a wide span cover structure. Gas leaks, however, occurred and it was determined that gas molecules were diffused through the porous concrete. Therefore, steel became the preferred construction material for digesters irrespective of its higher costs. Steel tanks either were welded constructions or enamel steel plate elements bolted together with flexible sealing between the joints. Similar types of tanks are widely used for grain silos. In Denmark, three main categories of biogas plants are found:

- Community biogas plants, each 500–20,000 m^3, delivering electricity to the grid and heat to the town district heating network from 50 % to 70 % manure and 30 % to 50 % industrial waste
- Large, rather farm biogas plants using a concrete or steel tank digester with cogeneration and co-fermentation
- Smedemester (Blacksmith) farm biogas with steel digesters, 37–45 °C operating temperature, 150–1,000 m^3 digesters, 2–5 % fish waste oil co-fermentation, cogeneration units of 100–500 kW

The first community biogas plants were built in the early 1980s. This was part of a desire to supply villages and townships with biogas for cogeneration in regions that were not going to be supplied by the new Danish fossil gas distribution network. It was anticipated that daily operation of the community biogas plants would become the responsibility of well-trained staff with insight into the biogas process that individual farmers with an already wide variety of duties could not take.

After 1985, more stringent environmental legislation concerning storage and land application of animal manure was introduced. Nine months of storage capacity became a legal requirement for Danish farms. Quantities of nitrogen and phosphates applied per hectare of land also became subject to public regulation. This increased farmers' interest in centralized plants with manure storage capacity included in the concept. The centralized biogas plants all co-digest animal manure and organic waste primarily from the food industry. In 1991, a biogas production level of 30–35 m^3 of biogas per cubic meter of slurry was evaluated as being a necessary precondition for the economic viability of centralized biogas plant. This production

Fig. 51 Community biogas plant with CHP. The tanker truck (*left*) collects 400 t of liquid waste from farms daily. In the 7,000 m^3Bigadan digester (*middle*), the biogas is produced which the Jenbacher gas engine (*right*) converts into heat and electricity (Jane Kruse/Nordic Folkecenter for Renewable Energy)

could only be achieved by co-digesting animal manure with wastes from the food industry, normally by admixing 10–30 % organic wastes depending on the character, biogas potential, procurement costs, and availability of the waste.

The animal manure for community biogas plants is transported from a number of farms to the plants by tank trucks or pumped through slurry network from the farms. After digestion, the slurry is returned as a nutritionally defined fertilizer, partly to the farms that delivered the fresh manure and partly sold as organic manure to farms engaged in crop farming only.

The volume of animal manure and industrial wastes daily delivered into the community biogas digesters range from 50 to 500 t with resulting biogas production of 1,000 m^3 up to 15,000 m^3 per day (Fig. 51).

At farm biogas plants, the gas is normally combusted at the farm more or less independent of the energy requirements of the specific farm. In that respect siting of community biogas plants ensures that the biogas production can be utilized with high efficiency in cogeneration systems with a total efficiency up to 90 % when the heat is used for district heating of towns, villages, and rural communities.

When installing farm biogas plants, export of heat for district heating is generally not possible. Therefore, high overall efficiencies can only be obtained in the event case the biogas farm has the necessary requirements for utilization of the generated heat.

In the future, availability of surplus heat generation will certainly lead to Integrated Energy Farm (IEF), using biogas and other forms of renewable energy technologies, energy storage systems, and settlements for the occupants of the complex in innovative forms of zero emission, ecological villages depending on renewable resources of local origin.

Community biogas plants in their present form include environmental and agricultural benefits, investment savings for the farmers, improved fertilization efficiency, reduced greenhouse gas emissions, and cheap, environmentally sound waste recycling of organic material that is generally delivered from the agriculture or fishery to the food industry.

By returning the waste to the fields from which it originally came, it helps to maintain the humus balance of the top soil as well as substituting chemical fertilizers

Fig. 52 *Left*: Tank truck collects liquid manure at the farm (Preben Maegaard/Nordic Folkecenter for Renewable Energy). *Right*: Storage of maize silage for the production of biogas, Nieboell, northern Germany

produced from fossil fuels. The main disadvantage of centralized plants compared to farm biogas plants is the significant cost of manure transportation.

Admixing is predominantly considered a major advantage for both biogas plants and waste suppliers but has, however, also given rise to uncertainties. Often the long-term reliability of industrial waste supplies has been unpredictable.

There are important aspects related to spreading of diseases with community biogas plants not least a risk of pathogens from one farm being transferred to other farms by the trucks visiting several farms every day, and due to mixing of manure from many places of origin, pathogens from one farm can be spread to other farms (Fig. 52).

The veterinarian authorities are of course aware of such risks and have implemented regulations to prevent these problems, however, at considerable costs; every time a tank truck departs for collecting a new load of manure, it has to be carefully cleaned. In order to prevent pathogens passing through the community biogas plant without being killed, all the slurry passing through the plant is subject to heat treatment (70 °C) for a minimum of 1 h in order to kill pathogens. Since farm biogas plants do not have this kind of additional expenses, farm biogas plants will have significant investment and operational cost advantages.

Technological Development of Farm Biogas Plants

With regard to costs, efficiency, and reliability, new standards have been set with the Smedemester (Blacksmith) biogas technology. Two versions were developed, both with steel tanks:

1. Horizontal tanks manufactured in industrial workshops of sizes from 50 to 300 m^3
2. Vertical tanks built on-site in 500 and 1,000 m^3 sizes

Fig. 53 Biogas plant at farm in Denmark. The gear motor for the internal slow-moving agitator is seen on top the digester (Jane Kruse/Nordic Folkecenter for Renewable Energy)

For agitation, slowly rotating blades were preferred due to low energy consumption. The Folkecenter for Renewable Energy developed the technology and supported manufacturers in Denmark, Germany, Lithuania, and Japan. After 1988, European biogas experts were involved in the development process, thus transferring the experiences gained within the various national farm biogas sectors. Erwin Köberle especially provided essential inputs for the success of the Smedemester technology. Also Dr Anton Perwanger, Dr Arthur Wellinger, and Ekkehard Schneider made valuable contributions.

In terms of quantities, community biogas plants in general get their waste supply from nonagricultural suppliers. However, this is mostly waste with low-content fermentable material coming from the food industry (slaughterhouses, dairies, fish processing), pharmaceutical industry, kitchens in hospitals, hotels, etc. The farm biogas economy benefits significantly from the use of small quantities of high-grade waste oil from the food industry, consisting of fish oil and animal fats and other types of organic industrial waste. The waste oil used contains up to 700–1,000 m^3 of biogas per cubic meter of waste substrate (Figs. 53 and 54).

Legislation

The Danish government together with political parties has developed ambitious energy policy agreement on 22 March 2012, which sets the framework for green transition in the country.

Fig. 54 Biogas storage tanks at community plant (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

Intermediate goals of the agreement are:

- Green biomass energy sector creating jobs for 4,000 people in 2013 and 2014 and for 6–7,000 people in 2015–2019
- Total phaseout of oil and coal for heating by 2030.
- Supply of 100 % renewable energy for heating and electricity by 2035.

Danish renewable energy policies are promising setting ambitious goals, whereas in Germany, Europe's biggest biogas producer and the market leader in biogas technology, after more than 20 years of rapid development and successful policies, situation has dramatically changed in 2014.

In the early 1990s, German government introduced *Law on ElectricityFeed* (StrEG), a law that guaranteed the producers of energy from renewable sources the feed into the public power grid, and the power companies were obligated to take all produced energy from independent private producers of renewable energy Scheer (2006).

The development of biogas and other renewable energy was rapid and successful in Germany (Fig. 55). By 2014, in Germany there were approximately 7,944 biogas power plants producing electricity fed to the public grid with total installed capacity of 3,859 MW, electricity supply of 27,55 TWh for 7.9 million households. Germany is the world leader for science and technology know-how in the biogas sector, with several billion of euros invested and over 40,000 jobs in the sector.

However, the amended Renewable Energy Act (EEG), approved by the German Parliament in June 2014, dramatically limited the development of energy produced from biogas (Fig. 56).

Fig. 55 Big farm biogas plant on the island of Rügen, Germany. In Germany there are several thousands of farm biogas plants with digestion of animal manure and energy crops. The biogas is normally combusted in gas engines on location (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

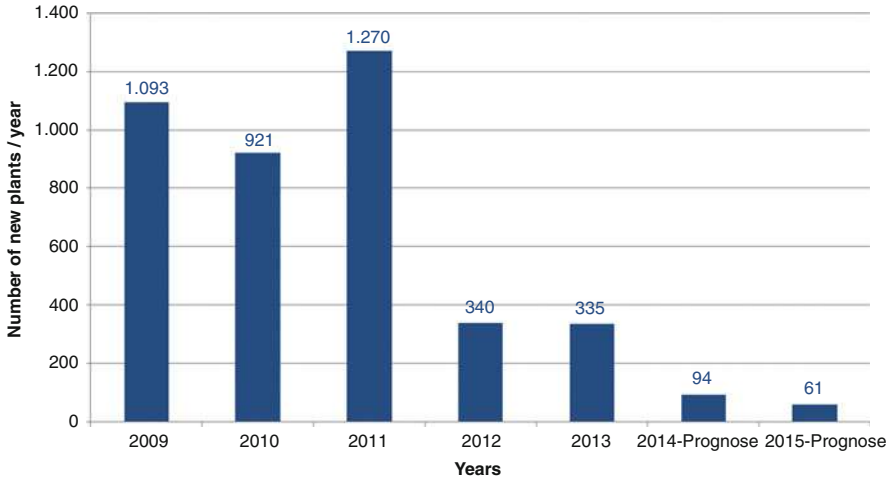

Fig. 56 Installation of new biogas plants in Germany on the yearly basis (data from 11/2014) (Fachverband Biogas e.V.)

Since 1980s, Denmark has been developing various policies supporting renewable energy. Some were more successful than others. For many years, the Danish biogas sector remained stagnating, due to insufficient framework. However, there are new policies favoring renewable energy sources, including biogas.

In 2012, the Agreement on Energy (VE-Lov) was updated and signed by the government, which increased feed-in tariffs not only for electricity production but

also enabled other biogas uses (injection, transport fuel, industrial processes) to be considered for the support scheme. Also, municipality-owned gas companies are now allowed to invest in production and a special Biogas Taskforce was established to support local authorities in implementing biogas projects in the period of 2012–2015.

The agreement changes focus from CHP production toward upgrade of biogas. By 2020, biogas production is expected to double and 75 % of produced biogas is expected to be upgraded for the gas grid and for transport. It is difficult to predict if these expectations are realistic, but Denmark is prepared for taking this challenge: the country has a well-developed natural gas grid, district heating networks in cities and towns, and many CHP plants, and the government and gas companies focus on the security of the grid to receive upgraded biogas.

Community-Owned Biogas Plants

In Denmark, by tradition, most biogas plants based on manure are owned privately: plants in farm scale by private farmers and larger plants by cooperatives. Publicly owned plants and investor-owned plants are lesser; however, in the recent years gas companies show increased interest in entering the biogas sector.

Case Study: Lemvig Biogas Plant

Since 1992, for 20 years, Lemvig Biogas has been the largest biogas plant in Denmark. The plant is owned by 69 local farmers in a farmer privately owned cooperative.

The plants receive and treat 615 t/day of slurry: 500 t (82 %) manure from approximately 75 farms and 115 t (18 %) organic waste to generate heat and power. The plant can process about 226,000 t of biomass per year, of which 183,000 t is animal manure and slurry and 43,000 t is suitable industrial waste. In 2011, biogas production was 8.5 million m^3 and, in 2012, 10.2 million m^3 on a yearly basis. There are four digesters with a total capacity of 14,300 m^3 (Fig. 57).

This simple exchange: manure and waste for electricity and heat is a good solution in terms of environment, reduction of pollution, but also economy, both for the biogas plant and households (consumers). Local farmers use the fermented slurry as fertilizer, as it performs positive values for farming and in the process of thermophilic digestion kills infectious species (bacteria, viruses, worms), reduces the smell, and inactivates plant seeds and weed. Compared to raw slurries, digestate has better balanced nitrogen-phosphorus content, is more homogenous which makes it easier to stir, and spread on the soil, not to mention social benefits. Biogas plants can contribute to better relations with the neighbors and form a positive perception of farming activities.

Lemvig Biogas Plant converts produced biogas into electricity and heat in a CHP unit (Jenbacher 316 gas engine of 836 kW_{el}, and since 2013 a new Caterpillar biogas engine of 1,560 kW_{el}). It generates over 21 million kWh/year of electricity from biogas, which is then sold to the local grid (Fig. 58).

Fig. 58 *Left*: Lemvig Biogas Plant (Jane Kruse/Nordic Folkecenter for Renewable Energy). *Right*: Slurry-to-slurry heat exchangers at Lemvig Biogas Plant reduce the demand for process energy for heating the digesters (Jane Kruse/Nordic Folkecenter for Renewable Energy)

Since 2011, part of the produced biogas is transported 8 km to the Klinkby district heating plant and combusted in a 889 kWel Jenbacher CHP unit. In 2012, 5.6 million kWhel was produced and used in about 300 households of Klinkby.

Transport of raw slurry from local farms to the biogas plant and in return, transport of digestate from the biogas plant to the farmers' storage tanks are carried out at the expenses of the biogas plant, which results in lower transportation costs for the farmers.

The plant can receive a variety of suitable wastes delivered by all kinds of vehicles such as articulated tip trailers, truck trailers, tankers and slurry trucks, as well as ships at Lemvig harbor or Thyborøn harbor.

Lemvig Biogas Plant besides the animal manure waste receives all types of waste like fish waste, slaughterhouse waste, organic household waste, feed waste/residues, pharmaceutical waste, soft drinks, beer, alcohol, even chemically or bacteriologically contaminated foods, and all organic matter with a high content of fat, protein, or sugar. However, recently organic farmers from the area consider a possibility to have their deep litter also treated in the biogas plant. To answer these needs, Lemvig Biogas plans a synergy with Lemvig Organic Biogas and builds a new organic plant nearby, which would use the gas processing, gas storage systems, and the same biogas pipeline as already existing plant. Biogas produced in both plants would be mixed and then delivered to CHP units in Klinkby and Nissum. The existing plant would supply excess process heat also to the organic plant.

Addressing future challenges, Lemvig Biogas together with the Center for Energy Technologies (AU), GreenHydrogen.dk, DTU Mechanical, and Elpatek is working on a new project called MeGa-Store (Methane Gas for the Storage of Renewable Energy).

Aim of the project is to develop a technology for upgrading biogas to natural gas quality by hydrogen produced by wind or solar energy. Upgraded biogas can then be sent directly and stored on the natural gas network. The technology is relevant for reduction of the use of fossil fuels (natural gas) and for solving the problem of storing of renewable energy sources such as wind and solar. There is a testing plant at the Lemvig Biogas for the MeGa-Store technology.

Biogas for Transport

Biogas consists of mainly methane CH_4 (40–75 %) and CO_2 (25–60 %), different proportions depend on substrate used for the production. Upgrading of biogas to content of CH_4 higher than 90 % means to remove carbon dioxide from its content and pressure it Luo and Angelidaki (2012).

The advantage is increased heating value of upgraded biogas as well as further use of it as renewable energy source, but most of all upgraded biogas can be an alternative to natural gas. Injection of upgraded biogas into the national gas grid gives the possibility to store it, which is practical and allows using biogas to balance fluctuating power from the wind. Upgraded biogas with natural gas quality can be used as fuel for vehicles (Fig. 59). It is also practical to use existing natural gas pipelines to transport upgraded biogas from rural areas where it is being produced to urban areas with more dense population. No extra pipeline network is neither needed, nor special transport.

According to a study from the Danish Energy Agency from 2010, upgraded biogas is one of the alternative fuels for transport with the lowest socioeconomic costs, despite its extra upgrading costs.

Biogas upgrading technology is relatively new in Denmark, but there are more and more projects dealing with this challenge. In 2011, the first biogas upgrading facility in the country was built in Fredericia with the capacity of 180 m^3/h. Following, there are a few other projects in a planning phase or under construction. DONG Energy, Denmark's biggest producer of renewable energy, signed a long-

Fig. 59 Neoplan biogas bus in Uppsala, Sweden, "for a better environment" *(Preben Maegaard/ Nordic Folkecenter for Renewable Energy)*

term agreement with the Swedish cleantech company Malmberg for building multiple biomethane plants in 2012. Malmberg already has built 40 gas pretreatment plants in Germany but also some in the UK or Norway.

From November 2014, Denmark's first regional buses on CO_2-neutral biogas have just started on the route Aalborg to Frederikshavn. The gas for the buses is provided by HMN Naturgas, which at the same time opens two biogas filling stations in Northern Jutland – in Aalborg and Frederikshavn. By early 2012, there were no gas buses in Denmark at all, but currently there are about 40 biogas buses around the country. They run as city buses in Fredericia, Holstebro, the Copenhagen area, and Skive. In neighboring countries, biogas is much more widely used for transportation, as biogas is a well-known and reliable technology for CO_2-neutral transport. In Denmark, biogas for transport is slightly more expensive than diesel.

Hydrogen and Biogas

There are various methods for upgrading biogas: chemical absorption, pressure swing adsorption, high pressure water scrubbing, membrane separation, physical and chemical technologies, high pressure, or chemical addition.

However, currently there are studies being carried in search for alternative solutions for biogas upgrading by hydrogenation of the biogas, which would transform most of the CO_2 (CO_2 is not combustible) from the biogas and hydrogen (H_2) to methane (CH_4) (Fig. 60).

Hydrogen used could be produced by electrolysis using excess energy from wind power. This option would provide more biogas for utilization.

$$4H_2 + CO_2 = CH_4 + 2H_2O$$

There are considerable advantages of this method: increased methane production without methane losses, minimal energy and chemical requirements in the process, and possibility of storage of fluctuating wind power as methane, which is easier to store and distribute. Simple and rational solutions are usually promising.

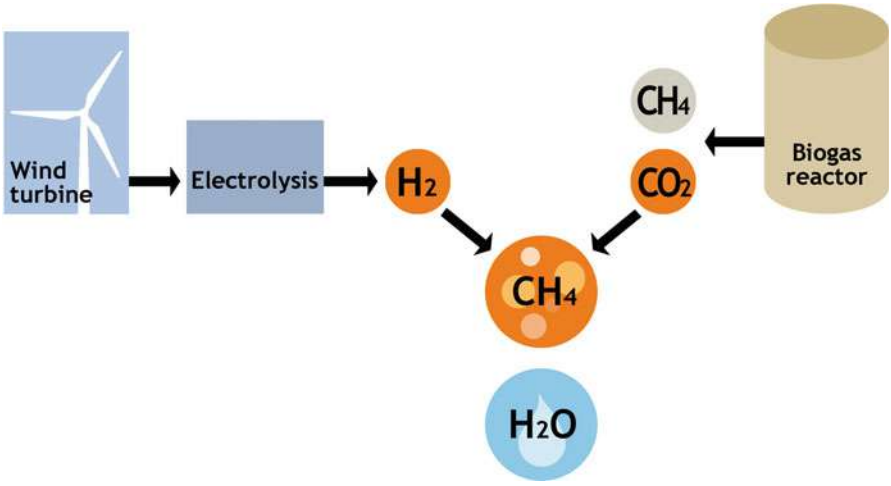

Fig. 60 Hydrogenation of methane by the use of hydrogen from wind power (Nordic Folkecenter for Renewable Energy)

European Union already develops R&D programs on the subject, and in other countries a combination of biogas and hydrogen as transport fuel is being researched. In Costa Rica, a team of researchers from the Ad Astra Rocket Company with Cummins Power Generation and EARTH University have successfully developed a new type of portable electric generator (Internal Combustion Engine) using a combination of hydrogen and biogas. This achievement has been implemented as a research prototype but is still in the process of testing.

Water electrolysis has been used industrially to produce hydrogen for more than a century. Earlier it was the preferred production method but later displaced by reforming of natural gas and other technologies. By 2014, some 5 % of hydrogen is produced by electrolysis. It has increased due to its potential to provide hydrogen from solar and wind and for load management in power grids CODE2 (2014).

Electrolyzers will have a role to operate when electricity generation is in excess of demand during periods of high solar irradiation and strong wind to reduce the need to curtail renewable electricity generation. The produced hydrogen can be stored locally or fed into the natural gas network for re-electrification in integrated energy systems (Fig. 61). Because the electrolyzers will need to respond to intermittent and fluctuating renewable power generation, the ability to operate dynamically is a requirement for electrolyzers to be integrated in fluctuating energy systems.

Water electrolysis can be expected to have a key role for the widespread use of hydrogen for mobility, industry, or energy storage. It is the most efficient and proven solution to hydrogen production from renewable electricity sources. Electrolysis also has the added advantage of being flexible where rapid changes of loads will be the normal in the future with increasing intermittent solar and wind energy. For balancing of power and storage of energy in integrated systems that are dominated by wind and solar energy, start-stop and dynamic operation and efficiency across

Fig. 61 H-TEC SYSREM PEM electrolyzer for decentralized production of hydrogen (*left*). A key technology for integration of wind, solar, and other renewable energies. (*right*) Pipe network for water, hydrogen, and oxygen of containerized H2 package (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

Fig. 62 Fully integrated 150 m^3 per hour hydrogen production package (*left*). Includes water treatment, power supply, electrolyzer, and ancillary equipment; (*right*) 150 m^3 per hour electrolyzer in container (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

much of the load curve will be basic operating parameters that will allow electrolyzers to interact with grids E4tech Sàrl and Element Energy Ltd (2014).

With increased amounts of fluctuating power, electrolyzers will play an important role in energy applications. The electrolyzers are technologically mature, but the industry is still rather small. Costs have not been reduced through mass production or supply chain optimization that is why the room for technology improvement is significant. Most present systems are designed for operation at full load and to run continuously (Fig. 62).

Alkaline electrolyzers are most mature, followed by polymer electrolyte membrane (PEM) electrolyzers and the solid oxide electrolyzer. Electrolyzers in the future will find widespread use in energy applications, leading eventually to

Fig. 63 (*Left*) London transport: hydrogen is widely used for urban mass transport. (*Right*) Hydrogen bus that has been in operation for many years in Hamburg, Germany (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

Fig. 64 (*Left*) Fuel cell car at hydrogen filling station at major radial road, Berlin, Germany. (*Right*) Compact hydrogen filling station for cars and vans in Ringkøbing, Denmark. Developed by H2 Logic (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

hundreds or thousands of megawatts of installed capacity within a pioneering period that may run till 2025.

The largest electrolysis plants of several thousands of m^3/h have historically been used in the fertilizer industry. Hydrogen from electrolysis can be found as well in making chemicals, food processing, metallurgy, glass production, electronics manufacturing, and power plant generator cooling. Only small amounts of hydrogen from electrolysis are used in energy applications, in sustainable transport program, and for renewable energy storage (Figs. 63, 64, and 65).

Case Study: Utsira Wind Power and Hydrogen Plant, Utsira Island, Norway

Utsira, a small island 20 km off the southwest coast of Norway, had an ambition to exploit wind resources and become self-sufficient with renewable energy. Utsira has

Fig. 65 *Left*: Standard car had the combustion engine converted into hydrogen by Professor Sun Baigang, BIT, Beijing, China. *Right*: The diesel engine of a Hamburg city bus is replaced by hydrogen fuel cells and storage (Preben Maegaard/Nordic Folkecenter for Renewable Energy)

the smallest population of all municipalities in Norway (about 235 inhabitants) and a total area of only 6.15 km^2.

In July 2004, Norsk Hydro (now StatoilHydro) and Enercon officially launched an autonomous wind/hydrogen energy demonstration project on the island. In the pilot project, 10 households are directly supplied by energy from wind turbines. Excess power from wind turbines is used to produce hydrogen in an electrolyzer, which is then compressed and stored. On days with low winds, a hydrogen engine and a fuel cell use stored hydrogen to produce the necessary electricity. This system ensures a continuous and reliable energy supply when wind power is not available and provides 2–3 days of full energy autonomy for 10 households on the island. Utsira plant is the first of its kind in the world.

The system consists of:

- 600 kW wind turbine
- Flywheel (5 kWh, 200 kWmax)
- Water electrolyzer (10 Nm3/h, 48 kW)
- Synchronous machine (100 kVA)
- Hydrogen gas storage (2,400 Nm3, 200 bar)
- Hydrogen engine (55 kW)
- PEM fuel cell (10 kW)
- Battery (50 kWh)

The plant's operation has been a success: for more than 18 months, the island was in a stand-alone mode, delivered power quality was very good, and the project contributed to local activities. There were no accidents and no complaints from customers. The project has been honored with the "Platt's Global Energy Award."

Case Study: Enertrag Hybrid Power Plant, Prenzlau, Germany

The Prenzlau power plant, commissioned in October 2011, is the world's first hydrogen-wind-biogas hybrid power plant. The plant is owned by companies: Enertrag AG, Vattenfall Europe, Total, and DB Energie.

The power plant consists of three Enercon E-82 E2 wind turbines, each of 2.3 MW capacity, and a 500 kW electrolyzer that uses the surplus electricity for hydrogen production. Two CHP units can be operated with a mixture of hydrogen and biogas. Both the CHP and wind turbines provide electricity that can be fed into the grid. Excess power can be used for electrolysis to produce water from oxygen and hydrogen, which is stored in high pressure tanks. These tanks are storage for windless times to meet the energy needs of consumers (Fig. 66).

Dike-Pond System with Comprehensive Integration

Full integration of crops for vegetable oil, fodder production, and biogas can be obtained in combination with the dike-pond system that is in itself an energy-neutral aquaculture system. The system combines production of domestic animals, plants, and fish in a balanced ecosystem where the waste from one level of organic production is the precondition of the following step. The water leaving the system has a low level of organic and mineral nutrients. It can be used as recycled water. Any stable biological system is based upon conservation of energy and matter. This means that the production is the surplus created by the system being the difference between the products leaving the system and the external supplies (Fig. 67).

All natural ecosystems tend to obtain an ecological balance where all organisms find a niche. A viable productive ecosystem adapted to certain nutrients and certain

Fig. 66 *Left*: Gas storage, Biogas plant and wind power at the Enertrag Hybrid Power Plant in Prenzlau, Germany (Molgreen); *Right*: Large-scale electrolyzer plant, at the Hybrid Power Plant in Prenzlau, Germany (Hanno Böck)

Fig. 67 Dike-pond system in the biodome, Nordic Folkecenter for Renewable Energy. The biodome is a unique greenhouse, which integrates water cycle, recycling of nutrients, insulation, and aquaculture (Anna Krenz/Nordic Folkecenter for Renewable Energy)

external conditions must follow the same basic principles including conservation of energy and matter. A successful system must be based upon well-adapted organisms in balanced niches and stable external conditions.

The dike-pond component of the integrated farm system has been derived by the experiences from the delta of the Pearl River in southern China. Here is an ancient system of cultivation consisting of ponds and dikes. It has high productivity, so it can provide a surplus of a wide range of products to the cities including fish, vegetables, fruits, pigs, eggs, and poultry. The production is obtained without any artificial external inputs in the form of chemical fertilizers and pesticides.

With carp ponds as the central element of this system, which integrates agriculture and freshwater aquaculture, this is considered one of the most productive cultivating systems in the world. The dike-pond system requires very little energy input. Since the waste originating from one production element is perpetually used as input resource for the next element, the system is virtually nonpolluting. The system is a complex chain of cultivation elements that is modeled on the cycles of nature. For this reason, the system gradually could become a model for the development of local complex cultivation structures in the industrial countries where monocultures and environmental problems make it obvious to seek solutions that respect the natural cycles and at the same time have high productivity.

It is calculated that the manure from one pig can yield 40 kg of carp meat per year and at the same time produce 20–30 % of the fodder for the pig. The food production per unit area is 4–5 times higher than in the traditional agriculture. This intensive biomass production is combined with water purification and energy production.

An advanced farm biogas plant can be connected directly to a greenhouse dike-pond system. This arrangement combines efficient systems of cultivation and energy production. One special advantage is the most efficient use of the nutrients in the manure without any transport. The clean water leaving the system may be used elsewhere on the farm or drained to supplement the groundwater resource.

Plant Oils

Agriculture and forestry are the primary production sectors which are directly based upon solar energy. This is done through production of various forms of biomass which can be used for food, directly and indirectly in the form of fodder, and for energy. From a general consideration of sustainability, it would be natural for agriculture to contribute a significant part of a country's energy supply bringing new income to farmers and to have a positive energy balance.

It would seem obvious to cover the agricultural sector's own energy consumption directly through biomass. As an element in this, the agricultural machinery can be operated on plant oil. This would also provide immediate environmental improvements in agriculture. Plants that produce high amounts of oil are known as oleaginous. Of these, only a few are used for commercial purposes. Each climatic region has its own particular oleaginous plants. Tropical regions are especially privileged by a larger variety of plants with higher yields. Most oleaginous plants are significant from an agricultural point of view and allow for crop rotation and crop combinations. Planting of oleaginous plants makes it possible to combat erosion, reclaim desert land, reforest, and manage soil – allowing a better water control and management.

The main by-product of vegetable oil is expeller cake. Sometimes the cake is the main commercial product and the oil becomes the by-product. The expeller cake is protein rich, can be used to feed humans and animals, and is highly valuable as a natural fertilizer.

Pure plant oil (PPO) helps the Integrated Energy Farm (IEF) to become self-sufficient in terms of energy through the use of vegetable oil. In temperate climates, the combined cultivation, harvesting, and supply of 1,000 l rape seed oil, expeller cake, and straw requires 140–160 l of oil, which can also be plant oil. The oil is physically extracted by means of an oil press (Bassam and Maegaard 2004).

The pressing is cold when the temperature does not exceed 60 °C. The simplicity of the process means that it can be on a large or small scale. The oil has to be cleaned by using a filter, centrifuge, or purifier. It is neither explosive nor flammable. It does not emit toxic, carcinogenic gases nor is it harmful to soil, water, animals, and humans in the event of accidental spillage.

The solid biofuels, such as straw of the oil plants, can be used for heat production in boilers. With the availability of more advanced biomass gasifier technology, straw from oil plants can fuel CHP. Liquid biofuels such as rape seed oil, biodiesel, and ethanol are the most versatile fuels because they can easily be used for heat production, CHP, and agriculture mobility purposes that can contribute to a more environmentally sound transport sector – that has shown a lack of positive environmental results and an increasing contribution to energy consumption and greenhouse effects. A breakthrough for plant oil can push this development.

Biodiesel can substitute fossil diesel right away. However, biodiesel presents health and fire hazards in itself, and it is polluting. The pressing and the following esterification comprise of an industrial process with relatively high energy consumption that requires needed costly infrastructure and production plants. In order to meet the requirements of diesel engines, vegetable oils can be modified into vegetable oil

ester (transesterification). The transesterification procedure includes the production of methylesters and glycerol (glycerine) by the processing of plant oils, alcohol, and catalysts. Biodiesel can replace diesel entirely or be mixed with it in different proportions for running diesel engines.

Folkecenter Autonomous Energy System

At the Nordic Folkecenter for Renewable Energy located in the Thisted Municipality, a prototype autonomous renewable energy system is installed. The energy system supplies heat and electricity to 2,000 m^2 of offices, meeting rooms, laboratories, workshops, and residential facilities. Sources of energy supply are wind turbines of 75 kWel and various 5–10 kWel wind turbines, 42 kWth electric boiler, 45 kWth wood pellet stoker with automatic start-up and stop, 8 kWel/20 kWth plant oil CHP unit with automatic start-up and stop, and 25 kWel PV and 50 m^2 solar thermal panels. Wind energy and solar energy are the primary sources for heat and electricity. Biomass (wood pellets and pure plant oil (PPO)) is used for backup (Fig. 68).

The overall operational strategy is:

- The power flow control (PFC) directs excess wind electricity through the thyristors to the electric boiler.
- When the electric boiler does not supply sufficient wind-generated heat, the wood pellet stoker is automatically activated.
- In case of no power from solar and wind, the CHP unit using plant oil is activated.

Excess production of solar and wind generated heat is stored in a 10 m^3 hot water storage.

The system is connected to the public grid. The overall principle is not-to-sell/not-to- purchase from the grid. The CHP unit, however, can operate in island mode in case of a power blackout. At summer nights with no wind and sufficiently stored solar-generated heat, the CHP unit will not start up; the grid will supply the need for power only, as there is no electric storage capacity in the system and the CHP-generated heat would be wasted. In practice, excess wind power covers 60 % of the annual demand for heat, with the balance coming from solar and biomass Maegaard (2010–2014).

The technology and strategy of the autonomous system was pioneered, developed, and implemented by the Folkecenter in 2007. For a 100 % supply of power and heat/cooling from renewable energies, the same principle and strategy should be applied at the regional and national level as well. The system delivers a realistic solution to questions often made about alternative energy sources.

The combined high CHP and wind power production causes a potentially major problem in the power sector. However, supply and demand can as demonstrated in the Folkecenter Autonomous Energy System be balanced by feeding on windy days the excess wind power into the electric boiler. The electric boiler makes it possible to

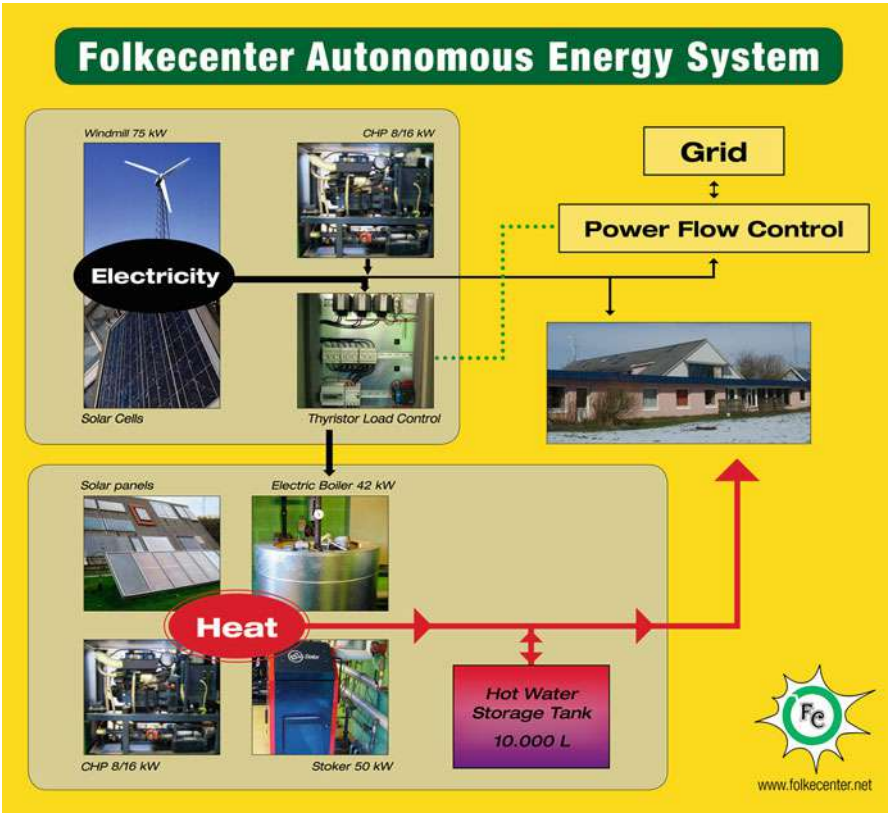

Fig. 68 Autonomous integrated energy supply system at the Folkecenter for Renewable Energy (Nordic Folkecenter for Renewable Energy)

avoid the combustion of wood pellets in the stoker and use of liquid biomass in the CHP unit at periods with excess wind and solar energy. With increased renewable energy shares in the future, more and more often fluctuating solar and wind energy will be sufficient to satisfy both the need for power and heat and can be given priority, while solid and liquid biomass is reserved for periods without sufficient wind and solar.

The Global Perspective

The necessity of sustainable development and the use of clean energy technologies are well recognized. Actions at national and international levels to tackle the problems of limited resources, environmental damage, and climate change are being developed, and these will require new directions for energy policy and technology. The scale and type of investment decisions in energy supply and

end-use systems will change. The "Rio Declaration on Environment and Development" in 1992 did, however, not recognize the intimate link between energy and development or the direct relation between environmental aspects and the use of conventional atomic and fossil fuel-based energy supply.

Conventional sources of power help populations live more comfortably than past generations, but while they meet new needs, they also carry the risk of irreversibly altering natural balances, both locally and globally. The fast-growing world population and the ever-increasing consumption of resources driven by the diffusion of lifestyles that have developed in industrialized societies are emulated in most of the world.

Under the conditions of nuclear and fossil energy use (as well as nonrenewable biomass), the target of a "sustainable development" cannot be reached. None of the pending and visible dangers can be overcome without substituting nuclear and fossil energy with renewable energies.

A great number of solar, wind, and biomass technologies for the production of fuel, heat, and electricity have become available or close to commercialization. They have been installed on a significant scale in both developed and developing countries. They are used in many different ways, stand-alone or integrated in conventional energy networks and grids. They are already providing energy services to individual homes, villages, and cities. Solar, wind, and biomass in some communities in the industrialized countries fully cover the need for power, heating, and cooling.

By 2013, wind energy production worldwide reached a level 510 TWh sufficient to cover the demand of electricity in Germany, the largest economy in Europe. By continuously increasing the rate of growth and applying the most advanced technology and principles of implementation, the wind industry will within a dozen years supply enough energy for a continent. However, when moving from examples to worldwide applications of renewable energy technologies in communities, cities, islands, and rural areas, society as a whole must demonstrate positive interest and provide its support. By applying appropriate legal framework, renewable energy infrastructure, whether installed in remote rural areas in a developing country or integrated within existing conventional infrastructure in a city in the developed world, needs to be better known, accepted, and given the necessary political support.

To increase the use of renewable energy and to spread it throughout the technologically advanced world to a needed extent – 50 % of world energy consumption by 2050 – it is necessary to involve many more renewable energy scientists and engineers, environmental scientists, entrepreneurs, financial experts, publicists, and architects. Above all, we will need many more politicians and civil servants who know the subject and are more courageous and determined. A new generation of renewable energy pioneers has to be nurtured, especially to work in local communities and industries.

The founding in 2009 of the International Renewable Energy Agency (IRENA) as an international governmental organization supports and advances the active utilization of renewable energies at a global scale. Since 1956, there has existed an international agency for the promotion of atomic energy, whereas the furthering of

renewable energies irrespective of their worldwide potential has been more random. These energies can, more than any other technologies, play a key role in the protection of the global climate and the environment, resource conservation, the fight against poverty in developing countries, and securing the long-term reliability of supplies.

IRENA has the status for promoting worldwide capacity building, best policy practice and technology transfer in connection with the renewable energies, and not least the necessary efficient and integrated utilization of energy to meet the most basic needs: decent homes, healthy food, clean water, health care, and education. If these legitimate and ever-growing needs are to be met, energy consumption must increase.

Development of a successful renewable energy sector will in the future make a useful long-term contribution to diversity, security, and self-sufficiency of energy supply, because in contrast to fossil fuels and atomic energy, they will not be depleted. Both in the industrialized countries and in the unserved areas with limited or no access to commercial energy supply, the transition to renewable energies will create new, labor-intensive, industrial sectors. The local and national economies will become less vulnerable to international conflicts and price fluctuations of fossil fuels.

Renewable energy exists everywhere, but has a weaker concentration or density of energy than fossil and nuclear sources. Using renewable energy will create a more balanced relationship with nature. A new culture of energy efficiency can lead to a more concerned, socially responsible use of all natural resources. The use of renewable energy – a local resource – can contribute to the preservation of local cultures and also promote new lifestyles and new concepts of prosperity and security that can help mankind meet the challenges of the twenty-first century.

A Promising Future for Renewables

In contrast to 2004, the application of renewable energy technologies to provide electricity, heating and cooling, and transportation 10 years later was widely spread across the globe; recent trends suggest sustained growth worldwide. At the turn of the century, renewables had a strong appeal to those who were interested in moving away from conventional fuels for environmental reasons. By 2014, renewables have demonstrated that, in addition to their environmental and climate benefits, they are also economic drivers, creating jobs, helping to diversify revenue streams, and stimulating new technological developments.

The share of renewables in global electricity generation continues to increase while the share of nuclear power has been declining. The idea of achieving very high shares of non-hydro renewable energy earlier was quite radical, yet today it is considered feasible by many governments and experts. Several local, regional, and national governments around the world have committed to 100 % renewable energy in one or more sectors within the coming decades.

Nonetheless, the renewable energy sector still faces numerous challenges. Enormous subsidies for fossil fuels and nuclear power persist, and they continue to vastly

outweigh financial incentives for renewables. Many countries are directing increasing resources toward the exploration and extraction of unconventional fossil resources, while most governments remain reluctant to internalize the external costs associated with the extraction and use of fossil fuels.

Further advances and investment in renewable energy, as well as improvements in energy efficiency, must continue if the increase in global temperature is to be limited to 2 °C. For this to happen, stable and predictable policy frameworks are key concerns. Integrated policy approaches that incorporate energy efficiency – considered as the low-hanging fruit on the path to sustainability – will further facilitate the global transition to renewable energy.

The development since 2000 has set the wheels in motion for this transition, but a concerted and sustained effort will be required to fully achieve it. With increasingly ambitious targets, innovative policies, and technological advances, renewables can continue to surpass expectations and foster a cleaner energy future.

Thermoacoustics

Matthew E. Poese

Contents

Abstract

Thermoacoustic heat engines offer mechanically simple energy conversion that can utilize a wide variety of heat sources – including solar energy, biomass, and even the "waste" heat from internal combustion engines and industrial processes. This chapter will address the gas thermodynamics that enable such machines and discuss the practical elements that comprise thermoacoustic machines that act either as a converter of heat energy to another form of energy (such as electrical or mechanical energy) or as a heat pump that "moves" heat from a cold region to a warmer one. The distinction between the two topologies of thermoacoustic

machines, stack-based and regenerator-based, will also be clarified and the differences between the two made clear. Finally, the latter portion of the chapter will discuss existing and potential applications for thermoacoustic machines.

Introduction

At the end of the last century, the National Academy of Engineering created a list called the "Greatest Engineering Achievements of the Twentieth Century." On that list, two of the top ten achievements have a heat engine at their heart: the automobile (rated second) and air-conditioning/refrigeration (rated tenth). After nearly 100 years of widespread adoption and significant incremental improvements to each of these products that have greatly improved the quality of life, the automobile engine and the cooling machine have also been identified as causing a large fraction of the atmospheric pollution problems. As a result, there is a significant global research and development effort underway to not only improve the efficiency of both automobile/truck engines and cooling machines, but also design automobiles that do not use fossil fuels and refrigerators that do not require HFC/HCFC refrigerants that are 2,000–3,000 times more potent as a global warming gas than carbon dioxide. To address these challenges, novel heat engines are being developed that utilize thermoacoustic energy conversion.

Thermoacoustic energy conversion technology can be a part of a strategy to reduce global warming gas emissions for four primary reasons:

- The working fluid of these machines is typically an inert gas, like helium, which has no global warming potential (GWP).
- The efficiency is comparable with existing power conversion technology and has room for growth.
- The machines are fuel-flexible and do not require fossil-fuel based liquids.
- The machines are mechanically simple, which makes them an attractive target for commercialization.

Thermoacoustic machines belong to the closed-cycle class of heat engines and are subject to Carnot efficiency restrictions. They are similar in many ways with Stirling machines. The goal for the technology development has been to create a closed-cycle engine technology that is both efficient enough to present significant fuel savings (and therefore reduce emissions) while also being mechanically simple enough to meet price and reliability targets. A schematic of a thermoacoustic refrigerator compared to a vapor-compression machine is shown in Fig. 1

This technology has been under active development since the late 1970s with the work of Peter Ceperley (Ceperley 1979) and, independently, John Wheatley, Greg Swift, and collaborators (Wheatley et al. 1983). In the three decades that have elapsed since the foundations were laid, the physical understanding of the hydro- and thermodynamics in these devices have been well developed and codified largely by Greg

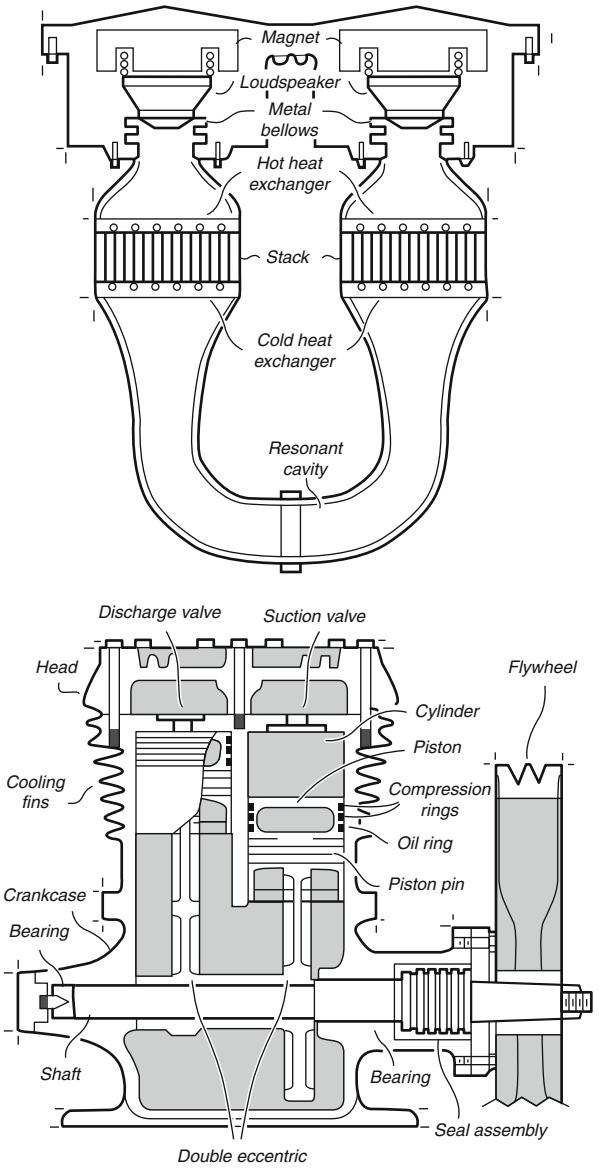

Fig. 1 The schematic of a thermoacoustic refrigerator is shown on the *left* which cooled radar electronics aboard the USS Deyo in 1995. A pair of linear motors convert electrical energy into a sound wave which fills the resonant cavity where cold heat exchangers allow heat from the cold radar electronics to enter the cavity and be pumped to the hot heat exchangers which exhaust that heat to the ambient temperature environment. The schematic of the thermoacoustic machine is somewhat mechanically simpler than the schematic of the vapor compression machine shown on the *right* which requires lubricated sliding/rotating seals and often relies on working fluids that have a high global warming potential (Artwork by Tom Dunne courtesy of The American Scientist, used with permission)

Swift in a textbook (Swift 2002) and, previously, in a comprehensive journal article (Swift 1988). This chapter will not attempt to recast or even improve upon this work; readers who have an interest in the detailed physics of thermoacoustic heat engines will find satisfaction in Swift's textbook treatment of the subject.

This chapter will provide an explanation of the two main types of thermoacoustic heat engines (stack-based and regenerator-based). Some of the applications to which

thermoacoustic technology has seen development efforts will be discussed followed by an outline of some of the challenges that have been discovered that pose hurdles to adoption on the scale that could have an impact on the mitigation of climate change.

Thermoacoustic machines can be broken into two broad application fields: machines that convert the flow of heat from a hot temperature to a colder one into sinusoidal oscillations in a gas (acoustic waves), and machines that use an acoustic wave as an input to "pump" heat from a cold temperature to a hotter one. Machines designed to accomplish the former are typically called engines, and they require some small oscillation of the gas to start an instability that grows and is sustained by the temperature difference and continuing flow of heat from hot to cold. In practice, the small oscillation required to trigger the instability occurs naturally from convection currents of the gas. Machines designed to utilize the energy in a sound wave to pump heat from a cold temperature to a warmer one are called alternately refrigerators, heat pumps and sometimes air-conditioners when targeted toward indoor climate control. In the case of the thermoacoustic heat pump, a source of sound is required: often this is accomplished using a transducer (e.g., linear motor) but the sound could also be provided by a separate (but coupled) thermoacoustic engine.

At the core of the machine is a pair of heat exchangers which bookend a slab of porous media. The working gas of the machine can flow through the heat exchangers and through the porous media between them. As the gas in thermal contact with these core elements experiences pressure and velocity changes with the correct phase, the desired effect (either amplification of the oscillations or heat pumping) is realized.

This core is mounted into a container of carefully designed dimensions so that the gas oscillations will be resonant, which not only sets the frequency of the gas oscillation, but provides an impedance (the ratio of the oscillating gas pressure to the oscillating gas velocity) enhancement favorable to the design and efficiency of the machine. From the standpoint of efficiency, a high impedance is preferable because the gas velocities are small for a given power flow (power in this case is the product of the oscillating pressure amplitude, the oscillating velocity amplitude, and the phase between them). The loss in the porous medium tends to be attributable more to drag than to non-adiabatic pressure oscillations since the pores have to be fairly small to get good thermal communication between the solid and the gas. Additionally, for heat pumps that are driven electromechanically, a high impedance means that a relatively small back-and-forth motion of the piston is enough to make large pressure swings: small piston motions can take advantage of many kinds of seals that do not require lubrication, like flexure seals or dry-fit clearance seals.

Thermoacoustic machines are also categorized on another criterion: the pore size of porous medium that is placed between the two primary heat exchangers mentioned above. One category uses a porous medium called a "stack," and the other category uses a medium called a "regenerator." The fundamental difference between the two is the size of the pores. This difference will be discussed later the chapter. The regenerator-based machines have the potential to be more efficient than the

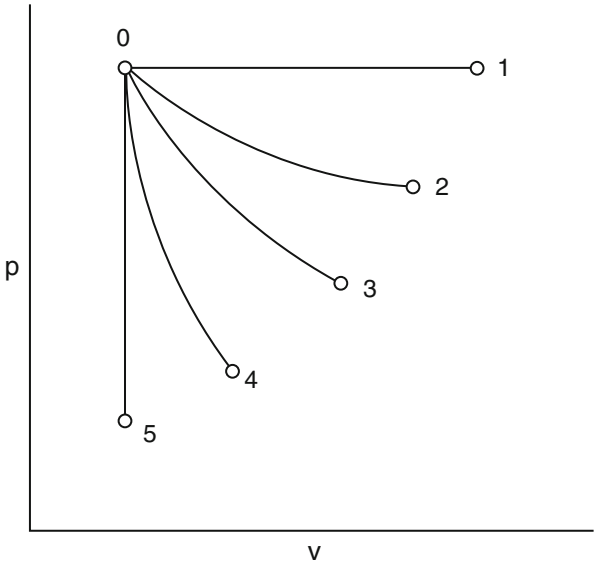

Fig. 2 The four special cases of polytropic state change are shown on a pV diagram. For an ideal gas, γ is the ratio of specific heats for the adiabatic case. When considering an ideal gas, there are no physically meaningful values of γ between the ratio of specific heats and ∞ (the constant volume case). The numbers correspond to the list of thermodynamic state change categories above

stack-based machines at the expense of slightly more complication. Each type of machine may have a role in particular applications.

A final element shared by many thermoacoustic machines is a transducer of some kind that either converts electricity to sound or the reverse, converting sound waves produced by an engine to electricity. A linear motor is a common device that can perform both of these functions; there are linear motors with moving magnets (Liu and Garrett 2005), which are typically preferred for reliability due to the coils being stationary. Moving coil designs have also been used, especially for research purposes (these are similar to a loudspeaker in design).

Heat Engine Cycles Background

A machine that either converts heat flow into mechanical work or forces heat to flow from a cold object to a hot one using mechanical work can be described in terms of the thermodynamic steps that make up one cycle of operation. The state of the working medium at the end of each step can be predicted (if the state before the change is known) using the expression $p_0 V_0^\gamma = p_n V_n^\gamma$, where γ is a variable that depends upon the details of the thermodynamic process by which the system changed state. Thermodynamic state change is commonly categorized in five ways listed below and shown on a *p-v* diagram in Fig. 2:

1. Isobaric (constant pressure, $\gamma = 0$)
2. Isothermal (constant temperature, $\gamma = 1$)
3. Polytropic ($1 > \gamma > c_p/c_v$)

Table 1 A chronological list of ten elementary heat engine cycles showing that the concept of a regenerator occurred early in the development of heat engines

Type of state change	Credit	Year
1 & 5, isobaric and isometric	Papin	1690
1 & 3, isobaric and polytropic	Cayley	1807
2 & 5, isothermal and isometric	Stirling	1816
2 & 4, isothermal and adiabatic	Carnot	1824
2 & 3, isothermal and polytropic	Reitlinger	1843
1 & 4, isobaric and adiabatic	Joule	1852
2 & 1, isobaric and isothermal	Ericsson	1853
4 & 5, adiabatic and isometric	Otto	1867
3 & 4, polytropic and adiabatic	Lorenz	1894
3 & 5, polytropic and isometric	Crossley	1896

4. Adiabatic (constant entropy, $\gamma = c_p/c_v$)
5. Isometric (constant volume, $\gamma = \infty$)

A heat engine cycle generally has four steps executed in succession. These four special cases of a polytropic process (and the generic case labeled "polytropic") can be combined to realize ten different heat engine cycles since only two unique processes can be included in a cycle. (One reason for the requirement that each process must occur twice per cycle is that a machine built to execute a heat engine cycle must repeat its motion; for example, if a machine executes a constant volume process during one-quarter of the cycle, it will (usually) mechanically execute another one to return to the initial state.) These five thermodynamic processes can be combined into ten identifiable elementary heat engine cycles, which are listed in Table 1 (Kolin 1995).

Rev. Robert Stirling's contribution in 1816 to the development of heat engines was to recognize the importance of the regenerator (he called it the "economizer") to increase efficiency, which was important as the price of coal had begun to rise steadily since the beginning of the Industrial Revolution (Urieli and Berchowitz 1984; Sier 1995).

How a Regenerator Is Utilized to Pump Heat Efficiently

Since regenerator-based thermoacoustic machines are the first choice for efficiency, it makes sense to lay out the phenomenological physics of how an acoustic wave passing within it pumps heat and how it relates to the Stirling cycle. Following Fig. 2, the pV diagram for the Stirling cycle is shown in Fig. 3. A schematic of a machine that can execute this cycle is shown in Fig. 4.

The schematic diagram of the alpha-Stirling refrigerator shown in Fig. 4 contains a regenerator sandwiched between heat exchangers with two pistons, one on either side of the regenerator (these will be referred to as the cold- and hot-side piston in this discussion). At steady state, the ideal regenerator has a linear temperature gradient across its length. The pistons are connected by some linkage that provides

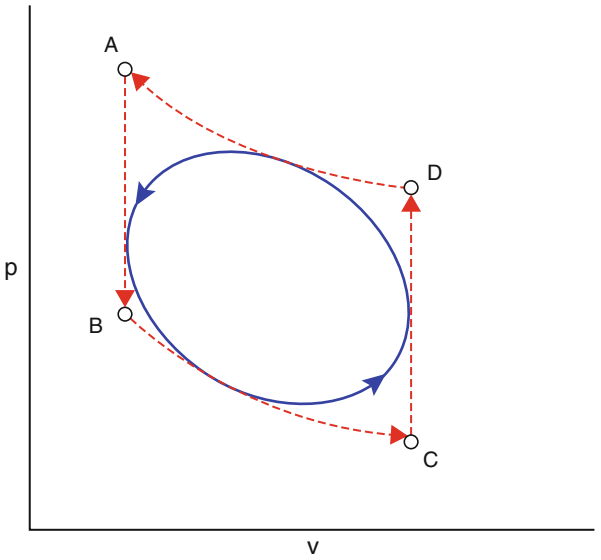

Fig. 3 A qualitative graph of pressure versus volume for an articulated Stirling cycle. The *oval* (*solid curve*) represents the cycle driven with sinusoidal pressure and velocity oscillations. The *outer curves* (*dotted*) represent an articulated cycle

for the correct relative motion of the pistons to make the machine function as a refrigerator or an engine (or nothing useful). One usual simplification is to suppose that each piston has the range of motion to be able to sweep out the entire volume of its cylinder, right up to the edge of the heat-exchanger/regenerator edge. The simplest view of the operation of this machine as a refrigerator contains four distinct strokes in the following order:

A-B Displacement: Both pistons move in concert to move the gas from the hot-side piston cylinder through the regenerator to the cold piston cylinder. The gas is cooled reversibly as it passes through the regenerator since the gas is assumed to be in perfect thermal contact with the regenerator material due to the porous design of the regenerator. Since the gas is colder, heat is (reversibly) absorbed by the regenerator from the gas. This movement through the regenerator is carried out so that the volume that the gas occupies is constant throughout the step. Since the temperature of the gas decreases at constant volume, the pressure of the gas must decrease during this step. Although no $p \cdot \Delta V$ work is done on or by the gas (since the volume did not change), the energy lost by the gas from thermal conduction can be expressed by the decrease in pressure at constant volume.

B-C Cooling: Now that the gas is at a low temperature, but at the starting volume, the cold-side piston moves away from the hot-side piston (the separation distance increases) which decreases the pressure of the gas even further. This expansion would cause the temperature of the gas to decrease to a temperature below the coldest temperature of the regenerator if the step were adiabatic. In the isothermal limit, during each differential step of this expansion stroke, the gas gets a differential amount colder which allows a differential amount of heat to move from the heat exchanger located at the cold end of the regenerator to the gas. The cold (or load) heat exchanger is assumed to have the same temperature as the cold end of the

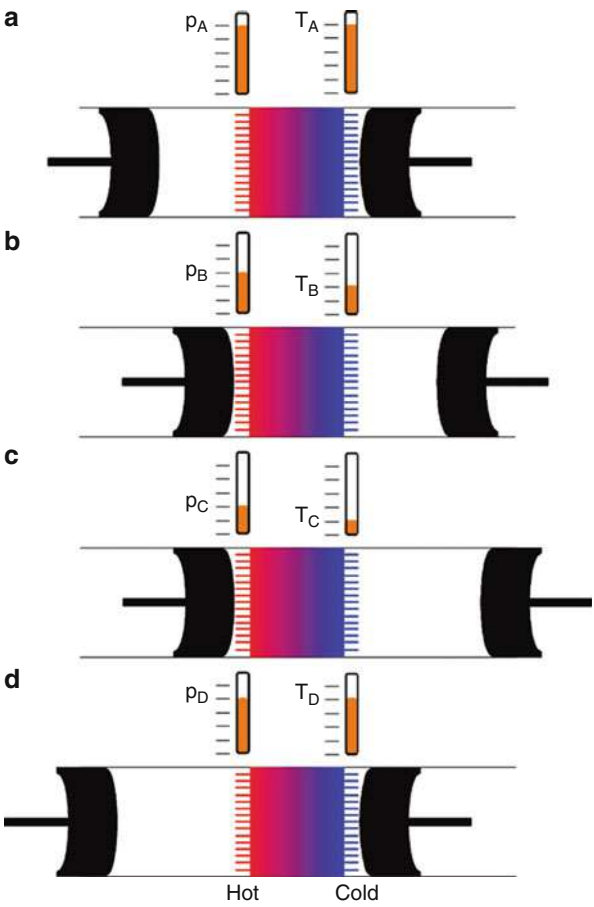

Fig. 4 This figure shows the piston motion in an alpha-Stirling refrigerator (the alpha configuration is where two distinct pistons are located in separate cylinders). The letter designations correspond to the *pV* diagram in Fig. 3, and the meters above each picture display the relative magnitudes of the gas pressure and average gas temperature

regenerator and, like the regenerator, this heat exchanger is in perfect thermal contact with the gas. Although the ideal Stirling refrigerator exhibits an isothermal expansion during this step, in real machines, this step is closer to an adiabatic expansion, as noted below. The job of the load heat exchanger is to move the heat from the thing to be cooled (e.g., ice-cream, medicine, foodstuffs) into the cold-side cylinder so that it can be transferred to the gas during this cooling step.

C-D Displacement: Following the cooling stroke, the pistons move together to drive the gas back through the regenerator toward the hot-side piston. During this constant volume displacement, the gas is reversibly warmed to the hot-side regenerator temperature. Since the warming occurs at a constant volume, the pressure of the gas increases during this step. It is during this step that the parcel of gas recovers the energy given to the regenerator from step *[A]–[C]*. It is in this reversible recovery of energy that the regenerator proves its worth; because of the regenerator, the expansion stroke only has to move heat *at the cold temperature* and does not have to cool the charge of gas from ambient temperature to the cold temperature

since the displacement stroke through the regenerator took care of that part. It is this idea of precooling and preheating the gas in preparation for heat transfer to or from a load that makes the Stirling cycle and other regenerative heat engine cycles useful. The fact that the regenerator can, in principle, do this precooling and preheating reversibly makes it efficient.

D-A Exhaust: Once all of the gas has been reversibly warmed to the hot-side temperature, the hot-side piston moves toward the cold-side piston compressing the gas that has been warmed. If isothermal, the amount of heat that was removed from the load exchanger plus the work done to remove it is absorbed by the exhaust heat exchanger. The job of the exhaust exchanger is to provide a path for that heat to leave the hot-side cylinder.

After reading this simplified step-by-step description of the operation some complications might be evident. First, a machine cannot produce such articulated motions to be able to easily mark, for example, the end of the cooling step and the beginning of the displacement step. In real machines, the pistons usually move in a sinusoidal motion (as shown in Fig. 3), which not only blurs the distinction between each of the four steps, but also reduces the power density of the machine for a given operating pressure range. This reduction in power density can easily be understood by appreciating that the area enclosed by the lines of the pV diagram is the amount of work required to move heat from material at the cold temperature to the environment. If a machine was operating at a constant efficiency, it would be able to move more heat for a specified pressure and volume oscillation amplitude if it could operate on the dotted curves in Fig. 3 (articulated piston motion) than it could if the pistons moved with sinusoidal motion as shown on the ellipse.

Secondly, it would be difficult to make a machine that could execute isothermal expansions and contractions in the cylinder spaces on the left and right of the regenerator in Fig. 4. If the relative scale of the schematic shown in Fig. 4 were used to build a machine, that machine would be better modeled with adiabatic compressions and expansions in place of the isothermal ones described above. These adiabatic compressions decrease performance below the Carnot limit since during the adiabatic pressure change, the gas gets measurably warmer or colder than the regenerator end-temperatures. Consequently, when this hotter or colder gas enters the regenerator (or heat exchangers), heat moves across a finite temperature difference, which is an irreversibility that decreases maximum theoretical performance below the Second Law limit. Also called the Carnot limit, the Second Law of Thermodynamics sets an upper limit for the amount of heat that can be moved from a mass at a cold temperature and exhausted to the environment at ambient temperature for a given amount of input work. This limit depends only upon the cold temperature, T_c, and the ambient temperature, T_0, and is expressed as $COP_C = Q_C/W = \frac{T_C}{T_0 - T_C}$, where Q_C is the amount of heat removed from the cold object and W is the amount of work required to move that heat (COP is an acronym that stands for coefficient-of-performance).

The Stirling cycle, as presented with isothermal compressions and expansions, is reversible (in the limit of zero viscosity) and, therefore, has the theoretical potential

to reach the Carnot limit of efficiency. In earlier days of Stirling machine design, assuming isothermal expansions and compressions made the analysis of potential designs tractable in closed form; the first published isothermal analysis of the machine was in 1871 by Gustav Schmidt, a professor at the German Polytechnical Institute at Prague. It was Schmidt, 50 years after the invention of the Stirling machine, who first represented the cycle with isothermal expansions and contractions because that model yielded a closed-form solution. Almost 100 years later, Finkelstein published the first analysis of a Stirling machine with non-isothermal expansions and compressions (Urieli and Berchowitz 1984).

The Function of the Regenerator and Its Advantages Compared to a Stack

The purpose of the regenerator in Stirling machines is to provide for the temporary storage of heat for the oscillating working gas. The gas must be brought to the cold temperature before the cooling (expansion) stroke is executed and then warmed before the exhaust (compression) is executed. The amount of heat removed to provide the cool gas for the expansion stroke is exactly the same amount of heat that must be returned to the gas in preparation for the exhaust stroke. The regenerator provides a place for the gas to temporarily store this heat; to do so, it must have enough heat capacity to be able to store the required heat to get the gas to the desired temperature and it also must be as thermally nonconducting as possible to reduce heat flow along its length, a heat flow that reduces the effectiveness of the regenerator. For this reason, many regenerators are made of stacked stainless steel screens, which provide plenty of heat capacity and a large array of pore size possibilities. Since each layer of screen has a significant amount of thermal contact resistance, heat conduction along the length is minimized to an acceptable level.

Stack-Based Thermoacoustics

In the last 20 years of the twentieth century, much research and design was dedicated to thermoacoustic machines that utilized an oscillating gas with nominally standing wave phasing (gas pressure and velocity 90° out of phase) in the presence of a "stack" of closely spaced, rather nonconducting plates (Swift 1988). This stack of plates was designed with a plate-to-plate spacing on the order of a few thermal penetration depths, or the acoustic thermal boundary layer thickness. This acoustic boundary layer is called a "penetration depth" because it is the distance that heat (or momentum, in which case, it is referred to as the viscous penetration depth) can diffuse in one acoustic cycle. The penetration depths are defined as

$$\delta_\kappa = \sqrt{\frac{2k}{\rho_m c_p \omega}}$$

$$\delta_v = \sqrt{\frac{2\mu}{\rho_m \omega}}$$

where ω is the angular frequency of the gas oscillation, ρ_m is the mean gas density, c_p is the gas specific heat at constant pressure, k is the thermal conductivity, and μ is the shear viscosity of the gas. Since the stack plate-to-plate spacing might be twice this thermal penetration depth, the rate of heat transfer between the plates and a gas parcel translating in a plane equidistant from two plates is not fast compared to an acoustic period, as it might be for a parcel of gas near to the plates. The lag of heat transfer with respect to the motion of the active gas parcels (those parcels that are not too near the plates) is what allows the gas to execute a useful heat engine cycle – one that either spontaneously converts heat input into sound energy or one that uses sound energy to move heat from a cold reservoir to an ambient temperature one.

This natural phasing idea, utilized by designing the stack with the proper plate spacing for a particular thermal penetration depth (which depends on working gas properties and frequency of oscillation), is considered an innovation since it rids a machine of any number of complicated methods to impose the required phase difference between heat transfer and gas motion. For example, in an automotive engine, each cylinder has at least two valves that must be opened and closed at the right time via the motion of rockers, cams, and pushrods. Most Stirling machines, as well as other air and gas engines, also have complicated linkages that impose the phasing of gas motion, pressure and heat input, and exhaust. However, the mechanical simplicity that comes with the exploitation of natural phasing brings with it a significant penalty in efficiency of the cycle. The fact that the thermal contact between the stack and the gas in the stack is not perfect (in order to get the right "natural" phasing) the heat that is exchanged between the stack and the gas is not exchanged in a reversible way (Wheatley et al. 1986). Since this heat transfer that occurs each cycle happens over a finite temperature difference, the *theoretical* limit in efficiency of the stack-based thermodynamic cycle is lower than the Second Law limit.

Regenerator-Based Thermoacoustics

As opposed to using a stack as the second thermodynamic medium, the use of a regenerator allows the theoretical thermodynamic efficiency to reach the Carnot limit. The function of a regenerator is slightly different than that of a stack. While both the stack and regenerator provide heat capacity for the temporary storage of heat, the details of how this heat is exchanged with the gas are different. In the stack, this exchange is irreversible because the active gas is one or a few thermal penetration depths away from the stack material (as explained above). It is this irreversibility that is the source of the natural phasing: a simplicity that can be desirable and worth the efficiency penalty. In a regenerator, the gas passage pores are much tighter. This ensures that all of the gas in the regenerator is well within a fraction of a thermal

penetration depth so that the thermal diffusion time is significantly shorter than an acoustic period. (A rule of thumb might be that the pore sizes are one fifth of the size of a thermal penetration depth.) Consequently, the transfer of heat between the regenerator and the gas is theoretically reversible which allows the efficiency to approach the Carnot limit. (However, since the pore size is small, the COP of any real incarnation of a regenerator-based heat engine will be limited by viscous loss in the regenerator, as well as other irreversibilities. In the comparison of stack-based to regenerator-based machines, it is somewhat arbitrary to compare the limiting case of a working fluid with zero viscosity since its effect is much bigger in the regenerator than the stack.) This gain in potential efficiency comes with the loss of the elegant natural phasing found within the pores of the stack. Therefore, the phasing of heat transfer and gas motion in the regenerator must be imposed by some other mechanism.

Using a Regenerator in an Acoustic Heat Engine

Since the natural phasing found in the stack is lost when taking advantage of the improved properties of the regenerator-based Stirling cycle, the correct phasing of heat transfer and gas motion must be imposed in some other way. In the late 1970s, Ceperley (1979) recognized that a traveling acoustic wave exhibits the correct phasing to force the oscillating gas to execute a Stirling cycle. This phasing, where oscillating pressure is in phase with the velocity of the gas, is enforced in conventional kinematic Stirling machines by way of the mechanical linkage. Ceperley built an acoustic-Stirling engine apparatus that included a regenerator inside of a pipe that was several wavelengths long, but his engines failed to produce acoustic energy. Although the regenerator was providing the needed energy storage, it also presented a significant viscous loss to the acoustic wave passing through the regenerator matrix. This attenuation, proportional to the square of the acoustic velocity, was much too large to allow any acoustic pressure oscillations to build in the tube; as the pressure would increase from the Stirling cycle taking place in the regenerator, the acoustic particle velocity would also increase, causing increased attenuation in the regenerator which robbed the wave of the power produced by phased heat transfer in the regenerator.

This is best understood by considering that the impedance (the complex quotient of oscillating pressure divided by the gas velocity) of the wave traveling along the tube that is several wavelengths long is simply the characteristic impedance of the gas in the tube: the product of density and sound speed. This impedance is relatively low compared to the impedance found near the closed end of a tube that is half of a wavelength long. In such a tube, the magnitude of the impedance near the closed end is large compared to the characteristic impedance of that gas; the oscillating pressure is large in magnitude compared to the relative magnitude of the gas velocity which becomes zero where the gas meets the capped end of the tube. This location would be a good place to locate a regenerator, except for the fact that in such a standing wave tube, the pressure is almost 90° out of phase with the gas velocity.

This preference for high impedance (ratio of driving potential to flow velocity) is also found in the electrical power transmission network. Electrical power (alternating current) is the real part of the product of the complex voltage (analogous to pressure) and complex current (analogous to acoustic velocity) in the form $\dot{E}_{\text{elec}} = \frac{1}{2}\Re\left[\tilde{e}\cdot\tilde{i}^{*}\right]$, where the asterisk represents the complex conjugate. The energy lost to Joule heating, which is the dominant loss mechanism in power transmission, is the product of the square of the current and the electrical resistance, $\dot{E}_{\text{loss}} = i^2R$, of the transmission line. Therefore, electrical power is transmitted at much higher voltage amplitudes than people like to use in their homes and at a significantly reduced current amplitude to reduce the resistive loss. Since power is the product of the potential and the flow, the amount of power transmitted can be maintained while the potential is increased and flow decreased proportionally to minimize losses.

In a regenerator-based acoustic machine, it is desirable to deliver a particular amount of power to the regenerator with the acoustic wave. The delivery of this power must have pressure and velocity in phase and at an acceptably large impedance so that viscous losses in the regenerator do not make the machine so inefficient as to be of no practical use. The first machines to successfully exploit this idea of an acoustic Stirling machine with the regenerator at a high impedance location was an engine built at Los Alamos by Scott Backhaus and Greg Swift (Backhaus and Swift 2000) and an engine of Kees de Blok and collaborators in the Netherlands (de Blok et al. 2001). Their pioneering concept for a thermoacoustic Stirling engine led the way for a new decade of thermoacoustic machine development that continues to this day.

The Acoustic Phasing Network

For successful utilization of a regenerator, several requirements must be met. First, pressure oscillations and velocity oscillations must be substantially in phase. The frequency of this oscillation must be low enough that the acoustic boundary layer thickness is several times larger than the average pore size of the regenerator matrix. The magnitude of the complex ratio of oscillating pressure to oscillating velocity must be relatively large in comparison to the characteristic impedance of the working gas. In addition to these elements, the energy flow in the machine is important.

In a Stirling refrigerator, the gas in the regenerator is a sink for mechanical (or acoustical) energy that passes from the exhaust (ambient temperature) side to the load (cold temperature) side. Energy in the form of mechanical work is supplied to the gas in the regenerator (see Fig. 5), and that gas absorbs some amount of this work in order to move heat against a temperature gradient from the cold end to the ambient (or hot) end of the regenerator. In a regenerator that transfers heat reversibly to a gas with no viscosity (this is a "perfect" regenerator and could also be thought of as one that generates no entropy), the remaining amount of work that flows out of the cold end of the regenerator is equal to the amount of heat removed from the load and pumped to ambient temperature. In this perfect regenerator, the amount of total

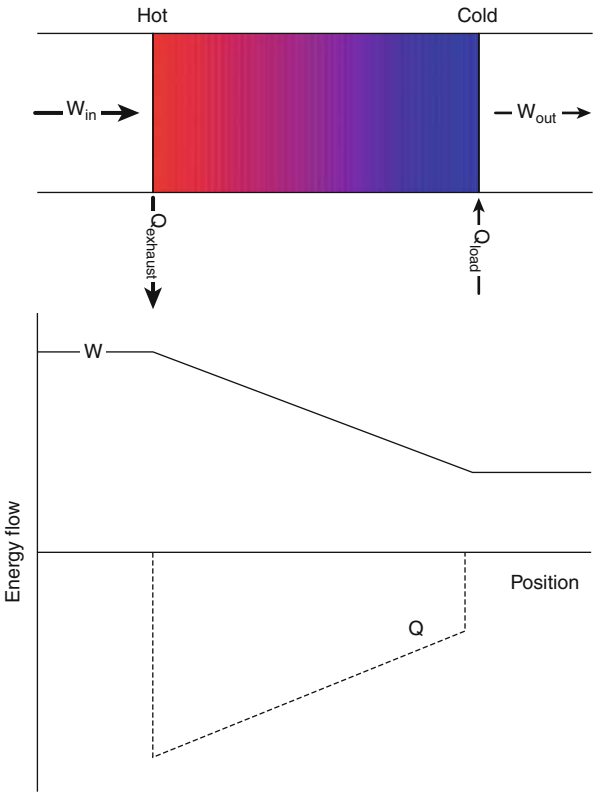

Fig. 5 This graph shows the energy flow through a regenerator that produces refrigeration. The *dotted line* represents the heat and the *solid line* shows the mechanical work. Note that everywhere in the regenerator, the sum of the heat and work is zero. The useful cooling capacity in an ideal regenerator is equal in magnitude to the amount of work that flows out of the regenerator at the cold (load) side

energy at any location along the regenerator's axis is zero. Since total energy or enthalpy, $\dot{H}_2$, is the sum of the work energy and the heat energy in the regenerator (and would include other types of energy if the magnitude was changing within the regenerator), the heat moving to the left ("up" the temperature gradient) is equivalent to the magnitude of work energy that is flowing to the right (the direction of propagation of the acoustic wave). In a machine with a perfect regenerator, in order to move an amount of heat, δQ per cycle some amount of work δW is absorbed per cycle in the regenerator as demanded by Carnot.

The work required by the Second Law of Thermodynamics to move an amount of heat δQ is related only to the temperatures between which the heat is moved T_0 and T_C: $\delta W = \delta Q \frac{T_0 - T_C}{T_C}$. In a real regenerator, the amount of work absorbed in the regenerator due to viscosity is greater than the Carnot minimum; since this work does not contribute to moving any useful heat, this extra work raises the total power in the regenerator to a value greater than zero. Likewise, since a real regenerator allows some conduction of heat from the ambient side to the cold (load) side and heat exchange in the real regenerator has irreversibility associated with it, the net amount of heat moved from the load to the ambient reservoir will not be as great as it could have been for the amount of work flowing into the regenerator. This reduction in the

useful amount of heat moved "up" the thermal gradient within the regenerator also increases the magnitude of total power in the regenerator above the ideal value of zero. The concept of total power allows a quantitative way to judge the "effectiveness" of the regenerator and allows the designer to know if a proposed change to the design of the machine or regenerator parameters will increase efficiency.

Within the Stirling community, machines are commonly classified into two major categories: kinematic and free-piston. In a kinematic machine, the two moving elements (either a piston and a displacer or two pistons) are connected together by a mechanical linkage and the motion of the two elements with respect to one another is completely defined by the mechanics of the linkage. Free-piston machines are a much more recent development, largely credited to Beale (1971), but could also be attributed to Ringbom (Sier 1995). The recognition that the mass of the displacer could be made to resonate against the stiffness of trapped gas in the machine created a renewed interest in Stirling machines in the early 1970s. Free-piston Stirling machines offer a more compact and mechanically simpler alternative to their kinematic brothers; however, these benefits come at the price of increased design complexity since the dynamics of the heat transfer directly impact the motion of the two moving elements which create the pressures – the pressures that dictate how much heat moves. In a kinematic machine, the motion of the piston/displacer is set mechanically and the thermodynamic events taking place in the machine cannot impact the displacement magnitude (or therefore, the pressure amplitude).

In either category, the free-piston or the kinematic, the energy flow in the device is the same; energy flows into the ambient temperature end (exhaust side) of the regenerator and out of the cold (load side). This amount of "left-over" energy that leaves the regenerator must be recycled to the front of the regenerator for the device to be efficient – this is another job of the mechanical linkage and flywheel of the kinematic Stirling machine, and in a free-piston machine, this energy is stored and released by the piston that resonates against the sealed volume of gas, that is, the "free" piston of the free-piston machine.

As shown in Fig. 6, the innovation of Beale (or Ringbom) was to recognize that the complicated and expensive linkages found in kinematic Stirling machines could be removed and replaced with a spring: either a mechanical spring or the stiffness formed by gas in a sealed chamber. The improvement made by Backhaus, Swift, and independently by de Blok et al. was to eliminate the piston that Beale left in his device. Backhaus and Swift substituted for the piston a "slug" of gas that has relatively more inertia than the rest of the gas in the cylinder that contains the regenerator.

The terms "inertance" and "compliance" are terms that describe sections of a gas-filled resonator that behave as acoustic analogs (in a complex impedance sense) to an electrical inductor and capacitor, respectively. A necked-down section of resonator has the effect of delaying the oscillating flow of gas through it in response to a pressure difference across the section. Once the gas is accelerated by this pressure difference, it continues to move even though the pressure difference has changed direction. In order to connote this function, the word "inertance" has both the sense of "inductor" and "inertia." A resonator section that has substantially more volume than the rest of the resonator acts like a capacitor because just as the

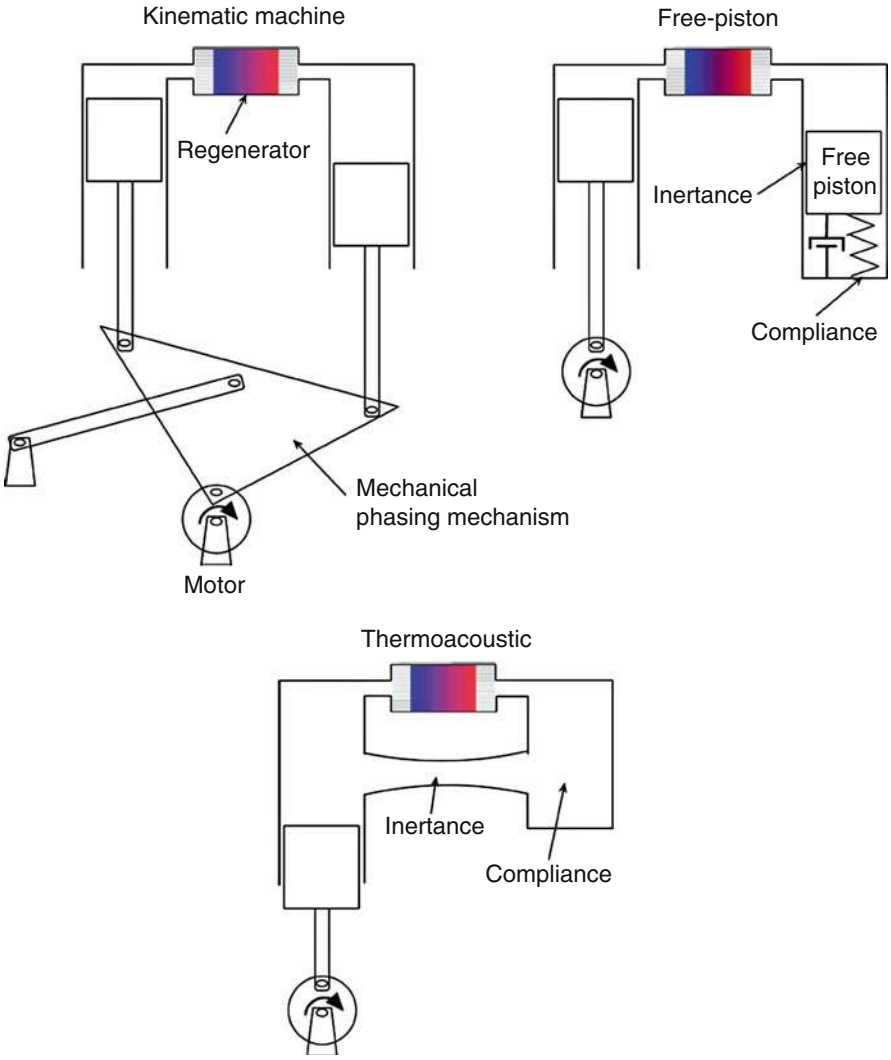

Fig. 6 The broad steps in the evolution of mechanisms to support a Stirling cycle are shown in this figure as refrigerators (these topologies are equivalent in the case of an engine). The kinematic machine, which was born in the early nineteenth century, has many forms and derivatives; only the simplest alpha configuration is shown here. The free-piston Stirling concept started to be developed in about 1970, and although the acoustic-Stirling idea was conceived of in the late 1970s, the first working prototypes were produced in the late 1990s by de Blok in the Netherlands and by Backhaus and Swift at Los Alamos National Laboratory

capacitor stores energy in the form of electrical charge temporarily, the compliance section of a resonator stores energy in the form of pressure. These pressure changes lag the flow of gas into or out of the section just like the voltage across a capacitor lags the flow of current. This equivalent circuit analog to acoustical systems is quite

convenient for the design of acoustic networks and is an established analytical tool in the field of acoustics (Beranek 1954).

The crux of Backhaus and Swift's 1999 engine is the concept of an acoustic phasing network that both delivers acoustic power to the regenerator at a high impedance and correct phase and then returns the power that is not utilized to move heat. (In the case of an engine, the amount of power that is not taken from the wave to do work on a load is returned to the regenerator.) The function of the phasing network is twofold: condition the impedance of the incoming acoustic energy so that it can be efficiently utilized by the regenerator and then return unutilized energy back to the regenerator.

Future Directions

Motivation for Development of Thermoacoustic Machines

Now that some historical and theoretical background has provided a context for thermoacoustic machines, it is important to describe the motivation for pursuing thermoacoustic-Stirling technology.

Thermoacoustic Machine Replacements to Vapor Compression Refrigerators

A candidate replacement technology for refrigeration equipment firmly established on the market must have at least three properties: increased effectiveness (efficiency), reduced cost (simplicity), or present less of a risk for legislative phaseout. In some sense, these three reasons all collapse to the issue of cost. In order for efficiency improvements to lead to lower lifecycle costs, the increase in acquisition cost must not be greater than the fuel savings due to increased efficiency. Legislation created to limit pollution is often driven by the high cost of cleanup associated with that pollution – this is the case for greenhouse gas emissions. Reducing the carbon dioxide in the atmosphere is either very costly or not even technically well understood (an understanding that might be attainable for a higher cost than society has been willing to spend).

Several thermoacoustic machines have been built to perform low-lift (small temperature difference) cooling. One such machine, pictured in Fig. 7, was built for Unilever's subsidiary Ben and Jerry's Homemade. This machine had a performance equivalent to the ice-cream storage cabinets that it was intended to replace but used helium as a refrigerant which has no global warming potential. The unit that it was designed to replace uses R134a (1,1,1,2-Tetrafluoroethane), which has a global warming potential (GWP) of greater than 1,400 over 100 years.

With that in mind, there are at least three considerations that can influence lifecycle cost:

Fig. 7 A view of the regenerator-based thermoacoustic ice-cream storage cabinet built at Penn State University with sponsorship from Unilever/Ben & Jerry's. The thermoacoustic cooler is the silver unit to the *right* of the off-the-shelf storage cabinet. Heat was moved out of the storage cabinet and to the oscillating helium in the thermoacoustic machine by circulating ethanol within the copper tubing of the cabinet that typically carries R134a refrigerant and into the thermoacoustic machine's internal load heat exchanger. The photo on the *right* shows the pump that moved the ethanol covered with ice from condensed water-vapor in the air. A thermocouple reader shows the temperature of the ethanol to be −19.8 °C (*Left* photo by Greg Grieco, used with permission)

- *Cost to Manufacture*: The commodity level vapor-compression refrigerator that is found in the kitchens of most homes in the industrialized world is inexpensive. However, since a thermoacoustic machine has a few moving parts, requires no exotic materials, and has no inherently close dimensional tolerances, a commodity thermoacoustic machine stands some chance of being manufactured as inexpensively as a vapor compression machine. It is true that thermoacoustic machines, as do all closed-cycle machines, require some secondary heat exchange mechanism on both the hot and cold sides. This subsystem does increase complexity, but for some applications like fountain beverage vending, this fluid loop is integral since it is the product delivery system. In grocery store display cases and geothermal heat pumps, secondary heat transfer systems are already in use with conventional compressor technology.
- *Cost to Operate*: The cost of energy purchased to operate the refrigeration machine is minimized by increasing its efficiency and reducing maintenance costs. Cost of energy is important for some applications where the energy is hard to transport to the location of the machine, or applications that demand significant amounts of cooling, and, therefore, reducing the energy demands of the machine saves a significant amount of money. On the other hand, the efficiency of a cooling machine is only a secondary metric for some applications; in the market of commercial ice-cream storage cabinets, the company who makes/markets the ice-cream usually provides a storage freezer to a grocery/convenience-store for no charge (as long as their product continues to sell at the store) and the shopkeeper pays the operating costs. In this case, efficiency may

be of secondary importance to the purchaser compared to acquisition cost. For large capacity applications, such as grocery stores and refrigerated warehouses, efficiency becomes more important since the energy and acquisition cost is borne usually by the same organization and the electrical power consumption is large. Thermoacoustic machines can be made to be competitively efficient and, like Stirling machines, may become competitive with vapor compression machines. However, vapor-compression refrigeration can be made to be quite efficient if cost is no object. Efficiency of vapor-compression machinery on the market is only constrained by the acquisition price tolerance of that market. Typically, reduced operating costs, even if that reduction makes the lifecycle costs smaller, do not offset a high acquisition cost as a priority driving the purchasing decision of many consumers in both the residential and commercial sectors.

- *Cost to Dispose*: Thermoacoustic machines use no environmentally harmful working fluids/gases. Consequently, disposal is inexpensive compared to vapor compression machines which currently utilize gases 2,000–3,000 times more potent as "greenhouse" gases than CO_2. Since the machine uses no lubricants, maintenance is expected to be small and lifetime should be long. Compared to large vapor compression machines which have compressors and rotating machinery that require maintenance and suffer breakdown of the seals, thermoacoustic technology with its linear motors and flexure or clearance seals can increase the useful lifetime of refrigeration equipment with decreases the costs of disposal and wasted material/labor.

Pitting thermoacoustic technology head-to-head with the established vapor compression technology (which is 100 years old) is daunting for as young of a technology as thermoacoustics, which has no established supplier base, a short design history and limited expertise. Vapor-compression is such a mature technology and the market has not yet found vapor compression to be deficient in the three categories above. However, if environmental legislation were to be enacted, either banning certain refrigerants or forcing consumers to pay a premium for buying and disposing of a machine that contains a global warming gas, thermoacoustic technology could become more attractive in the "cost to buy/manufacture" and the "cost to dispose" categories. As the direct cost of energy increases (direct cost is exclusive of the indirect costs such as those associated with natural resource depletion, military protection of oil prices, coal mine runoff and subsidence, etc.) due to pollution taxes or carbon credits as specified by the Kyoto Accords, thermoacoustics with its high inherent efficiency might also be attractive in the cost-to-operate category. Support for technologies that do not use global warming gases is much stronger in Europe at this time than it is in North America.

Thermoacoustic Machines as Power Generators

There are two primary applications for acoustic engines: those that convert the acoustic power to electricity or those that use the acoustic power to drive a

thermoacoustic refrigerator/heat pump (there is not much demand for energy in acoustic form, and the "one-note samba" of an acoustic machine is hard to dance to). Thermoacoustic machines that are built to convert heat energy to acoustic energy and then to electrical energy might be an attractive commercialization target for flexible-fuel, small-scale power generation between 5 and 500 kW of electrical output. In-home electrical generators that burn natural gas or fuel oil to provide both the electrical power for a home and heat the home and domestic water supply might allow a household to reduce the number of subscribed utilities by at least one and eliminate the significant transmission loss associated with electrical power delivery that is wasteful of the global natural resources.

Alternators for Power Generation

A significant component in a thermoacoustic machine that converts heat to electricity is the alternator that performs the conversion of the acoustic energy to electrical energy. Carefully engineered linear motors made for this purpose are commercially available today (QDrive Corporation in Troy, New York); these are the type employed to create the sound wave that powered the thermoacoustic ice-cream freezer shown above.

However, since the diameter of the thermoacoustic machine scales with power, at high powers, the linear alternator/motor and the pistons that attach to them will have to be large and heavy, which will create a challenge for high-frequency (and therefore high power density) operation. The recent invention of a piezoelectric alternator (Keolian et al. 2007) to enable power generation looks promising. Several advantages of an alternator of this design are that the piezoelectric material itself is robust, relatively inexpensive, and low maintenance. Since the design of the alternator allows the piezoelectric ceramic elements to be squeezed twice per cycle by the acoustic oscillation, the power density of the alternator is much higher than that of a linear motor. Figure 8 shows the bare alternator (left) and the alternator installed in a thermoacoustic engine generating 37 W of electricity. This photo was taken at an early stage of the development; this proof-of-concept alternator is capable of generating over 600 W of electricity.

This alternator was designed with the intention of including it in a system to capture the heat from the exhaust pipe on over-the-road trucks and convert it to electricity for use in the truck. A thermoacoustic electrical generator was designed and built at Los Alamos to power a space satellite (Backhaus et al. 2004). For that project, a specialized electrodynamic alternator was designed and built.

Engines Used to Drive Heat Pumps (Refrigerators)

A very compelling application for thermoacoustic technology is to utilize a heat source directly for heat pumping. This is especially elegant because a thermoacoustic machine to accomplish this is only comprised of heat exchangers and stack/regenerators – no moving parts or sliding/rotating seals are required. There are other technologies, like absorption refrigeration, that can have similar simplicity, but these

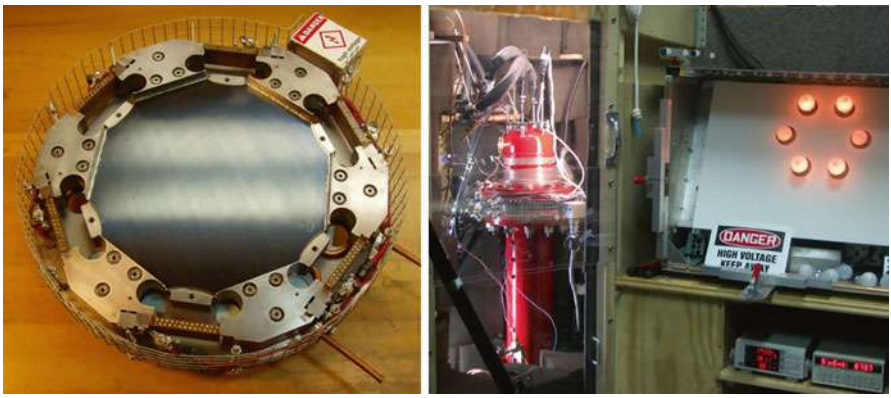

Fig. 8 Two photos show the piezoelectric alternator. On the *left*, the bare alternator is shown, and the piezoelectric elements are the six tan-colored rectangular prisms arrays on the perimeter of the alternator which has an overall diameter of 35 cm. As the oscillating pressure flexes the diaphragm, the piezoelectric elements are squeezed and produce electrical power. The diaphragm squeezes the piezoelectric elements when it moves up and down. On the *right*, the alternator is installed into a regenerator-based thermoacoustic engine (Bastyr 2004) and is powering six light bulbs with 37 W of electricity. This proof-of-concept alternator is capable of generating over 600 W of electricity (Photos by Robert Keolian, used with permission)

machines typically use chemicals like ammonia and hydrogen instead of helium. They also have to work around the phase change temperatures and pressures – phase change systems have a power density advantage over non-phase change systems, but this comes at some reduced flexibility for variable working temperatures.

Along with thermoelectrics and organic Rankine cycles, thermoacoustic machines are often considered as an option for reclamation of waste heat. In many industrial processes, there is low (100–200° C) and medium temperature (200–400° C) heat that is often allowed to escape to the atmosphere unutilized. Often, the heat is difficult to divert into some machine or storage mechanism, but there is also a lack of products available on the market that can accomplish the task in a cost effective way. The lower temperature waste heat reclamation is especially challenging because the size of a device to accomplish the task is large and the Carnot efficiency is low. Nevertheless, the simple combination of a thermoacoustic engine that powers a refrigerator offers one possibility of such a solution.

There are ongoing efforts at Los Alamos National Labs in New Mexico and Aster Thermoakoestische Systemen in the Netherlands to exploit this kind of opportunity. At Los Alamos, an extensive program was executed with the goal of utilizing stranded natural gas reserves – that is, natural gas that is hard to access with piping networks to carry the gas to market. Several systems were built in escalating size and efficiency to burn natural gas at remote well-heads to power a thermoacoustic system that would liquefy the remainder of the gas stream for easy transport from the remote area (Bayram et al. 2005). The largest of these systems is shown in Fig. 9. At Aster, a thermoacoustic heat-driven heat pump system was created to utilize waste heat

Fig. 9 A photo of the natural gas liquifier next to a six-foot (1.8 m) tall man shows the highest power thermoacoustic device ever built. At the *top* is a blower attached to the combustion chamber. The thermoacoustic engine is below the combustion chamber (the conical shaped component) and is connected via the wave tube to a vacuum can at the bottom next to John Wollan, one of the designers and builders of the machine. This device liquified 350 gal/day with a projected production efficiency of 70 % liquifaction and 30 % combustion of an incoming gas stream (Photo by Greg Swift, used with permission)

streams to pump the remainder of the heat to a higher temperature so that it could be utilized in another industrial process.

Cookstoves for Developing World Power Generation

There has long been an interest on the part of developed nations to enable developing nations to share in the technological bounty enabled by heat engines. In many of these countries, fuel for cooking and heating is biomass (mostly wood), collected daily or weekly and oftentimes at great distances from population centers. The relative scarcity of biomass in many places is exacerbated by the collection of it, so the distance of these daily/weekly journeys increases at alarming rates through difficult and/or dangerous terrain. Additionally, the relatively poor utilization of these fuels in stoves or open fires with incomplete combustion causes very poor indoor and outdoor air quality, and the health of women and children (who spend more time around the fires and in the house than men) suffers dramatically. Poor indoor air quality caused by inefficient cookstoves is as big of a health risk than any other in some developing countries, causing 1.9 million deaths each year and chronic illnesses such as low birth weight, acute pneumonia in children under 5, lung cancer, chronic obstructive pulmonary disease, and cardiovascular disease (Global Alliance

for Clean Cookstoves 2010). From the standpoint of global warming, the billions of inefficient, poorly constructed cookstoves in use today contribute to global warming through not only the CO_2, methane, and nitrous oxide present in the combustion products, but also the soot or black carbon emissions from these stoves. Particulate matter of elemental carbon is suspect as a major contributor to climate change and has an estimated GWP of 680 (Roden and Bond 2006).

It has been established (MacCarty et al. 2008) that a fan integrated into the combustion chamber of a stove can increase combustion efficiency and dramatically decrease particulate and black carbon emissions. Lowered emissions can improve atmospheric health in a very short timeframe, and increased efficiency translates to less deforestation and increased carbon sequestration in these areas. Since one way to power a fan is with electricity, there has been some interest to utilize a thermoacoustic electrical generator to provide this electricity using a small fraction of the heat produced by the stove's fuel. Cost is one of the dominant constraints for the successful adoption of technology in the developing world, and the mechanical simplicity of thermoacoustic machines, the lack of exotic materials, and no need for tight machining tolerances all make thermoacoustic technology a candidate for small-scale power generation in developing countries. The other likely technology to fill this niche, which has undergone more testing and commercialization for the application than thermoacoustics, is thermoelectric modules.

Aster Thermoakoestische Systemen has recently completed the testing of a prototype intended for this market with funding from the SCORE program at the University of Nottingham (SCORE stands for Stove for Cooking, Refrigeration and Electricity) and the FACT Foundation in Eindhoven, Netherlands. The topology of the thermoacoustic engine designed and built by Aster is novel (de Blok 2010) due to its planar geometry shown in Fig. 10, which allows integration to a stove by presenting a large heat exchange area to the hot gases above the fire. The thermoacoustic machine is a four-stage regenerator-based engine coupled to electro-dynamic alternators. Each of four regenerators is positioned on a set of ambient-side fins shown below on the left hand side of Fig. 10. The tubes connecting each of the four quadrants are part of the acoustic network. A similar finned plate is installed on the ambient plate which sandwiches the regenerators between the plates and making a series connection between each of the four stages of the machine. This ambient fin plate is shown immersed in the water bath on the right-side photo of Fig. 10, and the hot-side fin plate is facing the gas burner. In practice, the burner could be a three-stone fire or cookstove. The electrodynamic alternators for this design are still under-construction.

Commercialization Considerations

Direct competition with vapor compression technology may not be the only path toward commercialization of thermoacoustic cooling technology. There is surely an application for a machine that uses an environmentally benign working fluid, is quiet, efficient, has low moving mass, and can easily take advantage of proportional

Fig. 10 The ambient temperature heat exchange plate of the cookstove generator developed by Aster is shown on the *left-hand side*, and the full machine is shown on the *right* being fired by a natural gas burner. A pot of water serves as the exhaust-side sink; the device is intended to provide hot water and electricity for citizens of developing countries (Photo by Kees de Blok, used with permission)

control that could propel the technology to prominence even at a cost premium. Consequently, putting research efforts into increasing the power density, reducing cost, and increasing efficiency is not wasted – especially in light of the fact that thermoacoustic technology is functionally reversible. This means that knowledge gained by research into the machine as a refrigerator is directly transferable to the design of a machine that is built as an engine.

Now that a clear link has been established between the operation of thermoacoustic technology and Stirling machines, the next logical question is "Why spend money/time developing thermoacoustic machines in favor of developing Stirling machines?" Alternatively, this question could be asked of a developer of thermoacoustic technology: "What makes you think that thermoacoustic machines will be commercially feasible when Stirling machines have not reached a 'commodity status' during the nearly 200 year history of their development? " (Kinematic Stirling machines attained a brief "commodity status" at the start of the twentieth century as water pumps and compressors.) There are several clear advantages and some disadvantages of thermoacoustics when compared to Stirling (Fig. 11).

Mechanical Complexity: Stirling machines, and kinematic Stirling machines especially, are mechanically complex. A kinematic machine requires some mechanical means to link the pistons in such a way to create the correct phasing of pressure oscillation and gas displacement. In Fig. 6, two kinematic machines are shown that were made at the extremes of the twentieth century, and both are burdened with this linkage that requires lubrication, experiences wear, dissipates energy, and is costly to manufacture and maintain. Many Stirling machines, both kinematic and free-piston, have a piston (to create pressure oscillations) and a displacer (to move the gas through the regenerator at a roughly constant volume) that must move in the same bore. In many designs, this requires that the rod for the displacer penetrate the piston and sometimes that both of the connectors for these mechanical components penetrate the pressure vessel that contains the working fluid (usually helium).

Fig. 11 On the *left* is photograph of a Rider-Ericson engine produced in the late 1800s and early 1900s. Notice the complicated linkage that connects the flywheel to the piston rods that penetrate the *top* of the piston cylinder. On the *right* is a modern Stirling machine made by Whisper Tech (http://www.whispergen.com/) in 2002 that is used to generate electricity for residences, yachts, and motor-homes. Hidden in the stainless steel pressure vessel is a complicated linkage called a "wobble-yoke" (*left* photo in the public domain, *right* photo credit: Whispergen)

These dynamic seals, sometimes in the presence of either hot or cold temperatures, present a difficult engineering problem that is usually costly to implement due to close-tolerance manufacturing requirements that provide simultaneously low friction and low leakage. The most significant contribution of thermoacoustic technology to the development of regenerative heat engines is simplicity. By eliminating the displacer or second piston (and in a prime mover, by removing all moving metal) in favor of gas inertia and by exchanging a mechanical phasing mechanism for one that is executed using the compliance and inertia of the working fluid itself, a much simpler and consequently cheaper machine can be made. Thus far, this reduction of complexity has probably come at the price of power density. In the machines that are the subject of this chapter, the sliding seals that dominate Stirling machines have been replaced by flexure seals. These seals, while simple and low maintenance require careful design for "infinite" fatigue life. At this time, the metal bellows that are used are expensive.

Power Density: The power density of thermoacoustic machines tends to be neither as high as that of its Stirling "brothers" nor as high as either vapor compression refrigerators or internal combustion engines. The relatively low power density comes as consequence of relying on the stiffness (compliance) of gas trapped in the resonator to provide restoring force and moving gas to provide inertia. Compared to

a mechanical spring, gas springs are much bigger for a given stiffness and the density of gas is much lower than the density of metal or plastic used as pistons in traditional Stirling machines. That said, since the compliance of trapped gas is a function of the mean pressure in the gas $\left(C_g = V/\gamma p_m\right)$ and since density is also proportional to mean pressure, by increasing the mean pressure in a thermoacoustic machine, the power density can be improved, although the cost/weight/complexity of a stronger pressure vessel must be considered.

Moving Mass: The moving mass of thermoacoustic machines can be low for a given amount of cooling capacity (or power output if operating as an engine) compared to Stirling machines. This has advantages with respect to fatigue life as well as transmitted noise/vibration levels and radiated noise levels.

Resonance: One overarching advantage of thermoacoustic machines described herein is that since the energy storage medium is the working gas itself and the moving mass, there are no requirements for external energy storage elements (like flywheels) that are found in many traditional Stirling machines.

Limitations Imposed byHeat Exchangers: All closed-cycle engines suffer an efficiency penalty compared to open-cycle machines like internal combustion engines or vapor-compression refrigerators. This penalty comes from the extra heat-exchange step inherent in closed-cycle engines because the working gas does not directly contact the heat source and sink. In the internal-combustion engine, for example, the fuel enters the engine cylinder and explodes – the engine takes advantage of the very hot temperature of that explosion in the form of the expansion of the combustion products. Following that expansion, the hot gas is exhausted from the cylinder, whereupon a new charge of cool fuel/air mixture is injected. Because of this rapid exchange of hot gas with cool gas and the fact that the hottest temperature of the explosion only lasts for an instant, the metal of engine block does not have to sustain the high temperatures of which the engine gets to take advantage. Closed-cycle engines usually have to be designed for significantly lower temperatures due to material constraints, but they also suffer a temperature difference across the heat exchanger through which all of the heat that the engine uses must pass. As a result, the engine takes an efficiency penalty because it cannot utilize the highest temperature that the fuel is providing.

Temperature-related material constraints are not usually a factor in a heat pump application, but the same handicap arises due to the temperature drop on the heat exchangers that transfer heat from the cooling load and again out of the machine into the environment. Especially for low-lift applications (small temperature difference) like food refrigeration or air-conditioning, the temperature drop on the primary helium-to-secondary heat exchangers can be a significant fraction of the total temperature difference and therefore be the largest efficiency penalty in the system. In an open-cycle vapor compression system, where the refrigerant undergoes a phase change, the compressor effectively pumps the refrigerant between two heat exchangers that directly exchange heat with the load and exhaust. Consequently, these systems have half of the heat exchange steps than a closed-cycle machine (like one that utilizes thermoacoustics) would have. The designer of a thermoacoustic

machine that has to compete only in terms of efficiency has to carefully consider the primary (oscillating gas to secondary fluid) and secondary (secondary fluid to load/environment) heat exchangers. Ideas to eliminate the secondary heat exchange step have been explored with some success; for example, a design was tested at Los Alamos that acoustically pumped helium out of the resonator to the heat source/sink (Swift and Backhaus 2004). A flow-through design was also tested at Los Alamos that allowed a steady flow of air to move through the resonator; this machine used air at atmospheric pressure as the working gas and, therefore, was not particularly power dense in either weight or volume (Reid and Swift 2000).

Hydrogen Production

Qinhui Wang

Contents

Abstract

Hydrogen (H_2) is mainly used in chemical industry currently. In the near future, it will also become a significant fuel due to advantages of reductions in greenhouse gas emissions, enhanced energy security, and increased energy efficiency. To meet future demand, sufficient H_2 production in an environmentally and economically benign manner is the major challenge. This chapter provides an

overview of H_2 production pathways from fossil hydrocarbons, renewable resources (mainly biomass), and water. And high-purity H_2 production by the novel CO_2 sorption-enhanced gasification is highlighted. The current research activities, recent breakthrough, and challenges of various H_2 production technologies are all presented.

Fossil hydrocarbons account for 96 % of total H_2 production in the world. Steam methane reforming, oil reforming, and coal gasification are the most common methods, and all technologies have been commercially available. However, H_2 produced from fossil fuel is nonrenewable and results in significant CO_2 emissions, which will limit its utilization.

H_2 produced from biomass is renewable and CO_2 neutral. Biomass thermochemical processes such as pyrolysis and gasification have been widely investigated and will probably be economically competitive with steam methane reforming. However, research on biomass biological processes such as photolysis, dark fermentation, photo-fermentation, etc., is in laboratory scale and the practical applications still need to be demonstrated.

H_2 from water splitting is also attractive because water is widely available and very convenient to use. However, water splitting technologies, including electrolysis, thermolysis, and photoelectrolysis, are more expensive than using large-scale fuel-processing technologies and large improvement in system efficiency is necessary.

CO_2 sorption-enhanced gasification is the core unit of zero emission systems. It has been thermodynamically and experimentally demonstrated to produce H_2 with purity over 90 % from both fossil hydrocarbons and biomass. The major challenge is that the reactivity of CO_2 sorbents decays through multi-calcination–carbonation cycles.

Introduction

Fossil fuels (i.e., petroleum, natural gas, and coal), which meet most of the world's energy demand today, are being depleted fast. Also, it is now widely acknowledged that combustion of fossil fuels contributes to the buildup of CO_2 in the atmosphere, which in turn contributes to the greenhouse effect, causing the well-known global warming. Many engineers and scientists agree that the solution to this problem would be to replace the existing fossil system by the hydrogen energy system. The idea of a hydrogen economy with decarbonizing energy supply has merit. Additional drivers for the switch to a H_2 energy economy can include opportunities for increased energy security through greater diversity of resources for supply and greater efficiency and versatility with the mastery of hydrogen fuel cell technology.

Hydrogen is the simplest element known to man. It is also the most plentiful gas in the universe. Hydrogen gas is the lightest gas; thus, it rises in the atmosphere. Therefore, hydrogen as a gas (H_2) is not found by itself on earth. It is found only in compound form with other elements. Hydrogen combined with carbon forms

different compounds such as methane (CH_4), coal, and petroleum. Hydrogen combined with oxygen forms water. And hydrogen is also found in growing things – biomass. The amount of energy produced during hydrogen combustion is higher than released by any other fuel on a mass basis, with a lower heating value (LHV) 2.4, 2.8, and 4 times higher than that of methane, gasoline, and coal, respectively. The product of hydrogen combustion is only water, and thus, the utilization of hydrogen is pollutant zero emission.

About 38 Mt (5000 petajoules) of hydrogen is produced worldwide annually, a market valued at about $60 billion (Levin and Chahine 2010). An idyllic vision of a "hydrogen economy" is one in which H_2 and electricity are the sole energy carriers and both are produced without harmful emissions, from renewable resources. H_2 would be used in transport, industrial, commercial, and residential applications, where fossil fuels are currently used. As hydrogen is not an energy source, but a carrier, so it must be produced from other natural sources, not only fossil fuels but also biomass and water. Sufficient H_2 production to meet future demand is the major challenge in moving toward a H_2 energy economy.

Hydrogen Production from Fossil Fuel

At the present time, H_2 is mainly used in chemical industry, e.g., to upgrade crude oil and synthesize methanol and ammonia in the petroleum and chemical reactors. Fossil fuel is the major sources to produce hydrogen, which amounts to 96 % of total hydrogen production in the world. The mostly common hydrogen production methods are (1) steam methane reforming (SMR) (48 %), (2) oil reforming (30 %), and (3) coal gasification (18 %) (Ewan and Allen 2005). Although ammonia and methanol are also used for H_2 production, the proportion is minor. During the transition phase to a sustainable hydrogen economy, hydrogen from fossil fuel will continue to be paid large attention due to the need of considerable cost reduction and technology improvement throughout the entire hydrogen system (production, delivery, storage, conversion, and application).

Steam Methane Reforming (SMR)

The dominant industrial process used to produce hydrogen is the SMR process. About 59 % of hydrogen production comes from SMR of natural gas, but hydrogen production by SMR is responsible for the emission of about 30 million tonnes of CO_2 per year (Levin and Chahine 2010). The first industrial application of SMR was implemented in 1930 (Barelli et al. 2008). And it is a mature technology, which has been in use for several decades as an effective mean for hydrogen production. The SMR process is characterized by multiple-step and harsh reaction conditions. Typically, four steps are necessary, namely, (1) desulfurization, (2) steam reforming, (3) water–gas shift (WGS), and (4) H_2 purification. Figure 1 shows the diagram of a typical SMR process.

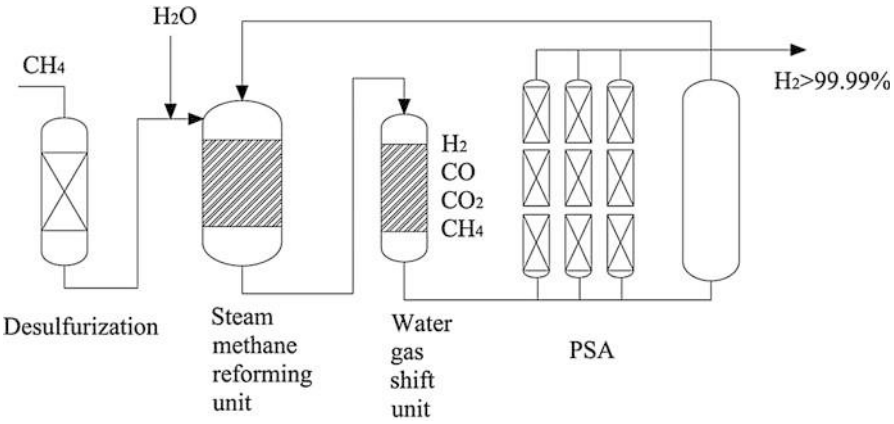

Fig. 1 A diagram of a typical SMR process

Desulfurization

Sulfur that contained in raw natural gas will lead to catalyst deactivation and facility destruction during H_2 production; thus, desulfurization from natural gas to keep the sulfur content being in a very low level is a primary and necessary procedure. Typically, the desulfurization proceeds by two steps.

The first step is wet desulfurization, which is usually performed by the natural gas provider. In this step, natural gas reacts with monoethanolamine (MEA) to remove most sulfur content. The reaction can be expressed by two equations:

$$2CH_3CH_2OHNH_2 + H_2S \rightleftarrows (CH_3CH_2OHNH_3)_2S$$

$$(CH_3CH_2OHNH_3)_2S + H_2S \rightleftarrows 2(CH_3CH_2OHNH_3)HS$$

The MEA solvent can be recovered through being heated to a higher temperature ($>$105 °C). After wet desulfurization, the sulfur concentration in the raw natural gas will be lowered to approximately 200 ppm.

The second step, dry desulfurization, is conducted just prior to the SMR reactor. The aim of dry desulfurization is to realize organic sulfur removal and reach a very low sulfur concentration ($<$0.1 ppm) in the raw natural gas. The typical approaches can be categorized as chemical reaction technologies and adsorptive technologies (Holladay et al. 2009). Chemical reaction approaches include hydrodesulfurization (HDS) and alkylation. Most commercial large-scale applications use HDS; although selective alkylation has the potential advantage of not requiring high-pressure hydrogen compared with HDS, but to date it has not been implemented on a large commercial scale, only pilot-scale demonstration is being conducted. The mechanism of HDS is shown in the following equations, where HDS catalysts partially or completely hydrogenate the sulfur-bearing molecules, resulting in a release of sulfur as inorganic H_2S:

$$R - SH + H_2 \rightarrow RH + H_2S$$

$$R - S - R' + 2H_2 \rightarrow RH + R'H + H_2S$$

$$R - S - S - R' + 3H_2 \rightarrow RH + R'H + 2H_2S$$

$$C_4H_4S + 4H_2 \rightarrow C_4H_{10} + H_2S$$

$$CS_2 + 4H_2 \rightarrow CH_4 + 2H_2S$$

Adsorptive approaches employ adsorbents for sulfur removal from the fuel. Most often, this is achieved by (1) adsorption of the entire sulfur-containing molecule in activated carbon, modified zeolites, or other materials such as zinc oxide (ZnO) or (2) adsorption onto metal surfaces such as nickel, wherein nickel sulfide is formed and the remainder of the hydrocarbon is recovered. The former approach is conceptually quite simple to operate, as it can in principle be carried out at ambient temperature and pressure using conventional fixed bed equipment. The other approach is more complicated, requiring a fluidized bed operating at elevated temperatures and pressures. The following equations show the adsorption of entire sulfur by using ZnO:

$$H_2S + ZnO \rightarrow ZnS + H_2O$$

$$C_2H_5SH + ZnO \rightarrow ZnS + C_2H_4 + H_2O$$

$$C_2H_5SH + ZnO \rightarrow ZnS + C_2H_5OH$$

Steam Reforming

Steam reforming is a catalytic process that involves a reaction between natural gas and steam. The product is a mixture of H_2, carbon monoxide (CO), carbon dioxide (CO_2), and water (H_2O). The effluent gas from the steam reformer typically contains about 76 % H_2 (mol.%), 13 % CH_4, 12 % CO, and 10 % CO_2 on a dry basis (Barelli et al. 2008). The following equations show the steam reforming reactions:

$$CH_4 + H_2O \rightarrow CO + 3H_2$$

$$CH_4 + 2H_2O \rightarrow CO_2 + 4H_2$$

These reactions are highly endothermic and a large amount of heat is provided by feeding supplemental natural gas to the furnace. These reactions are typically carried out at a temperature of 800–1000 °C and a pressure of 14–20 atm.

The key issue for steam reforming is to select high-efficiency catalyst, so as to avoid coke formation due to the high operation temperature. The catalysts can be divided into two types: non-precious metal (typically nickel) and precious metals from group VIII elements (typically platinum or rhodium based). For nickel-based catalyst, steam to carbon ratios that are higher than stoichiometry (2.5 or higher) are

required to gasify coke. Coke formation is much less over the noble group VIII metals and these metals, particularly Rh, are preferred since they exhibit much higher specific activities than nickel catalysts. However, the high cost of Rh is driving some researchers to develop alternative catalysts such as Co-based catalysts. In addition, promoters, such as magnesia or potassium or other alkaline components, can be added to the catalyst support to minimize the coke formation.

WGS

The steam reforming process produces a product gas mixture with significant amounts of carbon monoxide. To increase the amount of hydrogen, the product gas is passed through a water–gas shift reactor to decrease the carbon monoxide content while increasing the hydrogen content. The water–gas shift reaction can be expressed as the following:

$$CO + H_2O \rightarrow CO_2 + H_2$$

Typically, a high temperature is desired in order to achieve fast kinetics but results in high-equilibrium carbon monoxide selectivity and decreased hydrogen production due to the exothermic characteristic of water shift reaction. Therefore, the high-temperature WGS reactor is often followed by a low-temperature reactor to decrease CO content to 1 % or less. TeGrotenhuis et al. (2002) have demonstrated the potential of using microreactors to build a gradient-temperature WGS reactor that contains the high-temperature WGS and low-temperature WGS in a single unit for >2–3 kWe units. The most common catalyst for WGS is Cu based, although some interesting work is currently being done with molybdenum carbide, platinum-based catalysts, and Fe-Pd alloy catalysts.

To further reduce the carbon monoxide, a preferential oxidation (PrOx) reactor or a carbon monoxide selective methanation reactor can be used. The PrOx and methanation reactors each have their advantages and challenges. The preferential oxidation reactor increases the system complexity because carefully measured concentrations of air must be added to the system. However, these reactors are compact and if excessive air is introduced, some hydrogen is burned. Methanation reactors are simpler in that no air is required; however, for every molecule of carbon monoxide reacted, three hydrogen molecules are consumed. Also, the carbon dioxide reacts with the hydrogen, so careful control of the reactor conditions need to be maintained in order to minimize unnecessary consumption of hydrogen. Currently, preferential oxidation is the primary technique being developed. The catalysts for both these systems are typically noble metals such as platinum, ruthenium, or rhodium supported on Al_2O_3.

H_2 Purification

The effluent gas from WGS reactors still contains considerable amounts of CO_2, CO, and CH_4 gases. In order to obtain H_2 with purity higher than 99 %, pressure swing adsorption (PSA) processes are designed and conducted after WGS reactors. Production of pure hydrogen by using PSA processes has become the state-of-the-art

technology in the chemical and petrochemical industries. Several 100 PSA-H_2 process units have been installed around the world. In the PSA units, impurity gases with high boiling points are absorbed on the absorbent (zeolites or active carbon) bed at high pressures; however, H_2 can pass through the absorbent bed due to the fact that it has the lowest boiling point. The absorbents are then regenerated by lowering down the unit pressure to release the absorbed impurities. In this way, pure H_2 is separated from the impurities and fed into the plant's H_2 grid. The released impurities (tail gases) are recycled to the steam reformer burners to provide the necessary heat for the endothermic reforming reactions. Currently, the research goals consisted of developing new H_2-PSA processes for (a) increasing the primary and secondary product recoveries while maintaining their high purities and (b) reducing the absorbent inventory and the associated hardware costs. A considerable effort was also made to develop new absorbents or to modify existing absorbents in order to achieve these research goals. It became a common practice to use more than one type of absorbents in these PSA processes (as layers in the same absorbent vessel or as single absorbents in different vessels) in order to obtain optimum absorption capacity and selectivity for the feed gas impurities while reducing the coabsorption of H_2, as well as for their efficient desorption under the operating conditions of the PSA processes.

Oil Reforming

Oil reforming is another significant commercial H_2 production technology. Comparing with heavy oil, such as bitumen or residual oil, which is easier to suffer from coke formation resulting to catalyst deactivation, light oil with relatively low molecular weight is much favorable to produce H_2. Generally, four reforming techniques, namely, steam reforming, partial oxidation (POX), autothermal reforming (ATR), and pyrolysis, are used to produce hydrogen from oil (Holladay et al. 2009). In fact, these techniques can also use methane as raw material and all should proceed with the similar four steps as mentioned in steam methane reforming (section "Steam Methane Reforming (SMR)"): desulfurization, reforming (steam), water–gas shift (WGS), and purification (not necessary for pyrolysis). This section will mainly focus on the distinction among each technology.

Steam Reforming

Steam reforming is typically the preferred process for hydrogen production in industry, using either natural gas or oil. The mechanism can be expressed by the following equation:

$$C_mH_n + mH_2O \rightarrow mCO + \left(m + \frac{n}{2}\right)H_2$$

Oil steam reforming is an endothermic reaction and requires an external heat source. It has advantages of not requiring oxygen, having a lower operating temperature than

POX and ATR, and producing syngas with a high H_2/CO ratio (~3:1) which is beneficial for H_2 production. However, it does have the highest emissions of the three processes. The catalysts used for oil steam reforming are similar to those in the SMR process. Developing improved and economically available catalysts with high resistance to coke formation is the main research goal.

Partial Oxidation (POX)

Partial oxidation (POX) of hydrocarbons and catalytic partial oxidation (CPOX) of oil have been proposed for use in hydrogen production for automobile fuel cells and some commercial applications. It converts oil to hydrogen by partially oxidizing (combusting) the material with oxygen, as shown in the equation:

$$C_mH_n + \frac{m}{2}O_2 \rightarrow mCO + \frac{n}{2}H_2$$

Partial oxidation has advantages of minimal methane slip, higher sulfur tolerance, and beneficial H_2/CO ratio (1:1 to 2:1) favored for the feeds to hydrocarbon synthesis reactors such as Fischer–Tropsch. However, in order to reduce coke formation, the non-catalytic partial oxidation process needs operating at high temperatures (1300–1500 °C). Although catalysts can be added to the partial oxidation system to lower the operating temperatures, it is proving hard to control temperature because of coke and hot spot formation due to the exothermic nature of the reactions. Krummenacher et al. (2003) have had success using catalytic partial oxidation for decane, hexadecane, and diesel fuel. But the high operating temperatures (>800 °C and often >1000 °C) (Krummenacher et al. 2003) and safety concerns may make their use for practical, compact, portable devices difficult due to thermal management (Holladay et al. 2004). In addition, this process requires an expensive and complex oxygen separation unit in order to feed pure oxygen to the reactor.

Autothermal Reforming (ATR)

Autothermal reforming adds steam to catalytic partial oxidation (CPOX). The reaction mechanism can be expressed as:

$$C_mH_n + \frac{m}{2}H_2O + \frac{m}{4}O_2 \rightarrow mCO + \left(\frac{m}{2} + \frac{n}{2}\right)H_2$$

Autothermal reforming is typically conducted at a lower pressure than POX reforming and has a low methane slip. It consists of a thermal zone where POX or CPOX is used to generate the heat needed to drive the downstream steam reforming reactions in a catalytic zone. The heat from the POX negates the need for an external heat source, simplifying the system and decreasing the start-up time. A significant advantage for this process over steam reforming is that it can be stopped and started very rapidly while producing a larger amount of hydrogen than POX alone. There is some expectation that this process will gain favorability with the gas–liquids industry due to favorable gas composition for the Fischer–Tropsch synthesis, ATR's relative compactness, lower capital cost, and potential for economies of scale

(Wilhelm et al. 2001). However, for ATR to operate properly, both the oxygen to fuel ratio and the steam to carbon ratio must be properly controlled at all times in order to control the reaction temperature and product gas composition while preventing coke formation. Similar to POX, this process also needs an expensive oxygen separation unit.

Pyrolysis

Pyrolysis is another H_2 production technology where the raw oil is decomposed (without water or oxygen present) into hydrogen and carbon. The reactions can be written in the following form:

$$C_mH_n \rightarrow mC + \frac{n}{2} H_2$$

Since no water or air is present, no carbon oxides (e.g., CO or CO_2) are formed, eliminating the need for secondary reactors (WGS, PrOx, PSA, etc.). Thus, this process offers significant emission reduction. Among the advantages of this process are fuel flexibility, relative simplicity and compactness, clean carbon by-product, and reduction in CO_2 and CO emissions. One of the challenges with this approach is the potential for fouling by the carbon formed, but proponents claim this can be minimized by appropriate design (Guo et al. 2005). Pyrolysis may play a significant role in the future. In Norway, the Kvaerner Oil and Gas Company has developed an attractive technique to simultaneously produce carbon and H_2 by oil plasma pyrolysis. It is said that this technique has an energy efficiency of 1.1 kW h m^{-3} H_2, and the commercial operation is feasible now.

Coal Gasification

Coal is an abundant energy source in many parts of the world. H_2 production by coal gasification is considered to be a promising option before economical H_2 production pathways from renewable energy sources are developed. Coal gasification can be defined as the reaction of solid fuels with air, oxygen, steam, carbon dioxide, or a mixture of these gases at a temperature exceeding 700 °C to yield a gaseous product suitable for use either as a source of energy or as a raw material for the synthesis of chemicals, liquid fuels, or other gaseous fuels. Figure 2 shows the diagram of a typical gasification process. Coal gasification is currently used to produce H_2 as an intermediate for the synthesis of chemicals. However, large-scale H_2 production project mainly for power generation is also under development. A well-known example is the FutureGen project sponsored by the department of energy (DOE) in the USA, which is a 10-year, US$ 1 billion, demonstration project started from February 2003 (Collot 2006). This section shows not only the three main conventional coal gasification technologies – moving bed gasification, fluidized bed gasification, and entrained flow gasification – but also an alternative method, denoted underground coal gasification (UCG).

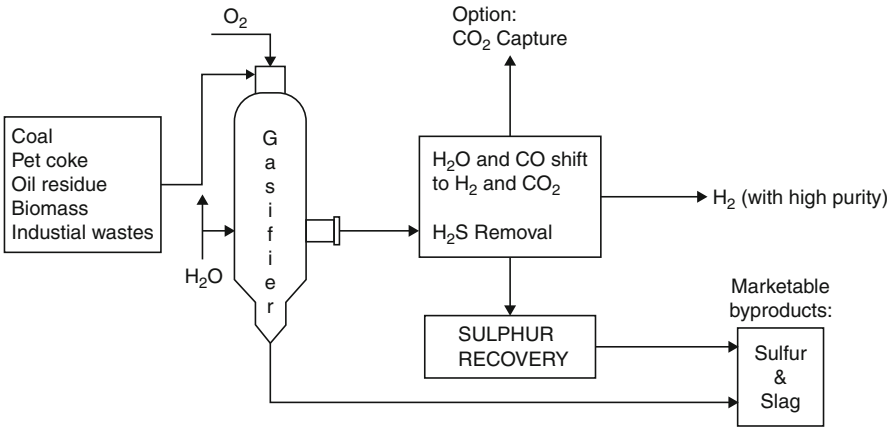

Fig. 2 A diagram of a typical gasification process

Moving Bed Gasification

Moving bed gasification is only suitable for solid fuels with a particle size in the range of 5–80 mm. Typically, a mixture of steam and oxygen is introduced at the bottom of the reactor and runs counterflow to the coal. Coal residence times in moving bed gasifiers are of the order of 15–60 min for high-pressure steam/oxygen gasifiers and can be several hours for atmospheric steam/air gasifiers. The pressure in the bed is typically of the order of 3 MPa for commercial gasifiers with tests realized at up to 10 MPa. Maximum temperatures in the combustion zone are typically in the range of 1500–1800 °C for slagging gasifiers and 1300 °C for dry ash gasifiers. Although moving bed gasifiers are presently less used than entrained flow gasifiers for the construction of new power plants, moving bed gasification presents the advantage of being a mature technology. The main requirement of moving bed gasifiers is good bed permeability to avoid pressure drops and channel burning that can lead to unstable gas outlet temperatures and composition as well as risk of a downstream explosion. A typical advanced moving bed technique is the British Gas/Lurgi (BGL) technology (Bailey 2001). It is said that this technology will be adopted in the Kentucky Pioneer Energy project, which is an Integrated Coal Gasification Combined Cycle (IGCC) project cosponsored by Global Energy Inc and DOE of USA. Table 1 shows the process characteristics of BGL technology.

Fluidized Bed Gasification

Fluidized bed gasification can only operate with solid crushed coals in the range of 0.5–5 mm. Coals are introduced into an upward flow of gas (either air or oxygen/steam) that fluidizes the bed of fuel while the reaction is taking place. The bed is either formed of sand/coke/char/sorbent or ash. Residence time of the feed in the gasifier is typically in the order of 10–100 s but can also be much longer, with the feed experiencing a high heating rate from the entry in the gasifier. High levels of

Table 1 Process characteristics of BGL technology (Collot 2006; Fc and Yf 2006)

Feeding mode and operating conditions	Lumped coal together with a flux is discharged at the top of the gasifier as a sequence of batches. A distributor plate slowly rotates to ensure even distribution of the coal
Gasifier	Double-walled cylindrical reactor surrounded by a steam jacket. O_2 and steam are added toward the bottom of the bed through tuyeres, resulting in high internal temperature within the gasifier (2000 °C)
Ash removal system	Slagging gasifier. Molten ash is tapped off and quenched with water
Cooling and cleaning modes	Tars, high-boiling-point hydrocarbons and particulates are removed in a quench vessel and reinjected in the bed near the tuyeres. The gas (450–500 °C) is cooled and cleaned by a water quench and scrubbed to remove H_2S
Remarks	It is a slagging gasifier modified from the Lurgi dry ash gasifier and not suitable for high reactive coals. O_2 consumption is higher than Lurgi dry ash gasifier. It is still difficult to develop very large commercial unit meeting the demand for large-scale industrial gasifier

back-mixing ensure a uniform temperature distribution in the gasifier. Fluidized bed gasifiers usually operate at temperatures well below the ash fusion temperatures of the fuels (900–1050 °C) to avoid ash melting, thereby avoiding clinker formation and loss of fluidity of the bed. The low operating temperatures may lead to incomplete carbon conversion of coal, but this can be overcome by char recirculation into the gasifier. Advanced fluidized bed gasifiers are also operated at elevated pressures. Among the main advantages of this type of gasifier are that they can operate at variable loads and more tolerant to coals with high sulfur content. But for fluidized bed gasification, it is necessary to process coals with a higher ash fusion temperature than the operating temperature of the gasifier to avoid ash agglomeration (which causes uneven fluidization in dry ash, fluidized bed gasifiers). Two types of fluidized bed gasification technologies have been operated at commercial scale. They are High-Temperature Winkler (HTW) and Kellogg Rust Westinghouse (KRW) gasification technologies, respectively, both of which can be used in IGCC plants. Table 2 gives the process characteristics of HTW and KRW technologies.

Entrained Flow Gasification

In entrained flow gasifiers, coal particles concurrently react at high speed with steam and oxygen or air in a suspension mode called entrained fluid flow. Short gas residence times (seconds) give them a high load capacity but also require coal to be pulverized. Coal can either be fed dry (commonly using nitrogen as a transport gas) or wet (carried in slurry water) into the gasifier. They usually operate at high temperatures of 1200–1600 °C and pressures in the range of 2–8 MPa. Although entrained flow gasifiers are the most widely used gasifiers, more critical operational requirements are needed compared to moving bed and fluidized gasifiers, such as

Table 2 Process characteristics of HTW and KRW technologies (Collot 2006; Fc and Yf 2006)

HTW	
Feeding mode and operating conditions	Coal dropped from a bin via a gravity pipe into the gasifier. Operating pressure is 1–3 MPa
Gasifier	Bed is formed of particles of ash, semicoke, and coal and is maintained at 800 °C
Ash removal system	Dry ash removal through a discharge screw
Cooling and cleaning modes	Using cyclone to remove particulates, water, or fire tube cooling system
Remarks	Plan to replace old Lurgi dry ash reactors at Vresova IGCC plant in Czech Republic. It is promising due to the elevated operation temperature and pressure compared to the conventional Winkler gasifier
KRW	
Feeding mode and operating conditions	Lock hoppers, operating pressure is up to 2 MPa
Gasifier	Coal partial combustion around the feed nozzle forming 1150–1260 °C high temperature zone
Ash removal system	Ash agglomerating to large particles then separated from the remaining coal char
Cooling and cleaning modes	Raw gas is cooled from 900 °C to 600 °C and enters a hot gas cleaning system. A portion of the gas is recycled to the gasifier
Remarks	Used in the Pinon Pine IGCC plant. Carbon content in the ash can be greatly lowered down

significant cooling of the raw syngas before being cleaned; controlling the coal/oxidant ratio within narrow limits through the entire operation in order to maintain a stable flame close to the injector tip; and strict requests on coal properties including a minimum ash content required for gasifiers with slag self-coating walls, a maximum ash content fixed for each type of entrained flow gasifier, ash composition (SiO_2, CaO, iron oxides) limitations to avoid the refractory cracking, optimum ash fusion temperature and critical temperature viscosity recommended for smooth slag tapping, etc. Entrained flow gasification is the most widely used technology. Table 3 shows the process characteristics of Texaco and Shell technologies, representing the wet feed and dry feed entrained flow gasification, respectively.

Underground Coal Gasification

Underground coal gasification does not need the construction of surface plants. In the process, injection and production wells are drilled from the surface and linked together in a coal seam. Once the wells are linked, air or oxygen is injected, and the coal is ignited in a controlled manner. Water present in the coal seam or in the surrounding rocks flows into the cavity formed by the combustion and is utilized in the gasification process. The produced gases (primarily H_2, CO, CH_4, and CO_2) can be used to generate electric power or synthesize chemicals after being cleaned. The

Table 3 Process characteristics of Texaco and Shell technologies (Collot 2006; Fc and Yf 2006)

Texaco	
Feeding mode and operating conditions	Slurry fed through burners at the top of the gasifier. Operate at temperatures in the range of 1250–1450 °C and 3–8 MPa pressures
Gasifier	Pressure vessel with refractory lining
Ash removal system	The molten slag flows out toward the bottom of the gasifier with the raw gas and is water quenched and removed through a lock hopper
Cooling and cleaning modes	Raw gas can either be cooled or cleaned from slag by water quenching or radiant cooler
Remarks	There are six Texaco-owned gasification facilities worldwide that produce power, chemicals, and H_2 from coal. It has wide applicability to various coal types
Shell	
Feeding mode and operating conditions	Coal powders are transported by N_2 gases, operation at 2–4 MPa, at 1500 °C and above
Gasifier	A carbon steel vessel enclosed by a non-refractory membrane wall
Ash removal system	Molten slag is removed through a slag tap and water quenched
Cooling and cleaning modes	Syngas is quenched with cooled recycled product gas and further cooled in a syngas cooler. Raw gas is cleaned in ceramic filters. Fifty percent gas is recycled to act as a quenching medium
Remarks	There are five gasification plants using the Shell gasification technology till 2006. Only the Nuon Power Buggenum IGCC plant in the Netherlands is fed with coal. More plants are planned to be built in China and the USA

former Soviet Union (FSU) performed intensive research on UCG from 1930s to 1960s, and over 15 Mt of coal has been gasified underground in the FSU, generating 50 Gm^3 of gas. Due to the discovery of extensive natural gas in Siberia in 1970s, FSU declined the usage of UCG. As a result of the increasing energy needs in recent years, interest in UCG has been rejuvenated all over the world (Shafirovich and Varma 2009). It is said that China is generally believed to have the largest UCG program currently underway. A pilot industrial UCG plant at the Gonggou coal mine, Wulanchabu, Northern Inner Mongolia Autonomous Region, is under construction. This $112 million project is a joint venture between the China University of Mining and Technology and Hebei Xin'ao Group. The UCG process has several advantages over surface coal gasification such as lower capital investment costs (due to the absence of a manufactured gasifier), no handling of coal and solid wastes at the surface (ash remains in the underground cavity), no human labor or capital for underground coal mining, minimum surface disruption, no coal transportation costs, and direct use of water and feedstock available in situ. In addition, cavities formed as a result of UCG could potentially be used for CO_2 sequestration. However, construction of a UCG process is quite complex as lots of criteria should be strictly considered, such as the coal seam conditions (thickness, depth, coal seam dip, coal amount and ranks), groundwater protection, and land-use restrictions.

Hydrogen Production from Biomass

Biomass comprises all the living matter present on earth. It is derived from growing plants including algae, trees, and crops or from animal manure. The biomass resources are the organic matters in which the solar energy is stored in chemical bonds. It generally consists of carbon, hydrogen, oxygen, and nitrogen. Sulfur is also present in minor proportions. Some biomass also consists of significant amounts of inorganic species. Biomass is the fourth largest source of energy in the world, accounting for about 12 % of the world's primary energy consumption in and about 22 % of the primary energy consumption in the developing countries in 2006 (Loo and Koppejan 2008). Since biomass is renewable and consumes atmospheric CO_2 during growth, it can have a small net CO_2 impact compared to fossil fuels. Biomass can be converted into useful forms of energy products using a number of different processes. Generally, there are two routes for biomass conversion into hydrogen-rich gas, namely, (i) thermochemical conversion and (ii) biochemical/biological conversion. The yield of hydrogen is low from biomass since the hydrogen content in biomass is low to begin with (approximately 6 % vs. 25 % for methane) and the energy content is low due to the 40 % oxygen content of biomass. Thus, hydrogen from biomass has major challenges. There are no completed technology demonstrations (Kalinci et al. 2009). However, biomass still has the potential to accelerate the realization of hydrogen as a major fuel of the future.

Thermochemical Conversions

Thermochemical conversion involves a series of cyclical chemical reaction for releasing hydrogen. There are main three methods for biomass-based hydrogen production via thermochemical conversions: (i) pyrolysis, (ii) conventional gasification, and (iii) SCWG (supercritical water gasification), respectively.

Pyrolysis

Pyrolysis is the heating of biomass at a temperature of 650–800 K at 0.1–0.5 MPa in the absence of air to convert biomass into liquid oils, solid charcoal, and gaseous compounds. Pyrolysis can be further classified into slow pyrolysis and fast pyrolysis. As the products are mainly charcoal, slow pyrolysis is normally not considered for hydrogen production. Fast pyrolysis is a high-temperature process, in which the biomass feedstock is heated rapidly in the absence of air to form vapor and subsequently condensed to a dark brown mobile bio-liquid. The products of fast pyrolysis can be found in all gas, liquid, and solid phases:

(i) Gaseous products include H_2, CH_4, CO, CO_2, and other gases depending on the organic nature of the biomass for pyrolysis.
(ii) Liquid products include tar and oils that remain in liquid form at room temperature like acetone, acetic acid, etc.

(iii) Solid products are mainly composed of char and almost pure carbon plus other inert materials.

Although most pyrolysis processes are designed for biofuel production, hydrogen can be produced directly through fast or flash pyrolysis if high temperature and sufficient volatile phase residence time are allowed as follows:

$$\text{Biomass} + \text{heat} \rightarrow H_2 + CO + CH_4 + \text{otherproducts}$$

Methane and other hydrocarbon vapors produced can be steam reformed for more hydrogen production:

$$CH_4 + H_2O \rightarrow CO + 3H_2$$

In order to increase the hydrogen production, water–gas shift reaction can be applied as follows:

$$CO + H_2O \rightarrow CO_2 + H_2$$

Besides the gaseous products, the oily products can also be processed for hydrogen production. The pyrolysis oil can be separated into two fractions based on water solubility. The water-soluble fraction can be used for hydrogen production while the water-insoluble fraction for adhesive formulation. Experimental study has shown that when Ni-based catalyst is used, the maximum yield of hydrogen can reach 90 %. With additional steam reforming and water–gas shift reaction, the hydrogen yield can be increased significantly.

Temperature, heating rate, residence time, and type of catalyst used are important pyrolysis process control parameters. In favor of gaseous products especially in hydrogen production, high temperature, high heating rate, and long volatile phase residence time are required. These parameters can be regulated by selection among different reactor types and heat transfer modes, such as gas–solid convective heat transfer and solid–solid conductive heat transfer. Fluidized bed reactor exhibits higher heating rates, and thus, it appears to be the promising reactor type for hydrogen production from biomass pyrolysis.

Some inorganic salts, such as chlorides, carbonates, and chromates, exhibit beneficial effect on pyrolysis reaction rate. As tar is difficult to be gasified, extensive studies on the catalytic tar elimination were carried out to converting more tar into product gases (Han and Kim 2008; Shen and Yoshikawa 2013). Effect of inexpensive dolomite and CaO on the decomposition of hydrocarbon compounds in tar has been conducted (Simell et al. 1997). The catalytic effects of other catalysts (Ni-based catalysts, Y-type zeolite, K_2CO_3, Na_2CO_3, and $CaCO_3$) and various metal oxides (Al_2O_3, SiO_2, ZrO_2, TiO_2, and Cr_2O_3) have also been investigated. Among the different metal oxides, Al_2O_3 and Cr_2O_3 exhibit better catalytic effect than the others. Among the catalysts, Na_2CO_3 is better than K_2CO_3 and $CaCO_3$. Although noble metals Ru and Rh are more effective than Ni catalyst and less susceptible to

carbon formation, they are not commonly used due to their high costs (Garcia et al. 2000).

In order to evaluate hydrogen production through pyrolysis of various types of biomass, extensive experimental investigations have been conducted in recent years. Agricultural residues; peanut shell; postconsumer wastes such as plastics, trap grease, mixed biomass, and synthetic polymers; and rapeseed have been widely tested for pyrolysis for hydrogen production. In order to solve the problem of decreasing reforming performance caused by char and coke deposition on the catalyst surface and in the bed itself, fluidized catalyst beds are usually used to improve hydrogen production from biomass-pyrolysis-derived biofuel. Yeboah et al. (2002) constructed a demonstration plant for hydrogen production from peanut shell pyrolysis and steam reforming in a fluidized bed reactor, and the production rates of 250 kg H_2/day was achieved. Padro and Putsche (1999) estimated the hydrogen production cost of biomass pyrolysis to be in the range of US$ 8.86/GJ to US$ 15.52/GJ depending on the facility size and biomass type. For comparison, the costs of hydrogen production by wind-electrolysis systems and PV-electrolysis systems are US$ 20.2/GJ and US$ 41.8/GJ, respectively. It can be seen that biomass pyrolysis is a competitive method for renewable hydrogen production. Demirbas (2006) carried out pyrolysis and gasification experiments in a self-designed device, and the highest yields (% dry and ash free basis) were obtained from the pyrolysis (46 %) and steam gasification (55 %) of wheat straw while the lowest yields from olive waste. Yang et al. (2006) studied on pyrolysis of palm oil wastes in a countercurrent fixed bed. The total gas yield was enhanced greatly while the temperature increased from 500 °C to 900 °C and reached the maximum value (∼70 wt.%, on the raw biomass sample basis) at 900 °C with big portions of H_2 (33.49 vol.%) and CO (41.33 vol.%). The optimum residence time (9 s) was found to get a higher H_2 yield (10.40 g/kg (daf)). The effect of adding chemicals (Ni, γ-Al_2O_3, Fe_2O_3, La/Al_2O_3, etc.) on gas product yield was investigated, and adding Ni showed the greatest catalytic effect with the maximum H_2 yield achieved at 29.78 g/kg (daf).

Gasification

Gasification is the conversion of biomass into a combustible gas mixture via the partial oxidation at high temperatures, typically varying from 800 °C to 900 °C. It is applicable to biomass having moisture content less than 35 %. Biomass is converted completely to CO and H_2 although in practice, some CO_2, water, and other hydrocarbons including methane in an ideal gasification. The char compositions occurring by the fast pyrolysis of biomass can be gasified with gasifying agents. Air, oxygen, and steam are widely used gasifying agents. Reaction conditions along with heating values are mentioned as follows:

(i) Oxygen gasification: It yields a better quality gas of heating value of 10–15 MJ/Nm^3. In this process, the temperatures between 1000 °C and 1400 °C are achieved. O_2 supply may bring a simultaneous problem of cost and safety.
(ii) Air gasification: It is most widely used technology as being cheap, single product is formed at high efficiency and without requiring oxygen.

A low-heating value gas is produced containing up to 60 % N_2 having a typical heating value of 4–6 MJ/Nm^3 with by-products such as water, CO_2, hydrocarbons, tar, and nitrogen gas. The reactor temperatures between 900 °C and 1100 °C have been achieved.

(iii) Steam gasification: Biomass steam gasification converts carbonaceous material to permanent gases (H_2, CO, CO_2, CH_4, and light hydrocarbons), char, and tar. This method has some problems such as corrosion, poisoning of catalysts, and minimizing tar components.

Hydrogen can be produced from the gasification gaseous products through the same procedure of steam reforming and water–gas shift reaction as discussed in the pyrolysis section. As the products of gasification are mainly gases, this process is more favorable for hydrogen production than pyrolysis. In order to optimize the process for hydrogen production, a number of efforts have been made by researchers to test hydrogen production from biomass gasification with various biomass types and at various operating conditions. Using a fluidized bed gasifier along with suitable catalysts, it is possible to achieve hydrogen production about 60 vol.%. Such high conversion efficiency makes biomass gasification an attractive hydrogen production alternative. In addition, the costs of hydrogen production by biomass gasification are competitive with natural gas reforming. Taking into account the environmental benefit as well, hydrogen production from biomass gasification should be a promising option based on both economic and environmental considerations.

One of the major issues in biomass gasification is to deal with the tar formation that occurs during the process. The unwanted tar may cause the formation of tar aerosols and polymerization to a more complex structure, which are not favorable for hydrogen production through steam reforming. Currently, three methods are available to minimize tar formation: (i) proper design of gasifier, (ii) proper control and operation, and (iii) proper additives/catalysts. The operation parameters, such as temperature, gasifying agent, and residence time, play an important role in the formation and decomposition of tar. It has been reported that tar could be thermally cracked at temperature above 1273 K (Milne et al. 1998). The use of some additives (dolomite, olivine, and char) inside the gasifier also helps tar reduction. When dolomite is used, 100 % elimination of tar can be achieved (Sutton et al. 2001). Catalysts not only reduce the tar content but also improve the gas product quality and conversion efficiency. Dolomite, Ni-based catalysts, and alkaline metal oxides are widely used as gasification catalysts. Researches on iron-based catalysts and the novel carbon-supported catalysts were reported recently (Xu et al. 2010). Process modifications by two-stage gasification and secondary air injection in the gasifier are also useful for tar reduction.

Another problem of biomass gasification is the formation of ash that may cause deposition, sintering, slagging, fouling, and agglomeration. To resolve the ash-associated problems, fractionation and leaching have been employed to reduce ash formation inside the reactor. Though fractionation is effective for ash removal, it may deteriorate the quality of the remaining ash. On the other hand, leaching can

remove biomass' inorganic fraction, as well as improve the quality of the remaining ash. More recently, gasification of leached olive oil waste in a circulating fluidized bed reactor was reported for gas production that demonstrated the feasibility of leaching as a pretreatment technique for gas production (Garcıa-Ibañez et al. 2004).

Supercritical Water Gasification (SCWG)

The properties of water displayed beyond critical point plays a significant role for chemical reactions, especially in the gasification process. Below the critical point, both the liquid and gas phases exhibit different properties, although it is apparent that these properties become increasingly alike as the temperature arises. Ultimately, when it reaches the critical point (temperature >374 °C, pressure >22 MPa), the properties of both liquid and gas become identical. Over the critical point, the properties of this SCW vary in between liquid-like or gas-like conditions. SCW is completely miscible with organic substance as well as with gases. When biomass has high moisture content above 35 %, it is likely to gasify biomass in a supercritical water condition, where biomass can be rapidly decomposed into small molecules or gases in a few minutes at a high efficiency. Supercritical water gasification is a promising process to gasify biomass with high moisture contents due to the high gasification ratio (100 % achievable), high hydrogen volumetric ratio (50 % achievable), and avoidance of biomass drying.

In the past 25 years, the US Pacific Northwest Laboratory, Hawaii Natural Energy Institute, Forschungszentrum Karlsruhe in Germany, National Institute for Resources and Environment in Japan, State Key Laboratory of Multiphase Flow in Power Engineering in China (Guo et al. 2007), and other research institutions have had some in-depth researches on the hydrogen production by SCWG of some organic compounds without catalysts. Studies covered glucose, methanol, cellulose, lignin, and some real biomass compounds and organic waste/water. As successful demonstrations have been accumulated, detailed reaction mechanism, kinetics, and thermodynamics have built a solid foundation for subsequent investigations (Guo et al. 2010). And in recent years, extensive research has been carried out to evaluate the suitability of various wet biomass gasification in supercritical water conditions. However, the works have been mostly on a laboratory scale and in an early development stage.

The solubility of biomass components in hot-compressed water has been first studied by Mok and Antal (1992). The results show that in hot-compressed waters, about 40–60 % of the biomass sample is soluble, though the reaction is maintained slightly below the critical water condition. Minowa et al. (1998) reported hydrogen production from cellulose gasification in hot-compressed water (subcritical) using nickel catalyst. Resende and Savage (2010) gasified cellulose and lignin in supercritical water, using quartz reactors, and quantified the catalytic effect of metals by adding them to these reactors in different forms. Yu et al. (1993) reported that the gasification of glucose at supercritical water condition, such as 873 K and 34.5 MPa, was different from the nonsupercritical water condition. One advantage is that, during gasification, neither tar nor char formation occurs. This early finding

stimulated extensive interests in supercritical water research. Using glucose as a model compound, hydrogen yield of more than 50 vol.% can be achieved with the use of proper catalysts in supercritical water condition. Tubular reactors are widely used in supercritical water gasification because of their robust structures to withstand high pressure. Calzavara et al. (2005) made an evaluation of the energy efficiency of biomass gasification, and results show that the energy efficiency from thermodynamic calculation reaches 60 % when considering hydrogen, carbon monoxide, and methane as valuable species in the ideal case. Including energy recovery from the water at 280 bar and 740 °C, the overall energy yield reaches 90 %, if the heat loss is ignored. Although supercritical water gasification is still at its early development stage, the technology has already shown its economic competitiveness with other hydrogen production methods. Spritzer and Hong (2003) have estimated the cost of hydrogen produced by supercritical water gasification to be about US$ 3/GJ (US$ 0.35/kg).

Hydrogen production from biomass thermochemical processes has already been shown to be attractive economically and demonstrated to be a feasible option. However, it should be noted that hydrogen gas is normally produced together with other gas constituents. Thus, separation and purification of hydrogen gas are required. Nowadays, several methods, such as CO_2 absorption, drying/chilling, and membrane separation, have been successfully developed for hydrogen gas purification. It is expected that biomass thermochemical conversion processes will be available for large-scale hydrogen production in the near future.

Biological Conversion

Another method for biomass-based hydrogen is biological conversions. These are summarized as photosynthesis process, fermentative hydrogen production, and hydrogen production by BWGS (biological water–gas shift reaction). All processes depend on hydrogen production enzymes.

Photosynthesis Process

Many phototropic organisms, such as purple bacteria, green bacteria, cyanobacteria, and several algae can be used to produce hydrogen with the aid of solar energy. Microalgae, such as green algae and cyanobacteria, absorb light energy and generate electrons. The electrons are then transferred to ferredoxin (FD) using the solar energy absorbed by photosystem. However, the mechanism varies from organism to organism but the main steps are similar.

Direct Biophotolysis

Direct biophotolysis of hydrogen production is a biological process using microalgae photosynthetic systems to convert solar energy into chemical energy in the form of hydrogen:

$$2H_2O \overset{\text{solar energy}}{\rightarrow} 2H_2 + O_2$$

Two photosynthetic systems are responsible for photosynthesis process: (i) photosystem I (PSI) producing reductant for CO_2 reduction and (ii) photosystem II (PSII) splitting water and evolving oxygen. In the biophotolysis process, two photons from water can yield either CO_2 reduction by PSI or hydrogen formation with the presence of hydrogenase. In green plants, due to the lack of hydrogenase, only CO_2 reduction takes place. On the contrary, microalgae, such as green algae and cyanobacteria (blue-green algae), contain hydrogenase and, thus, have the ability to produce hydrogen. In this process, electrons are generated when PSII absorbs light energy. The electrons are then transferred to the ferredoxin (Fd) using the solar energy absorbed by PSI.

Since hydrogenase is sensitive to oxygen, it is necessary to maintain the oxygen content at a low level under 0.1 % so that hydrogen production can be sustained. This condition can be obtained by the use of green algae *Chlamydomonas reinhardtii* that can deplete oxygen during oxidative respiration. However, due to the significant amount of substrate being respired and consumed during this process, the efficiency is low. Recently, mutants derived from microalgae were reported to have good O_2 tolerance and thus higher hydrogen production. The efficiency can be increased significantly using mutants for hydrogen production.

Benemann (1998) estimated the cost of direct biophotolysis for hydrogen production to be \$20/GJ assuming that the capital cost is about US\$ 60/m^2 with an overall solar conversion efficiency of 10 %. Hallenbeck and Benemann (2002) performed similar cost estimation and reported the capital cost of US\$ 100/m^2. However, in their estimation, some practical factors were neglected, such as gas separation and handling.

Indirect Biophotolysis

The concept of indirect biophotolysis involves the following four steps: (i) biomass production by photosynthesis; (ii) biomass concentration; (iii) aerobic dark fermentation yielding 4 mol hydrogen/mol glucose in the algae cell, along with 2 mol of acetates; and (iv) conversion of 2 mol of acetates into hydrogen. In a typical indirect biophotolysis, cyanobacteria are used to produce hydrogen via the following reactions:

$$12H\pm_2O + 6CO_2 \rightarrow C_6H_{12}O_6 + 6O_2$$

$$C_6H_{12}O_6 + 12H_2O \rightarrow 12H_2 + 6CO_2$$

Markov et al. (1997) investigated the indirect biophotolysis with cyanobacterium *Anabaena variabilis* exposed to light intensities of 45–55 A mol^{-1} m^{-2} and 170–180 A mol^{-1} m^{-2} in the first stage and second stage, respectively. Photoproduction of hydrogen at a rate of about 12.5 ml H_2/gcdw h (cdw, cell dry weight) was found. In the study on indirect biophotolysis with cyanobacterium *Gloeocapsa alpicola* by Troshina et al. (2002), it was found that maintaining the

medium at pH value between 6.8 and 8.3 yielded optimal hydrogen production. Increasing the temperature from 30 °C to 40 °C can increase the hydrogen production twice as much. The hydrogen production rate through indirect biophotolysis is comparable to hydrogenase-based hydrogen production by green algae. The estimated overall cost is US$ 10/GJ of hydrogen (Hallenbeck and Benemann 2002). However, it should be pointed out that indirect biophotolysis technology is still under active research and development. The estimated cost is subject to a significant change depending on the technological advancement.

Fermentative Hydrogen Production

Bio hydrogen production can be realized by anaerobic (dark fermentation) and photoheterotrophic (light fermentation) microorganisms using carbohydrate-rich biomass as a renewable resource. The first step is the acid or enzymatic hydrolysis of biomass to highly concentrated sugar solution which is further fermented by anaerobic organisms to produce volatile fatty acids (VFA), hydrogen, and CO_2. The organic acids are further fermented by the photoheterotrophic bacteria (*Rhodobacter* sp) to produce CO_2 and H_2 which is known as the light fermentation. Combined utilization of dark and photo-fermentations was reported to improve the yield of hydrogen formation from carbohydrates.

Dark Fermentation

Fermentation by anaerobic bacteria as well as some microalgae, such as green algae on carbohydrate-rich substrates, can produce hydrogen at 30–80 °C especially in a dark condition. Unlike a biophotolysis process that produces only H_2, the products of dark fermentation are mostly H_2 and CO_2 combined with other gases, such as CH_4 or H_2S, depending on the reaction process and the substrate used. With glucose as the model substrate, maximum 4 mol H_2 is produced per mole glucose when the end product is acetic acid:

$$C_6H_{12}O_6 + 2H_2O \rightarrow 2CH_3COOH + 4H_2 + 2CO_2$$

When the end product is butyrate, 2 mol H_2 is produced:

$$C_6H_{12}O_6 + 2H_2O \rightarrow CH_2CH_2CH_2OOH + 2H_2 + 2CO_2$$

However, in practice, the 4 mol H_2 production/mol glucose cannot be achieved because the end products normally contain both acetate and butyrate. The amount of hydrogen production by dark fermentation highly depends on the pH value, hydraulic retention time (HRT), and gas partial pressure. For the optimal hydrogen production, pH should be maintained between 5 and 6. Partial pressure of H_2 is yet another important parameter affecting the hydrogen production. When hydrogen concentration increases, the metabolic pathways shift to produce more reduced substrates, such as lactate, ethanol, acetone, butanol, or alanine, which in turn decrease the hydrogen production. Besides the pH value and partial pressure, HRT (hydraulic retention time) also plays an important role in hydrogen production. Ueno

et al. (1996) have reported that an optimal HRT of 0.5 day could affect maximum hydrogen production (14 mmol/g carbohydrate) from wastewater by anaerobic microflora in the presence of chemostat culture. When HRT was increased from 0.5 day to 3 days, hydrogen production rate was reduced from 198 to 34 mmol l^{-1} day^{-1}, while the carbohydrates in the wastewater were decomposed at an increasing efficiency from 70 % to 97 %. Due to the fact that solar radiation is not a requirement, hydrogen production by dark fermentation does not demand much land and is not affected by the weather condition. Hence, the feasibility of the technology yields a growing commercial value.

Photo-Fermentation

Photosynthetic nonsulfur (PNS) bacteria have the ability to convert VFAs to H_2 and CO_2 under anoxygenic conditions. PNS bacteria also have the ability to use carbon sources like glucose, sucrose, and succinate rather than VFA for H2 production. The most widely known PNS bacteria used in photo-fermentative H_2 production are *Rhodobacter sphaeroides* O.U001, *Rhodobacter capsulatus*, *R. sphaeroides-RV*, *Rhodobacter sulfidophilus*, *Rhodopseudomonas palustris*, and *Rhodospirillum rubrum* (Argun and Kargi 2011).

As presented in the equation below, theoretically 4 mol of H_2 can be produced from 1 mol of acetic acid when acetic acid is the only VFA present in fermentation medium:

$$CH_3COOH + 2H_2O \rightarrow 4H_2 + 2CO_2,\ \Delta G^{\circ} = +104\text{kJ}$$

Hydrogen can be produced by photo-fermentation of various types of biomass wastes. However, these processes have three main drawbacks: (i) use of nitrogenase enzyme with high-energy demand, (ii) low solar energy conversion efficiency, and (iii) demand for elaborate anaerobic photobioreactors covering large areas. Hence, at the present time, photo-fermentation process is not a competitive method for hydrogen production.

Design of photobioreactors enabling efficient H_2 production is still a challenge. Light distribution inside photobioreactors constitutes the most important parameter effecting H_2 production rate. Thus, optimization of light distribution with high reactor surface area was reported as an essential factor to enhance the light efficiency in photo-fermentation. Operating parameters also affect the photo-fermentation process efficiency. The concept of net energy ratio (NER) is used to determine the process efficiency which is the ratio of total energy produced to the energy required for plant operations like mixing, pumping, aeration, and cooling.

Biological Water–Gas Shift Reaction (BWGS)

The BWGS is a relatively new method for hydrogen production. Some bacteria (certain photoheterotrophic bacteria), such as *Rubrivivax gelatinosus*, are capable of performing water–gas shift reaction at ambient temperature and atmospheric pressure. Such bacteria can survive in the dark by using CO as the sole carbon source to

generate adenosine triphosphate (ATP) coupling the oxidation of CO with the reduction of H^+ to H_2:

$$CO + H_2O \leftrightarrow CO_2 + H_2,\ \Delta G^\circ = -20.1 kJ/mol$$

In equilibrium, the dominating products are CO_2 and H_2. Therefore, this process is favorable for hydrogen production. Organisms growing at the expense of this process are the gram-negative bacteria, such as *R. rubrum* and *Rubrivivax gelatinosus*, and the gram-positive bacteria, such as *Carboxydothermus hydrogenoformans*. Under anaerobic conditions, CO induces the synthesis of several proteins, including CO dehydrogenase, Fe–S protein, and CO-tolerant hydrogenase. Electrons produced from CO oxidation are conveyed via the Fe–S protein to the hydrogenase for hydrogen production.

Biological water–gas shift reaction for hydrogen production is still under laboratory scale and only few works have been reported. The common objectives of these works were to identify suitable microorganisms that had high CO uptake and to estimate the hydrogen production rate. Kerby et al. (1995) observed that under dark, anaerobic conditions in the presence of sufficient nickel, the doubling time of *R. rubrum* was less than 5 h by the oxidation of CO to CO_2 coupled with the reduction of protons to hydrogen. However, *R. rubrum* requires light to grow and hydrogen production is inhibited by medium CO partial pressure above 0.2 atm. An alternative new chemoheterotrophic bacterium *Citrobacter sp. Y19* was tested by Jung et al. (2002) for hydrogen production using water–gas shift reaction. The maximum hydrogen production activity was found to be 27 mmol/g cell h, which is about three times higher than *R. rubrum*.

Recently, Wolfrum et al. (2003) have conducted a detailed study to compare the biological water–gas shift reaction with conventional water–gas shift processes. Their analysis showed that biological water–gas shift process was economically competitive when the methane concentration was under 3 %. The hydrogen production cost from biological water–gas shift reaction ranged from US$ 1.75/kg (US$ 14.6/GJ) to around US$ 2.25/kg (US$ 18.8/GJ) for a methane concentration between 1 % and 10 %. Compared with thermochemical water–gas shift processes, the cost of biological water–gas shift processes is lower due to the elimination of reformer and associated equipment.

Hydrogen Production from Water

There is abundant water resource on the earth and it is widely available almost everywhere. Thus, hydrogen production from water is a convenient option and the amount can be boundless. Extensive research efforts have focused on this promising hydrogen production route. In fact, its commercial use dates back to the 1890s. Hydrogen production from water splitting consists of three categories: electrolysis, thermolysis, and photoelectrolysis.

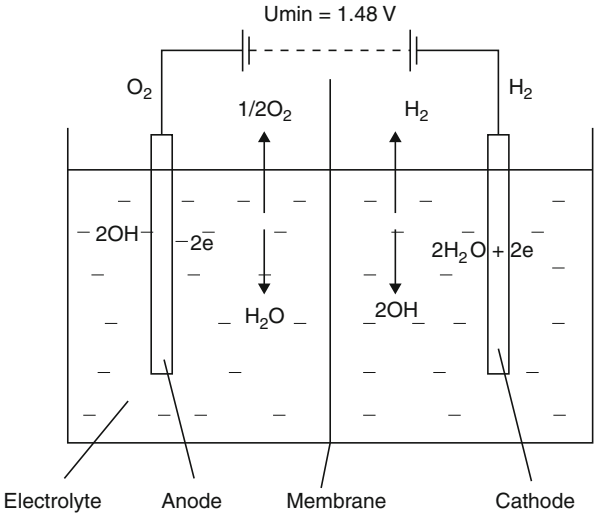

Fig. 3 A diagram of a typical water electrolysis process

Water Electrolysis

Water electrolysis is essentially the conversion of electrical energy to chemical energy in the form of hydrogen, with oxygen as a useful by-product. Figure 3 shows the diagram of a typical water electrolysis process. It is realized by an electrical current passing through two electrodes to break water into hydrogen and oxygen. The most common water electrolysis technology is alkaline based, but more proton exchange membrane (PEM) electrolysis and solid oxide electrolysis cell (SOEC) units are developing.

Alkaline Electrolyzer

Alkaline systems are the most developed and lowest in capital cost. They have the lowest efficiency so they have the highest electrical energy costs. Alkaline electrolyzers are typically composed of electrodes, a microporous separator, and an aqueous alkaline electrolyte of approximately 30 wt.% KOH or NaOH. In alkaline electrolyzers, nickel with a catalytic coating, such as platinum, is the most common cathode material. For the anode, nickel or copper metals coated with metal oxides, such as manganese, tungsten, or ruthenium, are used. The liquid electrolyte is not consumed in the reaction but must be replenished over time because of other system losses primarily during hydrogen recovery. In an alkaline cell, the water is introduced in the cathode where it is decomposed into hydrogen and OH^-. The OH^- travels through the electrolytic material to the anode where O_2 is formed. The hydrogen is left in the alkaline solution. The hydrogen is then separated from the water in a gas–liquid separation unit outside of the electrolyzer. The typical current density is 100–300 mA cm^{-2} and alkaline electrolyzers typically achieve efficiencies of 50–60 % based on the lower heating value of hydrogen. The overall reactions at the anode and cathode are:

Cathode:

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^-$$

Anode:

$$2OH^- \rightarrow \frac{1}{2} O_2 + H_2O$$

Overall reaction:

$$H_2O \rightarrow H_2 + \frac{1}{2} O_2 \, \Delta H = -288 \text{kJ/mol}$$

PEM Electrolyzer

PEM electrolyzers build upon the recent advances in PEM fuel cell technology. They are more efficient than alkaline and do not have the corrosion and seal issues as SOEC but cost more than alkaline systems. PEM-based electrolyzers typically use Pt black, iridium, ruthenium, and rhodium for electrode catalysts and a Nafion membrane which not only separates the electrodes but acts as a gas separator. In PEM electrolyzers, water is introduced at the anode where it is split into protons and oxygen. The protons travel through the membrane to the cathode, where they are recombined into hydrogen. The O_2 gas remains behind with the unreacted water. There is no need for a separation unit. Depending on the purity requirements, a drier may be used to remove residual water after a gas–liquid separation unit. PEM electrolyzers have low ionic resistances, and therefore, high currents of >1600 mA cm^{-2} can be achieved while maintaining high efficiencies of 55–70 %. The reactions at the anode and cathode are:

Anode:

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^-$$

Cathode:

$$4H^+ + 4e^- \rightarrow 2H_2$$

Overall reaction:

$$H_2O \rightarrow H_2 + \frac{1}{2} O_2 \, \Delta H = -288 \text{kJ/mol}$$

Solid Oxide Electrolysis Cells

Solid oxide electrolysis cells (SOEC) are essentially solid oxide fuel cells operating in reverse. These systems replace part of the electrical energy required to split water with thermal energy. The higher temperatures increase the electrolyzer efficiency by

decreasing the anode and cathode over potentials which cause power loss in electrolysis. It is said that an increase in temperature from 375 to 1050 K can reduce the combined thermal and electrical energy requirements by close to 35 % (Utgikar and Thiesen 2006). Another advantage of SOEC units is the use of a solid electrolyte which, unlike KOH for alkaline systems, is noncorrosive, and it does not experience any liquid and flow distribution problems. A SOEC operates similar to the alkaline system in that an oxygen ion travels through the electrolyte (typically ZrO_2) leaving the hydrogen in unreacted steam stream. The reactions are shown as follows:

Cathode:

$$2H_2O + 4e^- \rightarrow 2H_2 + 2O^{2-}$$

Anode:

$$2O^{2-} \rightarrow O_2 + 4e^-$$

Overall reaction:

$$H_2O \rightarrow H_2 + \frac{1}{2}O_2 \, \Delta H = -288 \text{kJ/mol}$$

SOEC electrolyzers are the most electrically efficient but are the least developed of the technologies. A major challenge of SOEC technology is that the high-temperature operation requires the use of costly materials and fabrication methods in addition to a heat source. The materials are similar to those being developed for solid oxide fuel cells (SOFC), yttria-stabilized zirconia (YSZ) electrolyte, nickel-containing YSZ anode, and metal-doped lanthanum metal oxides and have the same problems with seals which are being investigated.

Water Thermochemical Splitting

Water thermochemical splitting is also called water thermolysis, in which heat alone is used to decompose water to hydrogen and oxygen. It is well known that water will decompose at 2500 °C, but materials stable at this temperature and also sustainable heat sources are not easily available. Thus, chemical reagents have been proposed to lower the temperatures. Research in this area was prominent from the 1960s through the early 1980s. However, essentially all research and development stopped after the mid-1980s, until recently. There are more than 300 water splitting cycles referenced in the literature (Hydrogen 2005). All of the processes have significantly reduced the operating temperature.

In choosing the process, there are five criteria which should be met. (1) Within the temperatures considered, the ΔG (differential Gibbs free energy) of the individual reactions must approach zero. This is the most important criterion. (2) The number of

steps should be minimal. (3) Each individual step must have both fast reaction rates and rates which are similar to the other steps in the process. (4) The reaction products cannot result in chemical by-products, and any separation of the reaction products must be minimal in terms of cost and energy consumption. (5) Intermediate products must be easily handled.

Currently, there are several processes which meet the five criteria, such as the UT-3 process and the sulfuric acid decomposition process. The mechanisms of these two processes are shown as follows:

1. Iodine–sulfur process

$$2H_2O(l) + I_2(g) + SO_2(g) \rightarrow 2HI(l) + H_2SO_4(l)\,(100 \sim 120^{\circ}C,\ \text{exothermic})$$

$$2HI(g) \rightarrow H_2(g) + I_2(g)\,(400 \sim 500\ ^{\circ}C,\ \text{exothermic})$$

$$H_2SO_4(l) \rightarrow H_2O(g) + SO_2(g) + \frac{1}{2}O_2(g)\,(850\ ^{\circ}C,\ \text{endothermic})$$

Overall reaction:

$$H_2O \rightarrow H_2 + \frac{1}{2}O_2$$

Figure 4 gives the diagram of a typical water thermochemical splitting process for hydrogen production using the iodine–sulfur process.

2. UT-3 process

$$CaBr_2(s) + H_2O(g) \rightarrow CaO(s) + 2HBr(g)\,(700 \sim 750\ ^{\circ}C,\ \text{endothermic})$$

$$CaO(s) + Br_2(g) \rightarrow CaBr_2(s) + \frac{1}{2}O_2(g)\,(500 \sim 600\ ^{\circ}C,\ \text{exothermic})$$

$$Fe_3O_4(s) + 8HBr(g) \rightarrow 3FeBr_2(s) + 4H_2O(g) + Br_2(g)\,(200 \sim 300\ ^{\circ}C,\ \text{exothermic})$$

$$3FeBr_2(s) + 4H_2O(g) \rightarrow Fe_3O_4(s) + 6HBr(g) + H_2(g)\,(550 \sim 600\ ^{\circ}C,\ \text{endothermic})$$

Overall reaction:

$$H_2O \rightarrow H_2 + \frac{1}{2}O_2$$

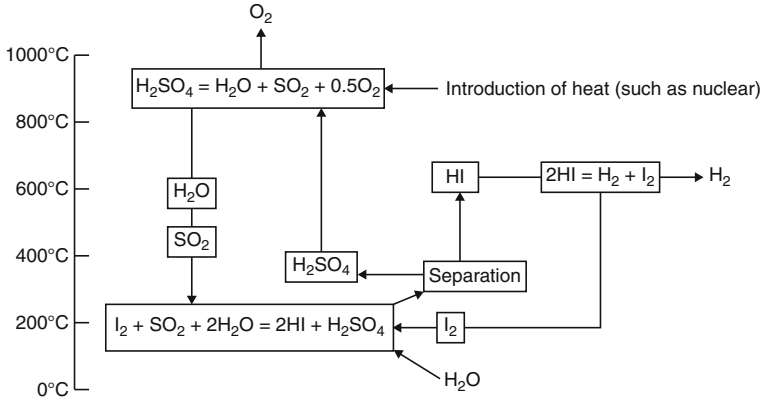

Fig. 4 A diagram of the iodine–sulfur water thermochemical splitting process

However, water thermochemical splitting is still not competitive with other hydrogen generation technologies in terms of cost and efficiency which is the major focus of research in those processes (Norbeck et al. 1996a). In addition, these processes require large inventories of highly hazardous corrosive materials. The requirements of high temperature, high pressure, and corrosion result in the need for new materials. The US DOE has active projects investigating several of these processes focused on improving materials, lowering cost, and increasing efficiency (Hydrogen 2005). Current research and development on hydrogen from water thermochemical splitting are ongoing in Canada on technologies that couple synergistically with Canada's present and future nuclear reactors. Also, several countries (Japan, USA, France) are currently advancing nuclear technology and corresponding thermochemical cycles. Sandia National Laboratories in the USA and CEA in France are developing a hydrogen pilot plant with a sulfur–iodine (S–I) cycle. The KAERI Institute in Korea is collaborating with China to produce hydrogen with the HTR-10 reactor. The Japan Atomic Energy Agency plans to complete a large sulfur–iodine plant to produce 60,000 m^3/h of hydrogen by 2020, an amount sufficient for about one million fuel cell vehicles.

It is believed that scaling up the processes may lead to improved thermal efficiency overcoming one of the principle challenges faced by this technology. In addition, a better understanding of the relationship between capital costs, thermodynamic losses, and process thermal efficiency may lead to decreased hydrogen production costs (Funk 2001). The current processes all use four or more reactions, and it is believed that an efficient two-reaction process as shown in the following equations may make this technology viable (Funk 2001):

$$\mathrm{ZnO(s)} \rightarrow \mathrm{Zn(g)} + \frac{1}{2}\mathrm{O_2}\,(2300\ \mathrm{K},\ \text{endothermic})$$

$$Zn(l) + H_2O \rightarrow ZnO(s) + H_2\,(700\ K,\ \text{exothermic})$$

Water Photoelectrolysis

Photoelectrolysis uses sunlight to directly decompose water into hydrogen and oxygen and uses semiconductor materials similar to those used in photovoltaics. In photovoltaics, two doped semiconductor materials, a p-type and an n-type, are brought together forming a p–n junction. At the junction, a permanent electric field is formed when the charges in the p- and n-type of material rearrange. When a photon with energy greater than the semiconductor material's bandgap is absorbed at the junction, an electron is released and a hole is formed. Since an electric field is present, the hole and electron are forced to move in opposite directions which, if an external load is also connected, will create an electric current. This type of situation occurs in photoelectrolysis when a photocathode, p-type material with excess holes, or a photoanode, n-type of material with excess electrons, are immersed in an aqueous electrolyte, but instead of generating an electric current, water is split to form hydrogen and oxygen.

The process can be summarized for a photoanode-based system as follows: (1) A photon with greater energy than the bandgap strikes the anode creating an electron–hole pair. (2) The holes decompose water at the anode's front surface to form hydrogen ions and gaseous oxygen, while the electrons flow through the back of the anode which is electrically connected to the cathode. (3) The hydrogen ions pass through the electrolyte and react with the electrons at the cathode to form hydrogen gas (Turner et al. 2008). (4) The oxygen and hydrogen gases are separated, for example, by the use of a semipermeable membrane, for processing and storage.

Current photoelectrodes used in PEC (photon-to-electron conversion) that are stable in aqueous solutions have a low efficiency for using photons to split water to produce hydrogen. The target efficiency is >16 % solar energy to hydrogen. This encompasses three material system characteristics necessary for efficient conversion: the bandgap should (i) fall in the range sufficient to achieve the energetics for electrolysis and yet allow maximum absorption of the solar spectrum (this is 1.6–2.0 eV for single photoelectrode cells and 1.6–2.0/0.8–1.2 eV for top/bottom cells in stacked tandem configurations), (ii) have a high quantum yield (>80 %) across its absorption band to reach the efficiency necessary for a viable device, and (iii) straddle the redox potentials of the H_2 and O_2 half reactions with its conduction and valence band edges, respectively. The efficiency is directly related to the semiconductor bandgap (Eg), i.e., the energy difference between the bottom of the conduction band and the top of the valence band, as well as the band edge alignments, since the material or device must have the correct energy to split water. The energetics are determined by the band edges, which must straddle water's redox potential with sufficient margins to account for inherent energy losses. Cost-efficient, durable catalysts with appropriate Eg and band edge positions must be developed. To achieve the highest efficiency possible in a tandem configuration,

"current matching" of the photoelectrodes must be done. Electron transfer catalysts and other surface enhancements may be used to increase the efficiency of the system. These enhancements can minimize the surface overpotentials in relation to the water and facilitate the reaction kinetics, decreasing the electric losses in the system. Fundamental research is ongoing to understand the mechanisms involved and to discover and develop appropriate candidate surface catalysts for these systems (Licht 2005).

In addition, it is possible to use suspended metal complexes in solution as the photochemical catalysts (Norbeck et al. 1996b). Typically, nanoparticles of ZnO, Nb_2O_5, and TiO_2 (the material of choice) have been used (Norbeck et al. 1996b). The advantages of these systems include the use of low-cost materials and the potential for high efficiencies. Current research involves overcoming the low light absorption and unsatisfactory stability in time for these systems.

Sorption-Enhanced H_2 Production with In Situ CO_2 Capture Using Carbon-Containing Resources

It is now widely acknowledged that "decarbonizing" energy supply will be essential in the near future due to the well-known global warming. Although utilization of H_2 is clean and no pollution, the production of H_2 from fossil fuels actually produces CO_2 emission. A typical SMR hydrogen plant with the capacity of one million m^3 of hydrogen per day produces 0.3–0.4 million standard cubic meters of CO_2 per day. If hydrogen is to be produced by coal gasification, the amount of CO_2 emissions would be doubled compared to SMR. Further, with regard to end-use applications of H_2, additional costs and process complexity are incurred for gas cleaning. Taking fuel cell applications, for example, the CO content in the product gas must be closely managed, a CO concentration of less than 10 ppm is required for low-temperature proton exchange membranes and alkaline fuel cells. The cost of separating H_2 from a H_2-rich gas with impurities, such as CO, CH_4, and tar, incurs major cost penalties. The increasing attentions on global warming and the demands for pure H_2 production together result in the great interest in the research on sorption-enhance gasification system where high-purity H_2 production and in situ CO_2capture can be realized in one single reactor. Figure 5 shows a simple diagram of the system.

It is seen that the core unit of the system is the dual gasification–regeneration reactors. And the system is apparently characterized by the addition of CaO additives to the gasifier. The corresponding introduced influences include the following: the water–gas reaction and the water–gas shift reaction are both enhanced to produce more hydrogen due to the CO_2 absorption by the CaO carbonation reaction, (ii) the necessary external energy consumption for hydrocarbons steam gasification can be partially substituted by the releasing heat of carbonation, and (iii) the formation of pyrolysis tars in the presence of CaO additives could be reduced. The reaction mechanisms of the system are as follows:

Reactions in the gasifier:

Water–gas reaction

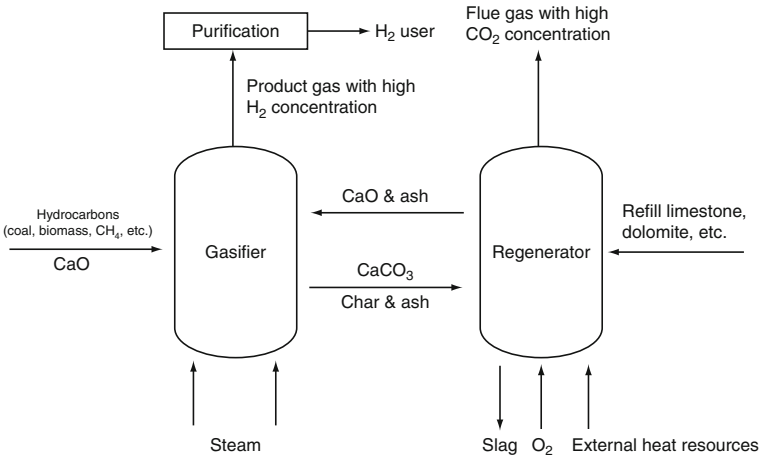

Fig. 5 A simple diagram of the sorption-enhanced gasification system

$$C(s) + H_2O(g) \rightarrow CO(g) + H_2(g) (\text{for coal})$$

$$CH_4(g) + H_2O(g) \rightarrow CO(g) + 3H_2(g) (\text{for natural gas})$$

$$CH_{1.5}O_{0.7}(s) + 0.3H_2O(g) \rightarrow CO(g) + 1.05H_2(g) (\text{for typical biomass})$$

Water–gas shift reaction

$$CO(g) + H_2O(g) \rightarrow CO_2(g) + H_2(g)$$

Carbonation reaction

$$CaO(s) + CO_2(g) \rightarrow CaCO_3(s)$$

The global reaction in the gasifier can be summarized as:

$$C(s) + 2H_2O(g) + CaO(s) \rightarrow CaCO_3(s) + 2H_2(g) (\text{for coal})$$

$$CH_4(g) + 2H_2O(g) + CaO(s) \rightarrow CaCO_3(s) + 4H_2(g) (\text{for natural gas})$$

$$CH_{1.5}O_{0.7}(s) + 1.3H_2O(g) + CaO(s) \rightarrow CaCO_3(s) + 2.05H_2(g) (\text{for typical biomass})$$

Reactions in the regenerator:

Combustion reaction

$$C(s) + O_2(g) \rightarrow CO_2(g)$$

Calcination reaction

$$CaCO_3(s) \rightarrow CaO(s) + CO_2(g)$$

It should be noted that beside Ca-based oxides, a number of candidate CO_2 sorbents have been also studied including potassium-promoted hydrotalcite (K-HTC) and mixed metal oxides of Li and Na (Harrison 2008). HTCs are members of the family of double-layered hydroxides that, when doped with K_2CO_3, can serve as high-temperature CO_2 sorbents. They react rapidly and the sorbent regeneration is possible with less external energy input. But HTCs have much lower CO_2 capacity than Ca-based sorbents and are also considerably more expensive. Mixed metal oxide sorbents of Li and Na such as Li_2ZrO_3, Li_4SiO_4, and Na_2ZrO_3 were spawned, on the one hand, by the desire to find a replacement for Ca-based sorbents that could be regenerated at lower temperature and, on the other hand, would have considerably higher CO_2 capacity than HTC. However, because of less favorable thermodynamic properties associated with these sorbents, the equilibrium CO_2 pressures are higher and product H_2 concentrations must be lower than can be obtained using Ca-based sorbents at equivalent reaction conditions. Anyway, Ca-based sorbents are considered to be the most promising option. As a result, current studies on sorption-enhanced H_2 production are mostly being conducted using CaO. This section also just discusses sorption-enhanced gasification using Ca-based sorbents. Different feedstocks including both solid fuels (coal, biomass) and natural gas are all summarized.

Sorption-Enhanced H_2 Production from Solid Fuels

A new near-zero emission coal (also biomass) utilization technology with combined gasification and combustion has been proposed by Zhejiang University in China (Qinhui et al. 2003; Wang et al. 2006; Guan et al. 2007; Han et al. 2010). Figure 6 displays the diagram of the system.

In this system, solid fuels are partly gasified with steam in a pressured circulation fluidized bed gasifier, producing H_2, CO, and CO_2. As CaO is used as the CO_2 acceptor to absorb CO_2 and release the heat for the gasification processes in the gasifier, CO is depleted from the gas phase by the water–gas shift reaction. The H_2-rich gas stream produced in the gasifier is oxidized in the solid oxide fuel cell. The remaining char with low reaction activity is transferred in a circulating fluidized bed combustor together with the carbonated $CaCO_3$. The char and the unreacted H_2, in the hot off-gas from the fuel cell, are oxidized with oxygen in the combustor to supply the heat for the $CaCO_3$ calcination. The CO_2-rich gas stream produced in the combustor is suitable for disposal after the heat is recovered by a gas–steam-combined cycle. The authors firstly examined the influences of gasifier operation temperature, pressure and fuel type (coal and biomass), and H_2O/C on hydrogen production based on chemical equilibrium calculation (Wang et al. 2006; Guan et al. 2007). The results showed that the increase of CaO addition can obviously

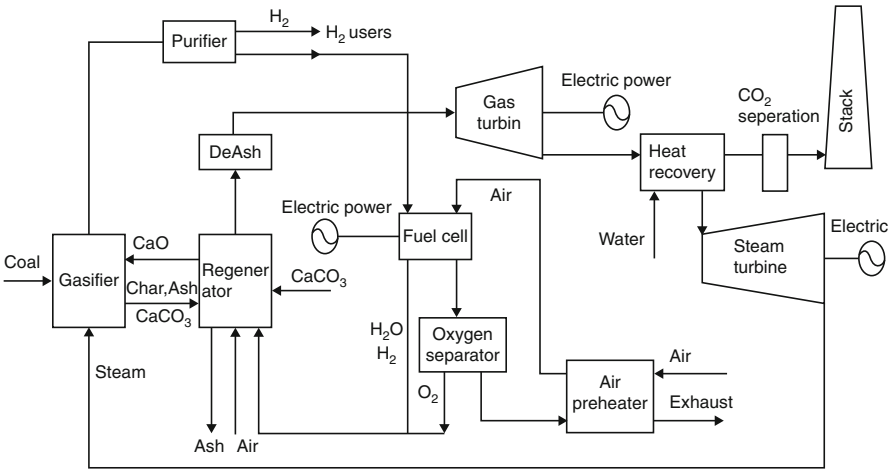

Fig. 6 The near-zero emission system proposed by Zhejiang University

increase H_2 mole fraction in C/H_2O reaction products. The process may achieve high conversion efficiency from coal energy to electrical energy (around 65.5 %) with near-zero gaseous emissions. Our study (Han et al. 2010) also showed that the CaO additives cannot only absorb CO_2 gases but also enhance the tar reduction reactions in biomass steam gasification with in situ CO_2 capture. Sorption-enhanced coal/biomass gasification in pressurized fluidized bed reactor is also being performed in Zhejiang University. Biomass and coal gasification experiments were carried out aiming to investigate the influences of operation variables such as CaO to carbon mole ratio (CaO/C), H_2O to carbon mole ratio (H_2O/C), reaction temperature (T), and pressure(P) on hydrogen (H_2) production(Han et al. 2010, 2013; Wang et al. 2014). Pressurized operation not only promoted gasification reactions but also apparently enhanced CaO carbonation. Within the experimental ranges investigated in the biomass gasification work, H_2 fraction and H_2 yield were both elevated with the increase in reaction pressure, CaO/C, H_2O/C, and T. Pressurized operation also increased the carbon conversion and cold gas efficiency for CaO sorption-enhanced sawdust gasification. A maximum H_2 output with a fraction of 67.7 % and a yield of 68 g/kg sawdust was achieved at CaO/C = 1.2, H_2O/C = 0.89, T = 680 °C, and pressure of 4 bar. In the case of Chinese bituminous coal as feedstock, the highest H_2 concentration of 77.98 vol.% was achieved under a condition of 4 bar(highest pressure condition the system can achieve), 750 °C, $[H_2O]/[C]$ = 2, and [Ca]/[C] = 1.

In Japan, the hydrogen production by the reaction-integrated novel gasification (HyPr-RING) process is under development (Lin et al. 2001). The mechanism of this process is very similar to the system proposed by Zhejiang University. HyPr-RING process has been conducted for both coal and biomass. For coal, conditions in the gasifier of 873–973 K and 3 MPa are reported to result in slightly over 50 % carbon

conversion with about 90 % H_2 in the product gas. The remainder of the product gas is predominantly CH_4 with less than 0.4 % ($CO + CO_2$). The regenerator operates at 1073 K and 0.1 MPa. For biomass, Lin et al. (Hanaoka et al. 2005) examined the H_2 production from woody biomass by steam gasification using CaO as a CO_2 sorbent. Firstly, it is said that in the absence of CaO, the product gas contained CO_2. On the other hand, in the presence of CaO ([Ca]/[C] = 1, 2, and 4), no CO_2 was detected in the product gas. And at a [Ca]/[C] of 2, the maximum yield of H_2 was obtained. Secondly, they reported that the H_2 yield and conversion to gas were largely dependent on the reaction pressure and exhibited the maximum value at 0:6 MPa, which indicated a much lower pressure compared to other carbonaceous materials such as coal (>12 MPa) and heavy oil (>4.2 MPa) in steam gasification using a CO_2 sorbent. As a result, they concluded that woody biomass is one of the most appropriate carbonaceous materials in H_2 production by steam gasification using CaO as a CO_2 sorbent, taking the reaction pressure into account. A further kinetic study conducted at 923 K and pressure of 6.5 MPa using a batch reactor with 50 cm^3 capacity also demonstrated the complete absorption of CO_2 from the gasification syngas (Fujimoto et al. 2007).

Another significant sorption-enhanced gasification process is the absorption-enhanced reforming (AER) developed within the frame of EU Project AER-Gas II. The atmospheric dual fluidized bed technology developed at Vienna University of Technology realizes the steam gasification through circulation of hot bed material. The technology has been realized in pilot plant scale of 100 kW fuel input (at Vienna University of Technology) as well as in industrial scale at the combined heat and power plant (CHP) guessing in an industrial scale of 8 MW fuel input in Austria. A comparison of dual fluidized bed gasification of biomass with and without selective transport of CO_2 from the gasification to the combustion reactor is performed by using the facility with 100 kW fuel input. In the case of convention gasification, the hydrogen content in the product gas of gasifier is about 40 vol.% (dry basis). However, in the case of carbonate addition to the bed material, much higher hydrogen content up to 75 vol.% (dry basis) can be achieved at lower gasification temperatures (Pfeifer et al. 2009). The first time application of the AER process on the 8 MW industrial facility also realizes the continuous CO_2 removal by cyclic carbonation of CaO and calcination of $CaCO_3$. Results obtained in the industrial facility are presented to be comparable with those obtained at pilot plant scale (Koppatz et al. 2009).

In addition, other similar sorption-enhanced gasification processes for solid fuels are also under development. One is the ZEC process developed at Los Alamos National Laboratory (Ziock et al. 2001). It is designed to first hydrogasified coal to produce CH_4, which is then reformed to H_2 using the calcium-based sorption-enhanced process. A system analysis performed by Nexant Corp. (Nawaz and Ruby 2001) estimated coal to electricity conversion efficiency on the order of 70 %. Research on this concept is continuing in a joint study at Cambridge University and Imperial College in the UK (Gao 2009). The other is the innovative fuel-flexible advanced gasification–combustion (AGC) process developed by

General Electric Energy and Environmental Research Corporation (GE EER) (Rizeq et al. 2001). The R&D on the AGC technology is being conducted under a Vision-21 award from the US DOE NETL with co-funding from GE EER, Southern Illinois University at Carbondale (SIU-C), and the California Energy Commission (CEC). The AGC technology converts coal and air into three separate streams of pure hydrogen, sequestration-ready CO_2, and high-temperature/high-pressure oxygen-depleted air to produce electricity in a gas turbine. The program integrates lab-, bench-, and pilot-scale studies to demonstrate the AGC concept. Besides, research on lab-scale H2 production from sorption-enhanced solid fuel gasification was also performed by Madhukar (Mahishi and Goswami 2007) and Wei et al. (2008). Fan et al. (2008) and his research group from Ohio State University developed the concept of Calcium Looping Process (CLP) for clean coal and biomass conversion and hydrogen production, and comprehensive simulations allow for a direct comparison of the CLP with other processes developed for post-combustion carbon dioxide removal. The comparison indicates that the CLP always provides a lower energy penalty under similar operating conditions.

Sorption-Enhanced H2 Production from Natural Gas

The effectiveness of both sorption-enhanced steam methane reforming (SE-SMR) and the use of calcium-based CO2 sorbents have been demonstrated in previous works. In particular, Rostrup-Nielsen (1984) reports that the first description of the addition of a CO2 sorbent to a hydrocarbon-steam-reforming reactor was published in 1868. Williams (1933) was issued a patent for a process in which steam and methane react in the presence of a mixture of lime and reforming catalyst to produce hydrogen. A fluidized bed version of the process was patented by Gorin and Retallick (1963). Brun-Tsekhovoi et al. (1988) published limited experimental results and reported potential energy saving of about 20 % compared to the conventional process. Recently, Kumar et al. (1999) reported on a process known as unmixed combustion (UMC), in which the reforming, shift, and CO2 removal reactions are carried out simultaneously over a mixture of reforming catalyst and CaO-based CO2 sorbent. In related work, Hufton et al. (2000) reported on H2 production through SE-SMR using a K2CO3-treated HTC sorbent, although the extremely low CO2 working capacity above was discussed. Average purity of H2 was about 96 % while CO and CO2 contents were less than 50 ppm. The methane conversion to H2 product reaches 82 %. The conversion and product purity are substantially higher than the thermodynamic limits for a catalyst-only reactor operated at these same conditions (28 % conversion, 53 % H2, 13 % CO/CO2). In an earlier work, Balasubramanian et al. (1999) showed that a gas with a H2 content up to 95 % (dry basis) could be produced in a single reactor containing reforming catalyst and CaO formed by calcination of high-purity CaCO3. The reported methane conversion was 88 %. Arstad et al. (2012) studied the continuous hydrogen production by SE-SMR using a CFB reactor with calcined natural dolomite as CO2

sorbent and Ni/NiAl2O4 as catalyst. The sorbent and catalyst materials we have used appear to have quite good mechanical properties at the time scale used (8 h), but only a fraction of the sorbent's CO2 capacity appears to be in use. Johnsen et al. (2006) use dolomite as CO2 sorbent in SE-SMR investigation, and a 100 mm-diameter bubbling fluidized bed reactor was operated alternating between reforming/carbonation conditions and higher-temperature calcination conditions to regenerate the sorbent. Equilibrium H2 concentration of above 98 % on a dry basis was reached at 600 °C and 1.013×10^5 Pa. Esther Ochoa-Fernández et al. (2007) compared the conventional steam reforming plus CO2 capture with the SE-SMR system, and SE-SMR resulted in competitive H2 yields and thermal efficiencies. The best efficiencies were obtained using CaO as acceptor due to its more favorable thermodynamics and high reaction rates, but the stability of CaO has to be improved, while Na2ZrO3 is a promising alternative due to the good kinetics for CO2 removal and the stability.

A large number of numerical study and simulation works on the SE-SMR are also carried out these years. Zhen-shan Li and Cai (2007) developed mathematical models of multiple cycles for SE-SMR and Ca-based sorbent regeneration in a fixed bed reactor, of which the results agree with experimental data. The effect of reactivity decay of dolomite, CaO/Ca12Al14O33, and limestone sorbents on sorption-enhanced hydrogen production and sorbent regeneration processes was studied. Jannike Solsvik and Jakobsen (2011) studied the performance of a combined catalyst/sorbent pellet design for the SE-SMR process. Different mathematical model complexities have been studied and parameter sensitivity analyses have been performed, which showed that the combined pellet performance is promising compared to the conventional two-pellet design. Reijers et al. (2009a, b) built a one-dimensional reactor model to describe the performance of an SE-SMR and water–gas shift reactor and verified using the results of an analytical solution for the increase of CH4 conversion over the bed and finally validated using the results of SE-SMR laboratory-scale experiments. Solieman et al. (2009) presented an analysis of the relation between different process conditions and parameters during both adsorption and desorption modes using Aspen Plus, and a relatively high (methane) reforming reaction conversion of 85 % could be achieved at 600 °C, 17 bar, and a steam to carbon ratio (S/C) of 3. Compared to Li2ZrO3 and BaO, CaO is the most suitable sorbent for achieving the targeted 85 % carbon capture ratio. Wang et al. (2011) developed a three-dimensional (3D) Eulerian two-fluid model with an in-house code to simulate the Ca-based SE-SMR process using such model combined with the reaction kinetics. Jakobsen and Halmøy (2009) built an SE-SMR reactor model which comprises simplified mathematical representation of the flow regime, differential equations for mass and heat transfer, sub-model for chemical reaction kinetics, and absorption equilibria. The model was used to investigate various operational modes for the reformer as well as for comparison of the reformer performance with use of various sorbents (Li4SO4, Na2ZrO3, CaO). Di Carlo et al. (2010) investigated the SE-SMR process numerically through computational fluid dynamics Eulerian–Eulerian Code. Dry hydrogen mole fraction of >0.93 is

predicted for temperatures of 900 K and a superficial gas velocity of 0.3 m/s with a dolomite/catalyst ratio >2. Fernandez et al. (2012) present a dynamic pseudo-homogeneous model to describe the operation of a packed bed reactor in which the SE-SMR reaction is carried out under adiabatic conditions. The results demonstrated that the SER process can yield a CH4 conversion and H2 purity of up to 85 % and 95 %, respectively, under operating conditions of 923 K and 3.5 MPa, a steam/carbon ratio of 5, and a space velocity of 3.5 kg/m^2 s.

One process that utilizes natural gas is designated Zero Emission Gas Power Project (ZEG) and is being led by the Institute of Gas Technology in cooperation with Christian Michelsen Research AS and Prototech AS in Norway. A brief discussion of the process may be found on the Internet, and an update on the status of the project was recently presented by Johnsen (2007). A number of candidate sorbents have been considered with Arctic dolomite, which does not require pretreatment for sulfur removal, receiving the most attention. H2 is to be used to produce electricity in a high-temperature solid oxide fuel cell with the exhaust heat used for sorbent regeneration. Electrical efficiencies from 50 % to 80 % based on the net power output (LHV) of four process configurations having varying degrees of heat integration are reported.

The other sorption-enhanced H2 production process from natural gas is the Pratt and Whitney Rocketdyne (PWR) process. It is now in the pilot stages. While few details have been released, the company claims a 90 % size reduction, 30–40 % reduction in capital costs, 5–20 % higher H2 yield, and reduced product purification requirements that will lead to a smaller PSA system. The comparisons are relative to a standard steam methane reforming process with PSA purification. Upon completion of the current pilot tests, PWR plans to construct a 5 MM scf/d commercial demonstration plant (Stewart PAE and WR, 2007, Personal Communication).

Reactivity of CaO Sorbents Throughout Cyclic Calcination–Carbonation (CC) Reactions

A critical challenge for applications of the sorption-enhanced gasification process is the activity durability (Florin and Harris 2008) of CaO sorbent. It is estimated that the CO2 capture process would not be economical unless the value of CaO conversion after 20 cycles increased to a value of at least 0.45. However, previous studies show that CaO sorbents lose activity dramatically during cyclic CC reactions, which would increase both consumption of fresh sorbents and storage of spent sorbent, consequently reduce process economic, and result in environmental problem.

Reasons that are responsible for the calcium-based sorbent reactivity loss can be summarized as: (i) Thermodynamic equilibrium limitation. Higher temperatures are favorable for H2 generation; however, increasing the temperature at a constant total pressure will limit the capture of CO2 by CaO sorbents. (ii) Tars and coke formation. Interaction between CaO and the tar and coke is expected to hamper CO2 capture (Delgado et al. 1996). There is a trade-off between the optimal temperatures for

eliminating tar and decomposing coke and maximizing CO2 capture by CaO. (iii) Sintering of sorbents. Sintering leads to a reduction in both surface area and pore volume, which in turn affects the rate and extent of gas–solid reactions. (iv) Decay in reactivity through multiple CO2 capture and release cycles. Abanades and Alvarez (2003) concluded that the decay in activity throughout CC cycles was due to a decrease in microporosity and an increase in meso-porosity. They proposed a simple equation to estimate the CaO conversion, XN, after the Nth CC cycles, claiming that values of fm = 0.77 and fw = 0.17 fit most experimental data of both previous researchers and themselves well:

$$X_N = f_m^N(1 - f_w) + f_w \tag{3}$$

In order to improve the reactivity of calcium-based sorbents, various methods have been proposed, including (i) using mild calcination conditions, (ii) steam/water hydration or addition, (iii) the use of nano-sized sorbent particles, and (iv) thermal pretreatment. Barker (1974) hypothesized that if the particle size (diameter) of CaO is smaller than the product layer thickness that may form on a single particle, then 100 % conversion could be achieved. Barker reported a conversion of 0.93 after 24 h of carbonation, maintained for 30 reaction cycles.

The use of mild calcination conditions, i.e., inert atmospheres (N2 or Ar) and low temperatures (700 °C), were reported to produce a more reactive sorbent (Hughes et al. 2004). However, it may be necessary to use steam as a diluent gas in the regenerator to lower down the CO2 partial pressure while simultaneously obtaining high-purity CO2 gases. The introduction of a water hydration step, or the utilization of steam as a "carbonation–catalyst," has been reported to enhance CO2 capture through multiple reaction cycles (Hughes et al. 2004; Kuramoto et al. 2003; Manovic and Anthony 2007). Rong et al. (2013) studied the effects of hydration temperature, steam concentration, and hydration frequency on the sorbent reactivity during 10 carbonation–calcination cycles using a pressurized thermogravimetric analyzer with reagent-grade CaCO3 used as a precursor under atmospheric pressure. In comparison to other steam reactivation strategies, such as the steam addition during the carbonation and calcination process, separate steam hydration after calcination has shown excellent reactivation performance.

In conclusion, the development of a CO2 sorbent, which is resistant to physical deterioration and maintains high chemical reactivity through multiple CO2 capture and release cycles, is the limiting step in the scale-up and commercial operation of the sorption-enhanced H2 production process.

Future Directions

Given the advantages inherent in fossil fuels, such as their availability, relatively low cost, and the existing infrastructure for delivery and distribution, they are likely to play a major role in energy and H2 production in the near to medium-term future.

However, H2 production from fossil fuels produces large CO2 emission to the atmosphere, which may diminish the environmental appeal of H2 as an ecologically clean fuel. As a result, H2 production from fossil fuels must consider the CO2 capture problem in long-term future.

Biomass is a potentially a reliable energy resource for hydrogen production. Biomass is renewable, abundant, and easy to use. Over the life cycle, net CO2 emission is nearly zero due to the photosynthesis of green plants. Although the yield of H2 is low from biomass since the hydrogen content in biomass is low to begin with (approximately 6 % vs. 25 % for methane) and the energy content is low due to the 40 % oxygen content of biomass, the thermochemical pyrolysis and gasification hydrogen production methods are economically viable and are said to become competitive with the conventional natural gas reforming method. Biological dark fermentation is also a promising hydrogen production method for commercial use in the future. With further development of these technologies, biomass will play an important role in the development of sustainable hydrogen economy.

Hydrogen production from water electrolysis has been commercially available. Regarding the CO2 emission, electricity produced from renewable resources (such as wind, solar, hydro, biomass, tidal, etc.) is favored to be used for water electrolysis. Thermochemical water decomposition is one alternative process competitive to water electrolysis. The nuclear power systems have a great potential to be integrated with H2 production from water decomposition. The Advanced High-Temperature Reactor (AHTR) concept, proposed for the US Department of Energy's Generation IV nuclear plant development program, is specifically designed for H2 production (via high-temperature water electrolysis or thermochemical cycles). Thermochemical water-splitting cycles, such as UT-3 cycle and sulfur–iodine cycle, can potentially produce higher overall energy efficiencies (around 50 %) compared to electrolysis-based systems (around 24 %). However, a major shift away from the negative public perception of nuclear energy would be necessary in order to base a long-term energy scenario on the nuclear–hydrogen option. In addition, H2 production by direct water splitting, using the solar photocatalysis route, could become favorable if conversion efficiencies were increased by a factor of 2–3. It is anticipated that the low-cost, environmentally friendly photocatalytic water splitting for hydrogen production will play an important role in the hydrogen production and contribute much to the coming hydrogen economy. However, it is still very far from practical utilization.

Sorption-enhanced H2 production with in situ CO2 capture and then CO2 sequestration in geologic formations (e.g., deep coal seams, depleted oil and gas reservoirs, and salt domes), the ocean, aquifers, terrestrial ecosystems, etc., provides a promising solution for the CO2 release during H2 production from fossil fuels. For the future development, challenges for CO2 sequestration such as bringing its cost down and understanding the reservoir options (e.g., size, permanence, and, most importantly, environmental effect) should also be paid significant attention, besides improving the CaO sorbent cyclic reactivity to be practical.

Abstract

Fuel cells convert chemical energy to electrical energy via an electrochemical reaction. They are more efficient than traditional heat engine-based power systems and can have zero or near-zero emissions during operation. A leading alternative green energy technology, fuel cells are finding applications in many areas, including transportation, portable power, and stationary power generation. These divergent uses have driven development of several different types of fuel cell technologies. A brief overview of these will be provided in this chapter; however, the focus will be on low-temperature proton exchange membrane (PEM) technologies predominant in portable power and automotive applications. Fuel cell operating principles will be reviewed, focusing on thermodynamics, efficiency, reaction kinetics, and transport phenomena in order to develop a framework for evaluating different fuel cells and comparing them with other power systems. Theoretically, much improvement in fuel cell performance is possible and is needed along with means of lowering economic costs in order for fuel cells to see more widespread use. Some of the major technical challenges in these regards are outlined along with approaches being investigated to meet these challenges. Life cycle assessment and its application to fuel cells will be discussed to evaluate environmental impacts associated with manufacturing, operation, and disposal.

Introduction to Fuel Cell Technology

Fuel cells are one of the leading alternative energy technologies for a variety of applications, including automobiles, portable electronics, and many others. These electrochemical power generators convert chemical energy to electrical energy, in a manner similar to that of batteries. Fuel is oxidized at the anode to produce electrons and mobile ions. The mobile ions pass through an electrolyte to reach the cathode, while the electrons pass through a circuit, providing electrical current power some external load before returning to the cathode. At the cathode, the mobile ions are reduced, completing the reaction. This basic description applies to the most common fuel cells for which protons or other positive ions are the mobile ions, including the most common low-temperature fuel cell, the hydrogen proton exchange membrane (PEM) fuel cell, in which hydrogen fuel is oxidized to form protons (the mobile ions) and electrons. The electrons pass through an external circuit, while the protons pass through the PEM. Oxygen (the oxidant) combines with the protons and electrons at the cathode to form water, completing the overall reaction. This process continues producing electricity so long as fuel and oxidant are supplied to the cell, whereas in a battery, the fuel and oxidant are contained in the electrode materials themselves.

There are many different varieties of fuel cells in addition to the hydrogen PEM fuel cell discussed above. These may be classified based on the type of materials used for the electrolyte, the type of fuel utilized, or typical operation temperature.

Table 1 Summary of types of fuel cells

Fuel cell type	Fuel	Mobile ion	Electrolyte	Operating temperature	Main applications
Alkaline (AFC)	Pure H_2	OH^-	KOH	50–200 °C	Space program (historical)
Proton exchange membrane (PEMFC)	Pure H_2 (tolerates CO_2)	H^+	Solid polymer (e.g., Nafion)	30–100 °C	Vehicles and mobile power
Direct methanol (DMFC), formic acid (DFAFC), and other liquid fuels	Methanol, formic acid, other alcohols	H^+	Solid polymer (e.g., Nafion)	20–90 °C	Portable electronics
Phosphoric acid (PAFC)	Pure H_2 (tolerates CO_2, ~1 % CO)	H^+	Phosphoric acid	~220 °C	~200-kW CHP systems
Molten carbonate (MCFC)	H_2, CH_4, other hydrocarbons (tolerates CO_2)	CO_3^{2-}	Lithium and potassium carbonate	~650 °C	Medium- to large-scale stationary combined heat and power (MW capacity)
Solid oxide (SOFC)	H_2, CH_4, other hydrocarbons (tolerates CO_2)	O^{2-}	Solid oxide (e.g., yttria-stabilized zirconia)	500–1,000 °C	All-size stationary combined heat and power systems (2-kW to multi-MW capacity)
Enzymatic biofuel cells	Sugars or alcohols	H^+	Solid polymer (e.g., Nafion) or biological fluid	20–40 °C	Bio-implants and energy scavenging (research)

Some of the most common varieties of fuel cell are described in Table 1. This chapter will be concerned with the most common types of low-temperature fuel cells which primarily utilize proton exchange membranes, or PEMS: hydrogen PEM fuel cells, direct methanol fuel cells (DMFCs), direct formic acid fuel cells (DFAFCs), and other direct liquid fuel cells. High-temperature technologies such as solid oxide and molten carbonate fuel cells will be covered in more detail in the next chapter as they have very different technical challenges and are being developed primarily for larger-scale power generation.

Chapter Overview

The goals of this chapter will be to provide context for the evaluation of fuel cell technology as a green energy alternative. A short history of the development of this technology will be provided, followed by a discussion of means of comparing fuel cells with other energy technologies. Technical background on the thermodynamic, reaction, and mass transfer processes occurring in a fuel cell is then provided along with a brief overview of each of the major low-temperature fuel cell technologies. A fuel cell is only one part of a total power system. Fuel storage and delivery, thermal management, and power management subsystems are among the many components of a total fuel cell power system. Key characteristics and design criteria for each of these will be reviewed. Fuel cell technology, while holding much promise, is only beginning to find its way into commercial applications. Some of the major technical challenges that are providing roadblocks to more widespread use of fuel cells will be highlighted along with a brief discussion of current research aimed at solving these problems. If only efficiency and emissions are considered, fuel cells are a truly "green" technology. Emissions are primarily water vapor and carbon dioxide, and in well-designed systems, a very high fraction of the usable energy in the fuel is converted to electricity. However, a more rigorous analysis that considers everything from mining of raw materials to final disposal is needed to compare the environmental impact of different energy technologies. Life cycle assessment of fuel cell technology will be reviewed as a means of evaluating how truly "green" fuel cell, or any technology, truly is. This chapter will conclude with some speculation on what the future might hold for fuel cell technology.

A Brief History of Fuel Cells

Sir William Grove is credited with demonstrating the first fuel cell in 1839, ironically at about the same time the first internal combustion engines were developed. For much of the next century, fuel cells essentially remained a curiosity studied by academics and hobbyists. Beginning in the 1930s, F. T. Bacon made great advances in alkaline hydrogen fuel cells (Srinivasan et al. 1999). Bacon's designs were adopted and further developed by Pratt and Whitney and later United Technologies and utilized for power generation in American space program (Srinivasan et al. 1999). Throughout the Apollo space program, alkaline fuel cells were used to provide onboard power for electrical systems. The high energy density (energy per unit weight or volume) of fuel cells made them ideal for this use where minimizing payload weight is crucial. This concern has also been one of the primary drivers of ongoing research and development of fuel cells for portable commercial electronics (e.g., laptop computers, cell phones, etc.). Since 2000, several electronics manufacturers, including Samsung, NEC, Casio, and LG, have introduced fuel cell power systems for portable electronic devices, though these have yet to reach any large markets (FCB 2003, 2005). In the 1990s, environmental and regulatory concerns as well as issues relating to the cost and supply of oil led automotive companies begin

to develop hydrogen fuel cell technology for electric vehicles in earnest. This work has begun to bear fruit as many different types of hydrogen vehicles have been introduced around the world by auto manufacturers. Iceland in particular has embraced the move toward a hydrogen economy (Oil Gas European Magazine 2001). Daimler-Benz began developing hydrogen-powered busses in the early 1980s, which are now being utilized in Australia (FCB 2004) and many cities in Europe through the Europe-wide Clean Urban Transport (CUTE) (Energy 2004). Honda has developed its FCX Concept vehicle utilizing a 100-kW hydrogen fuel cell, which began road testing in Japan in 2002 and was available for lease in 2007 in California (FCB 2007a). Similarly, both Ford and General Motors have been developing vehicles with hybrid fuel cell power system, some of which have been evaluated on North American roads (FCB 2007b). These are only a few examples of the many fuel cell vehicles under development and/or evaluation in recent years. If the progress of recent years is any indication, fuel cell technology has a very exciting future.

Fundamentals of Fuel Cell Operation

Performance Metrics for Comparing Fuel Cells and Other Energy Systems

The most obvious measures of fuel cell performance metrics include current, voltage, and power output as well as the lifetime of the cell before refueling is required. These are of somewhat limited value in comparing different fuel cells or fuel cells to other power sources however, as they are dependent on size. In comparing different fuel cells to one another, current and power should be compared on a per unit area basis. Voltage is not impacted by the area of the electrodes, but can be increased by connecting cells in series as is done in batteries. As the lifetime of a fuel reservoir is primarily dependent on the size of that reservoir, a better measure for comparing fuel cells is the fuel utilization efficiency or the fraction of fuel fed to the system that is converted to power.

The most common measures used to compare fuel cells to other energy systems are energy density and power density. These can both be measured gravimetrically (i.e., energy or power per unit mass) and volumetrically (i.e., energy or power per unit volume). Graphically, plots of energy density versus power density called Ragone plots are often utilized to compare energy sources, such as the one shown in Fig. 1. One of the more attractive features of fuel cells is that they provide a relatively high energy density. A driving factor in the development of new electronic devices is reducing size and weight. Currently, batteries comprise a large fraction of the weight of laptop and tablet computers, mobile phones, and other devices, motivating efforts to develop fuel cells for such systems. Weight reduction is also important in automotive applications, though less critical than for portable electronics. Various efficiency measurements are also utilized in comparing fuel cells to other energy systems. In general, these are based on thermodynamics; however, because of

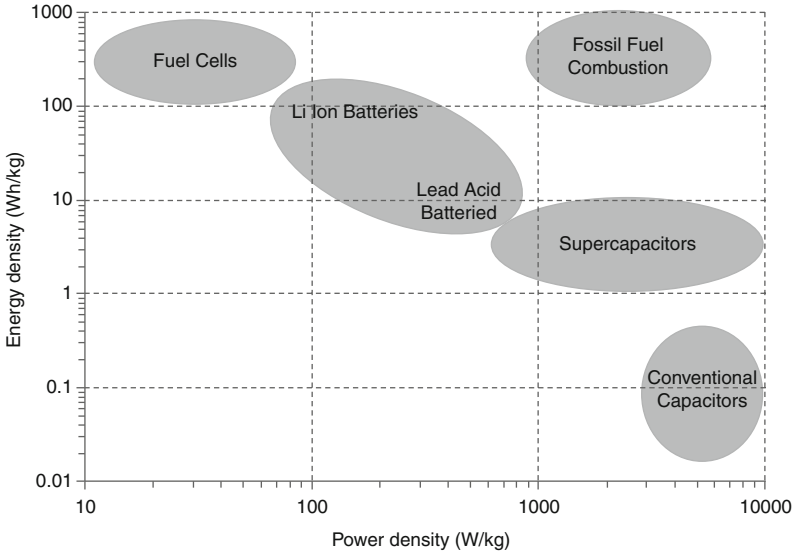

Fig. 1 A Ragone plot illustrating approximate energy and power densities of various energy technologies

fundamental differences in the mechanisms of operation, such measures often create more confusion than clarity. These measures will be discussed in greater detail later in this chapter.

Description of Basic Operation of a Fuel Cell

The hydrogen proton exchange membrane fuel cell (H_2 PEM FC) provides a chemically simple example to illustrate the fundamental principles for all types of fuel cells. In this type of cell, the hydrogen fuel is oxidized at the anode to form protons and electrons:

$$H_2 \rightarrow 2H^+ + 2e^- \tag{1}$$

An electrolyte acts to physically separate the two half-cell reactions and force the electrons to pass through a circuit where they can do electrical work before returning to the cathode while the mobile hydrogen ions pass through the electrolyte (see Fig. 2). The protons and electrons ultimately combine to reduce oxygen at the cathode and form water as a waste product:

$$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O \tag{2}$$

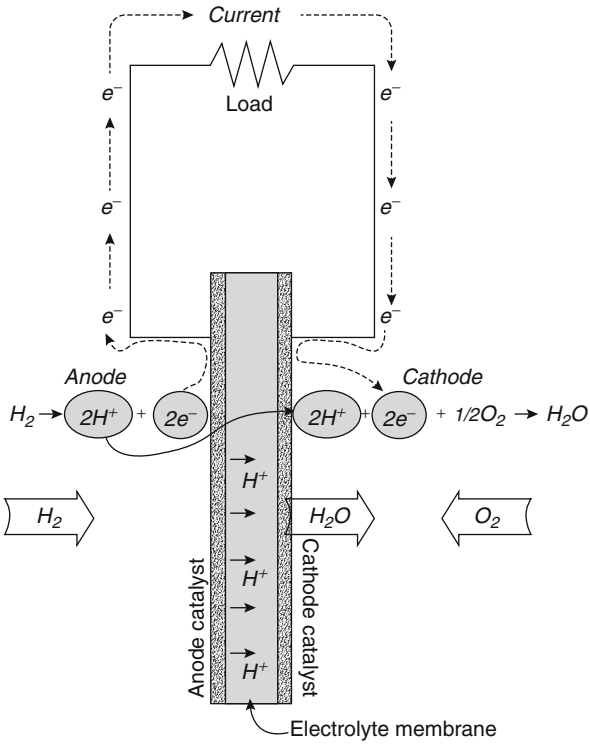

Fig. 2 Illustration of the basic operation of a hydrogen proton exchange membrane fuel cell

Thus, the overall reaction for a hydrogen fuel cell is

$$H_2 + O_2 \rightarrow H_2O \tag{3}$$

The various types of fuel cells outlined in Table 1 operate in the same general manner in that fuel is oxidized at the anode and electrons are forced through a circuit while mobile ions move through an electrolyte to combine at the cathode in a reduction reaction. They differ in the specific fuels, mobile ions, and typical operating conditions. As will become evident, each type of fuel cells has its own strengths and weaknesses, which determine the applications for which they are suitable.

In this section, some of the fundamental science and engineering principles of fuel cell operation will be reviewed, beginning with a discussion of thermodynamics in fuel cells. From thermodynamics, the maximum performance in terms of electrical potential that can be generated by a given fuel cell can be determined. This "ideal" limit also provides a means of evaluating the potential of a given fuel cell technology as well as providing important, but sometimes confusing, means of evaluating fuel cell efficiency. While thermodynamics provides theoretical limits on performance, practical limits are imposed by kinetic and transport processes. Reaction kinetics, particularly for oxygen reduction, significantly limit fuel cell performance driving

significant research to develop improved catalysts. An overview of these topics is provided in the following sections. For a more detailed discussion, the reader is referred to any of a number of fuel cell and electrochemistry texts (O'Hayre et al. 2009; Larminie and Dicks 2003; Hoogers 2003; Bockris et al. 1998; Bard and Faulkner 2001; Sawyer et al. 1995).

Thermodynamics and Efficiency

Fuel Cell Thermodynamics

For an isothermal, isobaric system, the maximum amount of work that can be done by the system is equal to the Gibbs free energy change for that system. In the case of a fuel cell, electrical work (W_{elec}) is of interest, and the Gibbs free energy change occurs as a result of the overall fuel cell reaction; thus, we can mathematically state:

$$W_{\text{elec}} = -\Delta G^0_{\text{rxn}} \tag{4}$$

where ΔG^0_{rxn} is the standard-state change in the Gibbs free energy of the reaction. The change in Gibbs free energy is related to the change in enthalpy of the reaction (H_{rxn}) by Eq. 5:

$$\Delta G = \Delta H - T\Delta S \tag{5}$$

where ΔS is the enthalpy of the reaction at absolute temperature T. The value $T\Delta S$ represents thermal energy unavailable for being converted to electrical work and places a fundamental limit on the efficiency of a given fuel cell. Electrical work is accomplished by moving charge carried by electrons through an electrical potential gradient ΔE; thus, electrical work can be expressed as the product of the total charge ($Q = nF$) and the field strength:

$$W_{\text{elec}} = \Delta EQ = nF\Delta E \tag{6}$$

where n is the number of moles of electrons produced in the fuel cell reaction and F is Faraday's constant. Combining Eqs. 4 and 6, we get ΔE_0, the maximum standard-state reversible voltage for the overall reaction in a fuel cell:

$$\Delta E^0 = -\frac{\Delta G^0_{\text{rxn}}}{nF} \tag{7}$$

Cell potential can be related to reactant and product concentrations at a given temperature by considering a general reaction of A and B to form products C and D:

$$\alpha\text{A} + \beta\text{B} \rightarrow \chi\text{C} + \delta\text{D} \tag{8}$$

The Gibbs free energy for such a reaction is familiar from basic thermodynamics as

$$\Delta G = \Delta G^0_{\text{rxn}} RT \ln\left(\frac{a_{\text{C}}^{\chi} a_{\text{D}}^{\delta}}{a_{\text{A}}^{\alpha} a_{\text{B}}^{\beta}}\right) \tag{9}$$

where a_{A}, a_{B}, a_{C}, and a_{D} are the activities of species A, B, C, and D, respectively, and R is the gas constant. The activities of course are dependent upon the physical state of the reactants or products. For an ideal gas, the activity of species i can be expressed:

$$a_i = \frac{P_i}{P^0} \tag{10}$$

where P_i is the partial pressure of species i and P^0 is the standard pressure (usually 1 atm). For an ideal solution, the activity of species i is expressed:

$$a_i = \frac{[i]}{[i]^0} \tag{11}$$

where $[i]$ and $[i]^0$ are the concentration and standard-state concentrations of species i. If the reactants and products for the generic reaction (Eq. 8) are presumed to be in an ideal solution, then Eq. 9 can be rewritten as

$$\Delta G = \Delta G^0_{\text{rxn}} RT \ln\left(\frac{[\text{C}]^{\chi}[\text{D}]^{\delta}}{[\text{A}]^{\alpha}[\text{B}]^{\beta}}\right) \tag{12}$$

Substituting Eq. 7 into Eq. 12 yields the familiar Nernst equation:

$$\Delta E = \Delta E^0 \left(\frac{RT}{nF}\right) \ln\left(\frac{[\text{C}]^{\chi}[\text{D}]^{\delta}}{[\text{A}]^{\alpha}[\text{B}]^{\beta}}\right) \tag{13}$$

relating the cell potential or emf, ΔE, to the standard-state potential and reactant concentrations at a given temperature. As this equation illustrates, the cell potential increases with the concentration of the reactants. The overall reaction in a fuel cell is of course the sum of two half-cell reactions, which often are studied separately. The total cell potential is expressed as a difference between the thermodynamic electrochemical potentials of the half-cell reactions at the cathode and anode, respectively:

$$\Delta E = E_{\text{cathode}} - E_{\text{anode}} \tag{14}$$

Thermodynamic Efficiency

As noted previously, the entropy of the overall fuel cell reaction places a fundamental limit on fuel cell efficiency. Thermodynamic efficiency is of course an important concept in evaluating fuel cells or any other system that converts energy to work. The standard definition of thermal efficiency, ε, for any system is

$$\varepsilon = \frac{W_{\text{out}}}{Q_{\text{in}}} \tag{15}$$

where W_{out} is the work done by the system and Q_{in} is the energy supplied to the system. For transportation applications where internal combustion engines are standard, it is useful to compare fuel cell efficiency to that of such heat engines. For a heat engine, the maximum efficiency is that of a reversible Carnot cycle. Applying the first law of thermodynamics to a completely reversible system requires that all thermal energy supplied to the system (Q_{in}) is either converted to work (W_{out}) or rejected to the surroundings (Q_{out}), so that Eq. 7 above can be expressed as

$$\varepsilon_{\text{Carnot}} = \frac{Q_{\text{in}} - Q_{\text{out}}}{Q_{\text{in}}} \tag{16}$$

where $\varepsilon_{\text{Carnot}}$ is the Carnot efficiency. This can also be expressed in the more familiar manner in terms of the low and high reservoir temperatures of the system:

$$\varepsilon_{\text{Carnot}} = 1 - \frac{T_{\text{low}}}{T_{\text{hi}}} \tag{17}$$

T_{hi} and T_{low} are the absolute temperatures of the respective thermal reservoirs in the heat engine. T_{low} is typically limited to the ambient temperature. As Eq. 17 illustrates, 100 % efficiency is approached as the temperature difference between the two reservoirs in a heat engine becomes very large. An internal combustion engine, however, is not a completely reversible Carnot engine. The combustion process introduces significant irreversibility to the system and serves to limit the achievable efficiency. Practical values for thermodynamic efficiency of heat engines are around 40 % (Wright 2004).

It is frequently noted that an advantage of fuel cells is that not being heat engines, they are not Carnot limited (O'Hayre et al. 2009; Larminie and Dicks 2003; Hoogers 2003). Fuel cells are often operated nearly isothermally and directly convert chemical energy to electrical work. Not surprisingly, Eqs. 16 and 17 are not valid or even meaningful for fuel cells. This does not mean that fuel cells are not thermodynamically limited as Eq. 15 above still determines the maximum thermodynamic efficiency possible. Neither should it be misunderstood that the theoretical limit of efficiency is higher for fuel cells than heat engines.

As shown in Eq. 7, the maximum amount of energy available to do work in a fuel cell is given by the Gibbs free energy of the overall fuel cell reaction, providing a limiting value for W_{out} in Eq. 15 when determining the maximum theoretical

thermodynamic efficiency of a fuel cell. It is common to assume that fuel cells are operating isothermally and in thermal equilibrium with the surroundings. Care should be taken before the latter of these assumptions is made, especially if the fuel cell operates at a temperature significantly above ambient (Haynes 2001).

The higher heating value of the fuel, or the enthalpy of combustion to a vapor phase product, ΔH_{HHV}, as shown in Eq. 18 is most commonly used for Q_{in}:

$$\varepsilon_{fC} = \frac{\Delta G_{\mathrm{rxn}}}{\Delta H_{\mathrm{HHV}}} \tag{18}$$

This is justified by the fact that fuel combustion is used to provide energy to a heat engine, thus providing a convenient means of comparison. Nonetheless, this choice presents some challenges that can lead to significant confusion. Equation 18 can also give efficiencies of greater than 100 % for some systems in which there is a positive entropy change on reaction. Lutz et al. proposed a modified solution to deal with this, noting that energy for a positive entropy change must be taken from the surroundings (Lutz et al. 2002):

$$Q_{\mathrm{in}} = \begin{cases} -\Delta H_{\mathrm{R}} & \text{if} \quad \Delta S_R \leq 0 \\ -\Delta H_{\mathrm{R}} + T\Delta S_{\mathrm{R}} & \text{if} \quad \Delta S_R < 0 \end{cases} \tag{19}$$

where ΔH_{R} and ΔS_{R} are the enthalpy and entropy of reaction, respectively.

In direct comparisons of the thermodynamic efficiencies of heat engines and fuel cells, conservation of exergy or availability, not energy, should be considered (Haynes 2001). For both an ideal fuel cell and a Carnot engine, exergy is completely conserved. However, when full systems are taken into account, the situation changes. An ideal heat engine is supplied with heat, not chemical fuel. Combustion irreversibility significantly limits the maximum efficiency of heat engine system, though not of the heat engine itself (Haynes 2001). Likewise, fuel processing and heat rejection by the fuel cell system should also be considered. A fair comparison would also use the same chemical fuel as a feed to both systems, though in practice such a situation may not be realistic.

Electrochemical Efficiency

Another measure of efficiency in fuel cells is the electrochemical efficiency, defined as the ratio of the actual cell voltage to the ideal cell voltage:

$$\varepsilon_{\mathrm{electrochem}} = \frac{\Delta E}{\Delta E^0} \tag{20}$$

The ideal potential was described previously in Eq. 6. The actual cell potential is inevitably reduced from the ideal value, due primarily to various cell polarization losses, which will be discussed in more detail later in this chapter. The primary value of this efficiency measure is in comparing fuel cells to one another. It is sometimes

referred to as the voltage or activation efficiency as it is closely related to limitations imposed by reaction kinetics, as will be discussed subsequently in this chapter.

Fuel Utilization Efficiency

Fuel utilization, mentioned previously, provides yet another type of efficiency measure for fuel cells. In practice, some fraction of the fuel supplied to a fuel cell remains unreacted. The fuel utilization efficiency can be thus defined as the ratio of the mass of fuel reacted in the cell to the mass fed to the cell:

$$\varepsilon_{\text{fuel}} = \frac{m_{\text{fuel}}^{\text{reacted}}}{m_{\text{fuel}}^{\text{fed}}} \tag{21}$$

By combining this measure with the electrochemical efficiency expressed in Eq. 20, yet another efficiency value can be defined, the total electrochemical efficiency:

$$\varepsilon_{\text{total}} = \varepsilon_{\text{fuel}} \frac{\Delta E}{\Delta E^0} \tag{22}$$

Summary

Thermodynamics are fundamental to understanding fuel cell operation. As shown above, the maximum achievable efficiency in a fuel cell is limited in that not all reaction enthalpy can be converted to work. Of course, this is true of any other type of system as well as some fraction of energy is inevitably lost to entropy. Several different measures of efficiency can be defined from thermodynamic considerations. Reported efficiency values are not always explicitly defined in the fuel cell literature, with further challenges introduced in comparing efficiency from different types of systems, requiring care on the part of anyone working with such values.

Kinetic Processes in Fuel Cells

Other limitations on fuel cell performance occur due to activation and ohmic and mass transfer effects (O'Hayre et al. 2009; Larminie and Dicks 2003; Hoogers 2003). The effect of these losses on a typical current–voltage curve for a fuel cell is shown in Fig. 3. Each of these will be described in more detail in this section.

Reaction Kinetics and Activation Polarization

Irreversible kinetic effect in the half-cell reactions of a fuel cell leads to activation losses in the observed voltage output. In terms of the current–voltage characteristic, activation losses are most evident under low current conditions. Often, the ideal open-circuit voltage is not observed due to these effects. The activation or voltage efficiency, described in Eq. 20, provides a measure of this loss term. A deeper look at the relationship between reaction kinetics and the current voltage characteristics of a

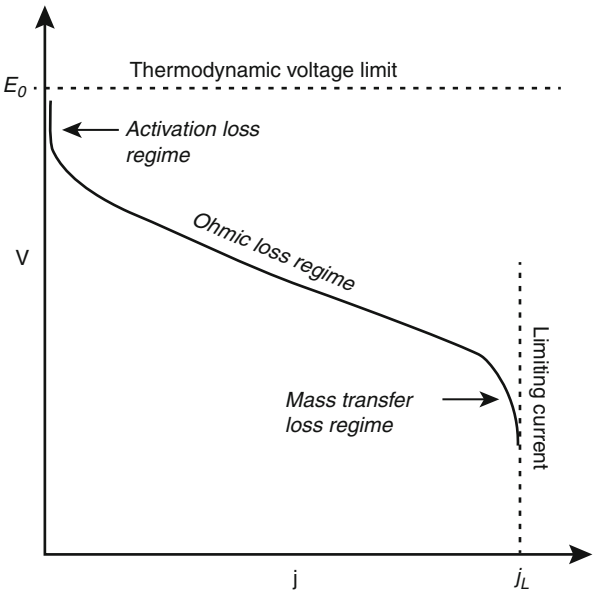

Fig. 3 Typical current–voltage characteristic curve illustrating major sources of voltage loss

fuel cell can provide some helpful insight into the source and means of preventing activation losses.

Equations 1 and 2 describe the reactions occurring at the anode and cathode of a hydrogen PEM fuel cell. More generally, an oxidation reaction where the reductant (Red) loses electrons occurs at the anode of a fuel cell:

$$\mathrm{Red} \rightarrow \mathrm{Ox} + ne^{-}, \tag{23}$$

while a reduction where the reactant, the oxidant (Ox), gains electrons occurs at the cathode:

$$\mathrm{Ox} + ne^{-} \rightarrow \mathrm{Red} \tag{24}$$

The overall reaction for a generic fuel cell can thus be expressed as

$$\mathrm{Ox} + ne^{-} \Leftrightarrow \mathrm{Red} \tag{25}$$

The activation barriers to these reactions determine the overall reaction rate, hence the rate at which electrons are generated and consumed at each electrode and how much current is supplied by the fuel cell. For simplicity, consider a single-step elementary reaction at each electrode. The rate of the half-cell reactions, R, can be expressed as

$$\begin{aligned} R_{\mathrm{Red}} &= k_{\mathrm{Red}}[\mathrm{Ox}]_{\mathrm{o}} \\ R_{\mathrm{Ox}} &= k_{\mathrm{Ox}}[\mathrm{Red}]_{\mathrm{o}} \end{aligned} \tag{26}$$

yielding a net reaction rate of

$$R = R_{\mathrm{Red}} - R_{\mathrm{Ox}} = k_{\mathrm{Red}}[\mathrm{Ox}]_{\mathrm{o}} - k_{\mathrm{Ox}}[\mathrm{Red}]_{\mathrm{o}} \tag{27}$$

where k_{Red} and k_{Ox} are the reduction and oxidation rate constants, while the [Red] and [Ox] are the surface concentrations of the reduced and oxidized species, respectively. The current density, j, at each electrode is related to reaction rate (R) by Faraday's constant for an n electron reaction:

$$j = RnF \tag{28}$$

so that the net current generated by the fuel cell is

$$j = j_{\mathrm{Red}} - j_{\mathrm{Ox}} = n\left(Fk_{\mathrm{Red}}[\mathrm{Ox}]_{\mathrm{o}} - Fk_{\mathrm{Ox}}[\mathrm{Red}]_{\mathrm{o}}\right) \tag{29}$$

The activation barriers for the anodic and cathodic reactions at the equilibrium potential can be defined as $\Delta G_{0a}^{\ddagger}$ and $\Delta G_{0c}^{\ddagger}$, respectively. In the presence of an electric field, E, the anodic activation energy for the oxidation reaction is decreased, and the cathodic activation energy for reduction increased by some fraction α of the applied field, as shown in Eqs. 30 and 31:

$$\Delta G_{a}^{\ddagger} = \Delta G_{0a}^{\ddagger} - n(1-\alpha)F\Delta\left(E - E^{0}\right) \tag{30}$$

$$\Delta G_{c}^{\ddagger} = \Delta G_{0c}^{\ddagger} + n\alpha F\Delta\left(E - E^{0}\right) \tag{31}$$

Rate constants can be expressed as a function of the Gibbs free energy of the reactions in an Arrhenius-type equation from transition state theory as

$$k_{\mathrm{Red}} = A_{\mathrm{Red}}\exp\left(\frac{-\Delta G_{\mathrm{c}}^{\ddagger}}{RT}\right) = A_{\mathrm{Red}}\exp\left(\frac{-\Delta G_{0\mathrm{c}}^{\ddagger}}{RT}\right)\exp\left(\frac{-\alpha F\left(E - E^{0}\right)}{RT}\right) \tag{32}$$

for the reduction reaction at the cathode and

$$k_{\mathrm{Ox}} = A_{\mathrm{Ox}}\exp\left(\frac{-\Delta G_{\mathrm{a}}^{\ddagger}}{RT}\right) = A_{\mathrm{Ox}}\exp\left(\frac{-\Delta G_{0\mathrm{a}}^{\ddagger}}{RT}\right)\exp\left(\frac{(1-\alpha)F\left(E - E^{0}\right)}{RT}\right) \tag{33}$$

for the oxidation reaction at the anode. At equilibrium, $E = E_0$ and the rate of the forward (reduction) and reverse (oxidation) reactions are equivalent, and the net current is zero. While the net current is zero, both half-cell reactions continue to occur and current does flow; however, the anodic and cathodic currents are equal and in opposite directions. This current is referred to as the exchange current density, j_0, defined in Eq. 34:

$$nFk_{\mathrm{Red}}^{0}[\mathrm{Ox}]_{\mathrm{o}} = nFk_{\mathrm{Ox}}^{0}[\mathrm{Red}]_{\mathrm{o}} = j_0 \tag{34}$$

Here, the standard rate constants are defined from Eqs. 35 and 36 for the case when $E = E_0$:

$$k^0_{\mathrm{Red}} = A_{\mathrm{Red}} \exp\left(\frac{-\Delta G^{\ddagger}_{0c}}{RT}\right) \tag{35}$$

and

$$k^0_{\mathrm{Ox}} = A_{\mathrm{Ox}} \exp\left(\frac{-\Delta G^{\ddagger}_{0a}}{RT}\right) \tag{36}$$

Exchange current is an indicator of catalyst activity; the more active the catalyst, the greater the exchange current. Substituting the rate constants from Eqs. 35 and 56 into Eq. 34 gives

$$j_0 = nFA_{\mathrm{Ox}} \exp\left(\frac{\Delta G^{\ddagger}_{0a}}{RT}\right)[\mathrm{Ox}]_{\mathrm{o}} = nFA_{\mathrm{Red}} \exp\left(\frac{\Delta G^{\ddagger}_{0c}}{RT}\right)[\mathrm{Red}]_{\mathrm{o}} \tag{37}$$

The Butler–Volmer equation describing the current density generated from a fuel cell is found by combining Eq. 29 with Eqs. 32, 33, and 37:

$$j = j_0 \left[\exp\left(\frac{-\alpha F\left(E - E^0\right)}{RT}\right) - \exp\left(\frac{(1-\alpha)F\left(E - E^0\right)}{RT}\right)\right] \tag{38}$$

The Butler–Volmer equation is considered one of the most important in electrochemistry and is presented with a variety of different forms with a more complete derivation in most electrochemistry and fuel cell texts (O'Hayre et al. 2009; Larminie and Dicks 2003; Hoogers 2003; Bockris et al. 1998; Bard and Faulkner 2001). The derivation presented here is only rigorously valid for a single-step reaction, though modifications can be made to account for more complex reaction mechanisms. Nonetheless, it still provides a good approximation of fuel cell kinetics and is instructive in describing key variables impacting reaction kinetics. The Tafel equation (39) describes an important limiting case of the Butler–Volmer equation for high overpotential, relating activation polarization, η_{act}, directly to the rate of an electrochemical reaction:

$$\eta_{\mathrm{act}} = E - E^0 = \left(\frac{RT}{\alpha nF}\right)\ln\left(\frac{j}{j_0}\right) \tag{39}$$

From the Butler–Volmer and Tafel equations, it is apparent that as more current is drawn from a fuel cell, a greater voltage loss is required. It also points the way toward how kinetic activity can be increased, namely, by increasing reactant

concentration, reducing the activation barrier to the reaction ($\Delta G_{0a}^{\ddagger}$), and/or increasing operating temperature (T).

Side reactions and catalyst poisoning are also important, acting to reduce the overall reaction rate in a fuel cell. Methanol and formic acid oxidations have more complex mechanisms than hydrogen oxidation, and the intermediates formed can impact reaction kinetics, in particular carbon monoxide, CO. Carbon monoxide poisoning is also an issue in hydrogen PEM fuel cells when the hydrogen comes from reformed hydrocarbons such as methane. These issues will be discussed further in the section on "Fundamentals of Fuel Cell Operation."

Charge Transport and Ohmic Losses

Ohmic losses are the result of resistance to charge transport in the system and include interconnect or electronic resistance ($R_{\text{interconnect}}$ or $R_{\text{electronic}}$) within the external circuit, contact resistances (R_{contact}) between different layers of the fuel cell associated with the transfer of electrons from the electrodes to the circuit or of ions from the electrocatalyst to the electrolyte (R_{anode} and R_{cathode}), and resistance to ionic motion in the electrolyte ($R_{\text{electrolyte}}$), illustrated in Fig. 4. The total ohmic resistance in the cell is described by Eq. 40:

$$\begin{aligned} R_{\text{ohmic}} &= R_{\text{interconnect}} + R_{\text{anode}} + R_{\text{cathode}} + R_{\text{electrolyte}} \\ &= R_{\text{electronic}} + R_{\text{contact}} + R_{\text{electrolyte}} \end{aligned} \tag{40}$$

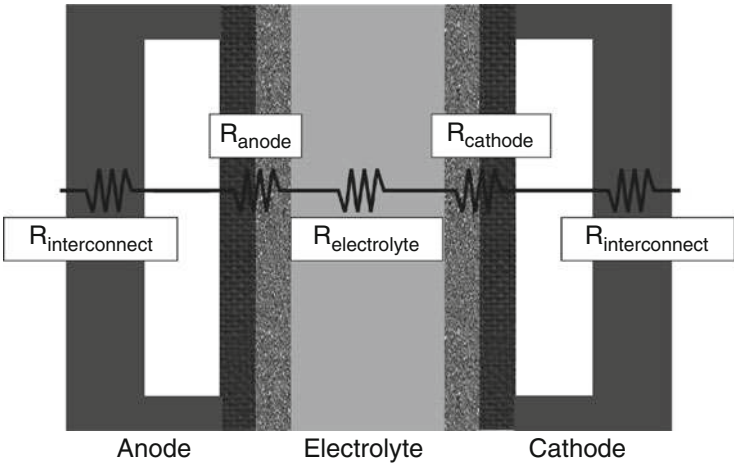

Fig. 4 Ohmic losses in a typical fuel cell result from resistances to current flow connected in series, including interconnect resistance ($R_{\text{interconnect}}$) due to the conductivity of the bipolar plate, electrode resistances (R_{cathode} and R_{anode}) in the catalyst and gas diffusion layers of the anode and cathode, respectively, and electrolyte resistance ($R_{\text{electrolyte}}$) due to the ionic conductivity of the electrolyte material

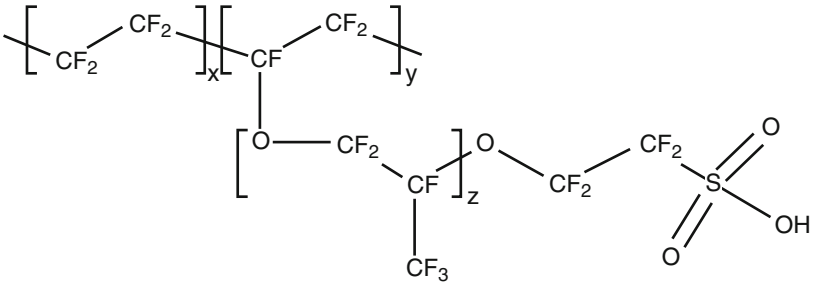

Fig. 5 Chemical structure of Nafion®

The different terms used here reflect the variation in the nomenclature found in the literature. Using Ohm's law, ohmic overpotential losses, η_{ohmic}, can be easily described:

$$\eta_{\text{ohmic}} = jR_{\text{ohmic}} \tag{41}$$

Generally, electronic transfer is rapid and contact resistance negligible, and thus have a minimal impact on fuel cell performance. The main source of ohmic loss is from the rate of ionic transport in the electrolyte. The slope of the linear region of the current–voltage plot in Fig. 3 at intermediate voltages is due largely to ohmic losses. In the presence of only an ohmic loss term, current density is directly proportional to the electric field driving the motion of the charge carrier, with the proportionality constant, σ, being the conductivity:

$$j = \sigma \frac{\mathrm{d}V}{\mathrm{d}x} \tag{42}$$

For an electrolyte of thickness L, the conductivity of interest is ionic:

$$j = \sigma_{\text{ionic}} \frac{V}{L} \tag{43}$$

Writing this expression in terms of the area of the electrolyte, we get the familiar expression for Ohm's law, where resistance is $\sigma A/L$:

$$i = \frac{A\sigma_{\text{ionic}} V}{L} = \frac{V}{R_{\text{ionic}}} \tag{44}$$

Equations 42, 43, and 44 make evident that it is desirable to maximize the ionic conductivity of the electrolyte as well as to minimize its thickness in order to minimize ohmic losses.

The most widely used electrolytes in hydrogen and other low-temperature fuel cells are solid sulfonated fluoropolymers, most notably DuPont's Nafion®, the general structure of which is illustrated in Fig. 5. Similar sulfonated fluoropolymer

membranes are marketed by 3M and Dow, among others. The fluoropolymer backbone of these materials provided a mechanically strong, chemically resistant structure, while the sulfonic acid groups lend both hydrophilicity and surface acidity that facilitate proton conduction. The performance of these membranes is a strong function of water content, with water acting as a vehicle to carry protons through the membrane (Choi et al. 2005). The phenomenon of water molecules being carried through the membrane by protons is referred to as electroosmotic drag. The production of water at the cathode in conjunction with electroosmotic drag creates a concentration gradient that leads to back diffusion of water. Total water transport is thus the sum of fluxes due to electroosmotic drag from anode to cathode and diffusion from cathode to anode (O'Hayre et al. 2009). The critical nature of water in proton transport limits the operating conditions of PEM-based fuel cells using Nafion®. At temperatures above ~80 °C and/or under conditions of low relative humidity, Nafion® can become dehydrated resulting in a loss of proton conductivity. At temperatures about ~120 °C, the polymer itself starts to degrade. As a consequence, practical operating temperatures are limited to below 80 °C, and humidification of hydrogen and airstreams is often necessary.

Mass Transfer and Concentration Polarization

In order for chemical reactions to occur at the respective electrodes, fuel and oxidant must reach the catalyst via mass transfer. Similarly, reaction products must be removed from the catalyst's surface. Under high current conditions, the fuel cell is limited by the rate of transport of fuel to the anode surface. Two regions are of interest in a fuel cell with regard to mass transport, the porous electrode surface where molecular diffusion is important and the flow field of the bipolar plate where bulk convective flow dominates.

The oxidation and reduction reactions occur at the catalyst surfaces on each respective side of the membrane electrode assembly. A concentration gradient develops as fuel and oxidant are consumed at the anode and cathode, respectively. The catalyst itself is on a support of microscale particles with nanoscale porosity; thus, diffusion is occurring both within the pores of the support and in the larger void spaces between catalyst particles. The rate of diffusive mass transfer of reactants in the catalyst layer provides a fundamental limit to fuel cell performance. Diffusive flux, J_{diff}, can be described by Fick's first law of diffusion, which for the case of steady state, one-dimensional diffusion in the x-direction in a planar catalyst layer becomes

$$J_{\text{diff}} = -D\frac{\mathrm{d}c}{\mathrm{d}x} = -D_{\text{eff}}\frac{c_R^* - c_R^0}{\delta} \tag{45}$$

where the diffusivity (D) and the concentration derivative in the x-direction ($\mathrm{d}c/\mathrm{d}x$) are expressed in terms of the surface and bulk concentrations of the reactant (c_{R}* and c_{R}^0, respectively), the effective diffusivity of the reactant in the catalyst layer (D_{eff}), and the diffusion length taken as the thickness of the catalyst layer (δ). The catalyst

layer is typically porous in order to maximize reactive surface area and on the order of 100–300-μm thick (O'Hayre et al. 2009). Effective diffusion coefficients in this layer are generally on the order of 10^{-2} cm^2 s^{-1} (O'Hayre et al. 2009). At steady state, the flux of reactants is equal to the rate of consumption of the reactant, which in turn determines the rate of current generation. The diffusion-limited current density can be related to the reactant flux using Faraday's constant:

$$j = nFJ_{\text{diff}} \tag{46}$$

Combining Eqs. 45 and 46, the current density due to diffusion can be expressed:

$$j = -nFD_{\text{eff}} \frac{c_{\text{R}}^{*} - c_{\text{R}}^{0}}{\delta} \tag{47}$$

A limiting current density, j_{L}, of the fuel cell would occur when the surface concentration reaches zero:

$$j_L = nFD_{\text{eff}} \frac{c_{\text{R}}^{0}}{\delta} \tag{48}$$

The higher j_{L} is, the greater the operating range of the fuel cell is. It is thus desirable to design catalyst layers and structures so as to minimize the diffusion length or layer thickness and to maximize the effective diffusivity. Combining the Nernst equation (Eq. 13) that describes the effect of concentration on voltage with the results described above from Fick's law yields an expression for the concentration polarization loss in a fuel cell, η_{conc}:

$$\eta_{\text{conc}} = \left(\frac{RT}{nF}\right) \ln\left(1 - \frac{j}{j_{\text{L}}}\right) \tag{49}$$

where j_{L} is the limiting current, as described by Eq. 48 where all of the reactant is consumed at the catalytic active site on the electrode surface.

The bulk concentration of reactants is determined by flow field design. Maximizing this value will also serve to maximize the limiting current as described by Eq. 48. With the exception of very small systems, most fuel cells are flow systems with multiple cells connected in series to supply sufficient voltage. In addition to collecting current from the fuel cells, flow field structures or bipolar plates serve to supply reactants to the cell through a series of channels machined into the plate. The channels may be arranged in any of a variety of complex patterns, some of the most common of which are illustrated in Fig. 6 including serpentine, parallel, and interdigitated designs. Critical dimensions of these channels are typically on the order of mm or cm. To date, no particular design enjoys consensus support as optimal. In addition to mass transfer, pressure drop and fuel utilization must also be considered in the design of flow fields, as well as material and manufacturing cost.

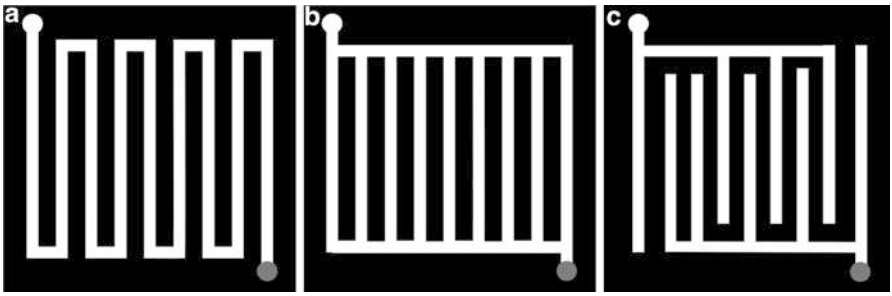

Fig. 6 Some common, simple flow field patterns, including (**a**) serpentine, (**b**) parallel, and (**c**) interdigitated channel designs

High flow rates favorable to mass transfer can result in incomplete fuel utilization and also result in a greater pressure drop, requiring more energy to move fuel and oxidant through the system. Analysis of flow field design using computational fluid dynamics continues to be an active area of fuel cell research (Nguyen et al. 2004).

Fuel Crossover Polarization

Ideally, a fuel cell electrolyte is impermeable to both fuel and oxidant. In practice, however, fuel crossover also presents challenges with Nafion, especially in direct methanol fuel cells (Heinzel and BarragÃn 1999; Jiang and Chu 2004; Neburchilov et al. 2007). Though not negligible, crossover is less of a concern in hydrogen (Cheng et al. 2007) and direct formic acid fuel cells (Rhee et al. 2003). The most obvious impact of crossover is in the reduction of fuel utilization efficiency. To quantify the effect of crossover, an internal current density, j_n, is defined:

$$j_n = v_{\text{fuel}}(nFA) \tag{50}$$

where v_{fuel} is the fuel crossover rate (mol s^{-1} cm^{-2}), n is the total number of the electrons participating in the reaction, F is Faraday's constant, and A is the area of the electrolyte membrane. Including this term in the expressions for activation and ohmic and concentration polarization losses (Eqs. 39, 41, and 49) illustrates the impact of crossover on each of these loss terms:

$$\eta_{\text{act}} = E - E^0 = \left(\frac{RT}{\alpha nF}\right)\ln\left(\frac{j + j_n}{j_0}\right) \tag{51}$$

$$\eta_{\text{ohmic}} = (j + j_n)R_{\text{ohmic}} \tag{52}$$

$$\eta_{\text{conc}} = \left(\frac{RT}{nF}\right)\ln\left(1 - \frac{j + j_n}{j_{\text{L}}}\right) \tag{53}$$

Activation overpotential can be further impacted by crossover if the fuel is oxidized at the cathode or acts as a poison to the cathode catalyst.

Summary of Electrode Polarization Effects

The major contributions to voltage loss in an operating fuel cell have been described in the preceding sections. These include activation and ohmic, concentration, and crossover polarization effects. The polarization losses at the anode and cathode are the result of activation and concentration polarization losses at each respective electrode:

$$\eta_{\text{anode}} = \eta_{\text{act},a} + \eta_{\text{conc},a} \tag{54}$$

and

$$\eta_{\text{cathode}} = \eta_{\text{act},c} + \eta_{\text{conc},c} \tag{55}$$

where activation and concentration polarization terms are described by either Eqs. 39 and 49 or Eqs. 51 and 53, depending on the relative importance of crossover. These overpotentials change the anode and cathode potentials from their theoretical values, as shown in Eqs. 56 and 57:

$$E_{\text{anode}} = E^0_{\text{anode}} + |\eta_{\text{anode}}| \tag{56}$$

and

$$E_{\text{cathode}} = E^0_{\text{cathode}} + |\eta_{\text{cathode}}| \tag{57}$$

The overall cell potential is then the difference between the cathode and anode potentials described above less ohmic polarization:

$$\Delta E_{\text{cell}} = E_{\text{cathode}} - E_{\text{anode}} - \eta_{\text{ohmic}} \tag{58}$$

where ohmic polarization is given by Eq. 40 or 52 depending on the importance of fuel crossover. Substituting Eqs. 56 and 57 into Eq. 58 yields

$$\Delta E_{\text{cell}} = \left(E^0_{\text{cathode}} - |\eta_{\text{cathode}}|\right) - \left(E^0_{\text{anode}} + |\eta_{\text{anode}}|\right) - \eta_{\text{ohmic}} \tag{59}$$

Rearranging terms and substituting the theoretical standard-state open-cell potential from Eqs. 7 and 14 yields

$$\Delta E_{\text{cell}} = \Delta E^0 - |\eta_{\text{cathode}}| - |\eta_{\text{anode}}| - \eta_{\text{ohmic}} \tag{60}$$

Equation 60 clearly illustrates how each of the polarization terms served to reduce the operating potential of a fuel cell from its theoretical maximum. Using basic concepts of thermodynamics, reaction kinetics, electrochemistry, and transport phenomena, we can see how relatively simple fundamental mathematical models of fuel cell performance can be developed, facilitating analysis of working cells, providing means of comparing research results, and enabling model-based control algorithms.

Low-Temperature Fuel Cell Technologies

One way of classifying fuel cell technologies is by the typical operating temperatures. As previously noted, this chapter will deal with low-temperature technologies. High-temperature fuel cells, including molten carbonate and solid oxide fuel cells, will be discussed in subsequent chapters. Proton exchange membrane or PEM fuel cells form the most widely studied category of fuel cells. These include hydrogen PEM fuel cells, direct alcohol cells such as the direct methanol fuel cell (DMFC), and direct formic acid fuel cells (DFAFCs). Alkaline and biological fuel cells will also be discussed briefly here, though these technologies are not currently of great importance for power generation.

PEM Fuel Cells

A key characteristic of these fuel cells is the proton exchange membrane, or PEM. The PEM is also sometimes referred to as a polymer electrolyte membrane as the most widely used materials are sulfonated perfluoropolymers such as Nafion®. This solid electrolyte serves as an electronic insulator, proton conductor, and the heart of the membrane electrode assembly, most notably for hydrogen PEM fuel cells but also for DMFCs and DFAFCs.

Hydrogen PEM Fuel Cells

In a hydrogen PEM fuel cell, hydrogen fuel is oxidized at the anode, while oxygen is reduced at the cathode in the reactions shown in Eqs. 1, 2, and 3. The mobile ion produced is the proton, H^+, with platinum on a carbon support serving as the catalyst at both the anode and cathode. The theoretical open-circuit voltage at 25 °C, assuming liquid water as the product, is 1.23 V (O'Hayre et al. 2009; Larminie and Dicks 2003; Hoogers 2003).

Hydrogen PEM fuel cells are without doubt the most widely studied and used today. This technology supplies power on NASA spacecraft and is the primary fuel cell technology being developed by the automobile industry. The low-temperature operation of hydrogen PEM fuel cells makes them suitable for portable applications as well.

Direct Alcohol Fuel Cells

Direct alcohol fuel cells utilize a proton exchange membrane in a manner similar to hydrogen PEM fuel cells. Methanol is the most common fuel for such cells (Wasmus and Küver 1999); however, significant research into ethanol has also been pursued. In these cells, protons are extracted directly from the alcohol, usually in a liquid state, at the anode. These are primarily being developed for portable power applications due to their high energy density and relative ease of fuel storage (O'Hayre et al. 2009; Larminie and Dicks 2003; Hoogers 2003).

By far, the most widely studied in this class of fuel cells is the direct methanol fuel cell, or DMFC. As the name implies, methanol is oxidized at the anode of a direct methanol fuel cell via the reaction shown below:

$$CH_3OH + H_2O \rightarrow 6H^+ + 6e^- + CO_2 \tag{61}$$

Oxygen is reduced at the cathode, similarly to a hydrogen cell:

$$\frac{3}{2}O_2 + 6H^+ + 6e^- \rightarrow 3H_2O \tag{62}$$

The overall reaction for a DMFC is then

$$CH_3OH + \frac{3}{2}O_2 \rightarrow 2H_2O + CO_2 \tag{63}$$

The theoretical open-circuit voltage of a DMFC is 1.18 V at 25 °C, though in practice, 0.6–0.8 V is more common due to kinetic limitations for both oxidation and reduction reactions. The slow oxidation kinetics are compounded by catalyst poisoning from carbon monoxide formed as an intermediate product in the oxidation mechanism (Wasmus and Küver 1999; Antolini et al. 2008). The other major limitation in DMFC performance is fuel crossover through the PEM (Heinzel and BarragÃn 1999; Jiang and Chu 2004; Neburchilov et al. 2007). This problem limits practical methanol concentrations to 1–2 M in working DMFCs. Despite these problems, DMFCs are one of the leading technologies being pursued for portable power generation.

Direct Formic Acid Fuel Cells

In recent years, direct formic acid fuel cells (DFAFCs) have emerged as a rival technology to DMFCs for portable power applications (O'Hayre et al. 2009; Yu and Pickup 2008). As the name implies, formic acid is oxidized at the anode:

$$HCOOH \rightarrow CO_2 + 2H^+ + 2e^- \tag{64}$$

As with hydrogen PEM fuel cells and DMFCs, oxygen is reduced at the cathode:

$$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O \tag{65}$$

The overall reaction in a DFAFC is thus

$$HCOOH + \frac{1}{2}O_2 \rightarrow H_2O + CO_2 \tag{66}$$

This cell gives a theoretical open-cell voltage of 1.48 V, much higher than that for either DMFCs or hydrogen PEM fuel cells (Yu and Pickup 2008). The leading catalysts for formic acid oxidation are palladium rather than platinum based, offering a potential cost advantage over DMFCs (Larsen et al. 2006; Liu et al. 2006a). The major drawback for formic acid is that its energy density is significantly lower than that of methanol (Yu and Pickup 2008). However, since formic acid crossover

through Nafion® is much lower than that of methanol, this problem can be compensated for by the use of higher fuel concentrations (Rhee et al. 2003; Yu and Pickup 2008). Progress with these fuel cells has been very rapid and they show much promise for the future.

Alkaline Fuel Cells

Hydrogen is utilized as the fuel in alkaline fuel cells; however, instead of protons, hydroxyl ions serve as the mobile ions in an alkaline electrolyte, most commonly potassium hydroxide. The anode and cathode reactions are given in Eqs. 67 and 68, respectively:

$$H_2 + 2OH^- \rightarrow 2H_2O + 2e^- \tag{67}$$

$$\frac{1}{2}O_2 + 2e^- + 2H_2O \rightarrow 2OH^- \tag{68}$$

Alkaline fuel cells hold a special place in fuel cell history as they were the first power systems demonstrated to be of practical use for power generation (Larminie and Dicks 2003; Perry and Fuller 2002). Francis Bacon is credited for pioneering development of these fuel cells in the 1940s and 1950s, and this technology was the one chosen by NASA to provide electrical power onboard its first spacecraft (Larminie and Dicks 2003; Perry and Fuller 2002). Alkaline fuel cells have several advantages over other fuel cell technologies, one of which is that the oxygen reduction reaction at the cathode occurs at a lower activation overvoltage than in acidic PEM fuel cells allowing the cells to operate higher voltages (up to 0.875 V) and consequently higher efficiency (O'Hayre et al. 2009; Larminie and Dicks 2003). Non-precious metal catalysts can also be utilized making these fuel cells very low in cost (O'Hayre et al. 2009; Larminie and Dicks 2003). In spite of these advantages, NASA and much of the fuel cell world began turning away from alkaline fuel cells in favor of PEM-based technology in the 1970s and 1980s, and today they receive far less research and development attention. The chief disadvantage of alkaline fuel cells is their sensitivity to CO_2, which reacts with the alkaline electrolyte to form carbonates and reduce the availability of hydroxyl ions as well as oxygen solubility in the electrolyte (O'Hayre et al. 2009; Larminie and Dicks 2003). The electrolyte must thus be sealed from the air to maintain a long cell life and very pure hydrogen must be utilized. Hydrogen reformed from hydrocarbon sources inevitably contains some degree of CO_2, which would have to be removed prior to use in an alkaline fuel cell. While this technology does have its challenges, they do not appear to be more substantially formidable than those associated with other technologies, as others have noted (Gülzow 1996; McLean et al. 2002). However, the limited research attention currently directed toward alkaline fuel cells makes it unlikely that they will surpass PEM fuel cell technology in importance or value in the near future.

Enzymatic and Other Biofuel Cells

Biological fuel cells utilize enzymes (either alone or with a microorganism) to catalyze the electrochemical reactions in a fuel cell (Bullen et al. 2006; Shukla et al. 2004; Barton et al. 2004; Heller 2004). As such, their operation is limited to conditions where the organisms can survive and/or the enzymes can remain stable and not denature, typically nearly neutral pH and from around 20–40 °C. Typical fuels include sugars and simple alcohols. A key advantage of these is their inherent selectivity as enzymes typically only catalyze very specific substrates. This selectivity, however, comes at a price as it is the result of a complex protein matrix surrounding the active center of a given enzyme where the reaction occurs. While conferring great selectivity on the enzyme, this matrix also serves in effect as an electrical insulator, reducing the transduction efficiency of electrons produced at the active center to an electrode where it can be collected. Poor transduction efficiency also plagues microbial fuel cells. Probably the greatest challenge associated with enzymatic fuel cells is the poor stability of the enzymes themselves. Currently, practical lifetimes of enzymatic fuel cells are limited to days or weeks as the enzymes denature in a working cell. Biofuel cells are not currently nor are they expected to be of major importance for power generation; however, they do have potential for some niche applications such as energy scavenging, biosensors, and in vivo power generation (Bullen et al. 2006; Shukla et al. 2004; Barton et al. 2004; Heller 2004).

Fuel Cell Systems

The fuel cell or fuel cell stack in and of itself is only part of a full power system. Specific requirements vary widely depending on the type of fuel cell and the application; however, several other systems and components are often necessary. These might include fuel delivery and fuel processing systems, thermal management systems, and power management systems (O'Hayre et al. 2009). These systems add cost to the total system and utilize a fraction of the energy produced. Accounting for these is important not just in cost and performance calculations but also in evaluating the environmental impact of a fuel cell.

Membrane Electrode Assembly, Flow Field, and Fuel Cell Stack

At the heart of a fuel cell is the membrane electrode assembly or MEA. This consists of up to five layers including the proton exchange membrane at the center, anode and cathode electrocatalyst layers on either side of the membrane, and gas diffusion layers, illustrated in Fig. 7. The proton exchange membrane is most commonly Nafion®, a perfluorocarbon polymer manufactured by DuPont. Gas diffusion layers are most commonly made from carbon paper or carbon fabric. The catalyst, most commonly platinum based, may or may not be supported on a high-surface area ($>75\ m^2\ g^{-1}$) conductive carbon support. Whether supported or pure metal, the

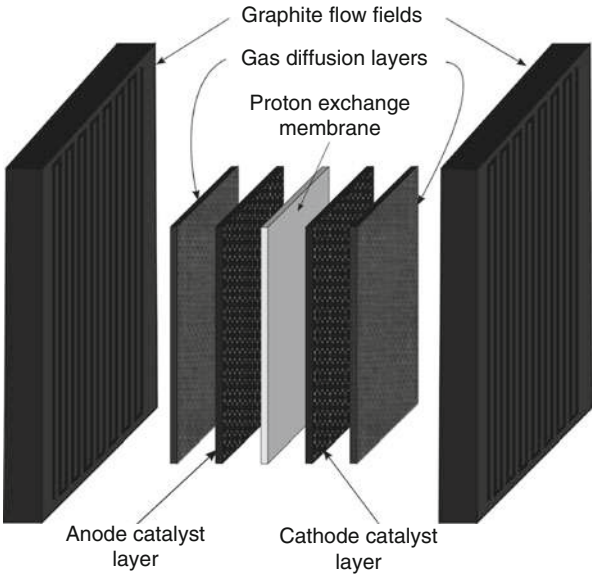

Fig. 7 Layers of a typical membrane electrode assembly and flow field

catalyst is used to make an ink with an appropriate solvent. Typically, a small amount of Nafion® is added to the catalyst ink. The ink may be applied to the proton exchange membrane or the gas diffusion layer via screen printing, spraying, ink-jet, or some similar technique (Ralph and Hogarth 2002). The layers are then bonded together, typically by hot pressing (Ralph and Hogarth 2002).

The MEA is in turn sandwiched between flow field plates which, often referred to as bipolar plates, also serve as current collectors. These are typically machined from graphite and contain flow channels to supply fuel and oxidant to the anode and cathode, respectively. As noted previously, a single fuel cell can supply a maximum, open-cell voltage of around 1 V, depending on the specific type of fuel cell being used. Practical operating voltages are usually around 0.6–0.7 V, where power output is maximized. Most applications, however, require anywhere from a few volts to several hundred volts. For this reason, fuel cells are commonly connected in series in vertical stack where a flow field plate serves as the anode for one cell and cathode for a neighboring cell, hence the name bipolar plate. Using a fuel cell stack in this manner allows the voltage requirements of any given application to be met.

Fuel Processing, Storage, and Delivery

One of the more challenging aspects of fuel cell design is providing fuel to the cell. The approach to solving this problem depends in large part on the type of fuel cell being employed and the needs of the target application. The approach to this design challenge has a major impact on the energy density of the overall fuel cell system. Trends in hydrogen storage research will be discussed in the subsequent section on "Hydrogen Storage."

Probably the simplest solution to the problem of fuel storage and delivery is that of liquid-powered fuel cells where the fuel is directly electrooxidized, such as in direct methanol and direct formic acid fuel cells. These types of fuel cells are of interest primarily for small-scale, portable power systems. While such fuels have high energy densities, kinetic and transport limitations limit fuel cell performance, imposed in part by the fuel delivery systems. For small-scale fuel cells, a passive fuel delivery system may be employed, placing the fuel reservoir in direct contact with the anode or using gravity, surface tension, evaporation, or a similar mechanism to supply fuel to the cell or stack. Such an approach helps to minimize the weight of the total system allowing a high system energy density to be achieved; however, it also can lead to mass transfer limitations. The use of a passive fuel delivery system is typically only sufficient for the smallest of fuel cells.

There are several fuel storage options for hydrogen PEM fuel cells. The most notable of these are direct hydrogen storage in the form of a compressed gas or cryogenic liquid, storage in the form of chemical hydrides, and the use of a hydrogen carrier such as methane or ammonia. Each of these involves a very different balance of plant requirements, as will be discussed below.

Current hydrogen vehicles utilize compressed hydrogen gas tanks for fuel storage. This approach is arguably the simplest and most straightforward. Tank pressures of up to 700 bar can currently be achieved. The safety of a high-pressure, explosive gas presents a significant concern in such systems. To safely maintain such high pressures requires the use of a heavy storage tank, as well as protective measures for lines, valves, regulators, etc. This weight dramatically reduces the overall energy density of the system, which has driven research efforts toward an alternative hydrogen storage methodology. Additionally, a significant amount of energy must be expended to pressurize the hydrogen. For fuel delivery, the pressure of the tank can in most cases provide a sufficient driving force to move hydrogen through the fuel cell stack. Liquid hydrogen presents similar, though magnified, challenges as even more energy is required to cool and liquefy the hydrogen and the cost and weight of a vacuum insulated storage tank are large.

One alternative approach to hydrogen storage and delivery that has attracted much attention is the use of solid-state, metal, or chemical hydrides or hydrogen adsorbents. Generally, these materials release hydrogen as they are heated; thus, thermal management is critical for a fuel delivery system using these materials. The hydrogen supplied in this manner can be extremely clean, lacking the performance-degrading impurities such as CO that are found in hydrogen obtained from hydrocarbons. There are still many challenges associated with solid-state hydrogen storage materials, including the need to further increase hydrogen capacity and to reduce the energy required for recharging the materials with hydrogen after use. To date, the use of these materials is still confined primarily to the research laboratory.

The use of hydrogen carriers provides another alternative for hydrogen storage and delivery in fuel cell systems. Common hydrogen carriers in fuel cell systems include organic hydrocarbons such as methane, methanol, formic acid, and even gasoline as well as inorganic compounds such as sodium borohydride and ammonia. These are attractive for many applications in that they provide greater gravimetric

and volumetric energy densities than hydrogen itself. They are also typically easier to store and transport, and often a supply chain infrastructure already exists for them. It should be noted that hydrogen gas is not naturally occurring and is most commonly derived from methane, natural gas, or some other source industrially. Hydrogen carriers are generally not able to be used directly by a fuel cell. Instead, they must be reformed or chemically processed to yield hydrogen. The need for fuel reforming or a fuel processing subsystem generally limits this hydrogen storage and delivery methodology to stationary power generation applications. Fuel reforming systems have an added advantage in that they can often be configured to run with multiple hydrogen carriers providing fuel flexibility.

Reforming of hydrogen carriers may occur internally within the fuel cell stack or more likely external to the fuel cell in a separate reforming subsystem. In either case, the carrier is chemically converted to hydrogen and by-products via a chemical reaction before it can be utilized by the fuel cell to provide power. Design goals for a fuel processing system include minimizing energy required by the system as well as the amount of impurities and pollutants produced (particularly CO and other catalyst poisons) and maximizing the hydrogen yield from the system. A common figure of merit for comparing different fuel sources is the carrier system effectiveness, defined as the ratio of the percentage of energy in the carrier converted to electricity to the percentage of energy in pure hydrogen converted to electricity in the same fuel cell. Care should be taken in using this or any other measure comparing fuel cell performance as often such calculations are reported based upon the fuel only, neglecting the energy used in the fuel processing step or other system components.

When using a hydrogen carrier, the required fuel processing subsystem is often extremely complex, which is why such systems are primarily of interest only for larger, stationary power systems. The major components of such a system include a fuel reformer or similar reactor to convert the carrier to hydrogen and by-products, a water gas shift reactor to increase the hydrogen to carbon monoxide ratio, and a hydrogen cleanup unit to remove carbon monoxide and any other impurities that may poison fuel cell catalysts or must otherwise be removed.

There are three common reforming reaction types for hydrocarbons: steam reforming, partial oxidation, and autothermal reforming. Operating temperatures for these reactions range from 600 to 1,000 °C depending on the fuel and type of process. Steam reforming involves the endothermic reaction of the hydrocarbon with steam, as the name implies:

$$\mathrm{C}_x\mathrm{H}_y + x\mathrm{H}_2\mathrm{O}(g) \Leftrightarrow x\mathrm{CO} + \left(\frac{1}{2}y + x\right)\mathrm{H}_2 \rightarrow \mathrm{CO}, \mathrm{CO}_2\mathrm{H}_2, \mathrm{H}_2\mathrm{O} \tag{69}$$

The endothermic reaction makes thermal management challenging in steam reforming reactors. This approach provides the highest hydrogen yield but also the least fuel flexibility. A generic partial oxidation reaction of a hydrocarbon is shown in Eq. 70:

$$C_xH_y\frac{1}{2}xO_2 \Leftrightarrow xCO + \frac{1}{2}yH_2 \tag{70}$$

Unlike steam reforming, this reaction is exothermic, simplifying thermal management and allowing for faster reactor start-up, though at a higher operating temperature. Partial oxidation provides a greater degree of fuel flexibility than steam reforming. Unfortunately, this approach to reforming provides the lowest hydrogen yield as well as the highest degree of pollutant emissions. Autothermal reforming combines aspects of both steam reforming and partial oxidation, as shown in the generic reaction for the process:

$$C_xH_y + zH_2O(g) + \left(x - \frac{1}{2}\right)O_2 \Leftrightarrow xCO + \left(z + \frac{1}{2}y\right)H_2 \rightarrow CO, CO_2H_2, H_2O \tag{71}$$

As both exothermic and endothermic reactions are combined in a single process, thermal management is somewhat simplified eliminating the need for heat exchangers and allowing a physically smaller system to be constructed. However, a more complex control system design is necessitated. Hydrogen yield from autothermal reforming is greater than with partial oxidation, though not as high as with steam reforming.

An alternative to reforming hydrocarbon fuels is production of hydrogen from solid carbonaceous material (e.g., coal) via gasification or from biomass through anaerobic digestion. A generic gasification reaction is shown in Eq. 72:

$$C + aO_2 + bH_2O \Leftrightarrow cCO_2 + dCO + eH_2 + \text{other species} \tag{72}$$

The full mechanism involves several elementary steps and varies depending on the carbon source. As with reforming, reaction temperatures are high, ranging from 700 °C to 1,400 °C. Common polluting by-products include sulfur and nitrogen oxides. Anaerobic digestion is attractive from an environmental standpoint in that it utilizes renewable biomass such as sewage, livestock waste (i.e., manure), plant matter, or food processing waste as the hydrogen carrier. Through a series of chemical reactions facilitated by bacteria, the biomass is converted to methane, CO_2, and subsequently to hydrogen. By-products include CO and CO_2 as well as hydrogen sulfide.

The hydrogen gas produced in the reforming, gasification, or anaerobic digestion stage cannot be fed directly to a fuel cell as it also contains by-products, notably carbon monoxide, which can poison fuel cell catalysts. Most hydrogen PEM fuel cell catalysts can withstand CO concentration levels no greater than about 100 ppm. Two processes are typically employed to clean up this hydrogen gas stream before it is sent to the fuel cell, a water gas shift reactor followed by a chemical separation/cleanup process. The reversible water gas shift reaction

$$CO + H_2O \Leftrightarrow CO_2 + H_2 \tag{73}$$

describes an equilibrium between water vapor and carbon monoxide with hydrogen and carbon dioxide. The goal in utilizing such a reaction is to maximize the hydrogen to carbon monoxide ratio in the product stream. Typically, CO content can be reduced to 0.2–1.0 mol% in this way.

The final cleanup of the hydrogen stream can be accomplished using any of several methods or a combination of methods. Chemically, selective methanation or selective oxidation of CO can be utilized. Unfortunately, both of these reactions also consume some amount of hydrogen. Physical separation processes, including adsorption and membrane processes, can also be employed. Adsorbents such as high-surface area carbon, silica, and zeolites can provide a great deal of selectivity and also consume very little power in an operating separation system. Palladium–silver alloy membranes can also be used as hydrogen diffuses through a membrane at a faster rate than other species.

Thermal Management

Not all energy from the fuel cell reactions is converted to electricity; some is lost as heat. A thermal management system serves to dissipate this heat in order to control the operating temperature of the fuel cell. The degree of thermal management required varies depending on the size and type of fuel cell system. For small portable systems, passive thermal management relying on natural convection is often sufficient as the amount of heat produced is small. However, for larger systems producing on the order of 100 W or more, significant heat can be produced, overheating the cell and/or creating significant thermal gradients. In such cases, active cooling is necessary. A common approach is to utilized forced convection with a fan, blower, or pump pushing air or cooling fluid through additional cooling channels within the bipolar plates. Liquid coolants with their high heat capacity are commonly used in automotive fuel cells. Liquid coolants create additional challenges in system design as their larger pressure drop requires greater energy to pump them through the system, and unlike ambient air, they are necessarily in limited supply onboard the system and must be recycled. A key figure of merit for an active thermal management system design is its effectiveness ratio, defined as the ratio of the heat removal rate to the electrical power consumption rate. The goal of system design is thus to minimize power consumed by fans, blowers, or pumps moving the cooling media through the system while maximizing the rate of heat dissipation. Typical values of effectiveness ratios for well-designed systems range from ~20 to 40 (O'Hayre et al. 2009). For systems that include a high-temperature fuel reformer and/or an afterburner to combust unused hydrogen leaving the fuel cell, employment of a heat recovery mechanism is necessary to maximize the overall efficiency of the system. Using one or more heat exchangers, heat emitted from the fuel cell or an afterburner that combusts unused hydrogen leaving the fuel cell can be used to supply energy to a fuel reforming subsystem.

Power Management

Power management is critical for any fuel cell-based power system and typically includes electrical circuitry for four tasks: (1) power regulation, (2) power inversion, (3) monitoring and control, and (4) power supply management (O'Hayre et al. 2009; Larminie and Dicks 2003). The power supplied by a fuel cell is not stable as the voltage varies with current load, environmental conditions (temperature, humidity, etc.), and other factors. Typically, DC/DC converters are utilized to convert fuel cell voltage output to a stable, specified value, forming the main component of a power regulation system. The DC power produced by the cell, however, must be converted to AC for many applications, such as supplying power to AC motors used in electric vehicles and other AC electric devices that traditionally might be powered from the electric grid. Power inversion serves to convert DC power to AC power. The total fuel cell system is essentially an electrochemical processing plant. Process monitoring tools such as thermocouple and pressure gauges provide inputs to feedback control loops. The process controls serve to adjust variables such as fuel feed flow rate and coolant flow rate in response to perturbations in the system to maintain steady performance of the system as a whole. Finally, power supply management is necessary to deal with rapid changes in load requirements. For example, a typical car would require ~25 kW of power on average, but as much as 120 kW at peak (e.g., during rapid acceleration). Fuel cells have a relatively slow response to rapid changes in power demands, on the order of seconds to hundreds of seconds, as pumps, compressors, and other components must respond in order for the power output to begin to change. Batteries and supercapacitors are the main components of the power supply management systems, acting as energy buffers to reduce response time to the order of milliseconds.

Technical Challenges and Current Research

Many technical challenges remain to be overcome if fuel cells are to be competitive both in terms of performance and economics with currently dominant technologies. The biggest of these are hydrogen storage, catalysis, electrolyte membrane, and bipolar plate materials. An overview of these issues will be provided here. References cited should provide a good starting point for the reader interested in a more in-depth study of these topics.

Hydrogen Storage

For automotive and other mobile applications, storage of hydrogen is one of the greatest technical challenges for fuel cell technology. High-pressure and cryogenic hydrogen storage, while conceptually simple, has an assortment of problems. An ideal hydrogen storage technology would have both high gravimetric and volumetric hydrogen density, be stable at temperature up to 50 °C, enable rapid delivery of

Table 2 Summary of DOE hydrogen storage goals

	2010	2015
Gravimetric system energy density (net useful energy/maximum system mass)	1.5 kW h kg^{-1}	3 kW h kg^{-1}
	6 wt% H_2	9 wt% H_2
Volumetric system energy density (net useful energy/maximum system volume)	1.5 kW h L^{-1}	2.7 kW h L^{-1}
	0.045 kg H_2 L^{-1}	0.081 kg H_2 L^{-1}
Storage system cost	4 $/kW·h net	2 $/kW·h net

hydrogen to the fuel cell, and be capable of being regenerated. The US Department of Energy has set targets in this regard as part of a National Hydrogen Energy Roadmap, some of which are summarized in Table 2 (US Department of Energy 2002). It should be noted that these targets are for hydrogen storage systems, not hydrogen storage materials. A number of materials are capable of meeting energy density goals, if only the material is accounted for.

Hydrocarbon materials meet DOE targets, but reforming of these fuels to produce hydrogen also yields CO_2 and catalyst-poisoning CO in addition to H_2. The reforming process is also energy intensive. As previously noted, this approach is generally seen as promising only for stationary power generation.

Solid-state hydrogen storage materials are currently a major research focus in fuel cell technology (US Department of Energy 2002; Hubert 2005; Züttel 2004). In general, solid-state hydrogen storage solutions can be grouped into two categories: hydrogen physisorption systems and chemical hydrides. The majority absorbents investigated for hydrogen physisorption are either various forms of carbon (e.g., graphene and carbon nanotubes) (Shiraishi et al. 2004; Thomas 2007; Yamanaka et al. 2004) or metal organic frameworks (Thomas 2007; Panella and Hirscher 2005), though these are certainly not the only materials under investigation. The advantages of physisorption systems are their low cost, simple design, and ability to adsorb hydrogen at low pressures (Züttel 2004). However, to date no absorbent material has been able to meet the DOE hydrogen density goals, much less system the hydrogen density goals for a full system. Further, they typically desorb hydrogen at near or slightly above room temperature, making them unattractive for many practical applications (Züttel 2004). Nonetheless, this approach continues to be widely investigated, and some new adsorbents, in particular metal organic frameworks, show promise.

Among the most promising solid hydrogen storage materials are metal and complex chemical hydrides. Metal hydrides of interest involve the lightest metals, such as Li, Be, Na, Mg, B, and Al, in order to meet hydrogen density goals (Züttel 2004; Van Den Berg and Areán 2008; Sakintuna et al. 2007). Some examples include $LiAlH_4$, $LiBH_4$, $LiNH_2$, $NaAlH_4$, $NaBH_4$, and MgH_2, among many, many others (Züttel 2004; Van Den Berg and Areán 2008; Sakintuna et al. 2007). Some of these advanced hydride materials can meet hydrogen density goals, but present a host of other system challenges. Many of these hydrides are unstable to the point of

explosion in the presence of air and/or water, requiring that they be sealed in a working system. Typically, hydrides are heated to release hydrogen, often in a highly exothermic reaction, leading to sintering of material; also there is typically a volume change on hydrogen discharge (Schüth et al. 2004). Heavier metals may be added to the system in small quantities as a catalyst to enhance dehydrogenation kinetics. Ball milling and other processes to create small particles, even nanostructured materials, are also commonly utilized as a means of enhancing reaction kinetics in metal hydrides (Bérubé et al. 2007). Rehydrogenation is accomplished by placing the used material in a pressurized hydrogen atmosphere, typically requiring an excessive amount of energy (Van Den Berg and Areán 2008; Sakintuna et al. 2007).

Among the most promising hydrogen storage materials are the chemical hydrides ammonia borane (NH_3BH_3) and related compounds (Stephens et al. 2007; Marder 2007). Ammonia borane (AB) is a stable power in air and readily soluble in a number of common solvents. Hydrogen is released in a three-stage process, shown below, with a 6.5 wt% hydrogen yield in the first stage, 13.1 wt% in the second, and 19.6 wt % in the third. A rehydrogenation process has not been perfected, but progress has been made on this front, and the reactions involved are all thermodynamically favorable (Hausdorf et al. 2008). As with the metal hydrides, improving reaction kinetics is a challenge as is the volume change on reaction. Enhanced kinetics have been observed with a number of metal catalysts as well as with ammonia borane incorporated into mesoporous matrices. A slightly acidic environment has been observed to considerably enhance dehydrogenation of AB.

Catalysis

Anode and cathode reactions in low-temperature fuel cells require catalysts to achieve reaction rates sufficient for fuel cells to be practical. Leading catalysts for fuel cells are based on expensive, precious metals such as platinum, palladium, and ruthenium. Sufficient progress has been made to reduce metal loading to the point that catalysts are often no longer the largest cost contributor to fuel cell systems. However, should fuel cell technology become more widespread, this may change as increasing demand for catalyst metals would be expected to drive up prices. The largest fraction of the environmental impact of fuel cell technology remains in the mining, processing, and transport of the catalyst material.

From a performance standpoint, the greatest activation losses occur at the cathode of hydrogen fuel cells in the oxygen reduction reaction. Not surprisingly, this is the focus of significant research and development efforts (Wang 2005). The complex mechanism of oxygen reduction provides insight into some of the challenges. The desired pathway for the reaction is the direct oxygen reduction shown in Eq. 74:

$$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O \tag{74}$$

However, the formation of hydrogen peroxide

$$O_2 + 2H^+ + 2e^- \rightarrow H_2O_2 \tag{75}$$

and various platinum oxides

$$Pt + H_2O \rightarrow PtO + 2H^+ + 2e^- \tag{76}$$

occurring at standard potentials of 0.68 and 0.88 V versus NHE at 25 °C, respectively, contributes to a reduction in the open-circuit voltage in the cell. The most active catalysts for oxygen reduction are platinum alloys, containing predominantly platinum (∼75 wt%, metal basis) (Ralph and Hogarth 2002). The stability of the alloy in contact with the acidic membrane surface is a key factor that must be considered, as the base metal in the alloy can dissolve into the membrane (Ralph and Hogarth 2002). Alloys that showed both high activity and stability included Pt–Cr, Pt–Zr, and Pt–Ti (Ralph and Hogarth 2002). Hydrogen peroxide produced at the cathode can also impact catalyst stability, especially for non-platinum catalysts (Lefévre and Dodelet 2003).

The considerable cost of platinum has also spurred research into cheaper catalyst materials (Wang 2005) though to date none has been found with sufficient activity and stability to supplant the platinum alloys. Iron- and cobalt-based catalysts have shown some promise, particularly in porphyrins and in the presence of pyrrole and pyridine structures (Feng and Alonso-Vante 2008; Bezerra et al. 2008). Metal-free carbon catalysts doped with nitrogen or nitrogen and boron have drawn considerable attention of late (Ikeda et al. 2008; Gong et al. 2009). Nitrogen appears to have some beneficial effect in each of these types of catalyst, though the mechanism is still a subject of investigation (Ikeda et al. 2008). Though the activity of these alternative catalysts is still not as good as that of platinum, the lower cost could justify their use in some applications.

A number of metals will catalyze the hydrogen oxidation reaction, though platinum is the most active. Activation losses at the anode of hydrogen fuel cells are generally quite small. The primary focus of research on hydrogen oxidation catalysis is related to poison resistance. Hydrogen is most commonly derived from natural gas reforming, which inevitably results in the formation of not only hydrogen but also CO and CO_2. CO in particular is a notorious catalyst poison (Camara et al. 2002). The most widely studied CO-resistant catalysts are Pt–Ru alloys, though others have been examined (Wee and Lee 2006).

Unlike with hydrogen oxidation, significant activation losses are associated with both the methanol and formic acid oxidation reactions in DMFCs and DFAFCs, respectively. Methanol oxidation catalysis research has been recently reviewed by several authors (Wasmus and Küver 1999; Wee and Lee 2006). As with hydrogen oxidation, improving resistance to carbon monoxide poisoning is one of the major challenges in improving methanol oxidation catalysts, though it is more critical as CO is formed through the electrooxidation reaction mechanism itself rather than appearing as an impurity in the fuel.

The electrooxidation of methanol occurs predominantly through an indirect pathway that is initiated by the adsorption of methanol (CH_3OH_{ad}) onto the catalyst,

a step that requires three to four adjacent metal atom sites arranged triangularly on the catalyst surface (Neurock et al. 2008):

$$CH_2OH \rightarrow CH_2OH_{ad} \tag{77}$$

This is followed by dehydrogenation of the adsorbed methanol on the surface of the catalyst, forming carbon monoxide (CO_{ad}) as a strongly adsorbed reaction intermediate (O'Hayre et al. 2009; Larminie and Andrew 2003; Parsons and VanderNoot 1988; Hogarth and Ralph 2002):

$$CH_2OH_{ad} \rightarrow CO_{ad} + 4H^+ + 4e^- \tag{78}$$

Subsequently, an activated hydroxyl, OH_{ad}, or similar activated hydrous intermediate is required for complete oxidation of the adsorbed carbon monoxide (O'Hayre et al. 2009; Neurock et al. 2008; Larminie and Andrew 2003; Parsons and VanderNoot 1988). The formation of this OH_{ad} species

$$H_2O_{ad} \rightarrow OH_{ad} + H^+ + e^- \tag{79}$$

is the rate-determining step for the overall methanol electrooxidation reaction. In the presence of the activated OH_{ad} complex, CO_{ad} is oxidized to carbon dioxide (CO_2), the final reaction product:

$$CO_{ad} + OH_{ad} \rightarrow H^+ + e^- + CO_2 \tag{80}$$

Summing Eqs. 78, 79, and 80 gives the overall electrooxidation reaction for methanol, shown previously in Eq. 61, which produces six protons and electrons per methanol molecule reacted. Platinum has the highest reactivity of any pure metal catalyst and is the predominant catalyst used for this reaction (O'Hayre et al. 2009; Parsons and VanderNoot 1988). Unfortunately, the rate-determining step for methanol electrooxidation, the dissociation of water to form an adsorbed active hydroxyl described in Eq. 79, occurs at well above the desired operation fuel cell anode voltages, requiring an overpotential greater than 0.6 V versus a reversible hydrogen electrode (RHE), well above the thermodynamic methanol electrooxidation potential of 0.03 V (O'Hayre et al. 2009; Neurock et al. 2008). Minimizing the overpotential required for active hydroxyl formation is key to improving anode electrocatalyst performance in DMFCs. The same challenge applies to improving CO tolerance in hydrogen oxidation catalysts.

Bimetallic Pt–Ru catalysts are the most widely used for enhancing CO tolerance for both hydrogen and methanol electrooxidation (O'Hayre et al. 2009; Wee and Lee 2006; Hogarth and Ralph 2002; Liu et al. 2006b). The overpotential required for the oxidation of water on Ru surfaces is significantly lower than on platinum at ~0.3 V versus RHE. While improving performance overall, ruthenium creates some additional problems with regard to its stability in a fuel cell environment (Piela et al. 2004) and high cost. The instability of multimetallic electrodes in general is

of concern due to metal dissolution in the acidic fuel cell environment and at excursion potentials typically experienced during start/stop cycling. Dissolved ruthenium from the anode has been shown to diffuse through the membrane and adsorb onto the cathode catalyst surface, negatively impacting the oxygen reduction reaction. Elimination of these problems and further improvement of the water electrooxidation overpotential limitation continue to drive research into alternative catalysts. A wide range of bimetallics and trimetallics combining platinum with an oxophilic cocatalyst have been explored (Hogarth and Ralph 2002; Liu et al. 2006b). In most cases, the mode of enhancement is via an electrocatalytic bifunctional mechanism, although some are thought to additionally experience to a lesser degree a ligand effect, reducing the strength of the Pt surface bond to the CO_{ad} reaction intermediate. Both enhancement mechanisms have been found in Pt–Ru catalysts. An interesting alternative to purely metallic catalysts, several groups have examined metal oxides as cocatalysts with platinum. These are believed to increase the availability of activated hydroxyl species for the bifunctional pathway through oxygen vacancies in the metal oxide structure (Bai et al. 2005; Song et al. 2008).

Formic acid oxidation catalysis has also drawn much attention in recent years, and the resulting reduction in activation losses has dramatically increased interest in direct formic acid fuel cells as an alternative to direct methanol cells (Yu and Pickup 2008). The best catalysts to date have been found to be Pd- and PdV-based materials (Yu and Pickup 2008; Larsen et al. 2006; Liu et al. 2006a). Resistance to CO poisoning is also a challenge with formic acid electrooxidation, though much less so than in methanol electrooxidation. Formic acid electrooxidation may proceed through one of three pathways: (1) through a formate intermediate

$$\mathrm{HCOOH} \rightarrow \mathrm{HCOO_{ad}} + \mathrm{H^+} + e^- \rightarrow \mathrm{CO_2} + \mathrm{H^+} + e^-; \tag{81}$$

(2) a direct pathway, shown above as Eq. 64; and (3) an indirect pathway through an adsorbed CO intermediate as seen in methanol electrooxidation

$$\mathrm{HCOOH} \rightarrow \mathrm{CO_{ad}} + \mathrm{H_2O} \tag{82}$$

where adsorbed CO is subsequently oxidized as illustrated in Eqs. 79 and 80 (Neurock et al. 2008). Poisoning due to impurities in formic acid, namely, acetic acid and methyl formate, has been shown to be a problem (Yu and Pickup 2008).

Electrolyte Membranes

The drawbacks of Nafion® and related ionomers have led to numerous efforts to develop new proton-conducting membrane materials. The greatest technical challenges associated with Nafion® and other related sulfonated fluoropolymers are poor performance at elevated temperatures and low humidity levels. The need for water as part of the proton conduction mechanism results in a practical limit of ~80 °C for the operating temperature in Nafion®-based fuel cells and leads to the requirement

that hydrogen and oxygen streams in hydrogen PEMS be humidified. Excessive methanol crossover is also a problem when using Nafion® in DMFCs. These shortcomings have led to innumerable efforts to develop alternative membrane materials. The characteristics of an ideal fuel cell membrane are outlined in Table 3. The relative importance of each of these is highly dependent on the application. For example, cost is of somewhat less importance for fuel cells targeting portable power applications as the cost per watt hour of current battery technologies remains quite high. Conversely, cost requirements are of great concern in automotive applications. One of the chief motivations for using fuel cells for portable power is to take advantage of their high theoretical energy density; therefore, it is desirable to utilize the highest fuel concentrations possible in these typically liquid-fed cells. The importance of resistance to fuel crossover is magnified by this desire to operate at high fuel concentrations, while the use of aqueous liquid fuels makes water retention concerns of much less significance. Despite much effort, sulfonated perfluoropolymer materials remain dominant for all PEM-type fuel cells today. Still, it is reasonable to expect that different classes of materials may eventually emerge from this ongoing research.

Several reviews of these efforts have been published recently (Hogarth et al. 2005; Kerres et al. 2003; Alberti and Casciola 2003; Kerres 2001; Knauth and Tuller 2002). New membrane materials that have been reported in the literature can be very broadly classified into four main groups: new ionomers, solubilized acids in a polymer matrix, composites of ionomers and insoluble solids, and inorganic solid acids and their composites. A significant number of ionomers have been investigated, the majority being sulfonated aromatic polymers and sulfonated fluorocarbons and perfluorocarbons with similar chemical functionality to Nafion®. Notable examples of the former include sulfonated polyetheretherketone (SPEEK) and sulfonated polyetherketone (SPEK). These have the advantage of low cost but tend to be less chemically and mechanically stable than sulfonated perfluorocarbons and do not provide significant advantages in proton conductivity (Kerres et al. 2003; Kerres 2001). Another approach has been to incorporate soluble acid species, most commonly a mineral acid such as phosphoric or sulfuric acid or a low molecular weight amphoter such as imidazole or pyrazole (Hogarth et al. 2005; Alberti and Casciola 2003; Kerres 2001). Examples of this approach include polybenzimidazole

Table 3 Summary of the ideal characteristics of an ideal proton exchange membrane. The relative importance of these is highly dependent upon the specific application

Ideal proton exchange membrane characteristics
High proton conductivity
Low electronic conductivity
Thermal stability
Water retention in dry environments
Low permeability to fuel
Low electroosmotic drag coefficient
Good mechanical properties
Chemical stability
Low cost

(PBI)/phosphoric acid membranes. The main problem with this approach is the tendency of the acid or amphoter to diffuse or leach out of the membrane (Hogarth et al. 2005; Alberti and Casciola 2003; Kerres 2001).

One of the most widely pursued approaches has been the development of composites of ionomers (most commonly Nafion® or SPEEK) and insoluble solid materials. This approach has shown promise, yielding moderate improvement in proton conductivity and water retention in comparison with ionomers alone (Hogarth et al. 2005; Alberti and Casciola 2001, 2003; Wang et al. 2002). The solids incorporated in these composites are typically chosen for their hydrophilicity and/or surface acidity and are most commonly incorporated as nanoparticles. Materials that have been incorporated into composites with Nafion® and/or SPEEK include alumina, silica, titania, zirconium phosphate, zirconia, and many others (Hogarth et al. 2005; Alberti and Casciola 2001, 2003; Arico et al. 2005). It has been speculated that proton conduction in ionomers with added ceramic nanoparticles is enhanced by proton transport along the surfaces of the nanoparticles (Hogarth et al. 2005; Alberti and Casciola 2001, 2003 Arico et al. 2005). The majority of the observed improvement is most likely due to increased water retention in these membranes (Hogarth et al. 2005; Arico et al. 2005). The perfluorocarbon backbone of Nafion® and related materials adds a degree of hydrophobicity contributing to their poor ability to retain water (Zawodzinski et al. 1993a, b). The addition of ceramic nanoparticles has been observed to enhance water retention in those membranes (Alberti and Casciola 2001, 2003; Arico et al. 2005), allowing the membranes to be effective at higher temperatures and lower relative humidity than ambient conditions.

Porous materials have been the subject of several recent studies, being used primarily as structural components in a PEM. One of the most notable examples of this approach is the GORE® membrane in which the pores of a porous Teflon® membrane are filled with Nafion® (Kerres 2001). Several other studies have utilized porous silicon, filling the pores with Nafion® and other ionomeric materials with some success. In a similar vein, porous alumina has been filled with solid acid materials for use as a PEM (Bocchetta et al. 2004; Park et al. 2004). Recent work has demonstrated that porous ceramics themselves may be viable as potential PEM materials. While metal oxides, clays, and other ceramics exhibit bulk proton conductivities several orders of magnitude lower than that of Nafion®, a fact which has led many to dismiss such materials from consideration as potential PEM materials, surface proton conductivities of these materials have been observed to approach or exceed that of Nafion® at the same temperatures (Vichi et al. 1999). A major advantage of ceramic materials is that they can readily be fabricated into very thin films; thus, the total proton conduction rate can be very rapid even if the conductivity of the material is low. This can be of particular value in microscale fuel cells being investigated for providing onboard power for computer chips, sensors, and similar small devices (Gold et al. 2004).

Recent work examining high-surface area, nanoporous metal oxide membranes has sought to take advantage of this rapid surface conduction, demonstrating membrane proton conductivities within less than an order of magnitude of Nafion® at

comparable temperatures (Vichi et al. 1999; Ioroi et al. 2004; Colomer and Anderson 2001). Thin, nanoporous metal oxide membranes have most commonly been formed by casting via a sol–gel process followed by a heat treatment to sinter the nanoparticles. Proton transport in such membranes at low temperatures is believed to be dominated by a surface mechanism. Anderson et al. when studying xerogel membranes of SiO_2, TiO_2, and Al_2O_3 noted that the proton conductivity of all three materials increased with temperature, but no correlation was found with water content of the ambient air (Vichi et al. 1999). The surface hydrophilicity of these materials combined with very large surface tensions in nanoscale pores should strongly enhance water retention and likely contribute to the observation of no correlation between proton conductivity and ambient humidity (Vichi et al. 1999). A strong correlation of proton conductivity with surface acidity was however seen (Vichi et al. 1999).

Bipolar Plate Materials and Manufacturing

Bipolar plates or flow fields are one of the largest contributors to the cost of fuel cell systems, contributing as much as a third of the total cost in some systems (Bar-On et al. 2002; Hermann et al. 2005; Cunningham and Baird 2006). Ideal materials for bipolar plate should be thermally and electrically conductive; chemically compatible with other fuel cell materials, reactants, and products; low in weight and volume; and mechanically strong enough to maintain high gas pressures when sealed (O'Hayre et al. 2009). The great challenge is finding materials that simultaneously meet performance requirements and can be easily and cheaply manufactured.

Graphite is most commonly used; however, its brittleness, porosity, and high cost of machining have led to research efforts to develop numerous alternatives. The brittleness and porosity of the material require relatively thick plates to be used, increasing the weight of the system. The difficulty and expense of machining graphite, however, present the greatest problem with using graphite for bipolar plates. Various metals have been suggested as alternative bipolar plate materials, including stainless steel, titanium, and aluminum (Tawfik et al. 2007). Machining costs remain a problem with metals; however, corrosion in a fuel cell environment provides the greatest barrier viability as the oxides of most metals are insulators. A number of different promising coatings to increase corrosion resistance of metal bipolar plates have been and continue to be studied (Tawfik et al. 2007).

Carbon/carbon materials have shown excellent performance properties as bipolar plates. These are manufactured by preforming a plate from a carbon fiber or graphite composite with phenolic resin. After the plate is formed, chemical vapor impregnation (CVI) is used to deposit carbon in the pores of the material providing a hermetic seal. The CVI process provides the main drawback of carbon/carbon materials as it utilizes methane as the carbon source and requires temperatures of 1,400–1,500 °C as well as long processing times (Cunningham et al. 2007). Warping of the material is also a common problem associated with the CVI process (Cunningham et al. 2007).

Polymer composites represent the most widely studied and promising alternative bipolar plate materials (Cho et al. 2004; Heinzel et al. 2004; Scholta et al. 1999; Kuan et al. 2004). Their chief advantage lies in the low-cost, rapid manufacturing techniques that can be employed, such as injection molding for thermoplastic composites and compression molding for thermoset composites (Cunningham and Baird 2006). Typical composites contain between 60 and 80 wt% graphite to supply sufficient electrical conductivity (Cunningham and Baird 2006). To enhance mechanical strength, small amounts of carbon or glass fiber are often added. Nonetheless, poor mechanical properties are the primary disadvantage of polymer composite bipolar plates (Cunningham and Baird 2006).

How Green Is My Fuel Cell or Life Cycle Analysis

Fuel cells offer many potential advantages, many of which have been highlighted here already, including very high thermodynamic efficiencies without directly using fossil fuels. While these are indicators of an environmentally friendly alternative energy technology, they can be deceiving. Life cycle assessment provides a means of systematically analyzing the environmental impact of energy systems or any device over the lifetime of that device, from raw materials to final disposal (Ayres 1995). This process goes by several different names, including life cycle analysis, cradle-to-grave analysis, and ecobalance. Procedures for this process are codified as part of the ISO 14000 environmental management standards (Finkbeiner et al. 2006). Life cycle analysis for fuel cells would involve both direct economic costs associated with the manufacturing and use of the fuel cell and environmental costs to society. While the process is useful and necessary, it is also complicated by a host of uncertainties associated with estimating each of these items and even determining what items to include. Some of these challenges have been reviewed recently by Reap et al. (2008a, b). Because fuel cells, as well as other energy technologies, are constantly evolving, it is important that life cycle assessment be a continual process, which will inevitably require some degree of forecasting until the technology matures (Pehnt 2003). Any change in the materials used or the manufacturing processes will impact the overall environmental impact.

Several life cycle assessment studies relating to fuel cells, especially for automotive applications, have been published in recent years which illustrate some of the challenges involved. As one might expect, the longer the lifetime of the fuel cell or any technology is, the less important the impact of the manufacturing process is. The manufacturing process for fuel cells is thus less important in long-lifetime cells used for stationary power generation than it is in cells used for transportation with shorter lifetimes (Pehnt 2003). Fuel cells offer definite environmental advantages in operation when compared to combustion engines. The impact of the manufacturing process, however, reduces this advantage significantly. A life cycle assessment of fuel cell manufacturing process by Pehnt compared impact of manufacturing to fuel cell use, accounting for production of graphite for the flow field, platinum mining and refining, and membrane production (Pehnt 2001). The biggest environmental

impacts were found to be from platinum metal production for catalyst; thus, recycling of these is important in minimizing environmental impact (Pehnt 2001).

If only economic factors are considered, fuel cells cannot yet compete with gasoline or hybrid gasoline/electric vehicles (Jeong and Oh 2002). However, Ogden et al. (2004) evaluating several different automotive engine and fuel technologies (hydrogen, internal combustion/hybrid, Diesel, Fischer–Tropsch liquids, etc.) concluded that hydrogen fuel cell vehicles offered the lowest "societal life cycle cost," which included vehicle first cost (assuming large-scale mass production), fuel costs (assuming a fully developed fuel infrastructure), externality costs for oil supply security, and damage costs for emissions of air pollutants and greenhouse gases calculated over the full fuel cycle. The assumptions employed here are a topic of some debate and an illustration of the challenges involved in life cycle analysis. It is likely that solid-state hydrogen would be supplied in the form of a replicable fuel cartridge or something similar.

Future Directions

The major technical challenges have been reviewed on the preceding pages, including hydrogen storage, catalysis, electrolyte membrane materials, and bipolar plate materials and manufacturing, among others. Progress in solving these technical challenges will certainly play a large role in determining the role of fuel cells in meeting future energy needs. In addition to progress on meeting technical challenges, the future of fuel cell technology and energy technology in general depends strongly on complex economic, political, and social factors. In order to achieve widespread use, fuel cells must be at a minimum cost competitive, though ideally offering a cost advantage, in comparison with the current dominant technology in a given market. Historically, interest in fuel cells and other alternative energy technologies has corresponded strongly with the price of oil and gasoline. Some have expressed concerns lithium prices may go up considerably as the use of advanced batteries becomes more widespread.

Beyond market considerations, energy prices are heavily impacted by government policies and geopolitical considerations. The world's largest oil reserves are also located in some of most politically volatile regions. Other energy technologies, including green technologies, are subject to such forces as well. Lithium used in advanced batteries is currently plentiful, but many of the world's largest reserves of this material are also found in volatile regions of the world. Fuel taxes, environmental regulations, and, in the USA, CAFE (corporate average fuel economy) standards are among the many governmental policies that impact the prices paid by consumers for energy. Research and development progress is also impacted by government funding priorities. For example, NASA's use of fuel cells in spacecraft beginning in the 1960s provided a major impetus to research and development efforts (Srinivasan et al. 1999). Some governments have also invested in green public transportation, including the use of hydrogen fuel cell-powered busses in Australia, Iceland, and the European Union (Oil Gas European Magazine 2001; FCB 2004; Energy 2004). In

2009, the Obama administration moved to eliminate Department of Energy funding for hydrogen fuel cell research, though this was ultimately restored by the Congress. Subsidies and rebates in various forms are also a way in which green energy technologies of one type or another have been advanced by governments.

Economically, it is reasonable to expect small-scale fuel cells for portable power applications to be the first to achieve widespread market penetration, likely in the very near future. Fuel cells can already produce power at costs per W/h close to those of current advanced battery technologies which dominate such markets. The importance of weight, volume, and lifetime in this market also provides a potential advantage to fuel cells with their high energy densities and the lack of a need for lengthy recharging cycles. Advances made for fuel cells in this market should help improve competitiveness of fuel cells in other markets, such as the automotive industry.

Though several major automotive companies are actively developing fuel cell vehicles, it will likely be some time before fuel cell vehicles become common on roadways, barring significant changes in economic conditions. Fuel cells and other electric vehicle technologies offer benefits in terms of lower emissions and fossil fuel usage, but are not currently cost competitive. Fuel cell vehicles currently in public use benefit from significant government subsidies. The key to fuel cell vehicles becoming a major force in the marketplace will be reducing their cost relative to internal combustion engines and competing electric vehicle technologies. Key technical challenges that impact the cost of fuel cells are discussed in the section on "Technical Challenges and Current Research" on the preceding pages. An additional challenge is posed by the need to develop infrastructure to support such vehicles. Currently, only a handful of hydrogen fueling stations exist in the USA, concentrated in California. Long term, it is likely that hydrogen will be stored in a solid-state form, as discussed in the section on "Hydrogen Storage." The nature of the infrastructure necessary to support vehicles using solid hydrogen storage materials is unclear.

Conclusion

Fuel cell technologies are among of the most promising green energy technologies for a number of applications. Their high energy density makes them a very attractive alternative to batteries for portable power applications. Unlike batteries, they need not be recharged, merely refueled. These characteristics along with having little or no emissions during operation and their high efficiency make fuel cell promising for transportation and stationary power generation.

That fuel cells are efficient and have minimal emissions should not be taken to mean they have no environmental impact. Fundamental thermodynamic considerations place a limit on the possible performance of a fuel cell, as they do with any energy technology. Kinetic and transport-related issues place practical limits on fuel cell performance. From life cycle analysis, however, it is found that the primary environmental impact of fuel cells occurs during manufacturing.

Fuel cell systems range from the very simple passive microscale and miniature power applications to complex stationary power systems. Subsystems making up the balance of plant, including fuel processing and delivery, thermal management, and power management, reduce the overall energy density of the system and add to the environmental impact of the overall system, requiring careful design.

There are currently only a few niche applications where fuel cells are widely used, though this can be expected to change in the near future. Many companies are actively developing fuel cells for an array of applications. The first to market will likely be for portable electronics. Automotive fuel cells are seeing use in public transportation and in some prototype vehicles, though it will likely be longer before roadways are filled with such vehicles. Improvement in the technology and its cost competitiveness is still needed in a number of areas for fuel cells to reach their full potential. Nonetheless, a number of indicators point to a hydrogen-based economy sometime in the future.

Abstract

This chapter describes the concept, electrochemical reactions, and fabrication of a solid oxide fuel cell (SOFC). It initially describes how SOFC systems differ from other electrical devices and how they differ from other types of fuel cells, for example, they are all solid state (ceramics), run at high temperature, and have the potential for directly running off hydrocarbon fuels. Then the basic principles of the fuel cell are studied and each of the components described in more detail (the anode, cathode, and electrolyte). The discussion then moves on to how single SOFC's can be stacked in a number of ways, to form systems, and what the advantages and disadvantages of each are. The chapter discusses one such SOFC system in more detail, that of the microtubular SOFC. Here, it examines how these microtubes are made, what they are made from, and how they have the potential for running at low temperature for small applications such as auxiliary power units (APU), for example. Then it deals with some micro- and macro-modeling on the microtubular SOFC, describing issues such as mass and thermal transport, the effect of altering a number of parameters, and how the modeling results compare to real data. Finally, the chapter concludes with some future directions on solid oxide fuel cells.

Introduction

Recent awareness of environmental protection and fast growth of the world's energy consumption has led the public, policy makers, entrepreneurs, technology developers, and scientists to search for alternative means to carry out and convert energy. Fuel cells are promising devices, potentially emerging as the substitutes for traditional energy converters, such as the internal combustion engine. Their improved environmentally friendly nature, and high efficiency, can potentially allow fuel cells to be employed from small portable applications, such as laptops and cell phones, to large-scale stationary applications for central heating facilities and electricity generation.

General Principles of a Fuel Cell

A fuel cell is an electrochemical energy conversion device that uses chemical energy to produce electricity. Similar to a battery, the electrodes are separated by an electrolyte in a fuel cell, and electricity is generated due to the electrochemical reaction going on inside the cell. However, reactants are stored inside the battery; thus, the performance of the battery decreases when the charge inside the battery

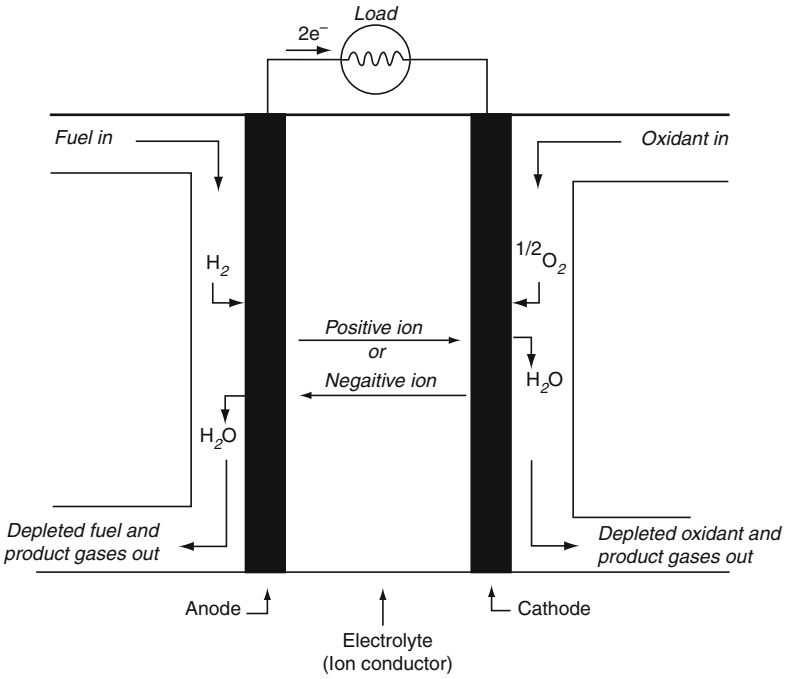

Fig. 1 Schematic of a generalized fuel cell

drops until it eventually goes dead and needs to be recharged. On the other hand, reactants flow into the fuel cell continuously and electricity is generated as long as the supply continues.

A general cross-sectional view of a fuel cell is depicted in Fig. 1. Fuel enters the negative electrode (anode) and oxidant enters the positive electrode (cathode) in a gaseous state. Porous electrodes that allow the reactant gases to pass through are separated by an electrolyte. The chemical reactions occur at the electrode-electrolyte interface often with the help of catalysts especially for the oxidation reaction. Fuel entering the anode is separated into electrons and ions, which are protons when the fuel is hydrogen. The ions pass through the electrolyte to the cathode side, while the electrons go through an external circuit connecting the anode and cathode providing electricity. At the cathode, ions combine with the oxidant and the electrons. To get a reasonable voltage and current output, cells are combined in parallel and series to form a fuel cell stack.

The types of fuel cells are defined by the electrolyte material. Though each type of fuel cell has different properties, they share some characteristics. The energy conversion process from the chemical reaction is common for all of them. Although other fuels such as methanol are used in fuel cells, hydrogen is used as the typical fuel. Finally, each type of fuel cell stack generates direct current (DC) electricity. The characteristics of fuel cells make them favorable over conventional energy

converters in many applications. These characteristics, which vary for the different types of fuel cells, determine the applications for which they can be employed.

Efficiency: Direct conversion of the chemical energy to electrical energy is not limited by the Carnot cycle efficiency; hence, fuel cell efficiencies are greater than heat engines. Depending on the fuel cell type, stack efficiency of up to 50–60 % is possible. If the surplus heat is utilized, an overall system efficiency of up to 80–90 % is realizable.

Power density: Higher power is maintained from a fuel cell that has the same size as that of most of the conventional energy conversion devices, such as internal combustion engines, partly owing to higher efficiency.

Low emissions: When pure hydrogen is used as the fuel, the fuel cell maintains a zero emission characteristic. However, in the case of utilizing hydrogen from carbon-rich fossil fuels, oxides of nitrogen, sulfur and carbon are released; yet the emissions values are far below those of conventional energy converters. Even when the hydrogen from natural gas is used as energy source, the higher conversion efficiency allows for the production of less CO_2.

Reliability and availability: Since the moving parts of a fuel cell system are in the auxiliary components and the fuel cell systems are relatively simple, the maintenance requirements are reduced, and the life of the fuel cells is generally longer than conventional systems, although there are a number of exceptions, depending on the material set utilized. Due to the low maintenance requirements, therefore, system availability is higher. It is reported that a PC25 (by UTC Power) fleet consisting of more than 200 units have demonstrated 90 % availability during four million operating hours. Also power is available 99.9999 % of the operating time.

Thermal output and cogeneration capability: Depending on the type of the fuel cell, product heat can be utilized by means of domestic hot water applications or space heating. Also, in case of higher thermal output, fuel cells can be used with other devices such as turbines to enhance the system efficiency.

Despite these positive characteristics, there are also a number of negative features of the fuel cells, such as high costs, insufficient infrastructure, and immaturity of the technology.

General Principles of an SOFC

The solid oxide fuel cell system will now be discussed in more detail. The SOFC consists of a ceramic electrolyte, usually yttria-stabilized zirconia (YSZ), with an air electrode (cathode) and a fuel electrode (anode) on either side, as described in Fig. 2. A solid oxide fuel cell (SOFC) is an all solid-state electrochemical device producing both electricity and waste heat directly from the electrochemical conversion of a fuel with an oxidant. Because it produces electricity by electrochemical means, there is no necessity to have any moving parts, and thus the SOFC overcomes the Carnot limitation inherent in all heat engines. Hence, the SOFC has high-energy efficiency, which can be further increased by using waste by-product heat in applications such

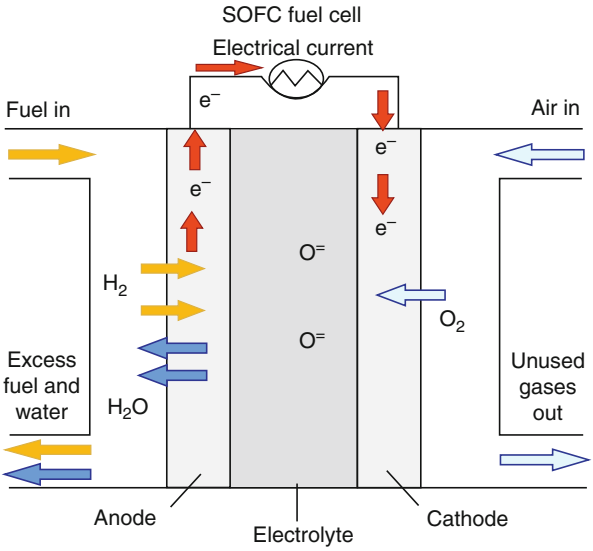

Fig. 2 Diagrammatic representation of the elements of the SOFC

as cogeneration (greater than 50 % electrical efficiency is possible, with efficiencies approaching 75 % with cogeneration).

The SOFC also has a number of advantages over conventional systems including its modularity whereby single units can be stacked, its flexibility, and its ability to use a number of different fuels. It has a number of disadvantages including cost (far greater than conventional systems/kW at the moment) and raw material availability (possibly a problem in the long term), and it has no real history, unlike the turbine engine. It should however be noted that the fuel cell was invented by Sir William Grove over 150 years ago, but was never commercialized possibly due to the invention of the turbine and its use and development in the turbine-driven aeroplane.

Now, as has already been stated, the SOFC system consists of a ceramic electrolyte, usually yttria-stabilized zirconia, with an air electrode (cathode) and a fuel electrode (anode) on either side. The electrolyte must be of a high percentage theoretical density so that the two fuels are physically separated and have no opportunity of mixing. The cell (anode/electrolyte/cathode) is operated at a high temperature primarily to allow the ionic conductivity of the electrolyte to be high enough to produce a reasonable current density, although other factors such as reaction kinetics must also be considered. Fuel (currently H_2, although other hydrocarbon fuels are being studied) is fed to the anode, where it undergoes an oxidation reaction and releases electrons to an external circuit. Oxidant (either air or pure oxygen) is fed to the cathode where it is reduced and accepts electrons from the external circuit. The flow of electrons around the external circuit produces DC electricity. The oxygen is transported as oxygen ions across the electrolyte via the vacancy mechanism. Figure 2 summarizes the SOFC operation.

As explained above, the electrolyte is usually based on yttria-stabilized zirconia, which is an oxygen ion conductor. Other oxygen ion conductors have been studied,

including doped-CeO_2 systems, perovskite-based systems, and doped-Bi_2O_3. Most of these other oxides, although they are superior oxygen ion conductors, are prone to reduction at low oxygen partial pressures (as found at the anode) and thus show n-type electronic conductivity, which reduces the efficiency of the overall system. Doped-$LaGaO_3$ is a new material that does show promise as an SOFC electrolyte, because it does not appear to be reduced at the anode. Much work is still necessary, as preliminary studies appear to show it to be mechanically weak.

Now it is important to study the reactions occurring in the SOFC cell. At the cathode (described in more detail below), reduction of oxygen occurs, via equation:

$$O_2 + 4e' = 2O^{2-}$$

The main function of the cathode is to provide reaction sites for the reduction reaction to take place.

At the anode, however, an oxidation reaction takes place, whereby the oxide ion is oxidized, releasing an electron.

$$2O^{2-} = O_2 + 4e'$$

Thus, the SOFC can be regarded as an oxygen concentration cell, and the electromotive force (EMF) is, therefore, dependent upon the oxygen partial pressure at the anode and the cathode. The oxygen partial pressure at the anode is based not upon oxygen being present, but upon the oxidation of the fuel. In this example, we will consider H_2. The oxidation of H_2 is given by

$$H_2 + \frac{1}{2}O_2 = H_2O$$

The oxygen partial pressure at the anode is, therefore, given by

$$P_{O_2} = \left[\frac{P_{H_2O}}{P_{H_2}K_{OX}}\right]^2$$

where K_{ox} is the equilibrium constant for the oxidation reaction described above. Substitution yields, where E^0 is the reversible voltage at the standard state, are given by

$$E = E^0 + \frac{RT}{4F}\ln P_{O_2} + \frac{RT}{2F}\ln\frac{P_{H_2}}{P_{H_2O}}$$

Under standard state conditions, E equals the reversible standard voltage at the standard state, E^0, and thus we can say that the following equation is applicable:

$$E^0 = \frac{RT}{2F}\ln K_{OX}$$

Now,

$$E^0 = -\frac{\Delta G^0}{4F}$$

where ΔG^0 is the Gibbs free energy of the reaction given in equation (at 1,250 K this is -178.2 kJ/mol). This value will differ for different combustion reactions, such as CO, CH_4, and CH_3OH.

Now, this reaction occurs at the anode, which, like the cathode, must perform under quite specific conditions. The reversible EMF produced by the reaction is approximately 1 V (0.924 V at 1,250 K and 0.997 V at 1,000 K). This EMF is of little practical benefit, and thus single cells are connected in electrical series in what is known as a stack. The height of the stack (or number of cells) varies depending on the design and the power output required. Many designs have been examined; however, the two most common ones today are the tubular and planar designs, described below.

Materials and Reactions

Electrolyte

The electrolyte must be fully dense so that the fuel and air are physically separated and have no opportunity of mixing. The cell (anode/electrolyte/cathode) is operated at a high temperature primarily to allow the ionic conductivity of the electrolyte to be high enough to produce a reasonable current density, although other factors such as reaction kinetics must also be considered. Fuel (such as H_2 or other hydrocarbons) is fed to the anode, where it undergoes an oxidation reaction and releases electrons to an external circuit. Oxidant (either air or pure oxygen) is fed to the cathode where it is reduced and accepts electrons from the external circuit. The flow of electrons around the external circuit produces DC electricity. The oxygen is transported as oxygen ions across the electrolyte via a vacancy mechanism.

The electrolyte is usually based on yttria-stabilized zirconia, which is an oxygen ion conductor. Other oxygen ion conductors have been studied including doped-CeO_2 systems, perovskite-based systems, and doped-Bi_2O_3. Most of these other oxides, although they are superior oxygen ion conductors, are prone to reduction at low oxygen partial pressures (as found at the anode) and thus show n-type electronic conductivity, which reduces the efficiency of the overall system, although this may not be such a problem for doped-ceria. Doped-$LaGaO_3$ is also a material that does show promise as a SOFC electrolyte, because it does not appear to be reduced at the anode.

Cathode

The cathode must be a good electronic conductor with a high surface area and catalytically active toward this reaction. The cathode must also have the following

requirements: stability at high temperature and under the oxidizing gas present, compatibility with the other cell components, similarity of thermal expansion coefficient to that of the other components (otherwise it is prone to peeling off the electrolyte), retention of its porosity (and thus the number of reaction sites) during the lifetime of the cell, and retention of its catalytic activity during the lifetime of the cell. Because of the high temperature and oxidizing environment, most metals cannot be used. Only noble metals will withstand the environments found at the cathode, but these materials are too expensive for a commercial system. Many oxide materials have a high electronic conductivity, but they are either incompatible with the electrolyte or have a thermal expansion coefficient very different to those of the other cell components. Doped-$LaMnO_3$ meets almost all the requirements of the cathode and is the most commonly used material. Traditionally, Sr-doped (on the A-site of the perovskite) is used, due to its good electronic conductivity. Sr enhances the electronic conductivity by increasing the Mn^{4+} content by substitution of La^{3+} by Sr^{2+}, as described in the equation below, and increases with increasing Sr content. At Sr contents greater than 20–30 mol%, metallic conduction is observed.

$$LaMnO_3 + xSr^{2+} \rightarrow La^{3+}{}_{1-x}Sr^{2+}{}_{x}Mn^{3+}{}_{1-x}Mn^{4+}{}_{x}O_3$$

Electronic conductivity occurs via the small polaron conduction mechanism. Ca doping has a similar effect to that of Sr doping, causing a significant increase in the electronic conductivity, with increasing Ca content.

Anode

The anode must provide the reaction sites for the electrochemical oxidation of the fuel gas to occur. Hence, the anode must be stable under the very reducing conditions of the fuel atmosphere, have sufficient electronic conductivity, have excellent catalytic activity for the reaction (and remain catalytically active during the lifetime of the cell), be chemically compatible with the other cell components, have a high surface area to allow a large reaction zone to occur (the anode must also remain with a high surface area and not degrade with time), have a similar thermal expansion coefficient to that of the other cell components, and be relatively low cost and easily fabricated. Because of the reducing environments, metals can be used, although the high temperatures limit these to Co, Ni, and noble metals. Electronically conducting ceramic materials can also be used (provided they do not reduce under the anode atmosphere). Currently, Ni is the anode of choice, primarily due to its good catalytic activity for hydrogen oxidation, its low cost, and its good stability. YSZ powder is added to the Ni metal in the form of a metal/ceramic composite for two reasons. Firstly, the YSZ inhibits the Ni coarsening during the operation, and secondly, the YSZ acts to lower the thermal expansion coefficient of the metal composite (which is much higher than the electrolyte) closer to that of the other cell components. The optimum amount of YSZ depends upon the percolation theory. Too much YSZ, and the sample does not electronically conduct (due to a minimal/no electron pathways);

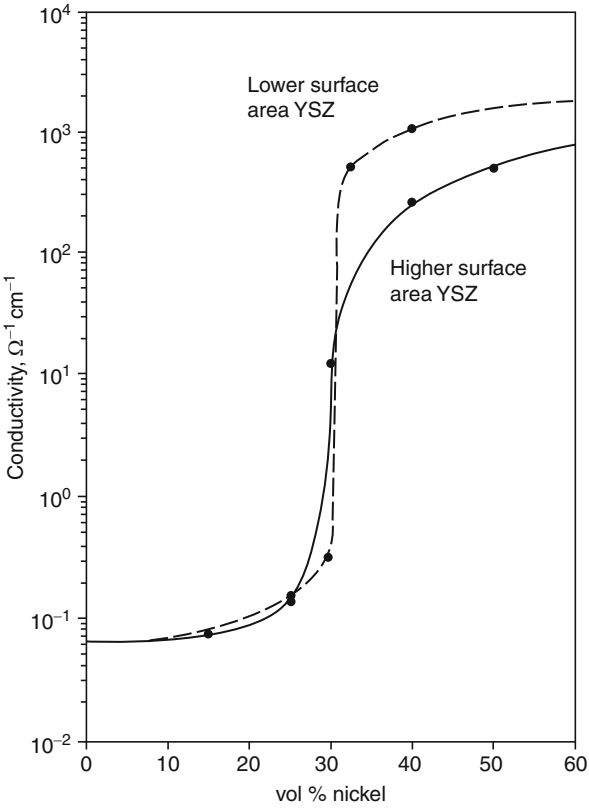

Fig. 3 The conductivity of Ni/YSZ as a function of Ni content, at 1,000 °C (After Dees et al. 1987)

too little YSZ, and the composite has too high a thermal expansion coefficient. The effect of Ni content on the electronic conductivity is shown in Fig. 3.

It is obvious that the percolation threshold is at approximately 30 vol% Ni. Most anodes have approximately 40–50 mol% Ni in the composite, which appears to produce a relatively stable system. However, all anodes are found to degrade with time, due to either slight oxidation of the Ni to NiO or due to sintering of the Ni particles.

Alternative anode systems are being studied, particularly in respect to internal reformation of hydrocarbons, rather than having to use H_2 as a fuel. Ni, although an extremely good catalyst for the oxidation of H_2, is also very good at cracking natural gas into C. The C is then liable to form whiskers which lift the anode from the electrolyte surface, thus greatly reducing its activity. Other catalytic electrode materials being studied do not cause methane (and other hydrocarbons to crack) and thus may allow for a direct internal reformation reaction to take place. These include doped-CeO_2-based systems and perovskites. Currently, however, there are still many problems to be solved when investigating alternative electrode materials, and the technology of today either externally reforms the hydrocarbon or uses a high steam to carbon ratio in the feed stream. Both of these are not totally acceptable, as large efficiency losses are observed.

Typically, the EMF produced by the reactions described above is of little practical benefit, and thus single cells are connected in electrical series in what is known as a stack. The height of the stack (or number of cells) varies depending on the design and the power output required.

Stacking and Types of SOFC

Many designs have been examined; however, the two most common ones today are the tubular and planar designs, shown in Fig. 4. The planar design consists of electrolyte components configured as thin (approximately 50 mm) planar plates or laid down on a cathode and, more typically, an anode support. On either side of these plates are the anode and cathode materials. Between each cell is what is known as an interconnect. The interconnect has two main purposes; it serves as a bipolar gas separator, contacting the anode and cathode of adjoining cells, and sometimes has ribs on both sides to form gas channels. The properties of the interconnect are quite tight, as it must be electronically conducting, stable in both reducing and oxidizing environments and at high temperatures, relatively cheap (as it is usually the thickest component), dense (for the same reasons as the electrolyte, so that the fuel and air gases do not mix), easy to fabricate, compatible with the other cell components, and possess a similar thermal expansion coefficient to those of the other cell components. The interconnect is usually based on the perovskite $LaCrO_3$. To increase the electronic conductivity, A-site (such as Ca or Sr) and B-site (such as Co or Fe) are added, which have the same effect as that of the Mn^{3+} in the cathode, to increase the amount of Cr^{4+} ions.

Once the stack has been fabricated, the system is sealed using a ceramic or glass ceramic seal with a similar thermal expansion coefficient as the cell, and gas manifolds are placed around it, similar to those shown in Fig. 5.

The tubular design, on the other hand, uses a very different concept. Here, an electrolyte tube (either anode or cathode supported or unsupported) has electrodes on the inside and outside. The Siemens design (which uses traditional SOFC materials) has an electrolyte that is typically electrovapor deposited (EVD) onto a porous cathode support tube (although other methods have been examined). On the outside of the electrolyte/cathode tube is placed the anode, using a dip-coating technique. The interconnect (Mg-doped $LaCrO_3$) is then added using EVD processing, and the

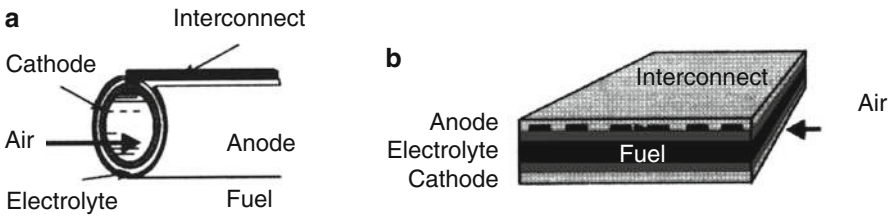

Fig. 4 The SOFC stack designs (**a**) tubular, (**b**) planar (After Kordesch and Simader 1996)

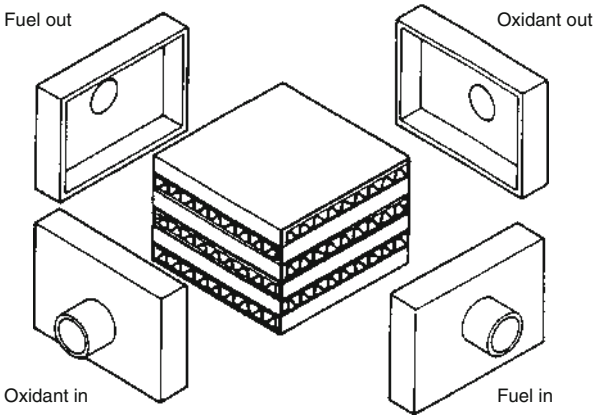

Fig. 5 Gas manifolding in the planar SOFC design (After Minh and Takahashi 1995)

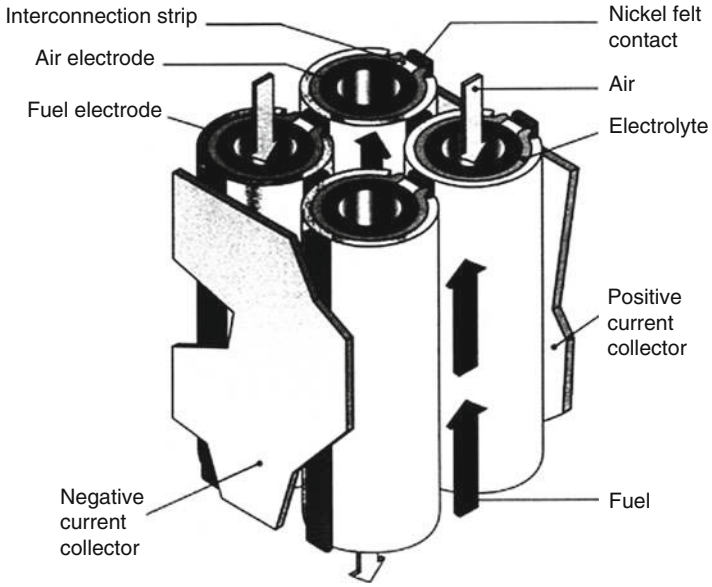

Fig. 6 Electrical connection in the tubular SOFC design (After Kordesch and Simader 1996)

tubular cells (which are closed at the bottom) are bundled together, using Ni-felt to connect the anode of one cell to the adjacent anode for parallel connection and to the Ni-plating on the interconnect for series connection as shown in (Fig. 6).

As the tubes are themselves already sealed, there is no requirement for a sealant, as required in the planar design. The gas manifolding is relatively straightforward with oxidant (air) being fed down the center of the tubes via an oxidant plenum. The fuel is fed from a fuel plenum at the bottom and up along the outside of the tubes, where the oxidation reaction takes place. The spent fuel flows through a porous ceramic barrier, enters the combustion chamber, and combines with the spent

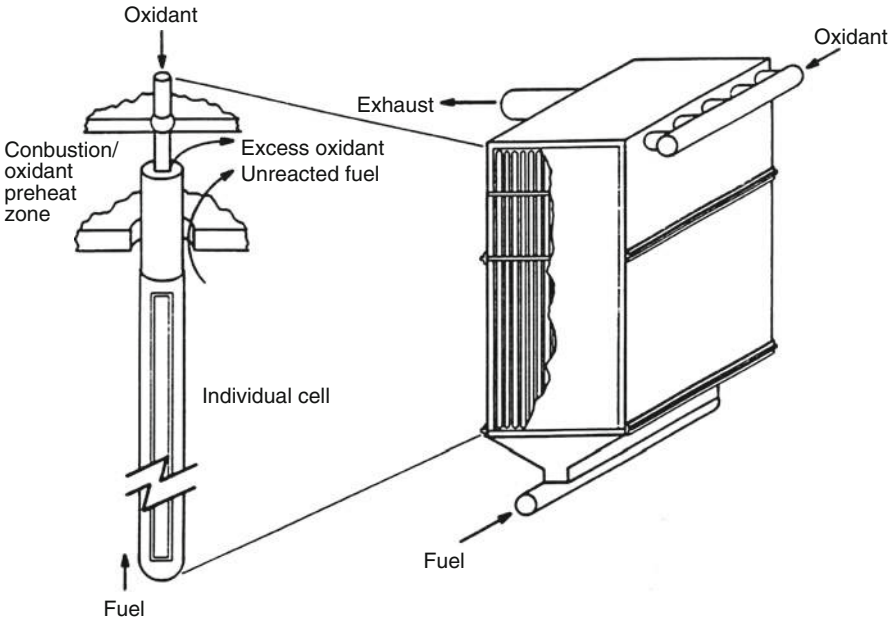

Fig. 7 Gas manifolding in the tubular design (After Singhal 1991)

oxidant. This heat is then used to preheat the oxidant entering the cell. The exhaust gases exit the generator at approximately 900 °C. The gas-manifolding concept is described in Fig. 7.

Power is obtained from the cell, or stack, by applying a load between the anode and cathode, and hence drawing current. The power output (P) is thus the product of the current drawn and the EMF across the cell, after the losses have occurred, namely, $P = I\,(E - R_{\mathrm{T}}I)$, where E is the thermodynamic EMF across the cell, and $R_{\mathrm{T}}I$ are the losses (R_{T} is the total resistance of the cell and I the current).

Power Output and System Efficiency

SOFC efficiency consists of a number of elements.

- *Thermodynamic efficiency.* This is given by the assumption that the Gibbs free energy of the cell reaction may be totally converted to electrical energy:

$$\epsilon_{\mathrm{therm}} = \frac{\Delta G}{\Delta H}$$

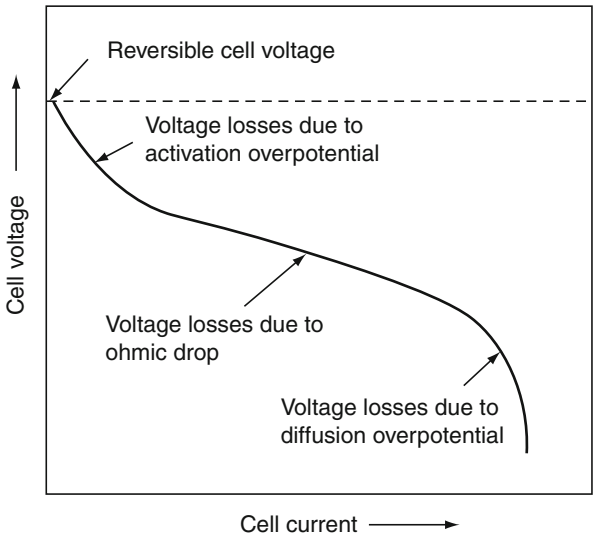

Fig. 8 Typical voltage losses in a running SOFC cell

- *EMF efficiency*. This is shown by the fact that the cell voltage, in an operating cell, is always less than the reversible voltage. As the current is drawn from the fuel cell, the cell voltage falls due to a number of losses, as described in Fig. 8. The EMF efficiency is given by the ratio of the operating cell voltage under load to the equilibrium cell voltage. This difference is due to a number of polarizations (or overpotentials), as described in the equation below, which shows that the total polarization losses (η) is the sum of a number of losses:

$$\eta = \eta_{\mathrm{a}} + \eta_{\mathrm{d}} + \eta_{\mathrm{r}} + \eta_{\mathrm{ohm}}$$

where the subscripts denote a = charge transfer polarization, d = diffusion polarization, r = reaction resistance, and ohm = ohmic losses.

Power is obtained from the cell, or stack, by applying a load between the anode and cathode and hence drawing current. The power output (P) is thus the product of the current drawn and the EMF across the cell, after the losses have occurred; $P = I\,(E - R_{\mathrm{T}}I)$, where E is the thermodynamic EMF across the cell, and $R_{\mathrm{T}}I$ are the losses (R_{T} is the total resistance of the cell and I the current).

New Concepts for SOFCs

Yttria-stabilized zirconia (YSZ) is the most common type of electrolyte material used in SOFC designs. However, due to its poor conductivity at lower temperatures, SOFCs using YSZ electrolytes operate at relatively higher temperatures, that is,

above 750 °C, to generate practical output power. This requires use of high quality alloy metal interconnects in order to prevent corrosion and increases the cost of these systems. On the other hand with the use of ceria-based rare earth oxides as electrolyte materials, which have high conductivities at lower temperatures, SOFCs running at intermediate temperatures (IT-SOFCs) possess desirable assets. Minimizing ionic interdiffusion between the electrode/electrolyte interfaces, mitigation of sintering problems seen at high temperature operation, use of inexpensive materials, and lower operating costs are the main advantages. Albeit providing these advantages, the common problem with ceria-based electrolytes is that they can be reduced under fuel cell operating conditions and become electronically conductive. As a result, the cell is short circuited and the performance decreases.

SOFC electrodes are designed to provide a good conductive medium for both ions and the electrons. Hence, they are typically compounds of metal and ceramic materials to serve as mixed ionic and electronic conductors (MIEC). Both anode and cathode are porous structures to supply reactants and remove by-products. However, the design of the porous structure should be carried out meticulously. An open network of pores must be maintained throughout the structure to utilize all the electrode volume. Also the porosity must be high enough to prevent mass transfer limitations; however, higher porosities may lead to structural instabilities. Thus, the supporting electrode is always less porous than the other.

One of the most important features of the electrode design is to maintain high catalytic activity. This is achieved by longer triple-phase boundaries (TPBs) where gas phase in the pores, ionic conductor, and electronic conductor regions in the electrodes has a common interface. TPBs are where the anode and cathode reactions take place. To have a high quality TPB distribution, the electrodes must possess an open network of pores as well as the electrode materials must be sintered well to provide good bonding between the metallic and the ceramic components.

Another important parameter for the SOFC design is the thermal expansion characteristics of the components. Using the electrolyte material in the anode and the cathode alleviates the mismatch between different layers. A common dilemma related to the cathode design is the trade-off between electronic conductivity, ionic conductivity, and the thermal expansion coefficient. The cathode design must be carried out taking into consideration all these three parameters simultaneously to optimize the cell performance while considering the structural stability.

Keeping all this in mind, SOFCs are still far from commercial viability, mainly due to problems such as cost targets, operating life, system optimization, and eventual integration with traditional devices in hybrid systems, aiming at maximizing the overall electrical efficiency.

Intermediate Temperature SOFCs

Solid oxide fuel cell applications have long been limited by the necessity to operate at high temperatures, causing prolonged start-up times and material constraints, among other cost-increasing constraints. Considerably, decreasing the operating

temperature of SOFCs seems an absolute necessity for efficient power production, specifically in mobile applications where start-up time and material cost is of increasing importance. Reducing the operating temperature of SOFCs below 650 °C can extend the lifetime of the SOFC stack, lower cost by allowing the use of metal materials, and can decrease the degradation of SOFC and stack materials. Tubular SOFC designs have been shown to be stable for repeated cycling under rapid changes in electrical load and in cell operating temperatures. However, tubular SOFC capital costs are very high. This is mainly due to their low power density and to the materials to be used for safe operation at the high temperatures typical of SOFC stacks. In this respect, microtubular SOFCs aim at solving both the problems affecting the typical tubular SOFC. In fact, their lower diameter and operating temperature promise to (1) reduce capital costs, (2) increase power density, (3) increase thermal shock resistance, and (4) reduce start-up and shutdown times. Microtubular SOFCs have also been shown to be able to endure the thermal stresses associated with rapid heating up to operating temperatures. In contrast to planar SOFC designs, when the diameter of tubular SOFC is decreased, it is possible to design SOFC stacks for high volumetric power densities.

However, the literature dealing with thermal, electrical, and electrochemical performance of microtubular SOFCs is scarce at best, since this is an emerging technology with respect to the tubular one. Here, one such microtubular SOFC technology will be discussed, that of the anode-supported microtubular SOFCs with a cermet anode of NiO and GDC (gadolinium-doped ceria), a GDC electrolyte, and a cathode in LSCF ($La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O_{3-y}$). These cells were tested at operating temperatures ranging from 450 °C to 550 °C. Such experimental analysis was carried out varying cell temperature and fuel flow, in order to assess the effects of these two parameters on the electrochemical performance of the cell. To this scope, a parametric study is also presented.

Concept, Manufacture, and Results of the Microtubular SOFC

The microtubular SOFCs were fabricated using traditional extrusion and coating techniques. The anode slurry was prepared and consisted of NO powder, GDC powder, and cellulose as the binder. The anode components were mixed with water using an industrial mixer for 1–2 h and left to age overnight. Placing a vacuum over the anode mixture allowed for excess air to be removed. Anode tubes were extruded from the anode mixture using a ram extruder and a custom-made die. The anode tubes were allowed to dry, were cut to the desired length, then dip-coated in GDC electrolyte slurry, and allowed to dry. The GDC electrolyte slurry is composed of the same GDC powder described above and organic ingredients such as binder (polyvinyl butyral), dispersant (fish oil), and solvents (toluene and ethanol). The desired electrolyte thickness was achieved through multiple electrolyte coatings, and subsequently, the tubes were sintered at 1,450 °C for 6 h in air. Next, the electrolyte-coated anode tubes were dip-coated in cathode slurry consisting of the LSCF and GDC powder and organic ingredients similar with those of the electrolyte slurry. The

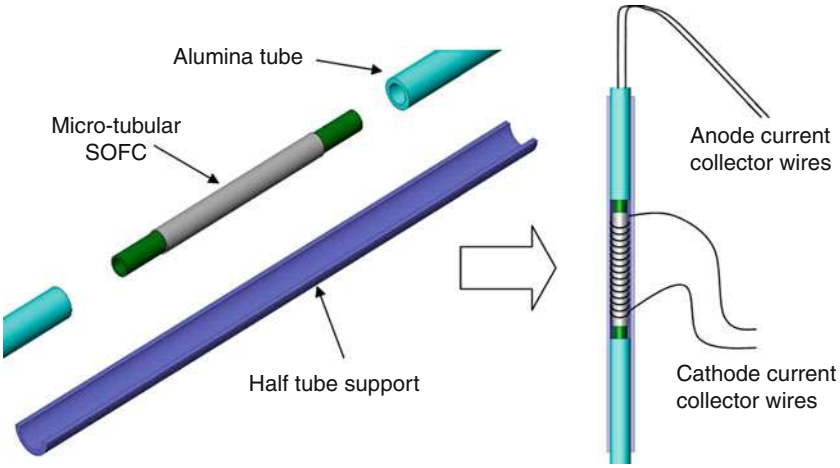

Fig. 9 Showing how the micro-SOFCs were supported for testing

cathode dip-coated tubes were dried in air and sintered at 1,000 °C for 1 h in air to complete the fuel cell fabrication.

An environmental scanning electron microscope (ESEM) was used to check the electrode and electrolyte microstructure. In order to carry out the experimental activities, measuring the fuel cell electrochemical performances, a specific support was also manufactured. Such a support is capable of sustaining the fuel cell when it is mounted in the furnace; it also allows the gas distribution on the anode and cathode sides and assures the electrical connection with the electrical load and potentiostat. Each tube was connected to two alumina tubes allowing the inner anode gas distribution, sustaining the cell in the furnace. The entire system was placed on an alumina half-tube support in order to yield stronger structure (Fig. 9). Figure 10 shows how each microtube was mounted for testing within a vertically mounted microtube furnace (Carbolite) and also shows a cross-sectional ESEM image of the fabricated microtubular SOFC, with porous electrodes and a dense electrolyte.

Cells were tested vertically as shown in order to ensure evenly distributed flow of fuel gas across the anode surface (horizontally oriented cells are subject to uneven fuel gas distribution due to gravity).

Each tube was equipped with four 0.5 mm silver sensor wires attached for collecting current for anode and cathode sides. The anode electrical connection was realized using two long silver wires fixed using nickel paste. A silver wire was wrapped around the tubular fuel cell (on the cathode), as a reel, and fixed with silver paste for the cathode electrical connection. The silver paste and nickel paste were brush painted on the cathode and anode surfaces to reduce the contact resistance between the silver sensor wires and the electrode surfaces. The pastes are porous enough at operating temperatures that fuel and oxygen are able to pass through them to arrive at their respective electrodes. Ceramabond 552 (Aremco)

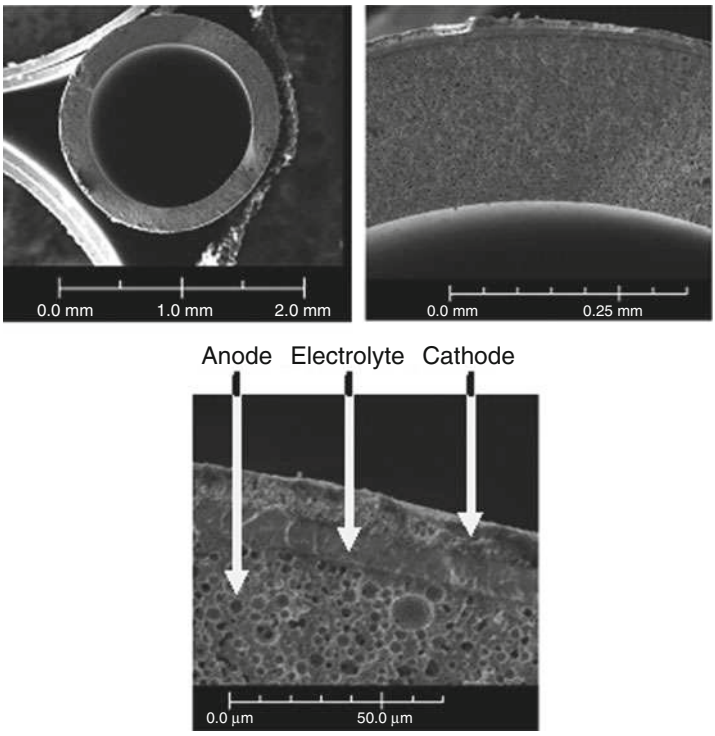

Fig. 10 Showing how the micro-SOFCs were mounted for testing

was used as a sealant between anode, alumina tubes, and alumina half-tube support. The four current collecting wires from the cell were connected to an impedance analyzer, and the electrical load at operating temperature ranges between 450 °C and 550 °C. Individual cells were run using humidified hydrogen gases (2–3 % of H_2O) as fuel to the anode side, while the cathode side (outside surface of tube) was exposed to atmospheric conditions. The microtubular SOFC was brought up to 450 °C at 3 °C/min from room temperature under atmospheric conditions with air exposed to both anode and cathode sides. After arriving at the operating temperature of 450 °C, the cell was exposed to 15 sccm-humidified H_2 (3 % H_2O by volume). The cell immediately began to reduce and produce a voltage as shown in Fig. 11. The cell voltage rose to 0.94 V after only 1 min and the cell continued to produce a voltage of 0.94 V thereafter. In order to understand whether the cell had fully reduced in this time, impedance measurements were taken in increments after the cell had started up. The start-up impedance information is shown in Fig. 12. The information gathered through the impedance analysis shows that the entire cell impedance decreases the longer the cell has been run. The ohmic impedance of the cell remains relatively constant at around 1 Ω; however, the electrode polarization resistances decrease with time until around 50 min where no further change in electrode polarization resistance is observed as a function of time. The electrode

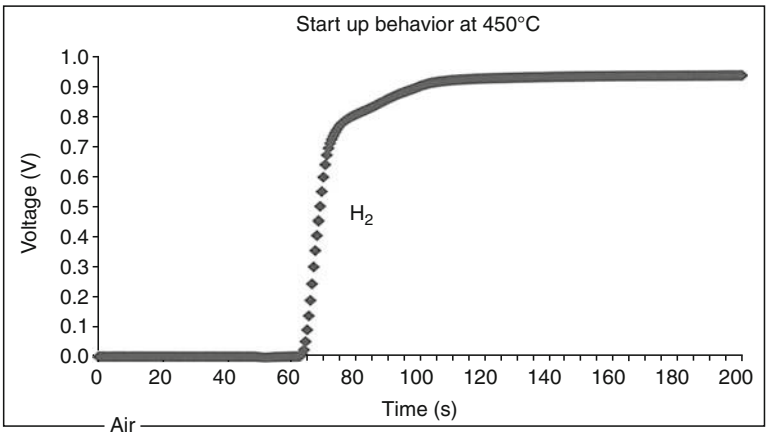

Fig. 11 *Microtubular* SOFC start-up behavior

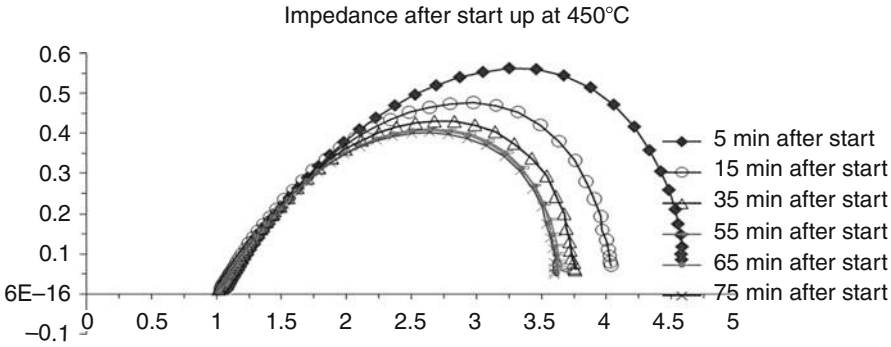

Fig. 12 Impedance spectra during the first 75 min of running

polarization resistance decreased by as much as 0.5 Ω in 10 min after the cell had started up. After start-up behavior analysis, the cell was held at 450 °C, and IV characterization of the cell was performed for varying flow rates of humidified H_2 (3 % H_2O by volume) through the cell. Figure 11a–c outlines the performance of the cell for varying fuel utilizations at 450 °C and concentration polarization losses are apparent in the IV curves shown. The fuel utilization was calculated from equation $U_f = i/(nFv)$, where the current drawn from the cell i), the number of electrons transferred in the reaction between H_2 and ½ O_2 ($n = 2$), the flow rate of fuel (v), and the inlet temperature of the fuel were used to calculate the fuel utilization (U_f) of the cell for the varying flow rates of fuel through the cell. The temperature of the inlet fuel stream is important because the density of H_2 entering the fuel cell is dependent on this parameter. As can be seen in Fig. 13a–c since at higher temperatures more current can be drawn from the cell, more hydrogen is necessary to drive the higher

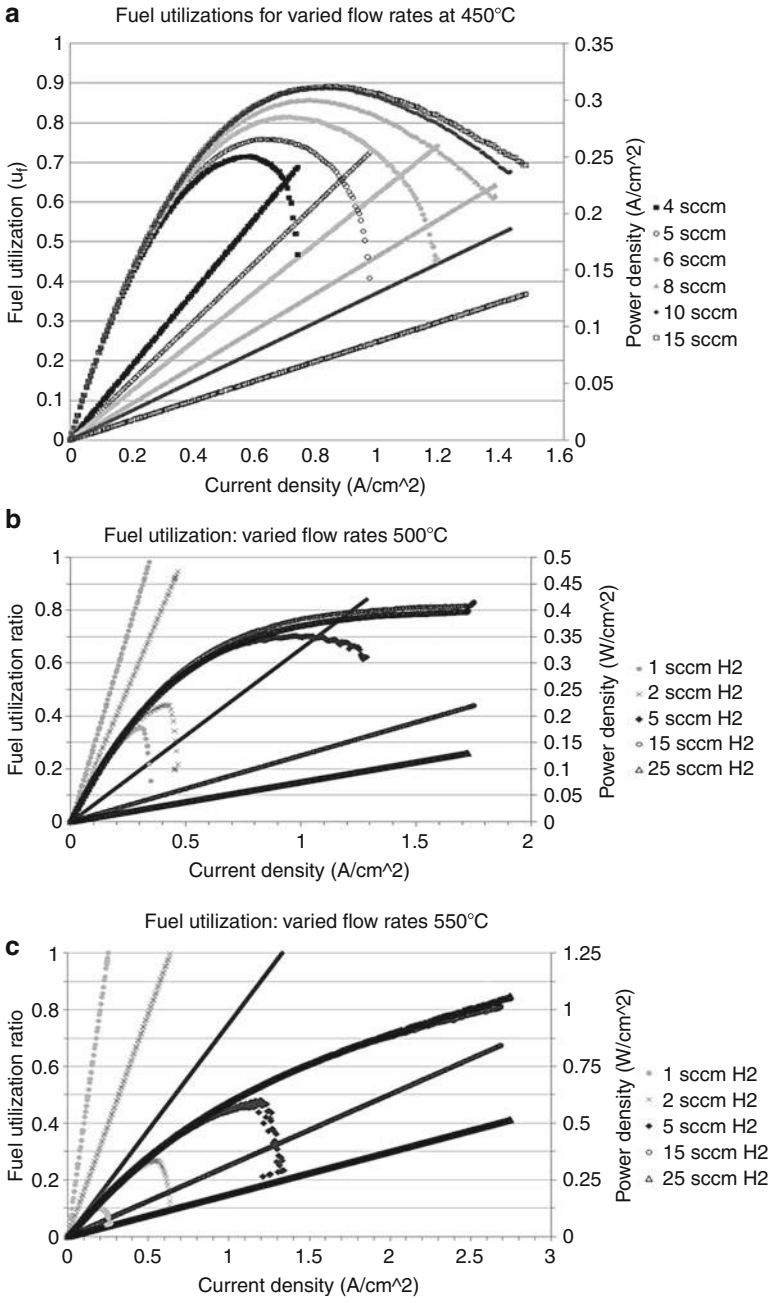

Fig. 13 (**a**–**c**) Fuel utilization and power density of the cells running at (**a**) 450 °C, (**b**) 500 °C, and (**c**) 550 °C

currents and fuel utilization values change for a specific flow rate. Thus, balancing fuel utilization with performance loss is an important issue when designing an efficient system since the performance of the cell is closely related to the fuel utilization.

Modeling of SOFC Systems

In modeling studies of solid oxide fuel cells, the common approach is to either model the cell isolated from its surrounding or to include some aspects of the surrounding environment by truncating the domain where the variables associated with the transport phenomena have not yet settled down to their "free stream" values. When large gradients (of these variables) are present, these approaches may lead to misrepresentation of the physics. For example, large differences in temperature or species concentration between the SOFC and its surroundings result in larger length scales for heat and mass transfer. Therefore, if a single cell is to be modeled with some portion of the physical domain, boundary conditions should be selected at the boundaries where truncation takes place; otherwise, a broader domain should be selected to cover spatial variations. However, selecting a larger domain requires further computational effort due to the mismatch between the aspect ratios of different parts of the computational domain.

Leakage Currents

There are a considerable number of studies to characterize the electron transfer process in the electrolyte. In early attempts, implicit relations of fuel cell electrochemical parameters were suggested as solutions to the electron transport equation in the electrolyte. Riess developed an explicit solution relating oxygen partial pressures and cell voltage to the electron flux across the electrolyte. His approach has been widely accepted in modeling studies. With some modifications to his derivation, some other forms of solutions also exist in the literature. Previously, Godickemeier developed a model to study the GDC electrolyte with the perspective of optimizing the cell design. Leah et al. developed a model to show that the use of MIEC electrolytes under certain conditions does not cause critical efficiency drops. Baron et al. further reported a reasonable fit of their model results to the experimental data when leakage currents were included.

Parametric Analysis

Although there are substantial works in modeling of SOFCs, few modeling studies have focused on the parametric analysis. Parametric analysis is an important method to understand the fuel cell behavior and compare the performance of the system affected by various factors. These factors can be related to either the cell geometry

and material properties or operational conditions. Changes in the geometry of the cell come along with uncertainties in the parameters related to reaction kinetics as the latter cannot be predicted without additional experiments. If the fuel cell performance is desired to be compared for two different cathode thicknesses, parameters related to reaction kinetics have to be updated for the new geometry as the distribution of the three-phase boundaries will change along with the percolation of the phases in the new geometry. Many of the modeling studies found in the literature carrying out parametric analyses of SOFCs focus on the geometrical aspects of the system. However, these studies neglect the abovementioned uncertainties arising with the change of the electrode geometry and are incapable of providing a precise tool to assess the effects of the geometrical parameters. Therefore, the effects of geometry on the fuel cell performance are not considered in this study. There are also studies focusing on the operational parameters such as utilization, flow rate, temperature, and pressure. Ni et al. developed a model to conduct parametric analysis to address the effects of operating conditions on the overpotentials. Their work constitutes a 1D model employing electrochemical relations and mass balances and does not include energy and momentum balances. Jiang et al. built a thermal and electrochemical model of a tubular SOFC to study the effects of operating conditions such as pressure, temperature, and flow rate. Their model is a lumped model and does not consider spatial distribution of the variables. Lisbona et al. analyzed an SOFC stack with the balance of plant to develop relations between cell performance and the operational parameters such as utilization, air flow rate, and inlet gas temperature. The developed model consists of only electrochemical relations, and the transport phenomena inside the stack are not considered. Colpan et al. developed a model employing thermodynamic calculations to identify the effects of utilization on cell output power and efficiency. Bove et al. carried out a utilization analysis for a tubular SOFC. Their model employs energy balance and electrochemical relations along with the simple algebraic relations for gas compositions. Although these models constitute significant contributions to the field, they either do not incorporate the sophisticated transport phenomena in the fuel cell rigorously or they underestimate the effects of spatial distributions of the transport variables.

Transient SOFC Modeling

While there are a number of significant modeling efforts, both in steady state and in transient, transient SOFC models typically are not as elaborate as steady-state models. Some of the transient models are lumped models neglecting all the spatial variations. They are mainly developed for control or to simulate the fuel cell as part of the larger system. Transient models incorporating transport phenomena vary from 1D to 3D models. 3D models are developed generally for planar SOFC, whereas exploiting the axial symmetry of the tubes, 2D models are preferred and most of the time sufficient to represent an SOFC with a tubular design.

Achenbach presented one of the first transient studies on SOFCs. He developed a 3D transient model to investigate the voltage responses of a planar SOFC to certain

load changes. Ioara et al. developed a 1D model for a planar direct internal reforming SOFC in which they concluded that neglecting the variation of the gas stream properties may lead to incorrect dynamic response predictions. Jia et al. provide detailed analysis of the effects of operating parameters on the steady state and transient performance of a tubular SOFC. Employing a 1D model, they represented the conservation laws with a control volume approach. In a recent study by Barzi et al., dynamic responses of a tubular SOFC are predicted during the start-up. Their 2D model incorporates mass, momentum, and species balances accompanied with a circuit representation of charge balances. Bhattacharyya et al. compared the dynamic behavior of the cell with the experiments in their 2D model of a tubular SOFC. Along with investigating dynamic response of the cell to the changes in voltage, they also predicted the response of the cell to the changes in hydrogen flow rate. Ota et al. compared transient characteristics of a standard tubular cell with a microtubular cell with a modeling framework presented therein. Their modeling framework is based on simplifications instead of taking into account full coupling of the sophisticated transport phenomena. They reported that timescales of a standard tubular cell to a specific voltage response are six times larger than that of a microtubular cell.

Another modeling study on microtubular SOFCs is presented by Nehter. In this study, he compared a common microtubular cell with a cascaded one. Although localized temperature and species concentrations are provided in his 2D axial symmetric model, momentum balance and multicomponent species transfer are not included. Mass balance is carried out in a simple way via algebraic equations describing the electrochemical and shift reactions.

Although there are many simplifications in the models of Ota et al. and Nehter, their studies are significant since, to the knowledge of the authors, they are the only modeling efforts emphasizing dynamics of microtubular SOFCs. Since the characteristics of a microtubular SOFC are very different than a standard tubular cell, there is still need for a rigorous model to study the dynamics of such a cell.

Thermal Fluid Model Description

The work performed by Serincan et al. employed two separate models to have a more accurate representation of the actual fuel cell test system: (1) a furnace model and (2) a fuel cell model. With the predictions from the former, boundary conditions were determined for the fuel cell model.

Figure 14 represents the geometrical domains for the furnace model and the fuel cell model. The model exploited the axial symmetry of the tubular geometry, therefore reducing the modeling domain into a 2D axisymmetric domain, assuming the anode and the cathode current collectors were uniformly distributed on the electrode surfaces. Figure 14 (not drawn to scale) also shows the cross section of the axisymmetric geometry.

The actual model geometry can be visualized by revolving this cross section around the symmetry axis, that is, centerline of the anode tube. Mass, species, and

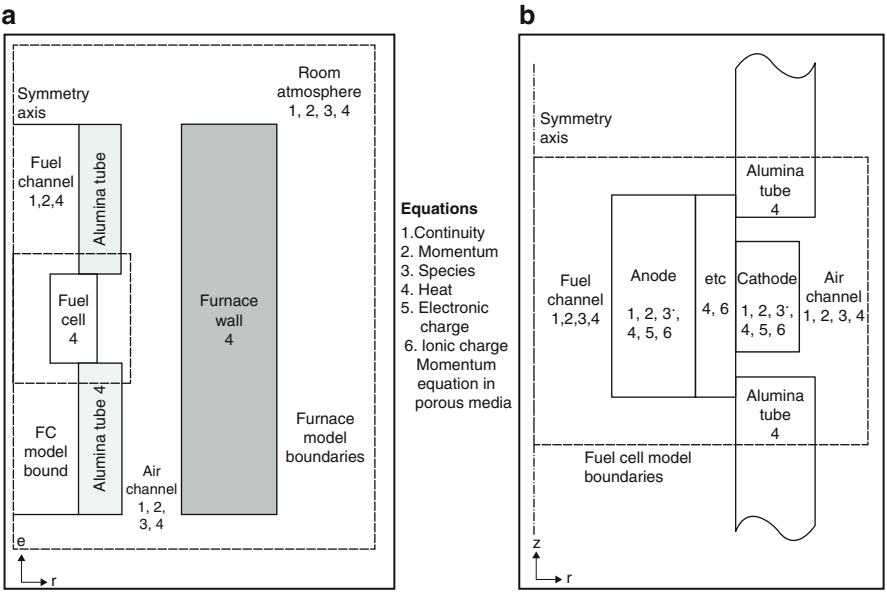

Fig. 14 (**a**) Furnace model domain. (**b**) Fuel cell model domain. Numbers represent the equations solved in each section of the domain

momentum conservation equations were solved in the gas channels and the porous electrodes, and energy conservation was applied for the entire domain. Ionic charge balance was applied in the anode, the electrolyte, and the cathode, whereas the electronic charge balance was applied in the anode and cathode.

The microtubular cells considered in this study were fabricated and characterized as described above. The anode-supported cells employed a GDC electrolyte coated on a NiO-GDC anode and (LSCF)-GDC cathode. It is well known that GDC electrolytes are prone to internal current leakages. GDC can reduce and become electronically conductive, especially at elevated temperatures. A fraction of the electrons generated at the anode can then be transferred to the cathode through the electrolyte. As a result, the cell is short circuited and a drop in the open circuit potential is experienced. The effect of current leakages becomes less significant at higher current densities, because they are inversely proportional to the ionic current density. In this work, the electronic current leakages were modeled as boundary conditions to the electronic charge equation at the electrolyte interfaces of anode and cathode while describing the boundary conditions. The furnace model was used to explicate the transport phenomena in the furnace and the surrounding room atmosphere and estimated the transport properties at the boundaries of the fuel cell model domain. Computational domain for furnace model was chosen by trying different dimensions until the gradients disappeared and/or not to have a significant effect on the distribution inside the furnace.

Results from Modeling

The furnace model consisted of the furnace, fuel cell as a whole, alumina tubes shown in (Fig. 9), air channel, and the surrounding room atmosphere. In the air channel and the room atmosphere species, momentum and heat equations were solved. In the fuel cell, these equations were modified accordingly to account for porous media transport. In the furnace walls and alumina tube, only heat equation was solved. The difference between the furnace temperature and the room temperature invokes natural convection, which transmits the air to the fuel cell. To implement natural convection in the model, a nonisothermal flow equation was used. Another approach could have been to apply a Boussinesq approximation to the Navier-Stokes equation, which would be based on linearization of density with respect to the changes in temperature and concentration. Further, Maxwell-Stefan equations coupled with heat and momentum equations were used to model the species balance.

On the other hand, the fuel cell model included truncated air and fuel channels, alumina tubes, anode, electrolyte, and cathode as is seen in Fig. 14. In the air and fuel channels, species, momentum, and heat equations were solved. In the anode and cathode, in addition to these equations that were modified for porous media, ionic and electronic charge equations were also solved. In the electrolyte ionic charge, equation was solved along with heat equation. In the alumina tubes, only heat equations were solved.

Maxwell-Stefan equations were used to model the multicomponent species balance instead of Fick's law, which is applicable only for binary mixtures. To model momentum transfer, nonisothermal flow equations were solved, with the nonisothermal continuity equation, to take into account the density changes with temperature and species concentration. In the porous electrodes, momentum equations were modified in the form of nonisothermal Brinkman equations. Darcy's law for momentum transfer in porous media was not chosen as it does not include stress tensors in its formulation. Heat equations were formulated in order to include enthalpy transfer. Heat transfer due to radiation was modeled as boundary conditions. Electronic and ionic charge balances were implemented in the form of Ohm's law throughout the anode, electrolyte, and the cathode domains.

The results of the furnace model described above showed that oxygen concentration at the boundaries strongly depend upon the fuel cell operation conditions and the importance of assigning the right boundary condition. The model results were also compared with experimental data, and related polarization curves show good agreement for a set of different operating temperatures. Having a good match with the same set of fitting parameters for three different polarization curves suggests the model captures the temperature dependence of the fuel cell electrochemistry well. Temperature distribution in the cell was evaluated and the average radial temperature gradient was calculated as 2.25 °C/mm, whereas the axial average gradient was

found to be 18 °C/mm. It was predicted that the temperature may rise by up to 120 °C for an SOFC operating at 0.2 V. This temperature rise is attributed to the ohmic heating due to the losses during fuel cell operation. It was further shown that it was a good assumption for a microtubular SOFC to lump all the losses at the anode due to the very small thickness of the tube.

Leakage currents were found to be the reason for an OCV drop of 0.18 V at 550 °C, and their effects diminish gradually until they vanish around cell voltages of 0.6 V. It was also shown that at higher operating temperatures, the internal current leaks associated with the electron transfer through the electrolyte were more significant. It was predicted that if the output current demand is 0.53 A/cm^2, the fuel cell has to generate an ionic current density of 0.65 A/cm^2 at 550 °C, as under this condition, the leakage currents sum up to 0.12 A/cm^2.

The dependency of current density on transport properties was also studied, and the effects of temperature and species concentration were shown on the current density profiles. Moreover, exchange current density as a measure of reaction rate was considered, and it was suggested from model results that anode thickness can be reduced to promote reactant diffusion to the active catalyst sites.

Effects of temperature, fuel flow rate, fuel composition, anode pressure, and cathode pressure on the SOFC performance were investigated. It was shown that increase in temperature results in better cell performance due to increase in catalytic activity, ionic conductivity, and decrease in mass transport losses. It was found that with higher flow rates, the performance of the cell increases; however, efficiency decreases due to the lower utilization. In conjunction with this, it was advised that the fuel flow rate should be chosen according to the desired operating range such as at midrange current densities lower flow rate as suggested because of the efficiency of the cell, and in the higher current density range, higher flow rate should be chosen (i.e., a stoichiometric flow control) because of the output power implications. It was also shown that the utilization of the fuel was not zero when the cell does not generate current because the reacted fuel is not enough to overcome the internal current leakages. When fuel composition was considered, higher hydrogen content was favorable for power output, efficiency, and thermal management. Increases in anode side and cathode side pressures have two distinct effects on cell performance: increase in pressure reduces reactant diffusivity but increases catalytic activity. However, the latter overwhelms the adverse effects of decreased mass transport and cell performance is always observed to improve with larger back pressure. When the effects of pressure on the anode and cathode sides are compared, it was seen that it was more sensitive to changes in the air pressure mainly due to the slow reaction kinetics of the cathode.

Response of the cell to a change in voltage was also investigated. An overshoot was observed in the current density response as a result of the combined effect of fast electrochemical reaction and slower dynamics of the mass transfer. It was predicted that timescales of a microtubular SOFC are in the order of 20 s governed by the dynamics of heat transfer.

Future Directions

Solid oxide fuel cells (SOFC) have tremendous potential for a number of applications from small mW to W scale, all the way up to MW scale systems. However, research around the world is concentrating in the development of suitable materials and fabrication processes to bring down the price of the SOFC to make it a commercially viable product. Programs are underway internationally to look at novel SOFC geometries utilizing cheaper materials that work at lower temperatures. The demonstration of a low-temperature SOFC running directly off methane or natural gas signals an important new opportunity for making simple, cost-effective power plants. Changes in cell composition and design have resulted in improved power densities, with higher power densities contributing to lower weight, size, and cost of the final fuel cell systems. This is the future direction that has to be optimized to allow these systems to become a reality.

Abstract

Molten carbonate fuel cell (MCFC) is a high-temperature fuel cell. Because of high-temperature operation, various fuel gases can be widely used and internal reforming of hydrocarbon fuel is also possible, resulting in improving fuel utilization and providing higher power generation efficiency. Many MCFC plants are being installed as the stationary cogeneration power supply using various fuels in various countries in the world, and among them, the world's largest fuel cell power plant has 2.8 MW electric capacity. The power generation efficiency of the systems including smaller 300 kW units reaches 47 % (LHV, net, same as above unless otherwise noted). In addition, the hybrid systems which contain both MCFC and gas turbine have been demonstrated, and a new carbon dioxide (CO_2) recovering hybrid system concept with extremely high value of 77 % efficiency is proposed. The advantage of MCFC is not only the use of city gas but also the use of digestion gas from the sewage disposal plant. In the future, it is expected to develop a large-scale centralized electric power generating plant using the coal gasification gas. The MCFC is one of the key technologies to reduce CO_2 emission for the future.

Introduction

The MCFC is a high-temperature fuel cell operated at approximately 600–650 °C. Along with the features of general fuel cells that are high power generation efficiency, capacity flexibility, and excellent environmental property, it has a lot of additional attractive features such as the variety of an applicable fuel and improvement of the power generation efficiency by a combination with the gas turbine and/or by the internal reforming. The MW class plants are already introduced, and its commercialization is just around the corner. This chapter outlines the features of MCFC, the principle, the basic performance, the configurations of cell/stack/system, and current development situations and issues. The future directions are also given.

Features

The MCFC uses carbonate which is in a molten state for an electrolyte, and the electrochemical reactions take place through carbonate ion. Besides the features of the general fuel cells such as high efficiency, capacity flexibility, and the superior environmental sustainability, the MCFC has additional features as follows.

High Efficiency

Because the operating temperature is around 600–650 °C, it can form the power generation systems combined with the gas turbine and the steam turbine by using the high-quality exhaust heat from the MCFC. It can attain much higher power generation efficiency.

Various Fuels

Due to high operating temperature, electrode reactions take place in fast speed, and thus expensive platinum (Pt) catalyst is unnecessary, resulting in avoiding carbon monoxide (CO) poisoning. Therefore, the application of the CO-containing gasification gases such as coal, biomass, and waste is also possible.

Internal Reforming

When methane-based fuel is in use, internal reforming can be applied using steam and heat generated inside the fuel cell. The internal reforming can be expected to improve the generation efficiency by increasing fuel utilization and lowering energy consumption for cooling the MCFC to maintain the operating temperature. The internal reforming can also simplify the system configuration by eliminating the external reformer.

CO_2 Concentration

Because the electrochemical reactions take place through carbonate ion, CO_2 is necessary for the cathode reaction. On the other hand, same amount of CO_2 is generated at the anode. Therefore, the CO_2 generated at the anode is generally circulated to the cathode side. It is called the CO_2 recycling. Because the generation of CO_2 at the anode increases the concentration of CO_2 at the anode exhaust, low concentration of the CO_2 at the cathode inlet can be increased at anode exhaust. For example, if low CO_2-containing flue gas from thermal power station is supplied to the MCFC cathode, we can obtain high CO_2-containing gas which can separate CO_2 easier.

Easier Manufacturing of Large Cells

The MCFC generally adopts a planar multilayered structure, using metal separators and sheets of active components manufactured by tape casting method. Therefore, it is rather easy to make it big and to be adopted by large-capacity power plants from the production viewpoint.

Principle

Figure 1 shows the principle of the MCFC operation (U.S. Department of Energy 2004). The electrolyte is a liquid that melts under the operating temperature. Hydrogen (H_2) supplied to the anode reacts with carbonate ion (CO_3^{2-}) in the electrolyte. The electron is discharged from the anode and steam (H_2O) and CO_2 are generated at the same time. Reacting with the electron, oxygen (O_2) and CO_2 supplied to the cathode generate CO_3^{2-}. These reactions are expressed as follows:

$$\text{Anode} : H_2 + CO_3^{2-} = H_2O + CO_2 + 2e^- \quad (1)$$

$$\text{Cathode} : CO_2 + 1/2O_2 + 2e^- = CO_3^{2-} \quad (2)$$

$$\text{Total} : H_2 + 1/2O_2 = H_2O \quad (3)$$

The electron is discharged from the anode and taken into the cathode through an external circuit in a series of reaction. Power generation by the fuel cell is achieved by flowing the electron. Because the operating temperature is high and nickel (Ni) is used for both electrodes, Ni acts as a catalyst and CO in the fuel gas (if there is any) supplies H_2 by the shift reaction ($CO + H_2O = H_2 + CO_2$) relating to the reaction of Eq. 1. The operating temperature of MCFC is high enough for the proceeding of

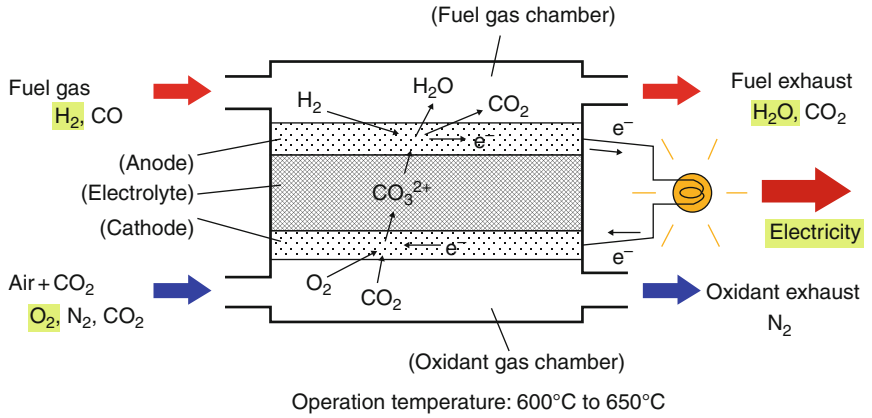

Fig. 1 Principle of the MCFC

the shift reaction. Therefore, it becomes possible to use the gasification gas of coal, biomass, and waste, which contain certain percentage of CO. In addition, a big characteristic of the MCFC is to have to contain CO_2 in the supplied oxidant gas, because the ion in the electrolyte that contributes to the reaction is CO_3^{2-}.

Cell Stack Configuration and Materials

The actual cell consists of the matrix sheet, the electrode (anode and cathode) sheets, and the metallic components that provide reactant gas passageway and current collection, as shown in Fig. 2. Then, the size of the cell is described.

Matrix and Electrodes

The matrix has a porous ceramic structure consisting of $LiAlO_2$. It is usually impregnated with the electrolyte liquid maintained by capillary force under the operating temperature. Mixed carbonate of Li_2CO_3 and K_2CO_3 or of Li_2CO_3 and Na_2CO_3 is used as the electrolyte. A γ type has been used for $LiAlO_2$ mainly, but the α type is examined recently from a point of the stability for carbonate. Moreover, the coarse particle or fiber of alumina (Al_2O_3) is mixed to keep the mechanical strength.

Both anode and cathode provide reaction places for the reactions (1 and 2) and are placed on the surface of the thin electrolyte film (matrix). Therefore, the electrodes are required to have high electric conductivity, optimal pore size, and porosity for providing sufficient active area (reaction places), adequate wettability for maintaining electrolyte stable, stable porosity structure, etc. Because mean pore sizes of the electrodes are larger than that of the matrix by single digit, capillary force in the matrix is stronger than that in the electrodes. Then, pores within the

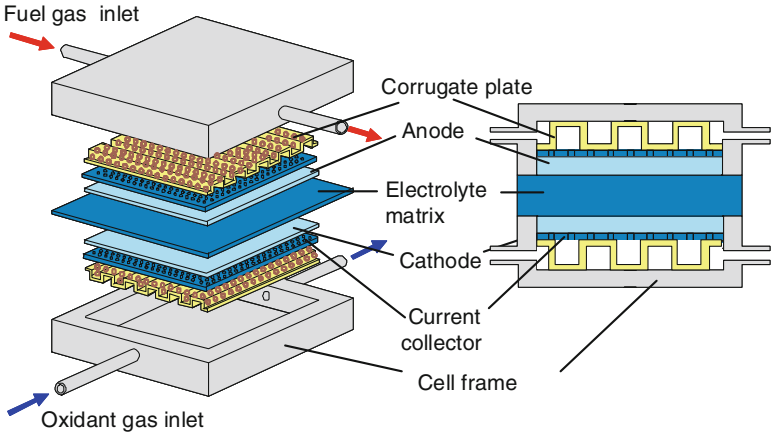

Fig. 2 Configuration of MCFC cell

matrix are firstly filled up and then excess electrolyte is impregnated in the pores within the electrodes. Matrix is usually filled up 100 % with electrolyte and the pores of the electrodes are filled by 20–40 % of the void volume.

1. Anode: The anode is required to have high corrosion resistance for melted carbonate under the fuel gas atmosphere. It also should be stable under steam and CO_2 generated at the anode. Therefore, the porous sheet sintered from fine nickel (Ni) particle is used. Chrome (Cr) and aluminum (Al_2O_3) are usually added for the improvement of creep resistivity at high temperature.
2. Cathode: The cathode is operated under a severe condition of oxidative atmosphere, and thus the metallic oxide is used. Typically, the porous media made of oxidized nickel particle is used. Nickel oxide (NiO) does not have sufficient electric conductivity; however, the electric conductivity is given by lithium in molten carbonate being doped in the cathode.
3. Manufacturing of the sheets: The electrodes and the matrix are made by the tape casting method and the formed sheets are cut for required sizes. The tape casting method is a useful process for simple, easy, quantitative, and cost-effective production. In the process, the slurry to the mixture of the fine particle of the raw material with the solvent is thinly spread by a doctor blade on a substrate sheet and dried. The spreadsheet is about 0.5 mm in thickness and about 1 m in width. The electrodes and matrix are called active components, and they are cut to have rectangular-shape-like PAFC.

Metallic Components

1. Gas flow channels: Gas flow channels for fuel and air (it is accurately called "oxidant gas" because it contains CO_2) are formed using the metallic end plates which sandwich active components. The outer periphery of the end plates touches the electrolyte matrix directly, and the wet seal covered with the liquid film of the impregnated electrolyte is formed and prevents gas leakage to the outside. Stainless steels such as SUS316L and SUS310S are machined or pressed for the end plate. The nickel clad steel is used as a center plate of the separator, which is exposed to both reducing and oxidizing condition on each side in consideration of corrosion resistance with the carbonate.
2. Current collector: Moreover, the current collector is placed within the gas flow channel for better electric contact between the electrode and the end plate. Perforated metal plates with same materials to the end plates are generally used.
3. Separator: Because the voltage of a single cell is about 0.7–0.8 V, it is necessary to obtain a high voltage of several 100 V or more to operate the power conditioner efficiently. Therefore, it is required to pile up the single cells through the metallic separator plates. This is called a stack. The separator has gas flow channels on both sides instead of the end plate for single cell, and it connects single cells in series electrically. The number of cells in the stack is usually 100–300.

4. Gas flow directions and manifolds: There are three ways for fuel and oxidant flow directions at a cell. These are cross flow, parallel flow, and co-flow. It is chosen in consideration of the operating temperature and the current distribution in the cell. There are also three ways for distributing reactant gases to each cell within a stack, which are external manifold, internal manifold, and hybrid manifold. External manifold is adopted in the PAFC stack. However, internal manifold which has a penetration hole through the cell is sometimes selected for MCFC stack. It is also chosen in consideration of reactant gas flow directions within the cell. External manifold is selected in the case of cross-flow-like PAFC. However, internal manifold could be adopted in the case of parallel flow and co-flow. There are both merits and demerits from the viewpoint of the manufacturing process, electrolyte migration in the stack, effective electrode surface area of the cell, etc.

Cell Size

The thickness of the single cell is several mm with the two electrodes and electrolyte matrix (active components). The size of stacked cell is slightly bigger than general PAFC, and the length is about 1 m on a side of the rectangular shape. The separator is produced using a metal part with about the same size. Table 1 shows a general specification of each material that composes the cell (U.S. Department of Energy 2004).

External and Internal Reforming

Either an external reforming or an internal reforming method is adopted for the supplying H_2 to the system as a reactant at the anode. Reforming reaction is expressed as follows:

Table 1 Specification of MCFC components

Component	Material	Thickness	Mean pore diameter (MPD), porosity, etc.
Anode	Ni–Al–Cr	0.7–1.0 mm	MPD: 4–6 μm
			Porosity: ca.60 %
Cathode	Lithiated Ni	0.3–0.8 mm	MPD: 8–10 μm
			Porosity: ca.80
Electrolyte support	γ-$LiAlO_2$, α-$LiAlO_2$	0.5–1.0 mm	Porosity: ca.60 %
			Specific surface: 15–20 m^2/g
Electrolyte	Li_2CO_3–K_2CO_3	–	–
	Li_2CO_3–Na_2CO_3		
Separator	SUS310S, SUS316L, Ni	–	–
	SUS316L-Ni clad		

$$CH_4 + H_2O = 3H_2 + CO \quad (4)$$

The external reforming is a method that the reformer is installed separately from the stack, same as the PAFC system, and H_2 is generated from natural gas outside the stack. In the internal reforming method, the reforming catalyst is loaded within the fuel flow channel of the cell and H_2 is generated in parallel with power generation. The MCFC can adopt the internal reforming method because of its high-temperature operation.

External Reforming

In the external reforming, natural gas and steam mixture are supplied to the separated reformer and H_2-rich gas is produced through a catalyst-loaded tube heated from outside. Reforming rate (methane conversion rate) is limited by the reforming condition, and the number of Balance of Plants (BOPs, equipments configuring the fuel cell system other than the fuel cell stack) is increased. The advantage of this method is that it can avoid undesirable effect of electrolyte on the catalyst (please see below) because the reformer is separated and located upstream of the stack.

Internal Reforming

The internal reforming enables a system compact, stack cooling load small, and to improve methane conversion rate and efficiency, because endothermic reforming reaction proceeds further by using both steam and heat, which are generated within the cell during consuming H_2 at the same time. On the other hand, the reforming catalyst is exposed to the electrolyte, which might cause damaging catalyst. Indirect internal reforming method is usually adopted to avoid this problem (http://www.fuelcellenergy.com). The exclusive reforming plates are sandwiched every several cells in the stack, and pre-reformed gas from the reforming plate is supplied to the cells.

Basic Performance

Current–Voltage (I–V) Characteristic

Basic performance of the fuel cell can be represented by the current–voltage characteristics which affect largely on the efficiency and cost of the plant. The current–voltage characteristic of the MCFC is expressed by a straight line as shown in Fig. 3. Because of high-temperature operation, voltage loss with electrode reaction is small. The cell voltage is generally over 1 V in no load and it becomes 0.7–0.8 V with load of 150 mA/cm^2 current density. The operating cell voltage of MCFC is higher than other types of fuel cells in the current density range

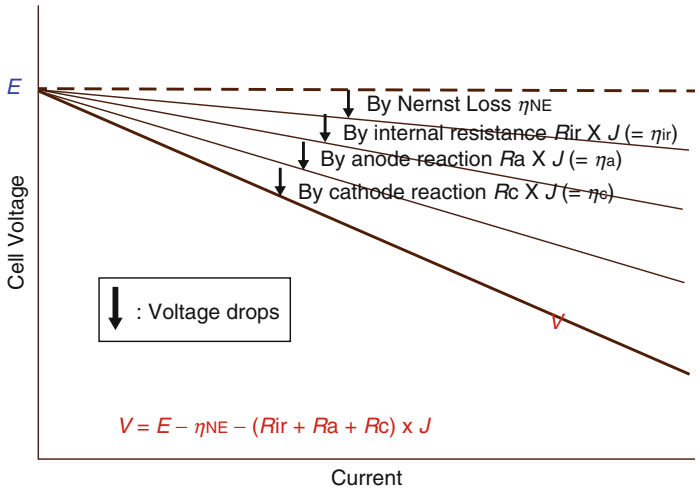

Fig. 3 Current–voltage performance

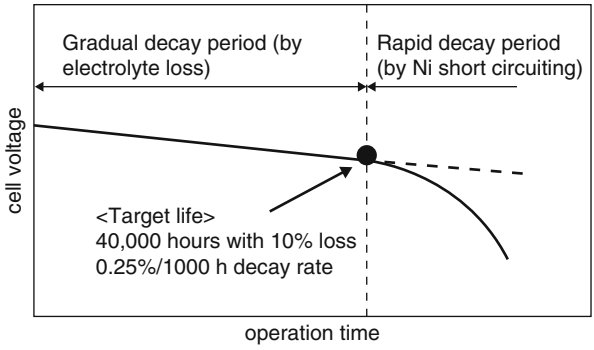
Fig. 4 Voltage decay pattern



of 100–250 mA/cm^2. It is one of the appropriate MCFC operating conditions at this current density range.

Life Characteristic

To discuss the stability of the cell, voltage decay characteristic (life characteristic) is important. It affects on the efficiency change and eventually on the cost of electricity. Typical voltage decay pattern of the MCFC is shown in Fig. 4. In general, the cell voltage decays gradually and linearly until certain time and then drops rapidly after. The rapid drop is caused by "nickel short-circuiting" as described later. The voltage drop means not only the decrease of plant efficiency but also the change in relevant BOP's operating conditions. Because it is generally considered that the acceptable change of the operating conditions is about 10 %, practical MCFC life should be the

time when cell voltage decreased to the ca. 90 % level from the initial voltage during the linear decay range or the time when the rapid voltage drop started. The reason of the voltage decay will be described in the next section. For keeping high efficiency and reducing cost of electricity, it is important to control the voltage decay rate as small as possible and to delay the starting point of rapid voltage drop after the target lifetime. The current goal of life is generally considered about 30,000–50,000 h as same as other types of fuel cells.

Performance Improvements

Enhancement

Voltage-Determining Factors

There are several voltage-determining factors as shown in Fig. 5 (Morita et al. 1998; Morita et al. 2002). The voltage loss caused by internal resistance is relatively small, and the loss caused by electrochemical reaction at both anode and cathode is large. The electrolyte of the MCFC is the mixture of Li_2CO_3 and K_2CO_3 (Li/K) or the mixture of Li_2CO_3 and Na_2CO_3 (Li/Na). The reaction voltage loss is large using either electrolytes, and the reaction voltage loss at the cathode is larger than the one at the anode. Nernst loss means the decrease of theoretical voltage caused by the gas composition change by electrode reactions, and it is mainly caused by the anode reaction. The composition of fuel gas changes larger than that of oxidant because H_2O and CO_2 are produced at the anode with higher fuel utilization (about 80 % in natural gas-fueled system) which means that the concentration of H_2 is drastically reduced. Oxidant utilization is usually set at lower level (about 30–50 %), meaning higher flow rate, for stack cooling. This is the reason why the fuel-side Nernst loss is larger than the oxidant side.

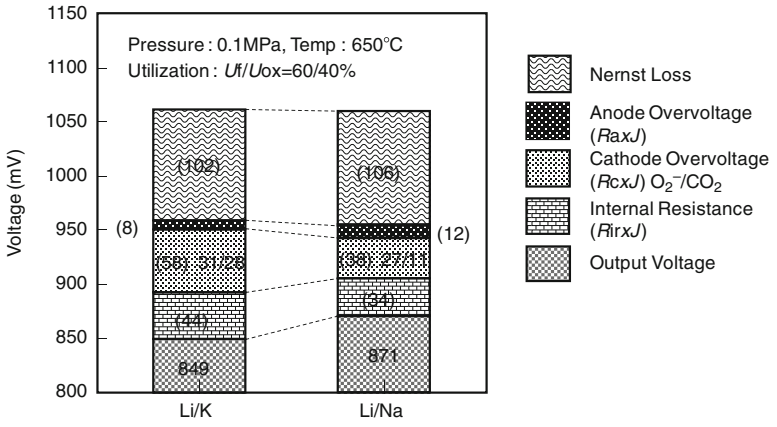


Fig. 5 Voltage-determining factors

Reducing Voltage Loss Factors

The MCFC is expected to replace the conventional centralized thermal power plants in the future. Such large-scale power plants are operated with very high efficiency; therefore, the MCFC power plant is required to be operated with much higher efficiency. If the fuel cell system generates electricity only by the fuel cell, the system efficiency is almost proportional to the cell voltage. Therefore, the fuel cell voltage should be maintained as high as possible, and it is important to reduce the voltage loss factors as can be seen from Fig. 5. It is effective to reduce the voltage loss, first of the cathode reaction and then of the anode reaction and the internal resistance. For the reaction loss reduction at the electrodes, it is important to realize adequate electrolyte distribution, designed by optimizing the microstructure and wettability of the electrodes. For the internal resistance reduction, higher ionic conducting electrolyte or thinner matrix is applied.

Pressurized Operation

Pressurized operation is another way to increase the cell voltage. Higher operation pressure increases theoretical voltage (Nernst potential) and reactant gas solubility which means the decrease of reaction voltage loss, and it can eventually provide higher plant efficiency. It corresponds to push up the voltage–current characteristic indicated in Figs. 3 and 6 shows the pressurized characteristic of the MCFC up to 5 MPa range (Yoshikawa et al. 1999). Regardless of electrolyte composition, the cell voltage increases in proportion to a logarithm of the pressure. However, above about 3 MPa, the cell voltage is suppressed or decreases in some cases. This is caused by the methanation reaction in which methane is produced from carbon and hydrogen elements in fuel gas, resulting in lowering hydrogen composition and decreasing theoretical voltage. The methanation reaction is described as follows:

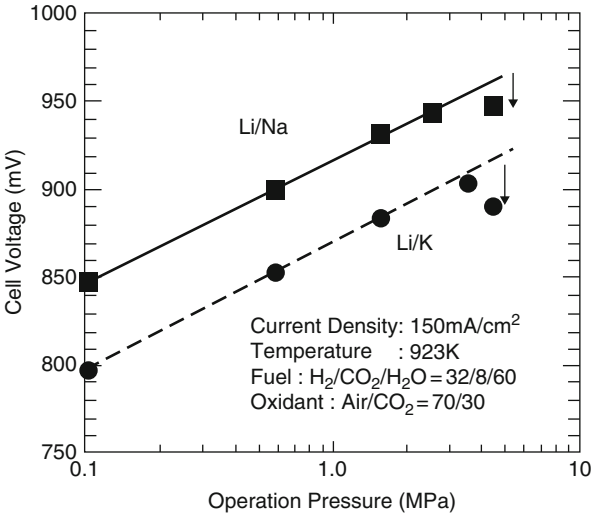

Fig. 6 Pressurized performance

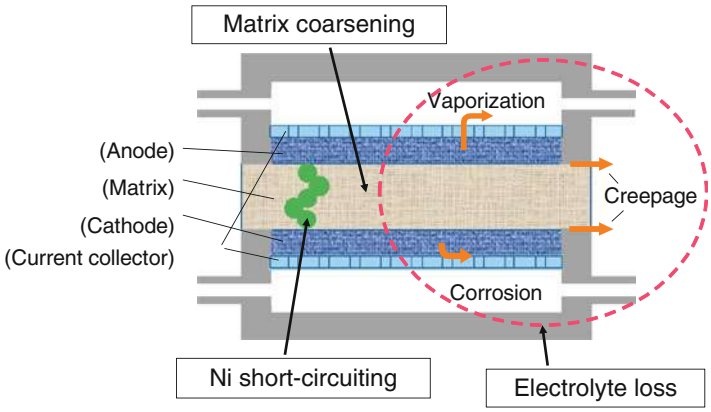

Fig. 7 Life-limiting issues

$$3H_2 + CO = CH_4 + H_2O \tag{5}$$

The reasonable operation pressure range might be up to about 3 MPa based on these data, and it is possible to use gas turbine for the existing combined cycle power plant, which pressure range is less than about 2 MPa.

Life Extension

The factors decreasing cell voltage during operation and determining MCFC life are electrolyte loss such as matrix pore coarsening and nickel short-circuiting, as described in Fig. 7.

Electrolyte Loss

Pores within the matrix are filled up with electrolytes. Excess electrolytes which cannot enter into the matrix are distributed to the anode and the cathode. The distribution ratio is determined by the balance of capillary forces between the anode and the cathode. High cell voltage is attained by adequate electrolyte distribution with proper amount within the electrodes. From its viewpoint, pore distributions determining capillary force and total electrolyte amount are important design factors which affect strongly on cell performance. Meanwhile, it is well known that the amount of electrolyte decreases with time by some reasons. Electrolyte loss changes the distribution to inadequate one and it leads to voltage drop. Most of the loss is caused by the corrosion reaction with metallic components of the cell, and the corrosion products with high electric resistance increase internal resistance. The electrolyte loss is also caused by vaporization and creepage. Usually, corrosion-resistant treatment is applied on the surface of the metallic components. In addition, electrolyte loss is controlled by reducing the number or the total surface area of the

metallic components. Current technology is considered to be able to control the loss that meets the present target life.

Matrix Pore Coarsening

Matrix pore coarsening is caused by dissolution and deposition of $LiAlO_2$ that is ceramic material constituting the matrix during longtime operation. The pore coarsening decreases electrolyte holding force and electrolyte moves out to the electrodes or leaks outside. The electrolyte distribution changes within the electrode and finally voltage decays. One of the solutions is the change of the phase of $LiAlO_2$ from γ to α.

Nickel Short-Circuiting

"The nickel short-circuiting" is a phenomenon that forms the internal short circuits between the anode and the cathode by metal nickel particles in the matrix. Figure 8 shows that NiO as cathode material dissolves as Ni^{2+} ion into the electrolyte by reacting with CO_2 in the oxidant gas, and metallic nickel particles are precipitated when Ni^{2+} ions react with dissolved H_2 from fuel gas. Those reactions are expressed as follows:

$$Ni^{2+} + H_2 + CO_3^{2-} = Ni + H_2O + CO_2 \tag{6}$$

$$NiO + CO_2 = Ni^{2+} + CO_3^{2-} \tag{7}$$

The nickel short-circuiting time can be expressed by the next equation (Mugikura et al. 1995; Yoshikawa et al. 2001):

$$t_s = APco_2^{\alpha} L^{\beta} \tag{8}$$

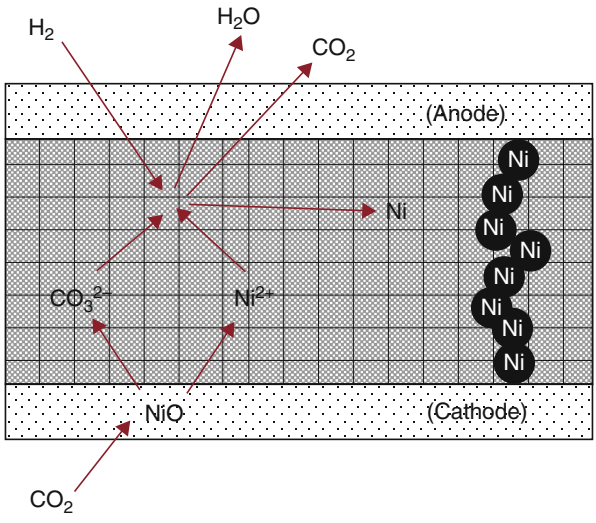

Fig. 8 Nickel short-circuiting phenomenon

[a]650 °C
[b]Li/K = 50/50

where A is a coefficient, PCO_2 is a CO_2 partial pressure at cathode, L is an electrolyte thickness, and $\alpha \cong -1$ and $\beta \cong 2$.

As can be seen, this phenomenon occurs in a shorter time under higher CO_2 partial pressure in oxidant gas, and the occurrence time of the short-circuiting can be delayed by using thicker matrix. However, thick matrix increases internal resistance and decreases cell voltage. There are several trade-offs for cell stack design. The setting of the electrolyte thickness is an example of a typical trade-off to influence the cell voltage, and it is one of the essential design points from the nickel short-circuiting viewpoint. In order to avoid the nickel short-circuiting, the changes of electrolyte composition, matrix material, and operation condition with lower CO_2 partial pressure are attempted.

Recently, it is proposed as one of the solutions to use Li/Na electrolyte instead of conventional Li/K electrolyte. As for the Li/Na electrolyte, the solubility of the nickel is about a half compared with Li/K system as shown in Table 2, and it would be possible to delay the nickel short-circuiting behind. Moreover, this electrolyte can decrease internal resistance because the electric conductivity of the ion is higher as shown in Fig. 5 and can improve the voltage of the cell. It is concurrently tried to decrease nickel solubility by a small amount of additive to the electrolyte or to control the precipitation of nickel particles by the improvement of the matrix structure.

System Configurations

Basic Configuration

The MCFC power generation system is composed of the fuel processing system, the air supply system, the MCFC, the inverter, etc., so that fuel and air can be supplied to the stack in appropriate temperature conditions, same as the case of PAFC system. Because the MCFC can utilize various kinds of fuels, the fuel processing system is

different from the kind of fuel. It will contain a steam reformer for natural gas and a gasifier and a gas cleanup unit for coal, biomass, or wastes.

In addition, the shift converter which was applied to reduce CO in fuel gas in the case of PEFC and PAFC is unnecessary. Because the operation temperature of the MCFC is about 600–650 °C, the exhaust heat can be used for temperature control at the inlet gas of the stack and for reforming reaction at the reformer. In addition, it is possible to configure a hybrid power generation system including a gas expander and a steam turbine at MCFC downstream as a bottoming cycle.

The details of the natural gas or coal-fueled MCFC power generation systems are described below. The natural gas-fueled pressurized external reforming system or ambient pressure internal reforming system has already realized about 47 % efficiency. As for the future large-scale plants, simulation results show that the natural gas-fueled pressurized external reforming system with 1,000 MW capacity would be about 65 %, the pressurized internal reforming system with 700 MW capacity would be about 69 %, and the integrated coal gasification system (IGMCFC) with 600 MW capacity would be about 57 % efficiency (Watanabe 2001).

Natural Gas-Fueled External Reforming System

Configuration of the natural gas-fueled pressurized external reforming MCFC power generation system is shown in Fig. 9 (Krumpelt et al. 1982). In this system, natural gas mixed with steam is supplied to the reformer, converted to H_2 and CO, and used at MCFC. CO should be a certain lower level for low-temperature fuel cells. However, the MCFC has no catalyst which has poisoning problem like low-temperature fuel cells. Moreover, CO can be shifted to H_2 by fast shift reaction under high-temperature condition. Even in the case that H_2 is consumed for power generation, CO can shift to H_2 very fast. Therefore, CO can be considered as an

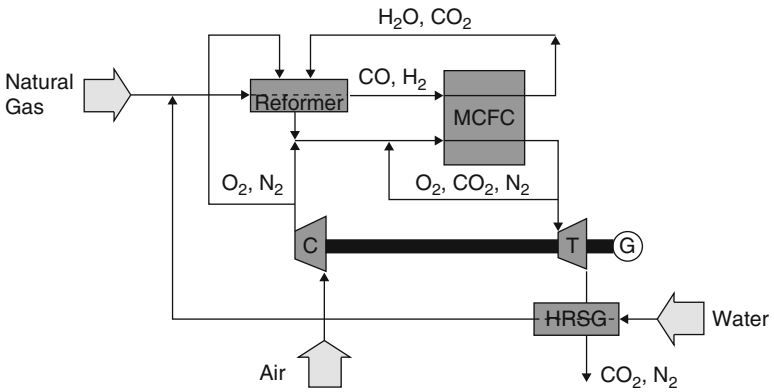

Fig. 9 Natural gas-fueled external reforming MCFC system

effective fuel in the MCFC. However, high-temperature condition also allows Boudouard reaction, which forms solid carbon from gaseous CO around fuel supply line. The Boudouard reaction is expressed as follows:

$$2\mathrm{CO(gas)} = \mathrm{C(solid)} + \mathrm{CO_2(gas)} \tag{9}$$

Thus, it is required that the fuel gas should be in a certain condition to avoid this reaction, and humidifying the fuel gas is one of the countermeasures.

MCFC exhaust gas from the anode contains combustible components, and they can be used as a heat source of an external reforming in the natural gas system. Actually, certain quantity of non-reacted fuel is necessary, and the quantity of H_2 and CO that can be utilized for anode reaction (fuel utilization) is decided from the calorific value required for reforming reaction.

Oxygen as one of the reaction species at the cathode is supplied from air compressor connected to the expander turbine at the same pressure to the fuel gas. Reaction specie, CO_2, is recycled from the anode exhaust, which contains the produced CO_2 at the anode. The amount of the produced CO_2 is same to the required amount for the cathode reaction. The fuel exhaust from the MCFC contains not only CO_2 but also unreacted flammable species, such as H_2, CO, and CH_4. It is supplied to the burner of the reformer to supply heat for reforming. The burner has another role to complete oxidizing the flammable species before supplying CO_2 mixed gas to the cathode. The combustion gas from the reformer combustor is mixed to the air from a compressor, and it is supplied to the cathode.

Heat is generated within the MCFC by the internal resistance or electrode reactions same as the PAFC. Therefore, it is necessary to control the MCFC temperature and to keep it at constant value. Because any liquid coolant such as water cannot be applied for cooling of high-temperature fuel cells, large quantity of the oxidant gas (cathode gas including O_2 and CO_2) is circulated through the cathode channel for cooling the MCFC. The inlet temperature of the circulated oxidant gas should be set around 600 °C, and the outlet temperature should be around 650 °C for adequate temperature operation. Therefore, the cathode gas recycling is adopted. The oxidant gas supplied to the cathode is a mixture of the combustion gas from the reformer, a part of cathode exhaust gas, and fresh air from outside. The generated heat in the stack is removed by the oxidant whose inlet and outlet temperatures are adjusted by controlling the flow rate of recycling gas and the fresh air from outside.

Finally, high-temperature pressurized exhaust gas from the cathode is led to the turbine expander and this recovers power for air compressor. In addition, the surplus power can generate electricity using a power generator connected to the expander, and this also contributes to enhance the entire system efficiency. The necessity H_2O (steam) for reforming reaction is supplied from the recovered water from the anode exhaust gas by condensing before supplying to the reformer.

Natural Gas-Fueled Internal Reforming System

As mentioned above, the internal reforming can be applied to the MCFC because of high-temperature operation (Krumpelt et al. 1982). The internal reforming can produce reaction specie H_2 from CH_4 within a stack. Therefore, the system can eliminate an external reformer. Conventional external reforming reaction has a limitation of the CH_4 conversion ratio by the equilibrium composition with given fuel composition, temperature, and pressure. In contrast, the internal reforming does not reach the equilibrium as long as electricity is generated; that is, H_2 is consumed at the anode. The reforming reaction proceeds further and eventually CH_4 conversion is approaching approximately to 100 %. This means that almost no residual CH_4 exists at the anode. As a result, the concentration of H_2 and the system efficiency increase. In addition, the heat generated from the stack can be used for reforming reaction, and the flow rate of the oxidant can be reduced so that the parasitic power for cathode recycling blower can be reduced. The operation temperature of the MCFC is 600–650 °C, which is slightly lower than the typical reforming temperature around 700–800 °C. Therefore, reforming catalyst must be placed inside the stack. On the other hand, there could be a problem regarding the catalyst performance decay caused by the electrolyte vapor, and therefore, pre-reforming plates are usually installed upstream and sandwiched between every several cells to avoid the problem. The internal reforming system is usually operated at ambient pressure condition for enhancing CH_4 conversion rate in the stack, and air blower can be utilized instead of using the expander turbine.

Integrated Coal Gasification MCFC Combined Cycle (IGMCFC)

Figure 10 shows the configuration of coal-fired power plant (Bonds et al. 1981). The high-temperature fuel cells, as described above, can use a fuel containing CO. The gasified coal gas containing mainly CO can be supplied directly to the MCFC after being purified. The coal gas contains trace impurities which adversely affect the performance, and therefore gas purification equipment is required. The stack has no upper limit of fuel utilization because there is no need to use anode exhaust as a heat source for reforming like natural gas-fueled system. Thus, the fuel utilization can be maximized to improve the efficiency as far as uniform fuel distribution to each cell is attained. Fuel exhaust from the stack contains CO_2, and it is recycled to supply to the cathode same as the natural gas-fueled system. Additional combustor is necessary instead of reformer burner to burn any flammable species contained in the anode exhaust with CO_2. The cathode exhaust gas is then fed to the heat recovery steam generator (HRSG) after recovering mechanical power and generating additional electricity at the expander turbine generator. The generated steam is supplied to the steam turbine with other generated steam at the stack or gasifier for producing additional electricity.

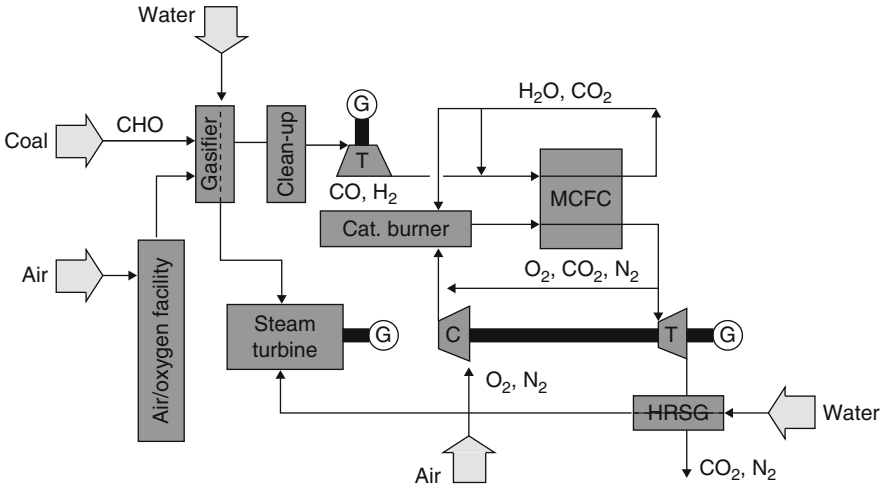

Fig. 10 Configuration of integrated gasification MCFC combined cycle

Development Status of MCFC in the World

Dawn of the Development

It is said that the development of MCFC started from the experiment by Baur of Germany using melted carbonate as electrolyte in 1921 at about 1,000 °C. The concept of the matrix where the electrolyte was impregnated was introduced in 1946 by Davtyan of the Soviet Union, and the porous nickel electrode was adopted in 1958 by the Netherlands Broers and others. The research was actively advanced for the combination of the electrolyte and the electrodes in the Netherlands and the USA. Meanwhile, the MgO matrix and the Fe, Ni, Co, Ag, and Zn electrodes have been attempted, and the current prototype was completed in around 1970 (Mamantov and Braunstein 1981).

Above fundamental research, results have been expanded in the USA since the late 1970s. The US ERDA (US Energy Research and Development Administration) started the national program in 1976 and the US DOE (Department of Energy) has taken over the program in 1978. Other countries such as the Netherlands, Japan, Italy, etc. have started their developments since around 1980 as if responding to the activities in the USA.

USA

The US DOE has promoted the development of MCFC in the USA. In the early 1970s, the final goal was set as a centralized power plants using coal. However, development focus has moved to the MW class small- or middle-sized distributed generators as a cogeneration plant since the 1990s.

The IGT (Institute of Gas Technology, presently GTI, Gas Technology Institute), UTC (United Technologies Co.), GE (General Electric Co.), etc. have developed and established basic technologies under the DOE's program. Afterward the venture companies such as the ERC (Energy Research Co., presently FuelCell Energy) and the MCP (MC Power Co.) have taken over the developments, and the governmental program for market introduction was continued focusing on the product development and performance improvement until 2003. Thereafter, getting a financial support from the government or the states, the systems as distributed generators are being introduced into the states which have great concern with the environmental issues in particular.

The main player of the development and the introduction is FCE Co. (FuelCell Energy) now (http://www.fuelcellenergy.com). FCE has a longtime development history in MCFC of the ambient pressure internal reforming type that is called DFC in the company. A 2 MW internal reforming system was demonstrated in 1997. FCE currently produces a lot of 300 kW commercial cogeneration systems (sub-MW system) with a Hot Module structure (horizontal stack) jointly developed with Germany MTU Onsite Energy Co. FCE now produces three different capacity models including two kinds of the MW system.

Sub-MW system (DFC300, 47 % net efficiency) has been installed about 70 units in total so far, mainly in the USA, Japan, and South Korea. MW class systems adopting FCE's own configuration are 1.4 and 2.8 MW system (DFC1500, DFC3000, respectively, both 47 % net efficiency) (Leo et al. 2007). These MW class plants are initially built by the combination of the sub-MW units. But now for lowering the cost, the module consisting of four vertical stacks in a container (one module in DFC1500, two modules in DFC3000) becomes a mainstream (Farooque et al. 2009). According to the company's report, the capacity of the base stack was initially about 250 kW (AC) around the year 2000, and it is increased to 300 kW in the year 2006. Now it is expected to be 350 kW shortly. The life of the stack was improved from 3 to 5 years, recently (Farooque et al. 2007). The plant's specifications of FCE are shown in Table 3 (http://www.fuelcellenergy.com).

Table 3 Specification of the MCFC plants (FCE)

Type		DFC300	DFC1500	DFC3000
Net output (kW)		300	1,400	2,800
Net efficiency (%, LHV)		47 ± 2		
Exhaust heat utilization	Temp. (°C)	121 (49)		
	Heat output (MJ/h)	506 (852)	2,338 (3,935)	4,677 (7,870)
Size (m) (L × W × H [chimney])		8.5 × 6.1 × 4.6	17.0 × 12.2 × 9.2	23.8 × 12.5 × 6.4
Total weight (t)		35	104	163
Noise (dB(A), @3 m)		72 (65)		
Exhaust (mg/MWh)		NOx: 4,500, SOx: 45, PM10: 0.009		

(): option

Europe

The MCFC has been developed as the distributed cogeneration in Europe. In Germany, MTU Onsite Energy is developing the Hot Module design from the viewpoint of low-cost BPOs (http://www.mtu-online.com/?L=1; Rolf 2006). The 250 kW stack made by FCE in the USA is introduced to the MTU's ambient pressure internal reforming 250 kW system. The Hot Module structure has a horizontal stack inside a cylindrical cathode gas-filled container. Cathode gas is circulated within the container for controlling stack temperature. The system has features such as less piping and compact. MTU Onsite Energy supplied the company's own 250 kW system (HM300) within Europe and is developing the larger HM400 system in recent years. Both systems can utilize biogas, digestive gas, methanol, and natural gas. In addition to these, the company's 320 kW stack was supplied to Wärtsilä Marine Inc. for the ship use demonstration project in Finland.

Italy developed 100 kW class stack (pressurized: 0.35 MPa, external reforming, external manifold, cross-flow type, and 0.75 $m^2 \times 150$ cells) and compact unit (CU) plants with Spain in the MOLCARE program in 1999. The compact unit contains the high-temperature modules including the stack and the reformer in the same pressure vessel. Based on the results, Ansaldo Fuel Cells Co. (AFCo) has been leading the development of the 500 kW modules with the twin-stack concept (http://www.ansaldofuelcells.com/en/index.htm). In this twin-stack concept, two stacks are integrated with catalytic combustor and reformer at the bottom of each stack (Marcenaro 2008). More than ten demonstrations were planned not only in Italy but also in Spain and Turkey, and about half were demonstrated. AFCo has developed a 200 kW stack until now.

Asia

In Japan, the development for energy conservation has been promoted as a national project in the earlier phase in the world in the late 1970s. In this project, the target was set especially for electric power company use, aiming immediate application as natural gas-fueled plant as well as considering the future coal-fueled plant. The 1,000 kW pressurized external reforming system was operated in 1999. Fuel was LNG and operation pressure was 0.5 MPa. The efficiency target of 45 % (HHV, gross) was attained (Nakayama 2000). Another 200 kW pressurized internal reforming system was demonstrated in parallel. These results were reflected in two 300 kW systems using fermentation digestion gas of the garbage and gasified wood biomass gas as part of the power supplies which constituted a microgrid at the world exposition at Aichi in EXPO 2005. The generation efficiency achieved 51 % (gross) at the maximum. Meanwhile, the longtime continuous operation over 66,000 h by a single cell was demonstrated. Its decay rate was less than 10 % per 40,000 h and met the present target. Also CO_2 concentration from the flue gas from the conventional coal-fired thermal plant was demonstrated by supplying the flue gas to the cathode side of 50 kW MCFC stack (Toyota and Dairaku 2009).

KEPRI (Korea Electric Power Research Institute) plays a key role to develop the pressurized external reforming system in Korea (Kim et al. 2008). Based on the fundamental researches in KIST (Korea Institute of Science and Technology), POSCO and RIST (Research Institute of Industrial Science and Technology) participate in the program. The 125 kW system developed with own technology was demonstrated in 2009. The internal reforming system is under development in parallel and its demonstration is planned in 2010.

Apart from these, POSCO Power has been promoting the introduction of MCFC plants (http://poscofuelcell.com/english/). Introducing the technology from FCE in the USA, the company built a new factory for BOPs with 50 MW annual productions in Korea in 2008. Mounted stacks have been supplied from FCE so far; however, POSCO Power has a plan to build another factory for stack assembling with cell components being supplied from FCE.

Development Issues

Cell Stack Issues

Not only applicable to the MCFC, it is necessary for a newly developed technology to achieve higher performance, longer life, and lower cost for accelerating the commercialization of MCFC. In MCFC, it is necessary to exceed above items of the existing power generation technology.

The basic cell and stack technology has been almost established to achieve the immediate objective except the cost. Among the remaining issues needed to be solved, a life extension issue is one of the most important ones. The nickel short-circuiting is the most important problem for the pressurized system aiming higher efficiency. Handling the impurities included in coal gasification gas should also be considered in the future. In addition, the stack design technology enabling lightening the weight of the stack, producing larger cells, and achieving uniform gas distribution for tall stack should be improved continuously.

The nickel short-circuiting is caused by the dissolution reaction of cathode NiO into the electrolyte, which needs to be avoided. The comprehensive measures are required from the viewpoint of the cathode material, the electrolyte composition, the operation condition, etc.

The effects of impurities in the fuel gas are not the urgent issue right now, but it must be resolved when gasified fuels, such as biomass, waste, and eventually coal, will be used on the way to promoting the expansion of application fields. These gasified fuels contain the sulfur compound, the halogenated compound, the nitrogenous substance, etc. These affect largely on the cell performance even though the concentration is ppm order. The effects are being clarified through every kind of actual cell test, and gas cleanup system that reduces impurity content to the acceptable level is under development. The maximum number of stacked cell is currently about 300, and it is expected to increase the number for efficient integration of the stack from the viewpoint of the entire plant. Thus, it is important to develop stacking

technology and to select an appropriate number of stacked cells, because the number of the cells in the stack is restricted by the gas distribution for each cell through the manifold.

Reducing the weight of the stack will become more important issue from the viewpoint of the economy or transportation in the future. Additionally, the improvement of the output power density is also important.

System Issues

It is thought that the development of the constitution apparatus was almost completed for the natural gas-fueled system. The plant operation method such as start/stop, load change, and emergency shutdown is considered to be almost established, because many natural gas units are shipped to the market from the USA and German manufacturers and much experience is being accumulated. The establishment of the operating method for the hybrid system and the pressurizing system combined with the gas turbine for higher efficiency will become important in the future. For the future system using biomass, waste, or coal, it is required to develop the technologies on gasification, gas cleanup, effective heat exchange, and system configuration including topping/bottoming cycle, operation of pressurized system including carbon deposition avoidance, etc.

Economy

About the economy, stack cost reduction is the most important at present. It could be attained by, for example, reducing the number of parts, reducing the amount of the material use, lightening weight, and increasing power density. A great decrease in the stack cost by mass production is necessary. The cost reduction of the BOP equipments is also important. It is said that the BOP cost occupies large part especially in sub-MW small-capacity system. FCE is developing multi-MW systems for this reason. In addition, not only fixed cost reduction but also variable cost reduction is important. Improving the system efficiency and accumulating operation experience, it is expected that the operation and maintenance cost will be greatly reduced in the future.

Fuel cell has shorter lifetime compared to the general power generation plants, so that the stack is expected to be replaced in the period corresponding to its lifetime. Replacing cost affects largely in the cost of electricity. Recently the tentative target of stack life is set around 30,000–50,000 h and it becomes achievable by technology developments except pressurized operation. However, there could be another increment of the cost to realize the target life. It is important to introduce the stepped performance targets based on the market introduction progress. In the initial market penetration phase, the plant price might be rather expensive, but initial market would be established. The stack production can be expected to increase dramatically and large cost reduction can be attained. Once an initial market is formed, the

introduction of a small system increases, reliability is confirmed, and the awareness level rises. It enters the cycle of the virtuous circle. Then it could be expected to lead to the application of a larger power plant.

Future Directions

Expansion of Market Introduction

The market introduction of the MCFC is pushed forward as a cogeneration system of the small or medium size mainly applying the internal reforming system developed in the USA or Germany now. However, it concentrates in the country and the state where the promotion plan of the subsidies and grant is well prepared. Therefore, the MCFC market can be understood to be never independent economically at present. As a future direction, fundamental developments such as high efficiency, long life, lower cost, etc. should be continued. Accumulating experience of more market introduction, it is required to reach the level of real competition to existing conventional technologies.

As mentioned above, the development of the following directions should be pushed forward:

- Addition of load following various operability functions to the abovementioned small power supply for load management
- Diversification of fuel that allows using waste and biomass, etc., for the community-based small power supply
- Enhancement of the efficiency higher than the existing large-scale thermal power plants, intending centralized natural gas-fueled MCFC plant
- Demonstration of high-efficiency integrated coal gasification MCFC combined cycle (IGMCFC)

Development of Power Generating Systems with Novel Function

In addition to the expansion of the abovementioned market introduction, the power generating system that has a new function to make the best use of a MCFC's inherent features has been proposed. Some of those systems have been demonstrated. It is possible to expand the application field much more by achieving those.

1. DFC/T (an internal reforming hybrid system)
   FCE proposed a highly efficient natural gas-fueled hybrid system that operates the internal reforming MCFC at ambient pressure and locates the gas turbine upstream. Figure 11 shows its configuration. The power generation efficiency of about 71 % is calculated in 20 MW class (Ghezel-Ayagh et al. 1999). In parallel to this, the company has applied DFC300 stack and micro-gas turbine to the system. Maximum output of 320 kW and 58 % power generation net efficiency were

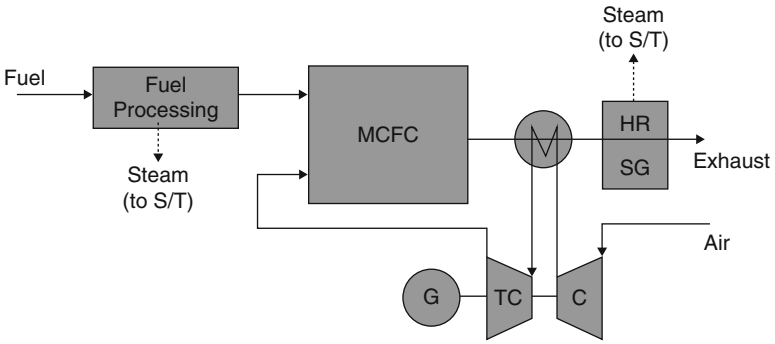

Fig. 11 Internal reforming hybrid system

achieved and approximately 8,000 h of operation was demonstrated (Ghezel-Ayagh et al. 2007). Based on current DFC3000, 3.4 MW scale has been engaged in system design (Ghezel-Ayagh et al. 2008); the first unit is planned to introduce a project underway in Connecticut.

2. DFC-ERG (a pipeline energy collection system)
   The DFC-ERG (Energy Recovery Generation) system is a highly effective hybrid system that applies the gas expander to the decompression process of the natural gas supplied by the gas pipeline in place of a conventional valve. It combines MCFC in addition and uses the rejection heat of MCFC for the preheating for preventing the gas temperature being decreased at the decompression process (http://www.fuelcellenergy.com/dfc-erg.php). FCE demonstrated the concept in the first 2.2 MW pilot plant set up in Toronto in 2009 and achieved average power generation efficiency 62.5 % and availability factor (uptime rate) 93 % during 1-year operation. In the latter half 6 months, the peak power generation efficiency was 70 % and availability was 96 % (http://www.fuelcellenergy.com).
3. DFC-H_2 (a trigeneration system)
   DFC-H_2 system is also being developed by FCE (Patell et al. 2009). Hydrogen aiming to be used for fuel cell vehicle can be generated as well as electricity and heat at the same time. This technology is to be built into hydrogen stations in California. The plan is underway to generate 300 kW of power and about 150 kg/day or more hydrogen, based on biogas generated in sewage treatment process.
4. CO_2 recovery system
   CRIEPI (Central Research Institute of Electric Power Industry) proposes the CO_2 recovery-type hybrid system using oxygen in place of air and showed the extremely high efficiency of 77 % in 300 MW class (Koda et al. 2006). Figure 12 shows its flow diagram. Only natural gas and oxygen are supplied with stoichiometric ratio to the system, and the final products are only H_2O (steam) and CO_2. CO_2 is easily recovered after condensing steam. In addition, O_2 and CO_2 with composition of 1:2 (noble gas) maximize the cathode potential and achieve the

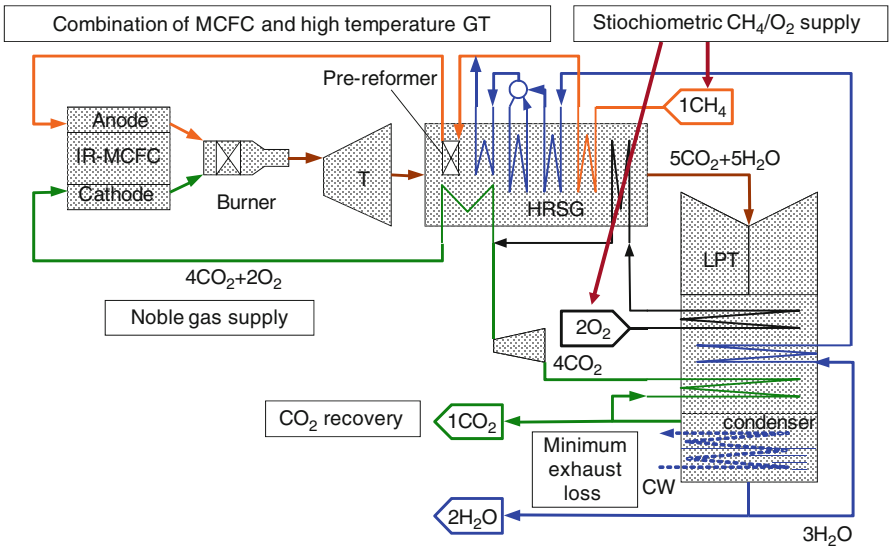

Fig. 12 Ultrahigh efficiency system with CO_2 recovery

high cell voltage. Moreover, no mixture of N_2 by not using air enables realizing minimum effluent gas flow and minimum exhaust heat quantity. It can also contribute to high efficiency.

Abstract

Nuclear fusion is the power of the sun and all shining stars in the universe. Controlled nuclear fusion toward ultimate energy sources for human beings has been developed intensively worldwide for this half a century. A fusion power plant is free from concern of exhaustion of fuels and production of CO_2. Therefore it has a very attractive potential to be an eternal fundamental energy source and will contribute to resolving problems of climate change. On the other hand, unresolved issues in physics and engineering still remain. It will take another several decades to realize a fusion power plant by integration of advanced science

DOI 10.1007/978-3-319-14409-2_31

and engineering such as control of high-temperature plasma exceeding 100 million °C and breeding technology of tritium by generated neutrons. The research and development has just entered the phase of engineering demonstration to extract 500 MW of thermal energy from fusion reaction in the 2020s. The demonstration of electric power generation is targeted in the 2040s.

Introduction

Nuclear fusion is the power of the sun and all shining stars in the universe. An artificial sun on the Earth, that is, controlled nuclear fusion, has a very attractive potential to offer an environmentally friendly and intrinsically safe energy source. Tremendous efforts have been paid globally in these 50 years toward the realization of controlled nuclear fusion (Meade 2010; Braams and Stott 2002). Hereafter, *nuclear fusion* is simply referred as fusion. At this moment, there still remain unresolved issues for a fusion reactor even with state-of-the-art science and technology. It would be said that it will still take another 30 years to realize the first fusion reactor. Nonetheless, fusion is no longer a dream or a mirage and the targeted goal and a roadmap to reach the goal can be defined clearly. Symbolically, the construction of the International Thermonuclear Experimental Reactor (ITER) (http://www.iter.org/; Green 2003), which plans to produce more than 500 MW of heat by fusion, has been just started by international collaboration.

The fuel for nuclear fusion is isotopes of hydrogen: deuterium and tritium. Deuterium can be extracted from water and tritium can be transmuted from lithium, which is abundant, in a fusion reactor. Therefore fusion is an inexhaustible energy source. When these fuels are heated up beyond 100 million °C, fusion reaction occurs. At this extremely high-temperature state, fuels become plasma which is ionized gas consisting of ions and electrons (Eliezer and Eliezer 2001). High temperature means that ions and electrons have large kinetic energy. It is necessary to put nuclei (ions) sufficiently close to each other to drive fusion reaction. Large kinetic energy is required to overcome the repulsive force between nuclei with positive electric charge. The product of fusion reaction is helium. To control fusion reaction, it is required to integrate advanced science and technology such as deep understanding of complex plasma physics, development of materials against high heat and neutron loads, and critical engineering related to superconductivity, vacuum, and electricity.

Nuclear fusion was discovered in 1932, which is earlier than nuclear fission in 1939. Although the physics study was initiated almost at the same time, these two nuclear reactions have traced different history. Nuclear fission was used for an atomic bomb in 1942 when it was only 3 years later since its discovery. The fission reactor started power generation in 1951, and more than 400 fission power plants are operated to provide base load of electricity worldwide now. In contrast, nuclear fusion was used for a hydrogen bomb in 1952, and its peaceful use for power generation awaits for another couple of decades. These two nuclear reactions are quite different and consequently they contrast with each other from the aspect of their

engineering control. Nuclear fission occurs in heavy atoms such as uranium and plutonium. Some isotopes of these heavy atoms are unstable and break apart easily or spontaneously. Although purification of fuels of nuclear fission requires a huge facility and operating cost, it has been industrialized. The control of nuclear fission means suppression of runway of reactions. In contrast, nuclear fusion does not occur easily. Since the reaction occurs between light nuclei which have positive electric charge, extremely high energy is required to bring nuclei closely enough to fuse. This reaction only occurs naturally only in the sun and stars. The required temperature is in the millions of °C. Therefore the control of nuclear fusion means how to heat the fuels to this extremely high temperature and keep them. The scientific assessment of a fusion reactor has been almost completed by more than 50-year research, and the development stage is shifting to the assessment of engineering and technological feasibility. A fusion reactor is not a dream but a target within hailing distance.

While another couple of decades of research and development is necessary to realize fusion energy, its realization will be able to resolve global issues related to environment and energy and change social structure. Patient long-term research and development should be conducted with global social endorsement of this highly innovative technology. Then, steady progress will enable commercial reactors to deliver one million kW of electric power to the grid in 2050. The fusion power plant has a promising potential to provide the base load of electricity in the later half of this century.

Two methodologies which are magnetic confinement fusion (Lie et al. 2010) and inertia confinement fusion (Mima 2010) are being developed in parallel worldwide. This chapter is devoted to the present status and prospect of magnetic confinement fusion which is now stepping up to engineering demonstration from successful scientific demonstration.

Why Fusion for Global Warming Suppression?

Fusion is on the stage of research and development, and it will take another half century to commercialize a fusion reactor. Nonetheless, fusion offers attractive advantages to other energy sources in terms of waste, fuel, and safety.

1. Waste
   Fusion does not emit CO_2. The effect of power plants on global warming is assessed by CO_2 emission intensity with consideration of construction and operation of a plant, consumed fuel, and release of methane in digging, etc. Figure 1 shows the CO_2 emission intensity of thermal power plants, a fission reactor and a fusion reactor (Report of Japan Atomic Energy Commission in 2005). Coal-fired, oil-fired, and LNG-fired thermal stations emit much larger amount of CO_2 than other power stations. Although the CO_2 emission intensities are reduced to one third by employing CO_2 collection, they are still major players to emit CO_2. Fusion power plant does not emit CO_2 in operation, and its CO_2 emission intensity is a little bit larger than hydraulic and nuclear fission power plants.

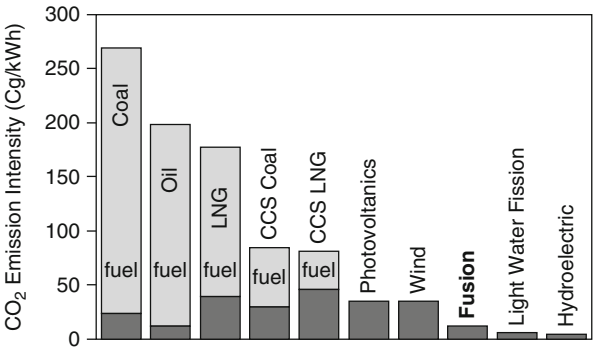

Fig. 1 Carbon dioxide emission intensity of fired (coal, oil, LNG), renewable (solar, wind), fusion, fission, and hydroelectric power plants. CCS stands for carbon capture and storage. Each bar is separated to the contributions from fuel and construction of a power plant

Fusion power is produced by nuclear reaction and fusion is not free from nuclear waste. However, a product of fusion reaction is helium, which is not radioactive at all, and nuclear waste is limited to structure materials with neutron-induced activation. Absence of very long-lived radioactive waste promises annihilation of radiotoxicity in the order of 100 years (see Fig. 2) (Jacquinot 2010). This property would ease the management of radioactive wastes compared with fission reactors. Hazard potential due to radioactivity of a fusion reactor is one thousandth of a fission reactor.

2. Fuel
   Fuels of fusion are abundant atoms: deuterium and lithium. They are substantially inexhaustible and widely distributed on Earth. Thirty-three grams of deuterium exists in 1 m^3 of water, which means 4.5×10^{13} t in oceans and is still a tiny amount of water itself. The amount of lithium as a mineral resource is estimated 940 million t and that in oceans is 230 billion t. Compared with these abundant fuels, a fusion power station producing one million kW of electricity only consumes 0.1 t of deuterium and 10 t of lithium a year. Readers can evaluate sustainability of fusion energy in terms of fuels easily.
3. Safety
   Fusion reaction occurs in very high-temperature gas; plasma and fuels are supplied to a reactor like a gas burner. Fuels do not stay for longer than a minute in a reactor core. The fusion reaction is intrinsically quenched by any accident to disturb the burning condition. Unlike the fission reaction, which is essentially a chain reaction in massive fuels, the fusion reaction does not run away in principle.

   Since fusion itself is completely unrelated to uranium and plutonium, it does not cause proliferation of nuclear weapons. Extreme temperature as high as 100 million °C is required to make fusion happen. Even if fuels of fusion (deuterium and tritium) are available, fusion does not take place. Therefore it is emphasized that fusion does not strictly adhere the nonproliferation treaty unlike fission. Also, it should be noted that there is a fusion-fission hybrid which utilizes neutrons generated by fusion reaction to drive fission reaction. This concept is not free from a proliferation issue.

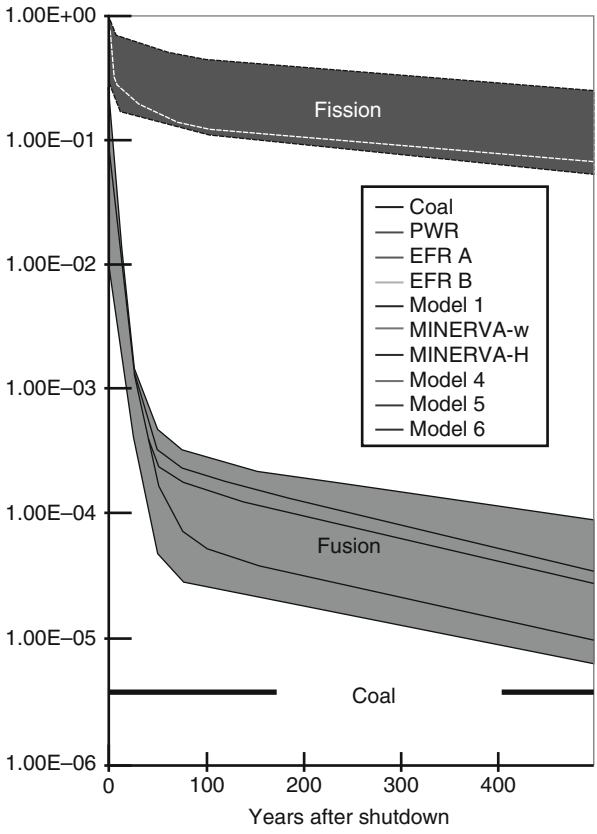

Fig. 2 Relative radiotoxicity of fission and fusion reactors versus time after shutdown. The bands correspond to differences in the fuel cycle (reprocessing) for fission and to the choice of structural material for fusion. The *bottom black line* is the radiotoxicity of coal (Reproduction of Fig. 1 in Jacquinot (2010))

What Is Fusion?

Fusion Reaction

Solar energy, which not only human kind but also almost all lives on the Earth enjoy, is delivered as light from the sun. The energy of light originates from fusion reaction taking place in the core of the sun. Four nuclei of hydrogen are fused into a nucleus of helium there. This fusion reaction has been taking place continuously, and the sun has been burning stably in these five billion years and will continue to burn in another five billion years. Physical process of this fusion reaction in the sun was identified in late 1930 after the establishment of quantum mechanics (Bethe and Peierls 1935). Studies to realize this reaction in a laboratory and utilize this reaction as energy source were launched soon after this discovery.

The special theory of relativity by Einstein gives the famous formula $E = mc^2$, where E, m, and c are energy, mass, and velocity of light, respectively. This formula means energy and mass are equivalent. It is known that the total rest mass of nuclei

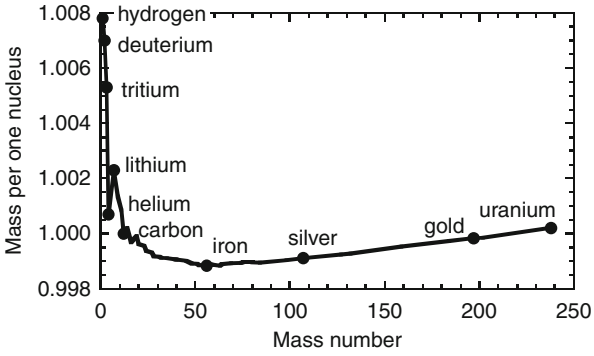

Fig. 3 Change of mass per one nucleus composing an atom

changes when the combination of nuclei is reorganized by nuclear reaction. If the rest mass after reaction is smaller than that before the reaction, loss of mass is transformed into energy. This relation is not only limited to nuclear reactions but also applicable to chemical reactions. However, while the loss of mass is usually amounted to one thousandth in the case of nuclear reaction, that in the case of chemical reaction is only in the order of 100 millionth. This is the reason why a nuclear reaction produces 100,000 to 1 million times larger power than a chemical reaction.

Figure 3 shows the mass per one nucleon (proton or neutron) which composes an atomic nucleus from the lightest element, hydrogen, to the heaviest element, uranium, in nature. Even at the nuclear reaction, the number of nucleon is conserved. Therefore, this figure indicates that mass is lost when combination (fusion) of lighter elements like hydrogen generates a heavier element like helium. Mass is also lost at the breakup of heavier elements like uranium to lighter elements. This is fission reaction has been already used in nuclear power plants. The mass of a composing nucleon is lightest as iron, thus the most stable element. In stars like the sun, fusion reaction proceeds stage by stage and ultimately generates iron. Heavier elements than iron are generated by another process, such as neutron capture at a supernova explosion. The fact that heavier elements than iron exist on the Earth means that the solar system is on and after the second generation which experienced a supernova explosion since the initiation of the universe.

There are a variety of fusion reactions and each has its own specific probability of reaction. Since this probability of nuclear reaction between particles has the dimension of area (m^2), it is referred to as cross section and expressed by σ. Probability of fusion reaction between two particles has been well investigated and quantified by various kinds of experiments using accelerators. The probability of the reaction of four hydrogen nuclei to a helium nucleus, which takes place in the core of the sun, is extremely low. The sun is so huge (100 times larger diameter than that of the Earth) that it can keep burning by this fusion reaction with very low probability. Therefore another fusion reaction of hydrogen isotopes (see Fig. 4) which has the largest probability is required to realize a fusion reaction in a plant size on the Earth. This reaction is the combination of D (deuterium) and T (tritium).

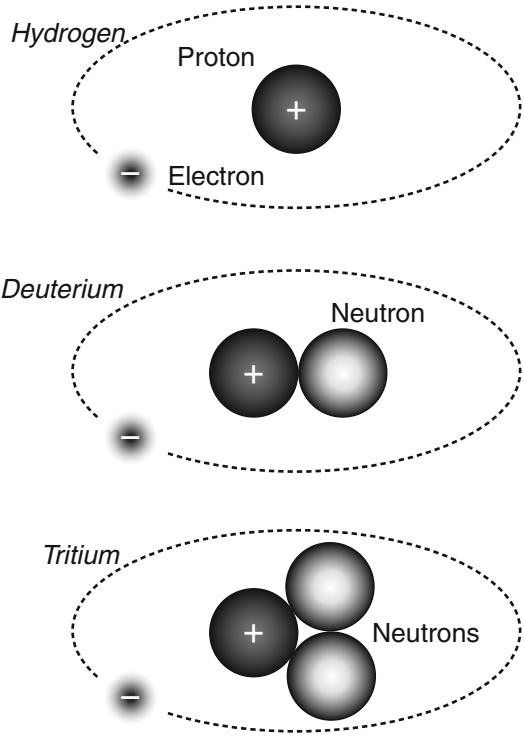

Fig. 4 Isotopes of hydrogen

In the case of the fusion reaction between D (deuterium) and T (tritium), the probability has the maximum at the relative speed of these two particles of 3×10^6 m/s. In order to use fusion reaction for energy production beyond a basic experiment of elementary particle physics by an accelerator, massive number of fusion reaction should be controlled. A cluster of particles with this speed forms very high-temperature gas: plasma. Then, the ensemble average of probability over distribution functions of all particles is more meaningful to evaluate released power. While the cross section is a function of the energy of particles, reaction rate (the number of reactions per unit volume and unit time) expressed by $< \sigma v >$ with the unit of m^3/s at the specific temperature is calculated by the integration of the cross section with regard to the velocity space. The reaction rate of representative fusion reactions is shown in Fig. 5 (Laby Online 2005). In the case of D (deuterium) and T (tritium), the cross section has the peak around several tens keV (1,000 million °C – note that 1 eV (electron volt) corresponds to 11,600 K).

Its rate equation is described as

$$\mathrm{D} + \mathrm{T} \rightarrow \mathrm{He} + \mathrm{n}$$

Consequently, helium and neutron are generated and simultaneously the energy of 17.6 MeV (2.8×10^{-12} J) is released. From the law of momentum conservation, the kinetic energy delivered to helium and neutron is 3.5 and 14.1 MeV, respectively.

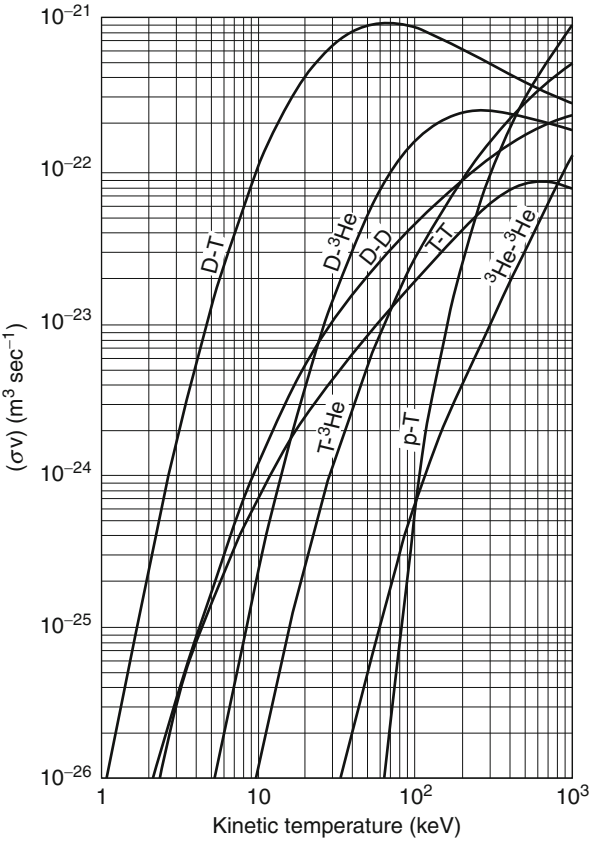

Fig. 5 Fusion reaction rate between light atoms (Reproduction from Laby Online (2005))

Fusion power density P_{fusion} is expressed by

$$P_{\text{fusion}} = n_D n_T \sigma v >_{DT} Q_{DT}, \tag{1}$$

where n_D, n_T, $<\sigma v>_{DT}$, and Q_{DT} are particle density of deuterium, particle density of tritium, rate of DT fusion reaction, and released energy by one DT fusion reaction (17.6 MeV = 3.5 MeV + 14.1 MeV), respectively. For example, a typical presumed condition of fusion reactor with $n_D = n_T = 1 \times 10^{20}/\text{m}^{-3}$ and the temperature of 20 keV (230 million °C) gives fusion power of 11 MW/m^3.

While deuterium exists as 1/7,000 (0.015 %) in hydrogen, abundance of tritium is quite low in nature. Therefore, a fusion reactor produces tritium in itself through the reaction of lithium with neutron which is generated by the following two reactions:

$$\text{n} + {}^6\text{Li} \rightarrow {}^4\text{He} + \text{T} + 4.8\text{MeV}$$

$$\text{n} + {}^7\text{Li} \rightarrow {}^4\text{He} + \text{T} + \text{n} - 2.5\text{MeV}$$

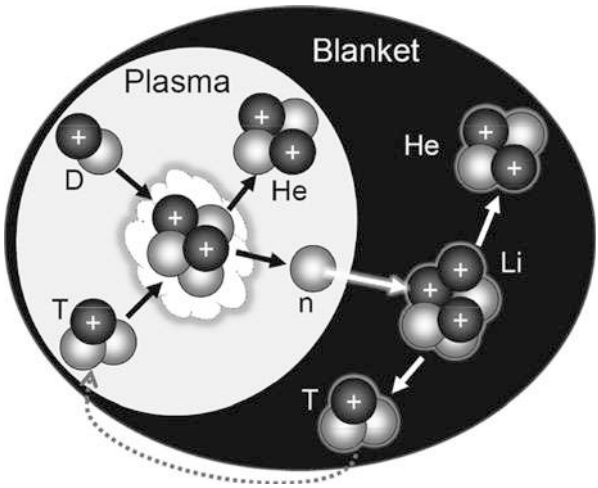

Fig. 6 Major nuclear reactions in a fusion reactor

Natural lithium is composed of 7.4 % ^{6}Li and of 92.6 % ^{7}Li. While the reaction between a neutron and ^{6}Li releases 4.8 MeV, the ^{7}Li reaction only occurs with neutron fast enough to absorb 2.5 MeV of energy. Therefore, enriched ^{6}Li to several tens% is placed around the fusion reactor core like a blanket to breed tritium (see Fig. 6). Various forms of breeding material have been proposed, such as ceramics like Li_2O and Li_2TiO_3, liquid metals like Li and LiPb, etc. Techniques for isotope separation of lithium have been established as the column exchange separation method which uses the difference in affinity for mercury and the vacuum distillation method which uses the difference in the mean free path of the evaporated isotopes.

Fuels from the amount of lithium in a single cellular phone (around 0.3 g) and deuterium extracted from only 3 l of ordinary water produce energy of 78,000 MJ which is equivalent to electricity of 22,000 kWh. A typical family in developed countries can be furnished with this electricity for a year.

A fusion power plant with electric power production of one million kW consumes 0.1 t of deuterium and 10 t of lithium a year as fuel. Needless to say, deuterium is truly abundant in seawater. Technology extracting heavy water (D_2O) is available as an industrial process. Since the fusion energy is one million times larger than the chemical binding energy, the cost for electrolysis of heavy water to get deuterium is easily recovered. Lithium is an abundant mineral resource and also available from seawater. Collection of lithium from seawater has not been industrialized yet; however, promising technologies are being developed. The increasing demand of lithium for batteries accelerates these technologies. Therefore, a fusion reactor is free from the issue of fuel.

Difference Between Fusion and Fission Reactors

While both fusion and fission accompany huge energy released by loss of mass at the change of nuclei, there exist contrasting features between them.

The first difference can be seen in the way how the reaction is controlled. The fission reaction that has been already employed in a power plant is driven by the absorption of neutrons into uranium-235. One fission reaction releases two or three neutrons, and consequently a chain reaction takes place. This means only one neutron can trigger a continuous and even explosive reaction within a certain amount of uranium-235, in principle. In a fission power plant, uranium fuel for several-yearlong operations is mounted on a reactor and burned gradually by applying the brake with control rods absorbing neutrons. In a fusion reactor, in contrast, hydrogen isotope fuel is fed continuously into a reactor like a gas burner. Therefore when the refueling is stopped, fusion reaction stops immediately. Burning takes place in plasma state which will be described in detail later. A very high temperature more than 100 million °C is required to give rise to a fusion reaction. This necessary condition is broken so easily since fusion is free from chain reaction in principle. For example, too much amount of fuel drops the temperature and quickly stops the fusion reaction since fusion power cannot keep the sufficiently high temperature of the inlet fuel.

The second difference is distinguished by products of reaction. In case of fission, elements with the mass number around 90–100, such as strontium and yttrium, and elements with the mass number around 130–140, such as iodine and barium, are produced as ash. Majority of these have large radioactivity and need a careful treatment as high-level radioactive waste. Also unburnable uranium-238 is converted to plutonium-239. While this plutonium can be used as fission fuel in a reactor, it is a long-lived radioactive element and has very high toxicity. Plutonium can be used to make nuclear weapons and must be controlled strictly under the Nuclear Non-Proliferation Treaty.

On the other hand, the product from fusion reaction is a stable element: helium. Simultaneously produced neutrons are used to make tritium by reacting with lithium in a surrounding blanket. Neutrons are also absorbed in peripheral components of a reactor and may activate them. Tritium is also a radioactive element with a half-life of 12 years and changes to helium-3 by the β-decay. Therefore, it should be noted that a fusion reactor is not free from issues related to radioactivity. However it is much mitigated. Its hazard potential can be compared by a potential radioactive risk factor. This factor assesses the risk of the maximum accident of reactors by how much air is required to dilute released radioactive elements to the tolerable level to human body. When iodine-131 and tritium, which are easily absorbed in the human body in fission and fusion reactors, respectively, are compared, the risk of a fusion reactor is less than that of a fission reactor by a factor of 1,500. The risk of a whole activated material of a reactor is about one hundredth at the operation, and the risk of fusion reactor decays quickly after shutdown since a majority of produced radioactive elements have short half-lives. The present material design of a fusion reactor aims at the reuse of materials after 100-year cooling phase.

Both fission and fusion power stations need fuel processing; however, the level of risks related to proliferation and radioactive wastes in the processing is much mitigated for a fusion power station. In the case of a fission power station, used fuels contain high-level radioactive wastes as a fission product, and plutonium is transformed from uranium-238. High-level radioactive wastes are hazardous and should be controlled safely for an extremely long time. Reprocessing of used fuels breeds fuels (plutonium), which is, in turn, concerned for proliferation. It should be also pointed out that this fuel processing is done in a fuel-cycle factory which is usually located apart from a fission power station. Tight security in transportation of used fuels and new fuels between a fission power station and a fuel-cycle factory should be in force. In the case of a fusion reactor, in contrast, tritium is bred in a fusion power station through the reaction between lithium and neutrons as described in the previous chapter. This process is confined in a fusion power station. Therefore, transportation of radioactive tritium outside a fusion power station is not required.

Core of Fusion Reactor: Burning Plasma

A schematic diagram of a fusion reactor is shown in Fig. 7. The energy source of a fusion reactor is the burning plasma in the core. In this chapter, the principle to confine the plasma leading to burning is described.

Characteristics of Plasma

The fusion reaction requires temperature beyond 100 million °C, which is higher than in the core of the sun by more than one order of magnitude. At this high

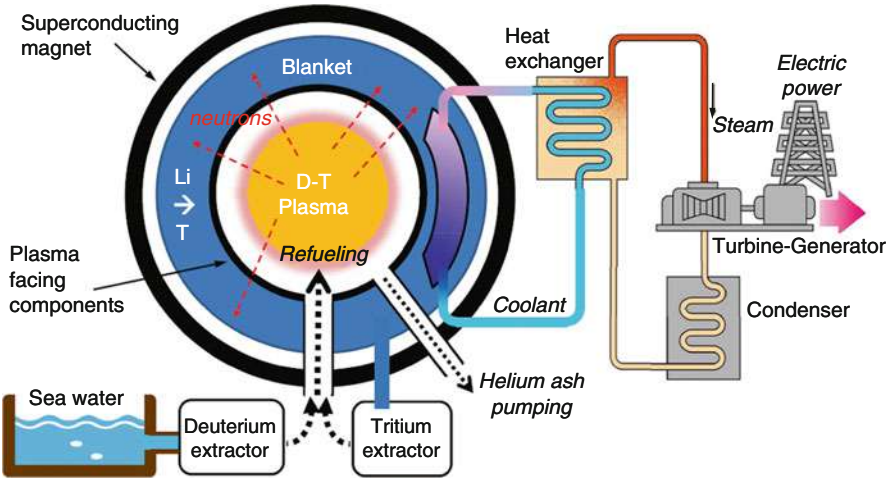

Fig. 7 Conceptual schematic view of a fusion power plant

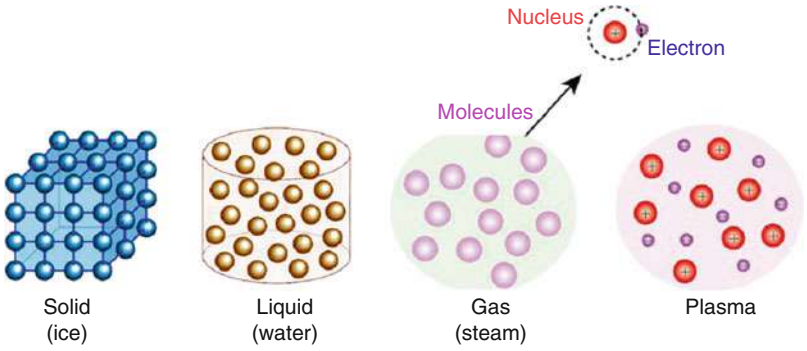

Fig. 8 Four states of matter

temperature, all materials become plasma, which is ionized gas. It is well known that the state of material has three phases: solid, liquid, and gas. And when material is heated to ten thousand °C, molecules composing gas dissociate into atoms and then electric restraint between nucleus with positive electric charge and electrons with negative electric charge is unbounded. This state is the fourth state of matter, plasma (see Fig. 8). All fixed stars shining in the sky including the sun are a mass of plasma. On the Earth, a flash of lightning and aurora are natural plasma, and plasma is used for neon lights and plasma displays.

It is necessary to confine high-temperature plasma to ignite fusion reaction and maintain burning. Here it should be noted that confinement does not mean absolute confinement so as not to release anything. To prevent fuel cooling, thermal insulation is needed like in a fireplace to keep burning. It is also necessary to supply new fuels continuously. Therefore, confinement here is defined as sustainment of the phase with sufficient condition of burning and continuous replacement of fuels. The temperature should be kept beyond 100 million °C. Usual materials such as metal used for a gas cylinder cannot withstand high temperature of plasma. In other words, plasma is cooled down by the cylinder wall.

In addition to temperature, appropriate density as high as 1×10^{14} ions per 1 cc (1×10^{20} ions/m^3) is also required to keep burning. This density is one over 200,000 of air, which means burning plasma is very rare. It should be noted, however, that the pressure of burning plasma reaches 10 atmospheres because of high temperature of 100 million °C. Balancing force against this pressure is required to confine the plasma. In the case of the sun, its own gravity balances the expansion due to the plasma pressure, since gravitation is, unfortunately, not large enough to realize the fusion burning condition by the same scheme on the Earth. There are two alternative potential concepts to realize and control fusion reaction, which are inertial confinement and magnetic confinement.

Very fast compression and heating of a small D/T fuel cell can be achieved by highly intensive laser reaching several hundred terawatt or even petawatt. This has been investigated to realize the required condition for fusion in very short timescale as long as the inertia confines the fuels (Atzeni and Meyer-Ter-Vehn 2004).

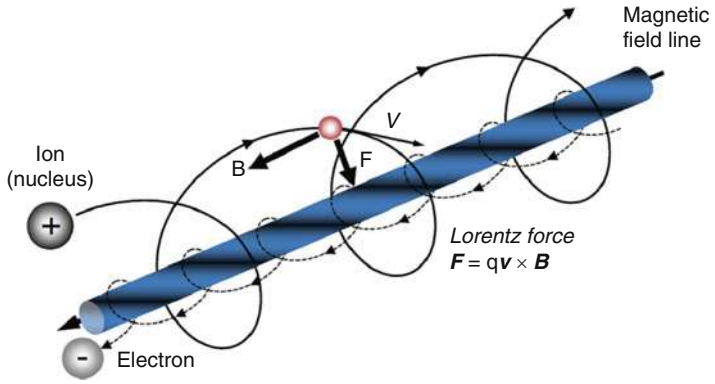

Fig. 9 Motion of an ion and an electron restricted by a magnetic field line

The outer layer of the fuel cell (typically a few millimeters in diameter) is heated by intensive laser itself or converted X-ray and explodes outward. This ablation produces the force to compress the inner part of the fuel cell. This implosion energy leads the D/T fuel to ignition.

The other method to keep the burning plasma is magnetic field confinement. Magnetic field forms invisible bottle to contain plasma apart from material wall in steady state. Since the plasma is composed of charged particles (ions and electrons), the invisible bottle made by magnetic field can confine the plasma. Charged particles rotate around the field line by the Lorentz force and consequently their motion is restricted by a magnetic field line as shown in Fig. 9. It should be noted that the rotating directions of positively charged ions and negatively charged electrons are opposite to each other. This is the principle of magnetic confinement of plasmas in a microscopic (particle) view. In a macroscopic (fluid) view, the expanding pressure of the plasma is pushed back by the pressure of magnetic field which is usually 20 times larger than the pressure of the plasma.

Magnetic Confinement of Plasma

If the magnetic field line intersects the material, the charged particles hit the material along the magnetic field line. Therefore, circulating magnetic field lines without end is required to avoid interaction with the material wall. Figure 10 shows the basic concept, where electric current on the major axis generates the circulating magnetic field lines. An important point here is that the strength of magnetic field is inversely proportional to the distance from the major axis. The charged particles rotate around the magnetic field lines and its rotating radius, which is called the Larmor radius, is inversely proportional to the strength of magnetic field. Therefore, the rotating radius becomes small in approaching the major axis and large in going away from the major axis. The combination of this change and rotating motion results in the vertical motion of particles. Remembering the difference of rotational direction of ions and

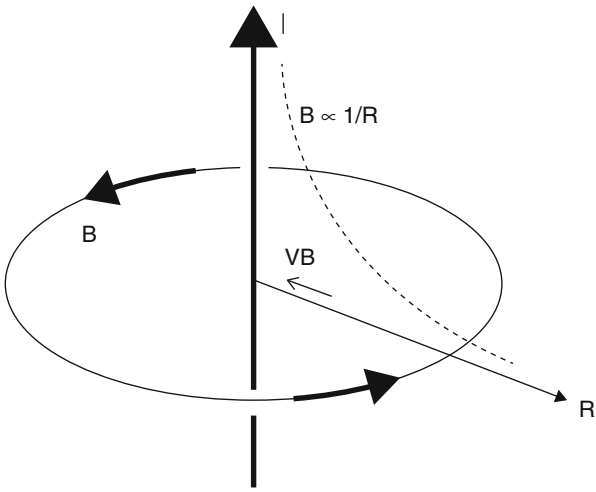

Fig. 10 Generation of circulating magnetic field line without an end. Electric current I generates magnetic field B

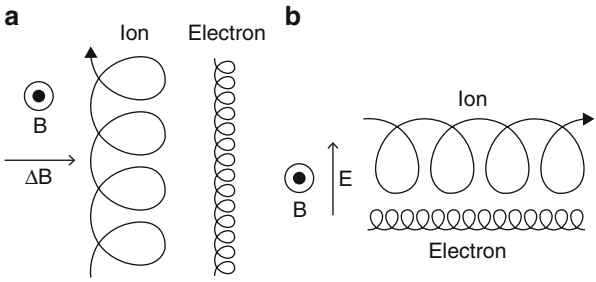

Fig. 11 Drift motion of charged particles in a nonuniform magnetic field. E and B denote an electric field and magnetic field, respectively. (**a**) A drift by the gradient of magnetic field. (**b**) A drift by resultant electric field due to the gradient of magnetic field

electrons, these two kinds of particles are separated upside down (see Fig. 11a). This separation of charged particles generates vertical electric field, which accelerates or decelerates the charge particles. Since the rotating radius is proportional to the velocity of the charged particle, rotating motion is affected by the electric field as shown in Fig. 11b. In this case, both ions and electrons go away from the major axis and are lost eventually. As a result, simple circulating magnetic field lines cannot confine charged particles.

By twisting magnetic field lines in a torus, the upper part and the lower part can be short-circuited and consequently unfavorable charge separation can be avoided. In reality, sophisticated modification of simple circulating magnetic field lines is required to keep high-temperature plasma stable. One element twists the magnetic field lines and another element forms nested magnetic surfaces composed of numerous turns around a doughnut. Most simply speaking, centrifugal force driven by the motion along the bended magnetic field line and electric field generated by charge separation are compensated by the geometrical arrangement.

There are two ways to form a magnetic bottle with fulfillments of these requirements. One is called "*tokamak*" (Wesson 2004) which was invented by Sakharov and Leontovitch (1961) and Tamm in the former Soviet Union in the 1950s. This concept

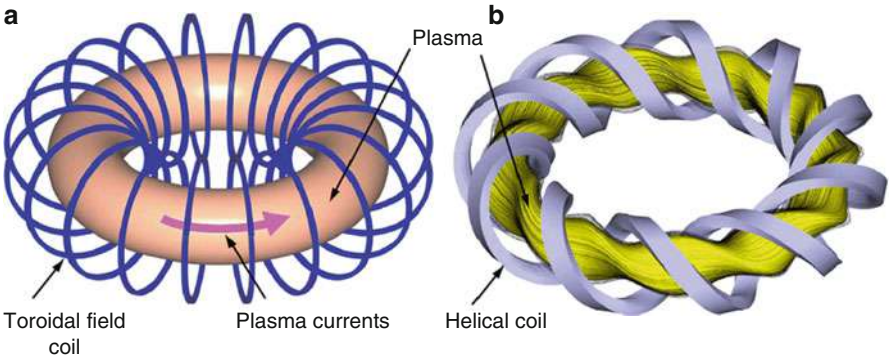

Fig. 12 Concepts of magnetic confinement fusion. (**a**) Tokamak and (**b**) helical system

is based on the combination of externally generated circulating magnetic field and the magnetic field generated by circulating currents in the plasma (Fig. 12a). Circulating magnetic field looking like a doughnut can hold the plasma apart from the material wall. A set of planar coils arranged around a doughnut generates simple circulating magnetic field and circulating currents in the plasma are driven by the principle of transformer. This concept is axisymmetric and simple in machine construction as well as theoretical analysis of plasma physics.

Another concept is a helical system. Only twisted (helical) coils generate the magnetic field to confine the plasma (see Fig. 12b). The American physicist Spitzer (1954) and the Japanese physicist Uo (1961) are pioneers in this concept. Their inventions are called stellarator and heliotron, respectively. A helical system does not require the currents in the plasma to generated twisted magnetic field. Therefore a helical system is free from issues related to the plasma currents, which are critical in a tokamak. A helical system has an intrinsic advantage of steady-state and stable operation. Although the complicated three-dimensional geometry has prevented the progress of this concept both experimentally and theoretically, the development is being accelerated by the first large-scale experiment (Large Helical Device: LHD (http://www.lhd.nifs.ac.jp/en/) in Japan) and large-scale simulations. Confinement capability has been proved to be equivalent to a tokamak.

Although the physical picture of particle confinement is well documented, plasma also behaves as a fluid. Dynamics of plasma is highly nonlinear and the modeling of plasma motion is still a challenging issue. Heat loss due to turbulence in the plasma has not been fully understood yet. The confinement capability of plasma is compared with the containment of water in a bucket with holes (see Fig. 13a). Supply of water from an external faucet P is balanced with the leak from holes L and consequently the water level W is kept. When the faucet is closed, the water level goes down exponentially with a specific time constant τ. In the case of fusion plasma, the plasma stored energy W is modeled by

$$dW/dt = P_{in} - W/\tau_E, \tag{2}$$

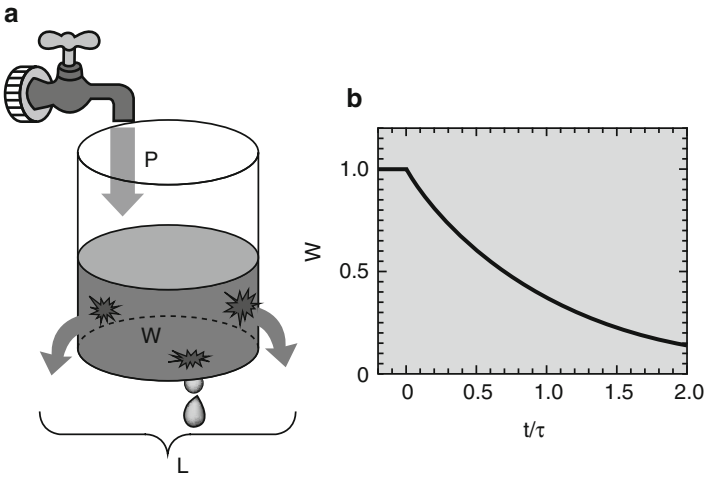

Fig. 13 (**a**) Concepts of confinement. Water is compared to energy. (**b**) Level (volume) of water decreases exponentially

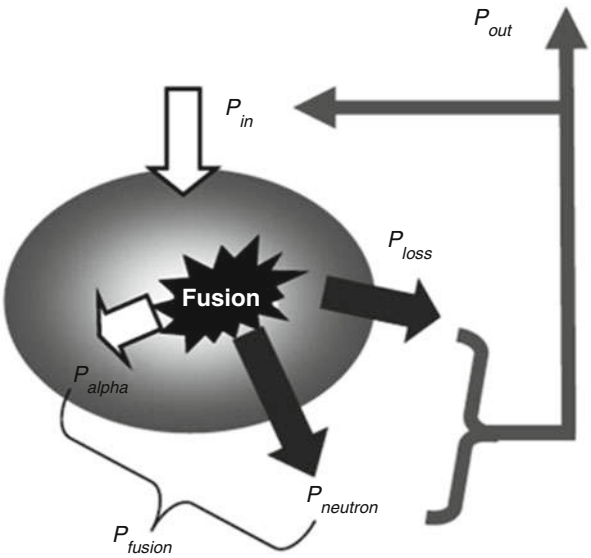

Fig. 14 Conceptual diagram of power balance in a fusion reactor

where P_{in} is input heating power and τ_{E} is called an energy confinement time. If there is no external heating, the plasma stored energy decays with $\exp(-t/\tau_{\mathrm{E}})$ as shown in Fig. 13b.

Power balance in a fusion reactor is schematically shown in Fig. 14. It should be noted that the fusion energy carried by fusion-producing helium contributes to heating of the plasma. Another fusion product, neutrons, is not confined by the

magnetic field because of no electric charge. The energy multiplication factor Q of a fusion reactor is defined based on this picture by

$$Q = P_{\text{fusion}}/P_{\text{in}} \tag{3}$$

This Q value should be larger than 50 to establish a fusion reactor as an energy source and the condition of $Q = 1$ is called breakeven. In steady state, Eq. 2. gives

$$P_{\text{in}} = W/\tau_{\text{E}}. \tag{4}$$

The combination of Eq. 1 in section "Fusion Reaction" and Eq. 4 yields

$$Q \propto n_D, n_T, \sigma v>_{DT}/(W/\tau_{\text{E}}), \tag{5}$$

where the bracket <> means the volume averaged value.

The cross section $< \sigma v >_{DT}$ can be approximated well by the temperature T squared in the targeted temperature range around 10 keV and n_D and n_T are ideally the same. Also the plasma stored energy W can be rephrased by $< nT >$, where n is the representative particle density. Consequently, Q is expressed approximately by $< n^2T^2 > / < nT > \tau_{\text{E}}$ and then $< n > < T > \tau_{\text{E}}$.

More simply, $nT\tau_{\text{E}}$ is called a fusion triple product and the most important parameter to describe the performance of fusion plasma. In early stage of fusion energy development, J. D. Lawson defined the condition to produce net energy (Lawson 1957) and indicated that the breakeven condition corresponds to 1×10^{21} m^{-3} keV s. More specifically, a typical target is simultaneous achievement of the density of 1×10^{20} m^{-3}, the temperature of 10 keV (around 120 million °C), and the energy confinement time of 1 s.

Although the plasma turbulence predominating the energy confinement has not been understood from the first principle yet, empirical scaling tolerable enough to foresee a reactor has been already available (Lawson 1957; ITER Physics Basis Editors 1999). The energy confinement time is described by the power laws with plasma and operational parameters, for example (ITER Physics Basis Editors 1999),

$$\tau_E = 0.0562 I^{0.93} B^{0.15} \overline{n}_{19}^{0.41} P^{-0.69} R^{1.39} a^{0.58} \kappa^{0.78} M^{0.19},$$

where I is the circulating current in tokamak plasma in MA, B is the magnetic field in T, $\overline{n}_{19}$ is the line averaged density in 10^{19} m^{-3}, P is the heating power in MW, R is the major radius of the torus in m, a is the minor radius of the torus in m, κ is the elongation of the poloidal cross section of the plasma (the plasma cross section is usually vertically elongated prolate shape and κ is the ratio of the height and the breadth of the plasma cross section), and M is the mass number (1 for hydrogen and 2 for deuterium). For helical systems, another scaling expression has been proposed (Dinklage et al. 2007) and both scaling expressions share large commonality in physics. As shown in Fig. 15, the scaling fits the experimental observation by a factor of 2 in 3 orders of magnitude.

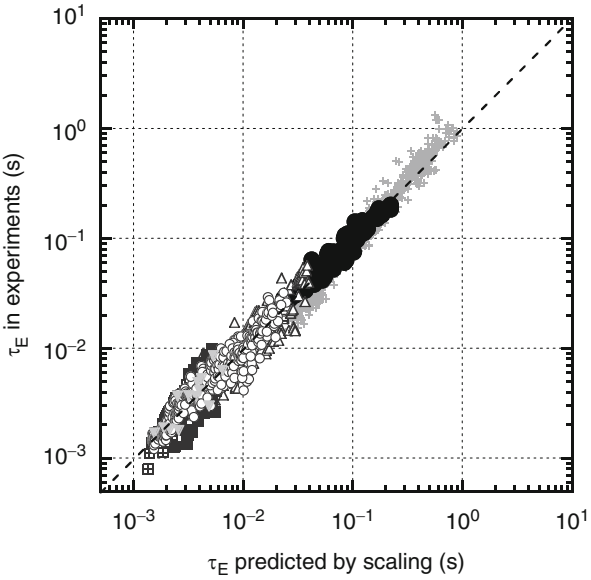

Fig. 15 Comparison of an energy confinement time in experiments with prediction from the scaling

Engineering Elements of Fusion Reactor

Structure of a Fusion Reactor

As shown in Fig. 7, fundamental components in the core are (1) confined plasma as energy source due to fusion reaction, (2) plasma-facing components surrounding the plasma, (3) blanket to receive neutrons and generate heat and tritium, and (4) superconducting magnets to generate confining magnetic field. Heat generated in the blanket is transferred by coolant like water. The consequent process of electric power generation is the same as a fission power plant and a thermal power plant. In addition, affiliate facilities which are not seen in other power plants are vacuum pumping system and heating system to bring the plasma to ignition.

A fusion reactor is basically a large-scale electromagnetic and nuclear device which requires extremely high-level integration of engineering and physics. Steady-state control of the plasma is a primary demand. Safety and materials are also key issues. Damage on plasma-facing components by high-energy (14 MeV) neutrons and helium irradiation should be assessed precisely to guarantee safety over their lifetime. For safe steady-state operation, peak heat loads exceeding 10 MW/m^2 should be managed safely. Also, an economically competitive power station must minimize the internal circulating power consumed in the plant. A fusion reactor needs a variety of large-scale electric facilities such as vacuum and cooling pumps, cryogenic system, magnets, and heating and control system. This internal circulating power in the present fission power station is only 3–4 % of the generated electric

power. If the circulating power becomes significantly large to operate a fusion reactor, a fusion reactor cannot gain economical attractiveness.

The abovementioned major three components besides the core plasma are explained in detail in the following sections.

Plasma-Facing Component and Structure Material

When the plasma is contaminated by impurities other than deuterium and tritium, radiation loss is enhanced to cool the plasma and fuels are diluted. Therefore, the plasma is generated in an airtight vacuum vessel. Although the plasma is held apart from the wall of the vacuum vessel by the magnetic field, a part of highly energetic particles and particles neutralized by the charge exchange process bombard the plasma-facing components located on the wall. Here it should be noted that the plasma with the pressure as high as 10 atmospheres is pressed down by the magnetic field and that the space between the plasma and the wall of the vacuum vessel is almost vacuum with very rare neutral gas.

While the temperature of the burning plasma exceeds 100 million °C, the direct interaction between the burning plasma and the plasma-facing component is avoided by the magnetic field. Even in this thermal insulation, the heat load to the plasma-facing component reaches 10 MW/m^2 due to radiation and the fluxes of neutrons and charge exchanged neutrals. The operational temperature of the plasma-facing component is evaluated up to 900° C, and the first planned material is tungsten which has high melting temperature (3,380° C). Although carbon is widely used as the plasma-facing component in the present fusion experiment devices, it is not compatible with the reactor condition due to large erosion and retention of tritium.

Neutrons generated by fusion reaction are not confined by the magnetic field and penetrate into the structure materials. Therefore, the plasma-facing components and structure materials are required to have sufficient tolerance against the heat and neutron loads. Relatedly, employed materials should have good heat removal property and reduced activation. Also it is preferable to keep sufficient tightness and mechanical strength during a lifetime of a plant. Alloys such as stainless steel have been usually used in the current experimental devices, but these alloys do not fulfill the requirement of a reactor. Ferritic steel is a promising material for the first generation of a reactor, and advanced materials using vanadium silicon carbide are being developed. In addition to heat and neutron loads, helium generates bubbles in the plasma-facing components and causes swelling and consequent blistering. Since falling flakes deteriorate plasma performance, materials should suppress this effect in addition to securing soundness of components themselves.

In general, materials show degradation of its properties, such as dimensional instabilities, yield strength, ductility, creep rate, fatigue life, and fracture toughness. Neutron radiation often accelerates this process (Zinkle 2005). The standard to assess irradiation damage is displacements per atom (dpa) (Norgett et al. 1975). The dose of 1 dpa corresponds to a 14 MeV neutron wall loading of 0.1 MW year/m^2

in steels. The structure component of a fusion power plant is expected to have a neutron dose of 100–150 dpa around temperatures of 500–600° C.

While stainless steel can be used in the experimental reactor level (ITER) where the neutron fluence is limited to 3 dpa, development of new material is prerequisite for a fusion reactor as a power plant. The promising material for the first generation of a fusion reactor is low-activation ferritic steel, which has been used in fuel tubes for a fast breeder fission reactor and evaluated to be used up to 40 dpa by 14 MeV neutron radiation. This tolerance corresponds to 1-year operation of a fusion reactor. Innovative and attractive materials such as vanadium alloy (V-4Cr-4Ti) (Muroga et al. 2002) and silicon carbide (SiC/SiC) (Katoh et al. 2007) are also under development.

In addition to mechanical properties, physical properties such as electric conductivity change due to neutron irradiation. These complicated phenomena depend on energy and dose of neutrons and operating temperature. A new neutron irradiation facility is planned to evaluate irradiation property of materials precisely for reliable design of a fusion reactor. This facility is called the International Fusion Materials Irradiation Facility (IFMIF) (Martone 1996) and simulates 14 MeV neutrons at the maximum capability of 50 dpa/year. The schematic view of IFMIF is shown in Fig. 16. The report of Martone (1996) defines the mission of IFMIF as to provide an accelerator-based, D-Li neutron source to produce high-energy neutrons at sufficient intensity and irradiation volume to test samples of candidate materials up to about a full lifetime of anticipated use in fusion energy reactors. IFMIF would also provide calibration and validation of data from fission reactor and other accelerator-based irradiation tests. It would generate an engineering base of material-specific activation

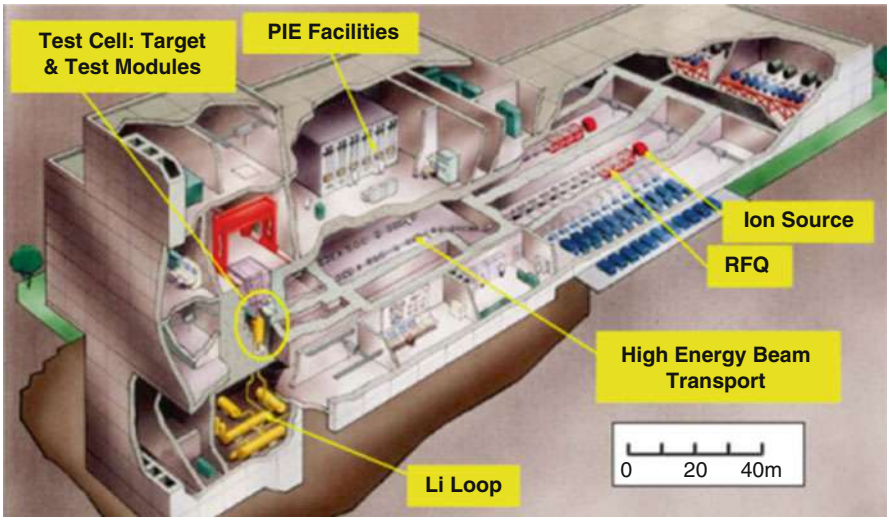

Fig. 16 Schematic view of the International Fusion Materials Irradiation Facility (*IFMIF*). PIE and RFQ stand for postirradiation examination and radio-frequency quadrupole, respectively

and radiological properties data as well as support the analysis of materials for use in safety, maintenance, recycling, decommissioning, and waste disposal systems. A deuterium beam with 40 MeV and 250 mA irradiates a lithium target and generates neutrons with the energy peak at 14 MeV through the D-Li stripping reaction. The Engineering Validation and Engineering Design Activities (EVEDA) for IFMIF are now being conducted by Japan-EU cooperation in Rokkasho, Japan (Garin et al. 2009).

Blanket

The blanket surrounds the plasma with protection by the plasma-facing components. The function of blanket is to produce tritium and extract heat from neutrons generated by the fusion reaction. Tritium breeding ratio (TBR) is a critical parameter for a fusion reactor. TBR is a measure of breeding capability of the blanket and is defined as

$$\text{TBR} = \text{rate of tritium production in the blanket} / \text{rate of burning tritium in the plasma}$$

Since the abundance of tritium in nature is tiny, a fusion reactor is required to produce more tritium than burned tritium, which means TBR >1.

The blanket consists of breeding material for tritium, multiplier of neutrons, and coolant which are designed to fulfill three major specifications: (1) sufficient tolerance against heat, neutrons, and electromagnetic forces due to confining magnetic field; (2) the tritium breeding ratio with more than 1; and (3) sufficiently high efficiency of heat removal.

Tritium breeding material produces more tritium than consumed tritium by using the reaction between lithium and neutron described in section "Fusion Reaction." There are two major categories in the form of lithium. One is a solid-breeding scheme in ceramic made of lithium and another is a liquid-breeding scheme of pure lithium(Li), lithium lead (LiPb), or molten salt (FLiBe). Solid breeding is progressing faster due to the advantages of easy handling and chemical stability. Liquid breeding has advantages of much reduction of radiation damage, simple design for easy maintenance, and potentially high TBR. However, liquid-breeding material is chemically active in general. In particular, careful attention should be paid to a chemical reaction with water which is the secondary coolant and corrosion of the cooling channel. Also liquid metal is an electrically conducting fluid and the electromagnetic force under the strong magnetic field prevents efficient flow. Therefore, research and development has been conducted to resolve these issues.

One neutron is generated by one fusion reaction between deuterium and tritium, and a fusion reactor must produce more than one tritium by this one neutron. Since some neutrons are absorbed in surrounding structure and lost, all neutrons cannot be used to breed tritium. Therefore, it is needed to multiply neutrons by the reaction using beryllium such as

$$^{9}Be + n \rightarrow 2n + 2^{4}He.$$

This kind of neutron multiplier is inserted between the plasma-facing component and tritium breeding material. Also the shield is located behind the breeding material to reflect neutrons back to use them efficiently and protect superconducting magnet located behind the breeding material.

Coolant should be compatible with tritium breeding material and have sufficient heat removal capability. The most conservative combination is to use solid breeding and water or helium as coolant. Operating temperatures are around 300° and up to 500° C for water cooling and helium gas cooling, respectively.

The blanket must hold a critical compound role in a fusion reactor. In addition, constraints due to configuration of magnets and economical viewpoints require the thickness of blanket limited to around 1 m.

In spite of limited availability of neutron fluence on ITER (around 3 dpa), the ITER project definition states that "ITER should test tritium breeding module concepts that would lead in a future reactor to tritium self-sufficiency and to the extraction of high-grade heat and electricity production" (Aymar 2001). Toward this goal, several fusion reactor-relevant Test Blanket Modules (TBM) (Giancarli et al. 2006) are proposed.

Superconducting Magnet

To confine the burning plasma described in "Core of Fusion Reactor: Burning Plasma," the strong magnetic field exceeding 10 T at the magnets is needed. Since the volume of the plasma is around 1,000 m^3, magnets produce this strong magnetic field with sufficient accuracy to cover the large volume. It is well known that Joule heating due to resistivity is accompanied by currents. The loss of this energy is critical in a fusion power plant. Therefore, superconducting magnets are inevitable since they are free from energy loss due to Joule heating because of no resistivity at cryogenic temperature. Superconducting magnets in a fusion power plant are characterized by large-scale, sufficient tolerance and preservation of accuracy against the large electromagnetic force and tolerance against nuclear heating and activation. Superconducting magnets using alloys such as NbTi and a compound such as Nb_3Sn have been developed to fulfill these specifications.

Figure 17 shows the development of large superconducting magnets in fusion devices (Yamada et al. 2009). The largest operating magnet system for fusion is the Large Helical Device (LHD) (Imagawa et al. 2010), and its magnetic stored energy is close to 1 GJ. The Large Hadron Collider (LHC) employs two large detectors with large-scale superconducting magnets, ATLAS and CMS, and each magnetic stored energy exceeds 1 GJ. The total stored magnetic energy of LHC reaches 15 GJ (Ross 2010). The stored magnetic energy of the superconducting magnet system in ITER is 50 GJ (Mitchell et al. 2010), which is well beyond the achievements so far.

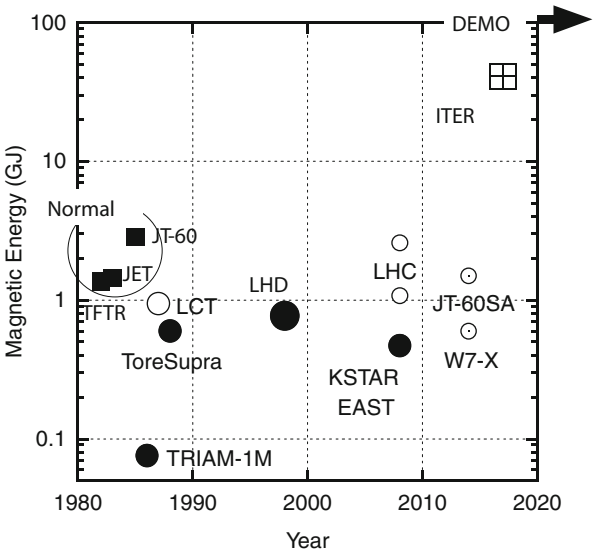

Fig. 17 Development of large-scale superconducting magnets in terms of magnetic energy. Three large tokamaks employing normal conductors and the superconducting magnets for the Large Hadron Collider (*LHC*) are also plotted as references (Reproduction of Fig. 4 in Yamada et al. (2009))

The specification of the magnets for ITER requires the mechanical tolerance against 1 GPa, the withstanding voltage of 10 kV, and irradiation dose on electric insulation of 10 MGy, which are the present technological limits. The prototype magnet employing Nb_3Sn conductors has demonstrated 13 T (Kato et al. 2001) and fabrication of real components has started. The specification required for a fusion reactor would be higher than that of ITER. The solution to the issue of Nb_3Sn having the critical current density that degrades by strain is inevitable to achieve higher magnetic field for a fusion reactor than in ITER. A strong candidate is Nb_3Al because of its outstanding property of critical current density against strain and magnetic field (Koizumi et al. 2005). Although basic engineering advantage has been already established for Nb_3Al, R&D to mitigate difficulty in mass production and cost is still required for its application to a fusion reactor.

Further development of conductors is being conducted to pursue capability to carry higher currents under higher magnetic field than these established conductors. In particular, a high-temperature superconductor which does not need cryogenic operation by liquid helium will have a big impact on a design of a fusion reactor.

Present Status and Future Direction of Nuclear Fusion

Fusion research was started as classified military research about 60 years ago. Then, global scientific research activity toward a peaceful use of fusion energy was launched by declassification at the second United Nations Conference on the Peaceful Uses of Atomic Energy in Geneva in 1958. Tabletop-sized experiments demonstrated proof of principle of physical ideas, and medium-sized experiments with the

major diameter of up to 3 m extended plasma parameters to the order of ten million °C. Then three large-scale tokamaks, TFTR (Hawryluk et al. 1998), JET (http://www.jet.efda.org/; Pamera and Solano 2001), and JT-60U (Ohyama et al. 2009), with the diameter of about 6 m and the plasma volume of several tens to more than 100 m^3 were constructed in the 1980s to demonstrate scientific feasibility of fusion. As an alternative line, a helical system is catching up with tokamak by large facilities, LHD (http://www.lhd.nifs.ac.jp/en/; Yamada et al. 2009; Komori et al. 2010) and Wendelstein 7-X (http://www.ipp.mpg.de/ippcms/eng/pr/forschung/w7x/; Bosch et al. 2010). In parallel with convergence to the first demonstration of burning plasma on ITER, a variety of experimental project are being conducted to resolve unresolved issues and create innovation by worldwide efforts as shown in Fig. 18.

Although the fusion power plant has not been realized like a fission power plant, the progress in these 50 years is remarkable (Meade 2010). For example, the most typical index to describe performance of fusion plasma, the fusion triple product of temperature, density, and energy confinement time, has been improved in the same speed as the density of an integrated circuit, which refers to the famous Moore's law (doubled in 18–24 months) (see Fig. 19) (Webster 2003). Figure 20 is the so-called Lawson diagram, which shows the performance of fusion plasmas on the plane of the product of central ion density and energy confinement time, and temperature. Recent experiments on JET (Team 1992) and JT-60U (Ishida et al. 1999) achieved the breakeven condition $Q = 1$ in the 1990s. It should be noted that the breakeven conditions have been equivalently satisfied by using only deuterium. Also more than 10 MW of real fusion power generation has been demonstrated using deuterium and tritium on TFTR (Bell et al. 1995) and JET (Gibson 1998) even for a short time period as long as a few seconds (see Fig. 21). These two major achievements, breakeven and DT burning, have motivated the next generation of a tokamak experimental reactor.

Based on accumulated achievements by worldwide tokamaks (Ikeda et al. 2007), fusion power development is stepping up the stage. Seven leading parties of fusion research, China, EU, India, Japan, Korea, Russia, and the USA, have jointly started construction of the International Thermonuclear Experimental Reactor (ITER) (http://www.iter.org/) in Cadarache, France. For this distinguished international project, the ITER Organization was formally established on October 24, 2007, after ratification of the ITER Agreement in each member party. ITER will be built largely (90 %) through in-kind contribution by the domestic agencies of seven parties. ITER is the largest tokamak ever built. Its plasma volume is close to 1,000 m^3 (see Fig. 22), and the total weight reaches 23,000 t. The goal of ITER is the demonstration of control of burning plasma and engineering feasibility of a fusion reactor. ITER plans to demonstrate 500 MW of fusion power production by DT fusion reaction at the temperature of 150 million °C for 500 s in the 2020s. This amount of fusion power is expected to be ten times larger than the external heating power put into the plasma, which means $Q = 10$. Figure 23 is the schedule of ITER (Ikeda 2010). The latest argument suggests an updated schedule that is a bit behind.

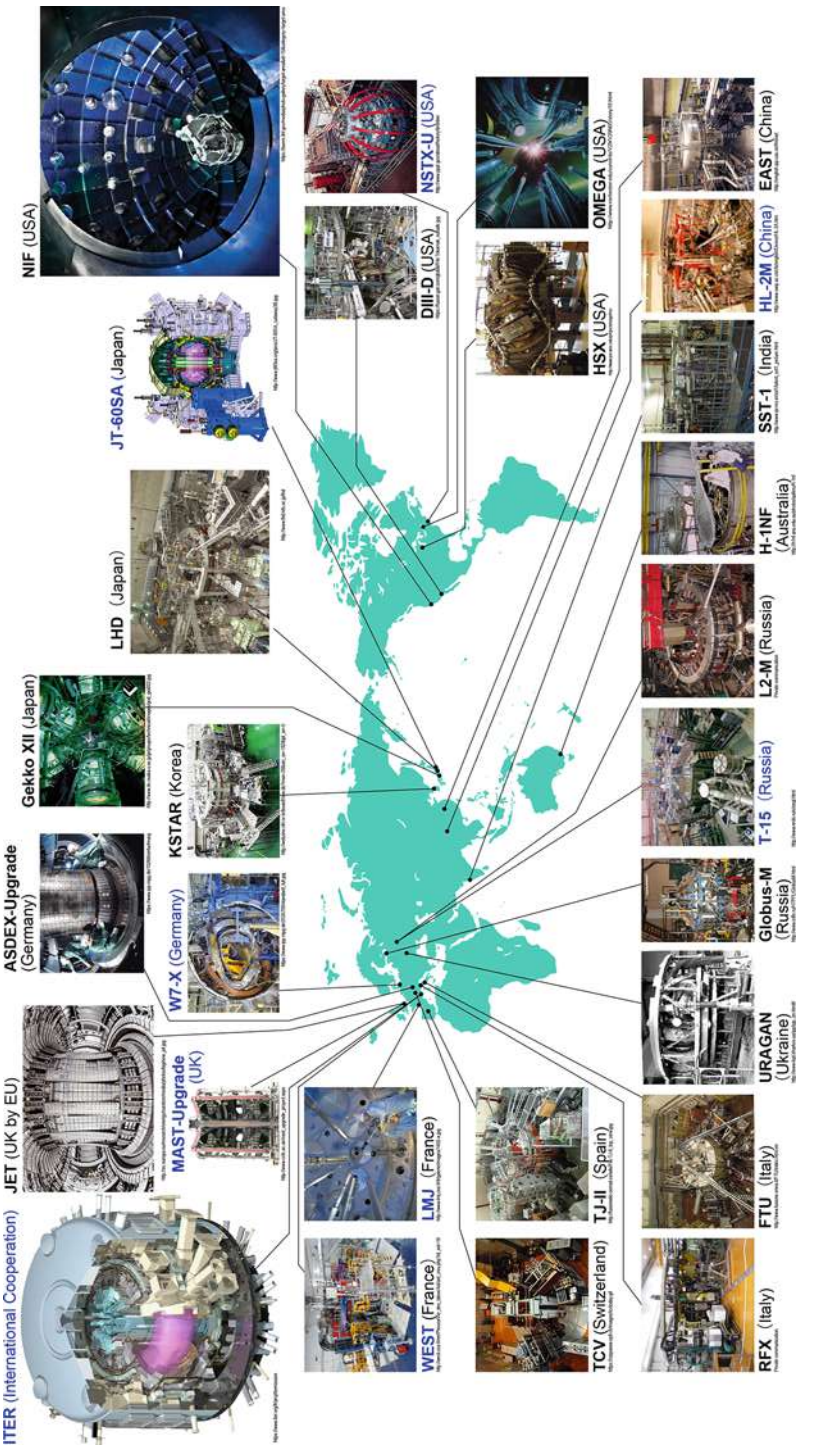

Fig. 18 Experimental facilities for magnetic confinement of fusion plasma in the world

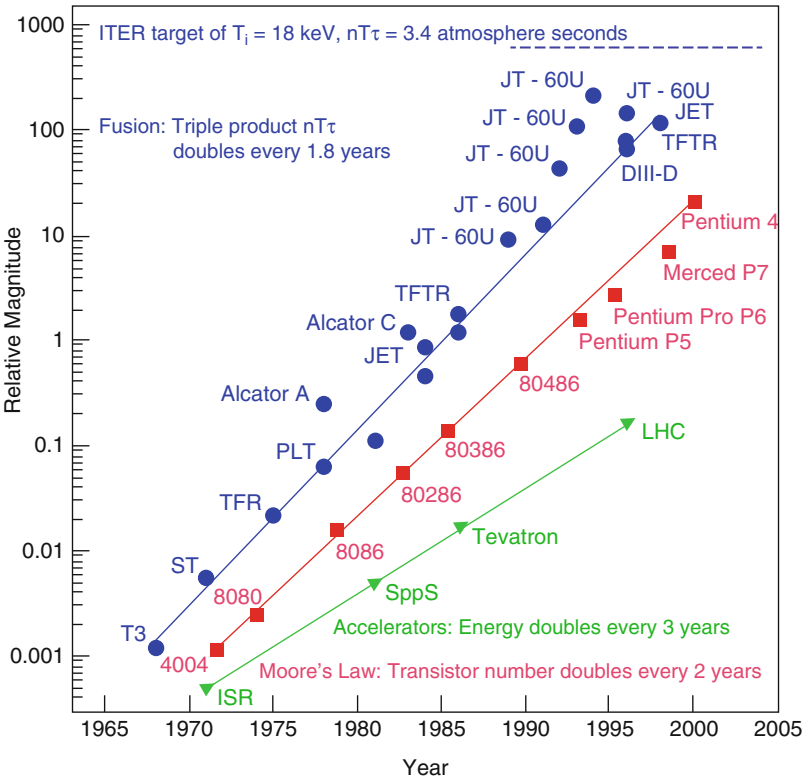

Fig. 19 The rapid progress toward harnessing fusion as a power source compares very favorably with progress in other high technologies such as computing performance and particle accelerators. This figure was originally produced by J. B. Lister, CRPP Lausanne (crpp www.epfl.ch), and M. Greenwald, MIT (www.psfc.mit.edu) (Reproduction of Fig. 3 in Webster (2003))

The first plasma with hydrogen is planned to be ignited in 2019, and the experimental campaign of DT burning will start in 2027.

ITER will also be a test bed for blanket technology as discussed in section "Blanket." The goal of ITER is defined as engineering demonstration of fusion energy. However, it should be noted that ITER does not have a plan to generate electric power. Then, a demonstration reactor which fulfills the requirement of a power plant including economical validity to some extent will come in the next. ITER is certainly the necessary condition to proceed to a demonstration fusion reactor but not sufficient for a demonstration fusion reactor. In particular, material development should be conducted by an intensive neutron irradiation facility (IFMIF) (Martone 1996) in parallel to assess property of materials, in particular lifetime.

ITER adopts the tokamak concept described in section "Magnetic Confinement of Plasma." Tokamak is the most promising concept to demonstrate controlled burning plasma from the presently available knowledge. However, when the system is

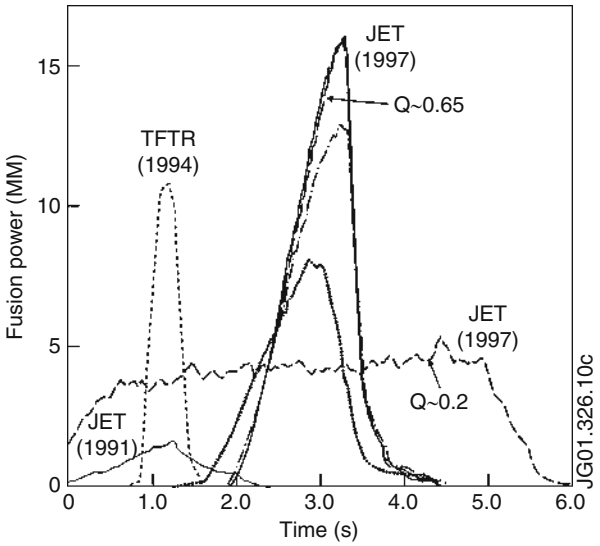

Fig. 21 Progress in fusion power and energy in time, from JET and TFTR which are capable of DT operation (Reproduction from http://figures.jet.efda.org/JG01.326-10c.eps)

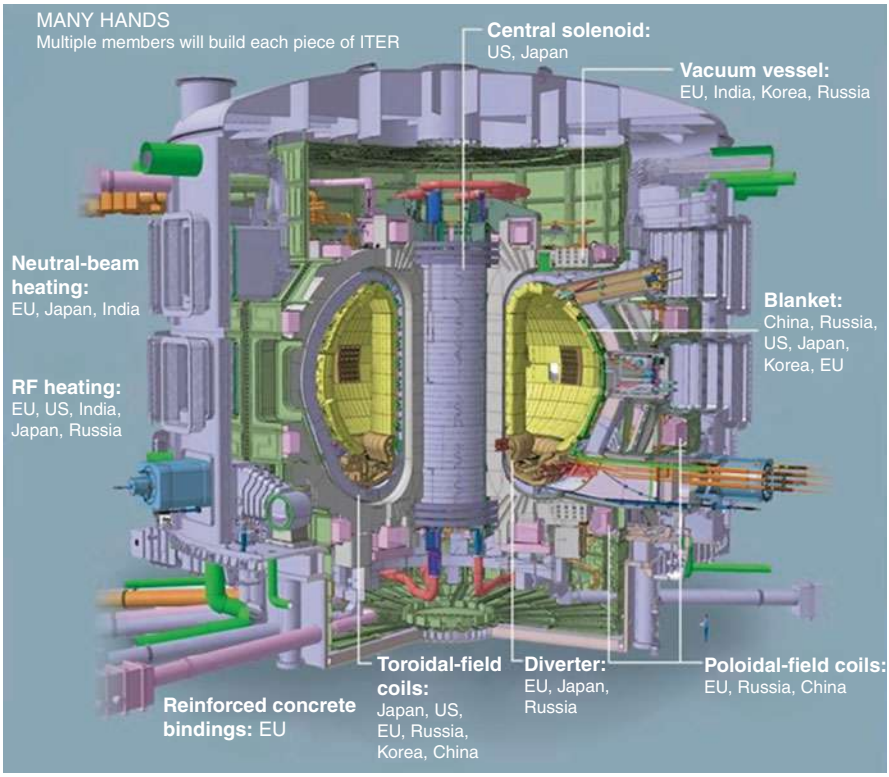

Fig. 22 A cutaway view of ITER (courtesy of the ITER Organization). The major diameter of a doughnut-shaped plasma is 12.4 m. Duplication from Nature 459: 488–489, 2009. Seven parties in the world share the responsibility of construction

assessed from the viewpoint of a fusion power plant, it is serious and critical to overcome the issues related to the control of huge currents in the plasma. In the case of ITER, electric current of 15 MA (1.5×10^7A) flows in very rare gas (plasma) with weight of less than 1 g. This plasma current should be stably held in steady state. This requirement poses two critical issues. One is avoidance of current disruption. Since a huge plasma current has huge electromagnetic energy, abrupt destruction of the plasma current called disruption occurs when the stability of the current is lost. This phenomenon happens in the order of 1 ms; huge transient electromagnetic forces are generated in the machine component. Therefore the control and mitigation of disruption is a prerequisite for a tokamak fusion reactor. Another requirement is current drive. In addition to transient induction as in a transformer, a reliable and efficient current-drive scheme should be established. Fortunately, to some extent, high-temperature plasma in a doughnut shape has a physical mechanism to drive the circulating currents spontaneously, called bootstrap currents. However these currents are not sufficient to sustain the burning plasma and an external source to drive the sufficient current. This means that some amount of produced electric power in a

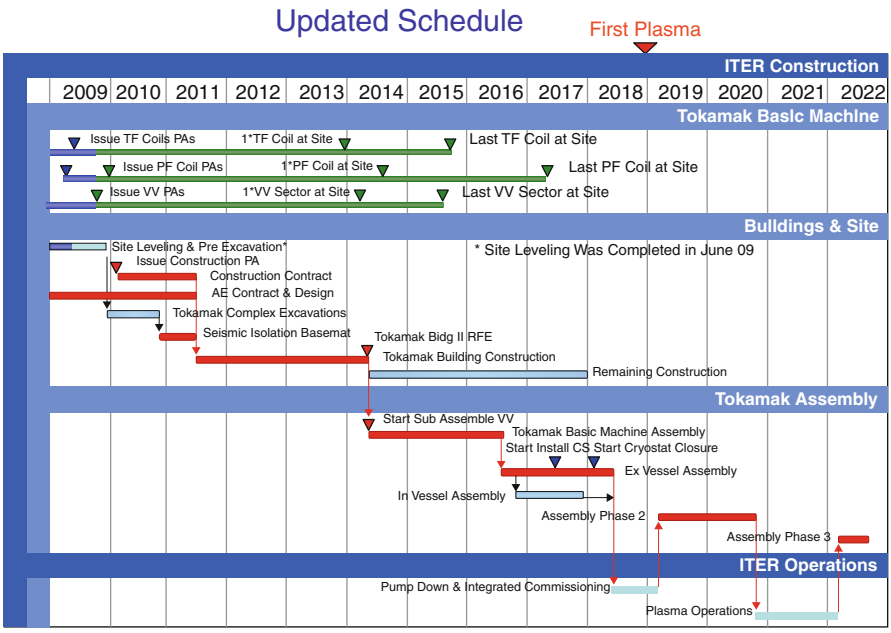

Fig. 23 Schedule of ITER (Reproduction of Fig. 13 in Ikeda (2010))

tokamak fusion power plant is consumed to drive the plasma currents. Simultaneous achievements of spontaneous current fraction of 70 % and efficiency of current drive from the plug of 50 % are required to deliver electric power to the grid economically. This requirement is very demanding, and ITER will not be able to resolve this issue. Therefore a new tokamak facility JT-60SA (Ishida et al. 2010) to explore the steady-state tokamak operation is now under construction by bilateral collaboration of EU and Japan.

Since a helical system which is alternative to a tokamak does not need plasma currents to confine the plasma and is free from challenging issues related to the plasma current, it is an extremely attractive concept of a steady-state stable reactor. Nonetheless, complex shape of magnets has caused troubles and difficulties in both experimental and theoretical approaches, and the progress of research and development lagged behind tokamak by one generation. However, the first large-scale helical device, LHD (see Fig. 24), has been in operation since 1998, and remarkable progress has been achieved recently (Komori et al. 2010). LHD employs superconducting magnets and has the capability of steady-state operation in both physics and engineering aspects. LHD has achieved the comparable plasma parameters such as temperature of 75 million °C and already demonstrated 1 h long operation of high-temperature plasma with 12 million °C. Another helical device, Wendelstein 7-X, is now under construction in Germany and will be operational in 2015 (Bosch et al. 2010).

Fig. 24 Photograph of the plasma vacuum vessel of *LHD*: the Large Helical Device (Courtesy of the National Institute for Fusion Science, Japan). The major diameter of a twisted doughnut-shaped plasma is 7.8 m

In the coming couple of decades, physical study and engineering demonstration of burning plasma will be conducted in ITER in parallel with research and development of steady-state operation by advanced tokamaks and helical systems. Reactor engineering, in particular material development, should be also pursued toward the establishment of an economical fusion reactor. Integration of all this knowledge will lead to the first demonstration fusion reactor which produces electric power of one million kW in the 2040s (see Fig. 25). The establishment of fusion as energy source is targeted in the mid of this century (Masionnier et al. 2005).

The National Ignition Facility (http://lasers.llnl.gov/) in the USA plans to demonstrate ignition by the completely different inertia confinement scheme in 2011. Operation is limited to a single-shot basis due to the availability of highly intensive laser, and the inertia confinement is in the stage of scientific demonstration.

Summary

Fusion is an energy source of the sun, and controlled fusion as an energy source for human beings has been developed intensively worldwide for this half a century. A fusion power plant is free from concern of exhaustion of fuels and production of CO_2 and has an advantage to a nuclear fission power plant in terms of high-level radioactive waste. Therefore it has a very attractive potential to resolve global warming and to be an eternal fundamental energy source. On the other hand, unresolved issues still remain. It will take another several decades to realize a fusion

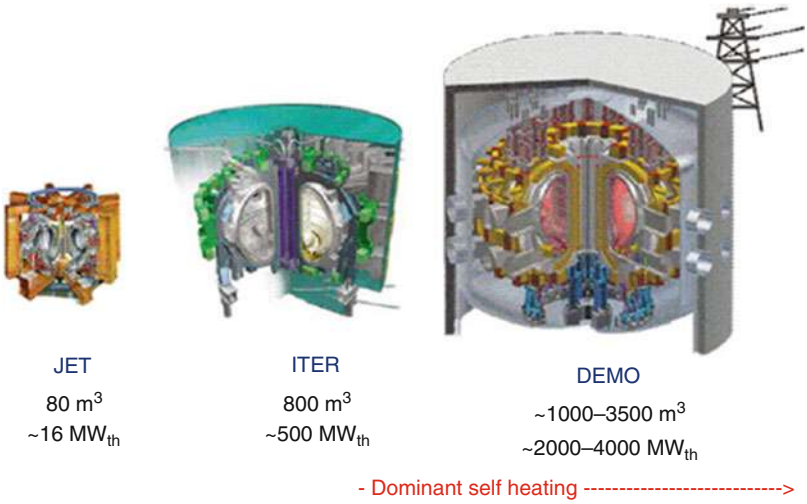

Fig. 25 The growth in scale of tokamak devices from JET, which produced the first DT fusion power, through ITER, aiming for Q = 10 at 500 MW thermal, to a DEMO reactor producing ~1GW electrical (Reproduction of Fig. 15 in Ikeda (2010))

power plant by integration of advanced science and engineering such as control of high-temperature plasma exceeding 100 million °C and breeding technology of tritium by generated neutrons. The research and development has just entered the phase to start the project to extract 500 MW of thermal energy from fusion reaction in the 2020s. The demonstration of electric power generation is targeted in the 2040s. Even the first-generation fusion demonstration reactor will produce electricity of one million kW.

Fusion reaction itself has been already demonstrated in an unpeaceful manner as a hydrogen bomb which is ignited by an atomic bomb. In peaceful use of fusion energy, a fusion power plant employs completely different principle that the fusion reaction in plasma is controlled stably in steady state. Since fusion energy is free from nuclear proliferation and unfair distribution of fuels, geopolitical issues can be much mitigated by its realization. Fusion energy, a sun on the Earth, has attractive and critical potential to resolve diversified issues related to energy and to change global social structure.

Lastly, the further sources about *fusion* can be found in books as cited by McCraken and Stott (2005), Stacey (2010), Kikuchi (2011), and Chen (2011).

DOI 10.1007/978-3-319-14409-2_90

Abstract

Biofuels have been commercialized, predominantly bioethanol, biodiesel, and biogas. Mostly, they are based on edible feedstock such as corn, maize, or soybean (so-called 1st-generation (1G) biofuels). The arising competition over arable land with food crops has caused significant debate, as well as the net contribution to climate change mitigation, where it was found that sometimes 1G biofuels perform even worse than petroleum-based fuels, due to land use change, fertilizer usage, and process yields, for instance. Biofuel research has hence targeted lignocellulosic feedstock, which exists in abundance. Due to the stability of these biopolymers, cost-effective 2G biofuels are now only at the verge of commercialization. Processes to break up the biomass into fuels are thermochemical and biochemical, using enzymes. 3G biofuels have been envisioned, where microorganisms are deployed. For instance, since algae can form up to 200 times more biomass per area than terrestrial biomass, they hold great promise for future biofuel production on marginal land or in the ocean. In this chapter, 2G and particularly 3G biofuel concepts, where bacteria and algae are used to obtain biofuels, are discussed. Standard industrial processes, like ethanol fermentation through microorganisms for regular 1G biofuels, are not covered here. Alternative biofuels from bacteria and algae, such as biomethanol or biohydrogen, are also addressed.

Introduction

Bioenergy is energy of biological origin, derived from **biomass**, and **biofuels** are fuels produced from biomass or renewable energy sources (RESs). They can contribute to sustainable transportation and electricity production. **Sustainability** is defined as creating and maintaining *"the conditions under which humans and nature can exist in productive harmony, that permit fulfilling the social, economic and other requirements of present and future generations"* (EPA 2015).

Main biofuel feedstocks, which are all produced by sun energy, are the following:

- Wood (forest management residues and fuel timber)
- Crops (annual and perennial ones, such as rapeseed and *Miscanthus*)
- Wastes (e.g., straw and animal manure)
- Others (e.g., algae)

Biofuels are a means of climate change mitigation, since less net CO_{2eq} is emitted than from fossil fuels. CO_{2eq} (CO_2 equivalent) is the amount of CO_2 that corresponds to the same amount of radiative forcing caused by an emitted greenhouse gas (GHG) such as CH_4 or N_2O; it facilitates comparison.

Theoretically, biofuels close the carbon cycle (see Fig. 1 below).

Other positive aspects are, e.g., less dependency on (foreign) crude oil, local and rural value generation, and more stable fuel prices. Policy measures to support

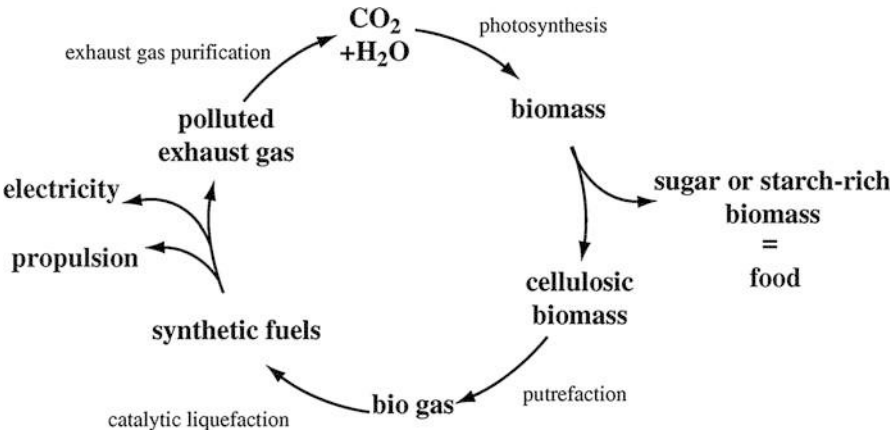

Fig. 1 A possible carbon cycle for synthetic fuel production from biomass (Source: Inderwildi and King 2009)

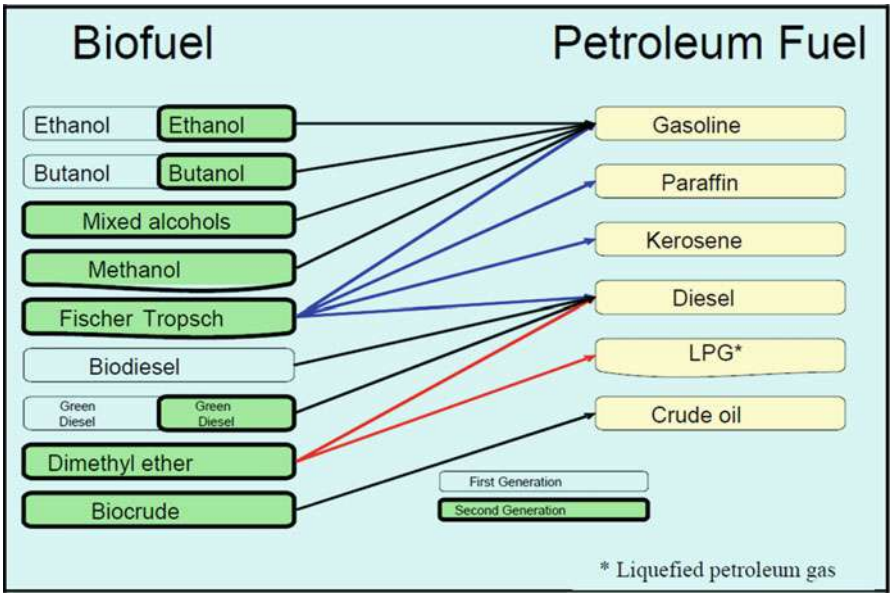

Fig. 2 Substitutability of biofuels with common petroleum-derived fuels (Source: http://unctad.org/en/docs/ditcted200710_en.pdf. Accessed 4 May 2015)

biofuel proliferation include biofuel blending obligations and fuel standards, duty exemptions, feedstock subsidies, and R&D and investment support.

Essentially, all fossil-based fuels can be replaced by biofuels, as Fig. 2 shows for the example of petroleum-derived fuels.

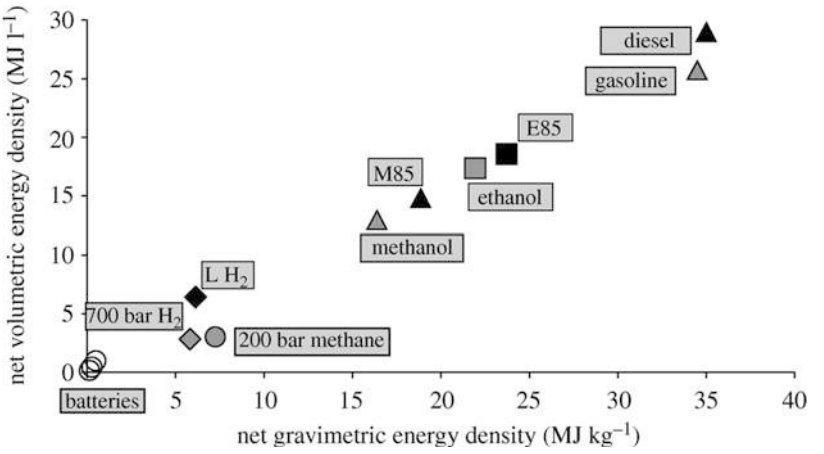

Fig. 3 Liquid fuels are particularly interesting because of their high energy densities. *L H_2* liquid hydrogen, *M85* 85 % methanol in gasoline, *E85* 85 % ethanol in gasoline (Source: Jiang et al. 2010)

Biofuels are solid, liquid, and gaseous fuels derived from renewable resources, suitable for energy production by combustion processes for light, heat and electricity generation, and propulsion. Combustion of fuels, which are predominantly fossil (e.g., coal, crude oil, natural gas), yields approx. 80 % of global primary energy production (Lackner et al. 2013). Traditional biomass burning, e.g., of wood, has been carried out for a long time (Miller 2013). Cheap coal and later crude oil have been increasingly used as of 1750, with the onset of the industrial revolution. Advantages of liquid fuels such as petrol (gasoline) and diesel are their high specific energy content (energy density), combined with ease of storage and handling (see Fig. 3).

Natural gas can be burnt with low emissions. With depleting conventional fossil fuel reserves, exploiting unconventional reserves has become profitable, e.g., of shale gas and tar sands. All of them contribute to climate change, as GHGs, predominantly CO_2 and CH_4, are being emitted into the atmosphere.

Generations of Biofuels

Based on their feedstock, biofuels can be grouped into families: 1st-generation, 2nd-generation, and 3rd-generation (or advanced) biofuels (see Fig. 4).

As Fig. 4 shows, there are many options for biofuels in terms of feedstocks and products. In Fig. 2, HVO stands for hydrotreated vegetable oil, also named "renewable diesel fuel," as opposed to "biodiesel," which is reserved for the fatty acid methyl esters (FAME) (Aatola et al. 2008). The process of HTU (hydrothermal upgrading) is described in Biofuels production via HTU and via pyrolysis; DMF (dimethylfuran) is a promising alternative biofuel (Tian et al. 2011), as is DME (dimethyl ether) (Wang et al. 2011).

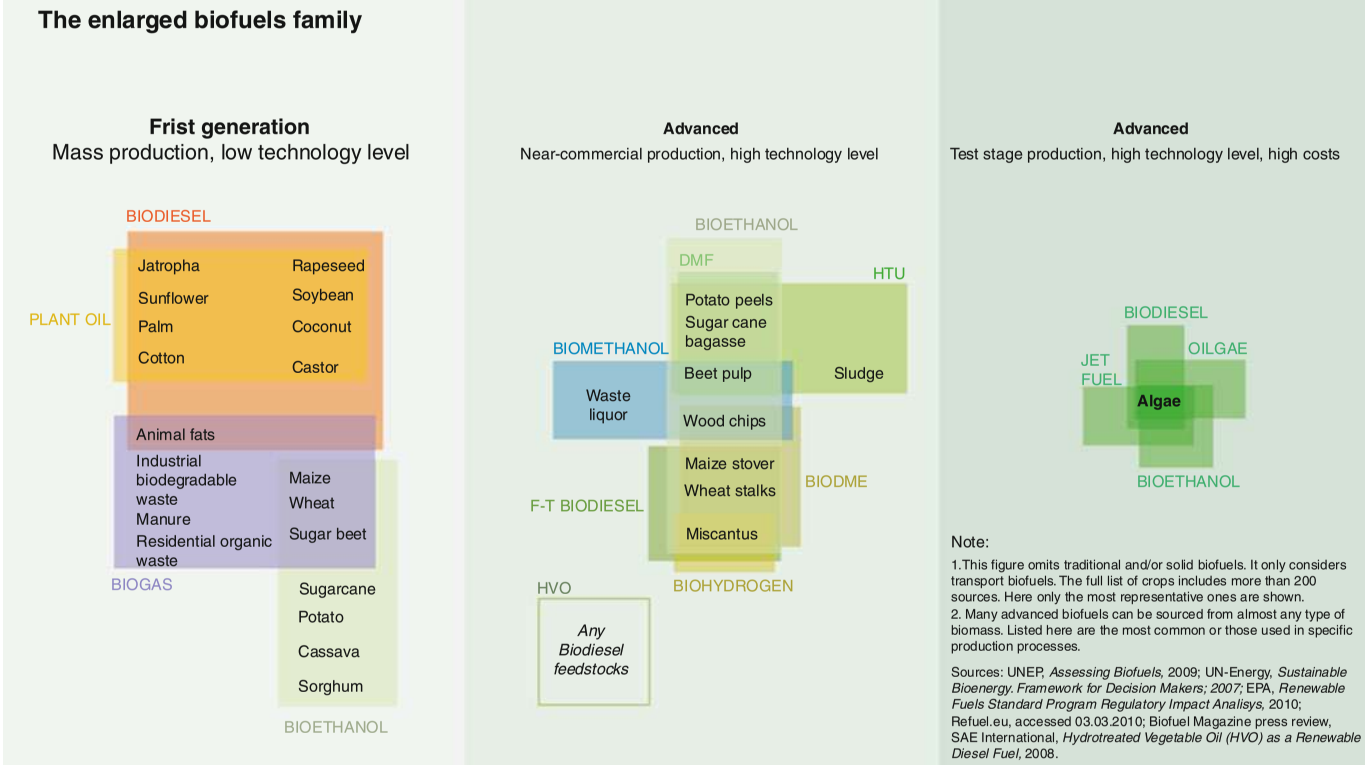

Fig. 4 The family of biofuels. *HVO* hydrotreated vegetable oil; *HTU* hydrothermal upgrading, *DMF* dimethylfuran, *DME* dimethyl ether, *FT* Fischer–Tropsch (Source: http://www.grida.no/publications/vg/biofuels/. Accessed 4 May 2015)

1st-generation biofuels use agricultural crops. The most prominent examples are biogas, biodiesel, and bioethanol. They are "drop in replacements," being compatible with their fossil fuel alternatives.

Biogas (synthetic natural gas (SNG), biomethane) is obtained from anaerobic digestion of sugar and starch (e.g., from sugar beets, maize, and wheat). It can also be collected from landfills (so-called landfill gas). Small-scale fermenters are used by farmers, who can be self-sufficient, or produce electricity and heat (cogeneration) with a gas engine. For details on biogas, see, e.g., Divya et al. (2015) and Deublein and Steinhauser (2010).

Bioethanol (BioEtOH, BioEt) is also obtained by fermentation of sugars, e.g., from corn, potatoes, or sugarcane. It can be admixed to conventional gasoline. The fuels E5 and E10 contain 5 % and 10 % ethanol, respectively. In Brazil and the USA, bioethanol fuel is extensively used. In 2010, US and Brazil's usage of corn and sugarcane, respectively, made 90 % of the world's bioethanol (Philbrook et al. 2013). Bioethanol can be made from brown algae (Fasahati et al. 2015). A recent book on advances in bioethanol is by Bajpai (2013).

Biodiesel is made by transesterification of plant oils (soybean, rapeseed, coconut, oil palm) with methanol, yielding FAMEs (fatty acid methyl esters) with glycerol as by-product. Straight vegetable oil (SVO), also called pure vegetable oils (PVOs) or pure plant oil (PPO), is produced through pressing or extraction, including refining (filtration), but without chemical modification. It has a too high viscosity for utilization in standard diesel engines; this is why the plant oils have to be further processed. The necessary methanol for transesterification can be obtained conventionally or from renewable resources. Depending on the source, biodiesel is called RME (rapeseed methyl ester), SME (soybean methyl ester), PME (palm methyl ester), etc. all subsumed under the generic term XME. Waste cooking oil or animal fat can also be used for biodiesel production. Higher alcohols can be used as a solvent for straight vegetable oil, the mixture being named BM. BM was mixed with diesel fuel (D) to yield biomix diesel (BMD) (Savvidis and Sitnik 2010). For a review on biodiesel, see, e.g., Demirbas (2010).

A major disadvantage of 1st-generation biofuels is their lack of sustainability. They are grown on arable land, where competition with food crops drives up food prices. In 2011, the World Bank and nine other international agencies produced a report advising governments to phase out biofuel subsidies as the use of food stock for 1G fuel production was linked to increasing food prices (Price volatility in food and agricultural markets: policy responses 2007).

Crop growth requires energy-intensive fertilizers, and sometimes, rainforests or other natural pieces of land are removed to create space for farming (land use change). 1st-generation (1G) biofuels are state-of-the-art; they are available in pure form or admixed to petroleum-based fuels. They are not considered sustainable any more. 1G biofuels are out of the scope of this chapter. Lessons learned from 1G biofuels are discussed in Mohr and Raman (2013).

The Role of Microorganisms

1G and 2G biofuels are made from plants and by/with microorganisms. Animals are not useful, since they are on a higher trophic state. However, microorganisms can be deployed for biofuel production in two ways:

1. Conversion of energetic compounds into biofuels (e.g., sugar to ethanol): 2G
2. Production of energetic compounds from sunlight (e.g., by algae): 3G

These two concepts are shown schematically in Fig. 5 below.

Leaving thermal methods aside, both 2G and 3G biofuels rely on microorganisms to convert the carbon feedstock into the desired hydrocarbon biofuels (Ruffing). Microorganisms can produce various biofuels, such as alcohols, hydrogen, biodiesel, and biogas, from multiple starting materials (Elshahed 2010). It is expected that microbially produced biofuels will eventually replace petroleum-based fuels as well as today's first-generation and second-generation biofuels (Singh et al. 2011). They are called "3rd-generation biofuels" in this chapter. Also for 2G biofuels, microorganisms (or their enzymes) are used. 2G biofuels focus on lignocellulosic material, which is challenging to break up into fermentable sugars (Faraco 2013). These 2G technologies utilize the full plant, for instance, dedicated energy crops. Lignocellulose, which forms the major part of plants, is composed of lignin, hemicellulose, and cellulose. In order to produce smaller fragment of these molecules, thermal methods or enzymatic methods have been proposed (Faraco 2013). Pretreatment and subsequent enzymatic hydrolysis are applied to produce fermentable sugars (saccharification). Fungi were also studied for the pretreatment of lignocellulose (see Table 1).

In Philbrook et al. (2013), different end products obtained from bacterial treatment of lignocellulose are presented.

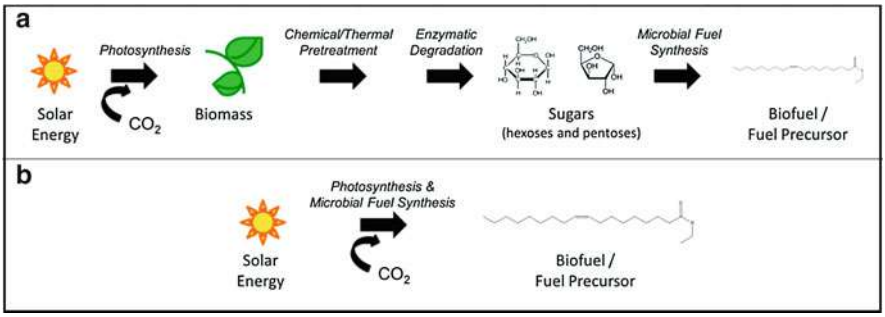

Fig. 5 Process steps for (**a**) 2G (biomass like lignocellulosic feedstock) and (**b**) 3G (i.e., inorganic carbon feedstock) biofuels (Source: Ruffing)

Table 1 Fungal strains studied for pretreatment of lignocellulosic biomass

Substrate	Species	Findings	Duration (days)
Bamboo	*Echinodontium taxodii*	29 % reduction in lignin	30
Bamboo	*Coriolus versicolor*	Enhanced saccharification rate of 37 %	2
Residues			
Bamboo	*Echinodontium taxodii*	5.15-fold increase in sugar yields	120

Table 2 1.5G biofuels are made from nonfood sugar/starch/oil crops

Fuel type[a]	Main product	Main feedstock	Status
1.0G biofuel	**Grain-based** ethanol	Corn, wheat	Industrialized (2004–)
	Waste oil-based diesel	Waste cooking oil	Industrialized (2006–)
1.5G biofuel	**Non-grain,** but sugar- or starch-based ethanol	**Cassava, sweet sorghum**	Industrialized (2008–)
	Nonedible oil-based biodiesel/ bio-jet fuel	Jatropha	Demonstration (2010–)
2.0G biofuel	**Cellulosic** ethanol	**Corn cob** Corn stalk	Demonstration (2010–); three scaled up (2013)
	BtL	Agricultural residue	Research stage

Source: (Kang 2014)
[a]It is not a standard but a conventional way to define biofuel types, 1.5 generation biofuels are produced by using nonfood sugar/starch/oil crops, to separate from the first-generation food-based fuels

The literature also describes "1.5G" biofuels, which are somewhere between 1G and 2G in terms of sustainability (see Table 2 for an example from China).

As Table 2 shows, Kang (2014) sees 1.0G biofuels as grain based and 2.0G biofuels as cellulose based. 1.5G biofuels are non-grain based, but still rely on sugar or starch, e.g., cassava or sweet sorghum in the case of bioethanol and nonedible oil (e.g., *Jatropha*) in the case of biodiesel. 3G biofuels are based on oleaginous material derived from microorganisms (algae, yeasts, bacteria). These can grow heterotrophically on organic waste/organic feedstock (e.g., sugar) or phototrophically, i.e., using only CO_2, sunlight, and nutrients. Photoautotrophic growth is considered the best mode, as sunlight is being used directly, whereas efficiency losses are encountered in case that energetic C-compounds such as sugars have to be produced first and are then fed to the microorganisms. Algae could be 200 times more productive per unit area than a land-based crop (http://www.cbd.int/doc/publications/cbd-ts-65-en.pdf. Accessed 4 May 2015).

Also, "4th-generation biofuels" (4G) are discussed in the literature (Lü et al. 2011), with varying definitions. 4G biofuels should be "carbon negative," e.g., by including CCS (carbon capture and storage). They are also based on microorganisms and seen as more "advanced" in terms of sustainability and yield than 2 and 3G biofuels, yet far from commercialization. Also, concepts for 4G biofuels are vague. 2G and 3G biofuels are where current research is focusing on.

Impact of Biofuels

When replacing fossil fuels by biofuels, one has to consider several dimensions of, e.g., farming, processing, and use of biofuels. The impact of biofuels is conceptualized in Fig. 6 below.

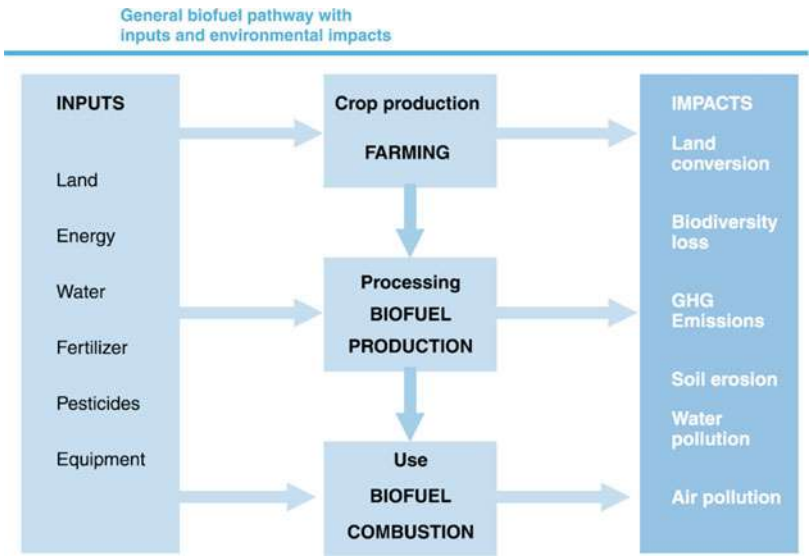

Fig. 6 Pathway to biofuels with inputs and environmental impact (Source: http://www.unep.org/pdf/Assessing_Biofuels-full_report-Web.pdf. Accessed 4 May 2015)

For instance, for crop production, land is needed, and land use change (LUC) can negatively affect the climate (Panichelli and Gnansounou 2015), as the N_2O emissions from fertilizer production and use (Crutzen et al. 2008). Air pollution from biofuel combustion, e.g., SO_x, NO_x, and dust, has to be taken into account as well (Lackner et al. 2013). Note: Apart from combustion, certain biofuels, after purification, can be used in **fuel cells**. Another aspect is water consumption (see the concept of virtual water). A valuable tool is life cycle assessment (LCA) or life cycle impact assessment (LCIA). Figure 7 below compares several biofuels in terms of GWP (greenhouse warming potential), smog formation, and eutrophication (i.e., excessive fertilizer usage).

It has to be noted that the different biofuels have not yet reached their maximum sustainability potential, as sometimes the technologies are not mature yet or economies of scale are missing. Nonetheless, a good indication can be derived, showing, e.g., that methane from manure has a high GWP reduction potential.

Growth Conditions of Microorganisms

Microorganisms are single-cell or multicell, microscopic living organisms. They include all bacteria and archaea and almost all protozoa, some fungi, algae, and certain animals, e.g., rotifers. Within this chapter, we focus on bacteria and algae.

Microorganisms have developed different strategies to obtain energy and carbon. Table 3 shows these growth conditions:

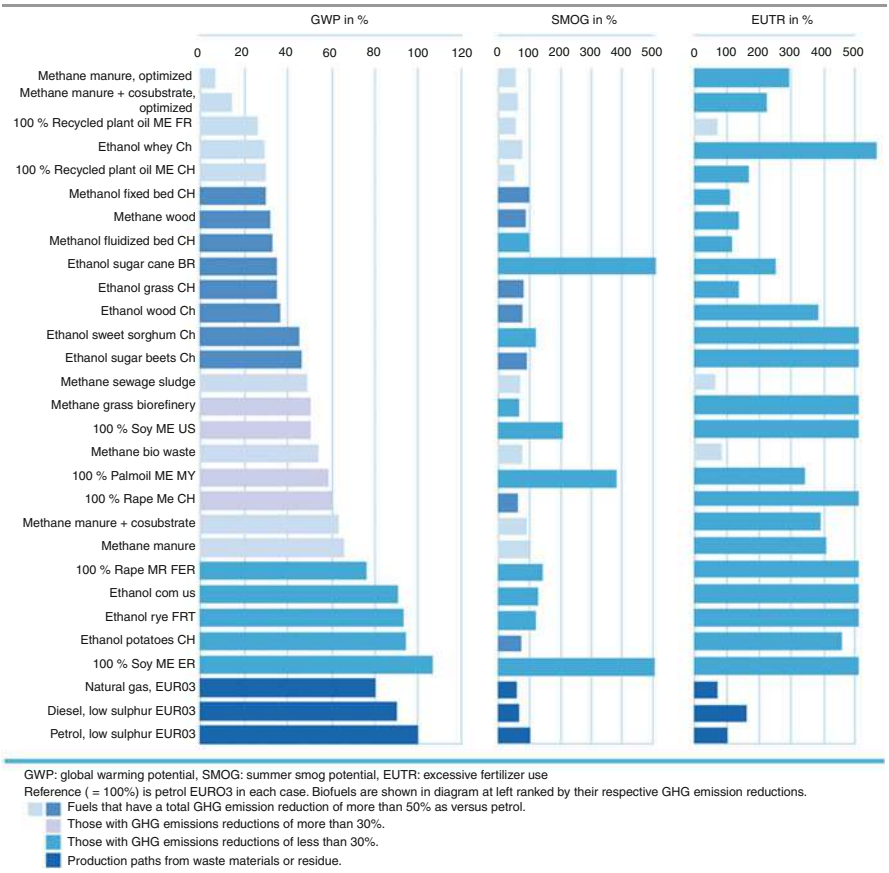

Fig. 7 Comparison of various biofuels in terms of global warming potential (*GWP*), smog and eutrophication (Source: http://www.unep.org/pdf/Assessing_Biofuels-full_report-Web.pdf. Accessed 4 May 2015)

The most common heterotrophic hosts for biofuel production are *Escherichia coli* (bacteria from the lower intestine of warm-blooded organisms, fecal indicator bacteria (Koschelnik et al. 2014)) and *Saccharomyces cerevisiae* (yeast for baking and brewing) (Gendy and El-Temtamy 2013). Advantages of these "model organisms" are the following:

- Fast growth rates
- Well-known genetics and regulation
- Availability of advanced molecular tools for genetic engineering
- Established use in the industrial setting (Gendy and El-Temtamy 2013)

Neither *E. coli* nor *S. cerevisiae* naturally produce hydrocarbon fuels, so metabolic engineering techniques (see further below in this chapter) are needed to express their production. For a discussion of genetically modified algae for biofuel production, see, e.g., Gendy and El-Temtamy (2013).

Table 3 Microorganisms can draw their energy from sunlight or organic compounds, or both. For details, see, e.g., (Cuellar-Bermudez et al. in press)

Mode	Description	Example
Photoautotrophic	Light is used as a sole energy source (autotrophic photosynthesis). CO_2 is converted into energetic compounds through photosynthetic reactions	Algae, e.g., microalgae, cyanobacteria
Heterotrophic	Only organic compounds are used as carbon and energy source (e.g., glucose, acetate, glycerol)	*Escherichia coli* and *Saccharomyces cerevisiae* (yeast)
Mixotrophic (bitroph)	Organisms may employ mixotrophy obligately or facultatively: Energy is derived from different modes. Combinations are photo- and chemotrophy, litho- and organotrophy, auto- and heterotrophy	Euglena
Photoheterotrophic	These organisms have a metabolism in which light is needed to use organic compounds as carbon source. The phenomenon is also known as photoorganotrophic, photoassimilation, or photometabolism	Purple non-sulfur bacteria, green non-sulfur bacteria, heliobacteria
Chemotrophic	Organisms that oxidize inorganic (chemolithotrophic) or organic (chemoorganotrophic) compounds as their principal energy source. Chemotrophs can be either autotrophic or heterotrophic	Bacteria in "black smokers" that feed on H_2S, iron- and manganese-oxidizing bacteria

Growth of Microalgae and Cyanobacteria

"Algae" encompass microalgae, cyanobacteria (the so-called blue-green algae), and macroalgae (or seaweed). Under certain conditions, some microalgae have the potential to accumulate significant amounts of lipids (more than 50 % of their ash-free cell dry weight) (http://www1.eere.energy.gov/bioenergy/pdfs/algal_biofuels_roadmap.pdf. Accessed 4 May 2015).

Microalgae (also called **microphytes**) are microscopic algae. Unicellular in nature, they exist individually, in chains and in groups, with sizes between 1 and several 100 μm. In contrast to higher plants, microalgae lack roots, stems, and leaves. They can be grown photoautotrophically, converting CO_2 into energetic compounds using sunlight.

Cyanobacteria is a phylum[1] of bacteria that obtain their energy by photosynthesis. Their name stems from the color of the bacteria, which are often called

[1] A taxonomic rank below kingdom and above class in biology.

blue-green algae. Cyanobacteria are no "true" algae, since cyanobacteria are prokaryotic and algae are eukaryotic cells.

Why Algae?

The biofuel yield varies geographically, with regions that provide optimum growth conditions having advantageous productivities. Also, the chosen type of crop plays an important role (see Table 4).

Using soybeans, 73 % of the global land area (!) would be needed to cover the global oil demand, whereas with algae, the space is significantly less, an estimated 0.3–2.7 % (Ullah et al. 2014). Considerations which make microalgae attractive for 3G biofuel production are the following:

1. High productivity per km^2
2. Nonfood-based feedstock resources
3. Use of otherwise nonproductive, nonarable land
4. Utilization of a wide variety of water sources (fresh, brackish, saline, marine, wastewater)
5. Production of both biofuels and valuable coproducts
6. Potential recycling of CO_2 and other nutrient waste streams (http://www1.eere.energy.gov/bioenergy/pdfs/algal_biofuels_roadmap.pdf. Accessed 4 May 2015.

The US DOE-supported Aquatic Species Program (ASP, 1978–1996) illustrated the potential of algae as biofuel feedstock.

Table 4 Comparison of crop-dependent biodiesel production efficiencies from plant oils. *TAGs* triacylglycerols (triglycerides). For the algae, two scenarios are shown

Plant source	Biodiesel L/ha/year	Area to produce global oil demand (10^6 ha)	Area required as % of global land mass	Area as % of arable land mass
Cotton	325	15,002	100.7	756.9
Soybean	446	10,932	73.4	551.6
Mustard seed	572	8,524	57.2	430.1
Sunflower	952	5,121	34.4	258.4
Rapeseed	1,190	4,097	27.5	206.7
Jatropha	1,892	2,577	17.3	130
Oil palm	5,950	819	5.5	41.3
Algae (10 g^{-2} day^{-1} at 30 % TAG)	12,000	406	2.7	20.5
Algae (50 g^{-2} day^{-1} at 50 % TAG)	98,500	49	0.3	2.5

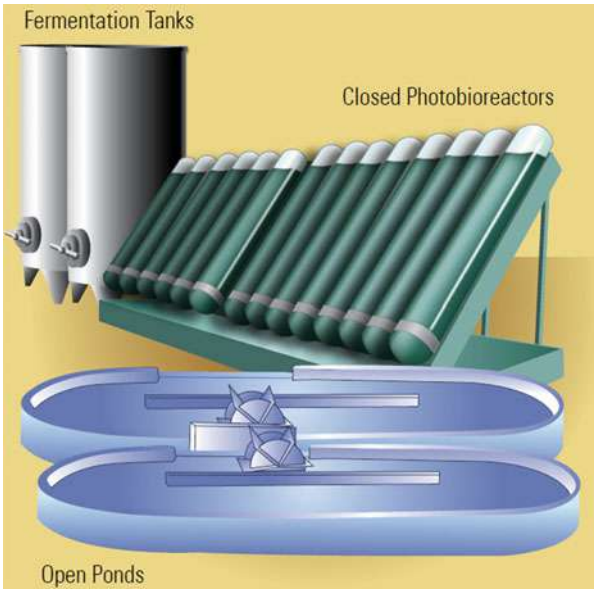

Fig. 8 Typical reactors to grow microalgae (Source: http://www1.eere.energy.gov/bioenergy/pdfs/algal_biofuels_roadmap.pdf. Accessed 4 May 2015)

In the ASP, over 3,000 species of microalgae from a diverse range of environmental habitats were isolated and screened. The focus of the program was on eukaryotic algae, as they naturally produce significant amounts of TAG (Ruffing).

Algae fuel, also called **oilgae**, is made from triglycerides (algal oil) within the algae. It is converted into biodiesel. The processing technology is essentially the same as that for biodiesel from 2G feedstocks (http://www.unep.org/pdf/Assessing_Biofuels-full_report-Web.pdf. Accessed 4 May 2015). Algae can also be fermented anaerobically to yield biogas, which eliminates the need for biomass drying.

Whereas chemotrophic organisms are cultured in fermenters, phototrophic ones have to be exposed to sunlight to harvest energy. This is achieved in various embodiments, the most common ones being open ponds (e.g., raceway ponds) and photobioreactors (PBRs). Figure 8 shows a figure of typical raceway ponds and PBRs.

Fermentation tanks and closed photobioreactors need to be fed with CO_2. Open ponds can take up CO_2 from the atmosphere. CO_2 fertilization will increase the yield, though. As light source, laboratory-scale photobioreactors often use artificial installations such as LED arrays, whereas large installations need to rely on sunlight. Energy efficiencies of the reactors shown in Fig. 8 above will be discussed in more details later.

In Table 5, the two systems “open raceway pond” and “photobioreactor” are compared.

In Table 6 below, the various cultivation approaches for microalgae are shown.

In heterotrophic cultivation, algae are grown without light and are fed a carbon source, such as sugars, to produce new, higher-value biomass. This approach

Table 5 Comparison between microalgae production in open and closed bioreactors

Factor	Open systems (raceway ponds)	Closed systems (photobioreactors)
Space required	High	Low
Area/volume ratio	Low (5–10 m^{-1})	High (20–200 m^{-1})
Evaporation	High	No evaporation
Water loss	Very high	Low
CO_2 loss	High	Low
Temperature	Highly variable	Required cooling
Weather dependence	High	Low
Process control	Difficult	Easy
Shear	Low	High
Cleaning	None	Required
Algal species	Restricted	Flexible
Biomass quality	Variable	Reproducible
Population density	Low	High
Harvesting efficiency	Low	High
Harvesting cost	High	Lower
Light utilization efficiency	Poor	Good
Most costly parameters	Mixing	Oxygen and temperature control
Contamination control	Difficult	Easy
Capital investments	Low	High
Productivity	Low	3–5 times more productive
Hydrodynamic stress on algae	Very low	Low–high
Gas transfer control	Low	High

Source: (Cuellar-Bermudez et al. in press)

capitalizes upon mature industrial fermentation technology (http://www1.eere.energy.gov/bioenergy/pdfs/algal_biofuels_roadmap.pdf. Accessed 4 May 2015).

Production cost is expected to be significantly lower in open ponds; however, PBRs are needed when pure cultures are to be grown. Open ponds are only suitable for extremophile organisms, such as halophiles, since else the pond would very fast become populated by other invading microorganisms. For "grazing" by ciliates, amoeba, rotifers, and other zooplankton taxa, see, e.g., Day et al. (2012).

In Table 7 below, the productivity of several microalgae species is shown, depending on growth scenarios.

3G biofuels based on algae and cyanobacteria are not yet commercially available yet. Today's plants producing microalgae focus on high-value products such as omega 3 fatty acids. Scale-up (Rogers et al. 2014) and downstream processing (algae harvesting and dewatering (http://www1.eere.energy.gov/bioenergy/pdfs/algal_biofuels_roadmap.pdf. Accessed 4 May 2015)) are major challenges that still need to be overcome.

Figures 9 and 10 below show simplified flowcharts on the two basic options of converting algae to biofuels: Using the entire organism or the extracted oil.

Table 6 Comparative features of microalgal cultivation approaches

		Advantages	Challenges
Photoautotrophic cultivation	Closed photobioreactors	Less loss of water than open ponds Superior long-term culture maintenance Higher surface to volume ratio can support higher volumetric cell densities	Scalability problems Require temperature maintenance as they do not have evaporative cooling May require periodic cleaning due to biofilm formation Need maximum light exposure
	Open ponds	Evaporative cooling maintains temperature Lower capital costs	Subject to daily and seasonal changes in temperature and humidity Inherently difficult to maintain monocultures Need maximum light exposure
Heterotrophic cultivation		Easier to maintain optimal conditions for production and contamination prevention Opportunity to utilize inexpensive lignocellulosic sugars for growth Achieves high biomass concentrations	Cost and availability of suitable feedstocks such as lignocellulosic sugars Competes for feedstocks with other biofuel technologies

Source: (http://www1.eere.energy.gov/bioenergy/pdfs/algal_biofuels_roadmap.pdf. Accessed 4 May 2015)

Table 7 Comparison of the growth characteristics and CO_2 fixation performance of microalgae strains under different CO_2 concentrations, temperature, and NO_x/SO_x contents. *N.S.* not specified

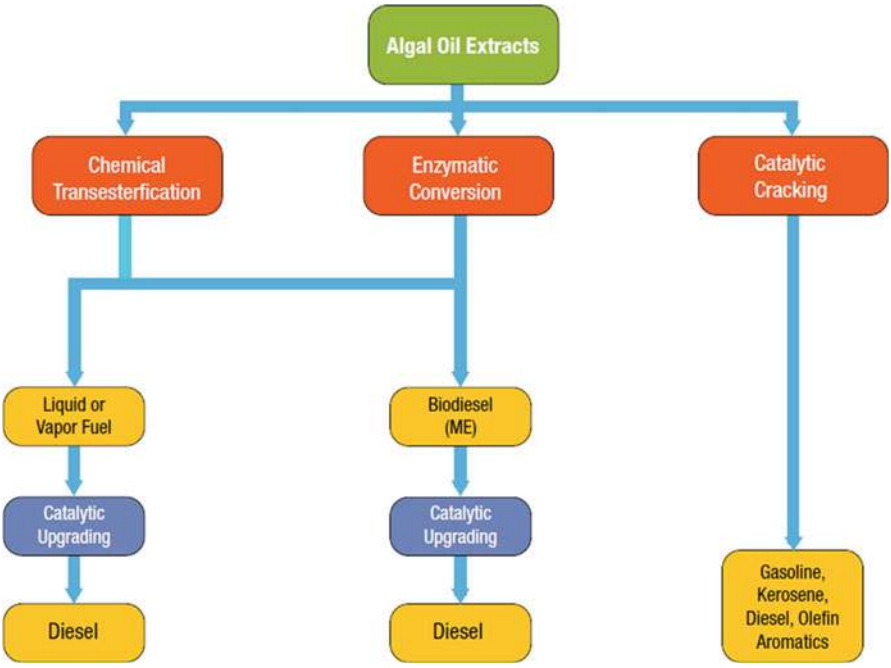

Fig. 10 Schematic of the various conversion strategies of algal extracts into biofuels (Source: http://www1.eere.energy.gov/bioenergy/pdfs/algal_biofuels_roadmap.pdf. Accessed 4 May 2015)

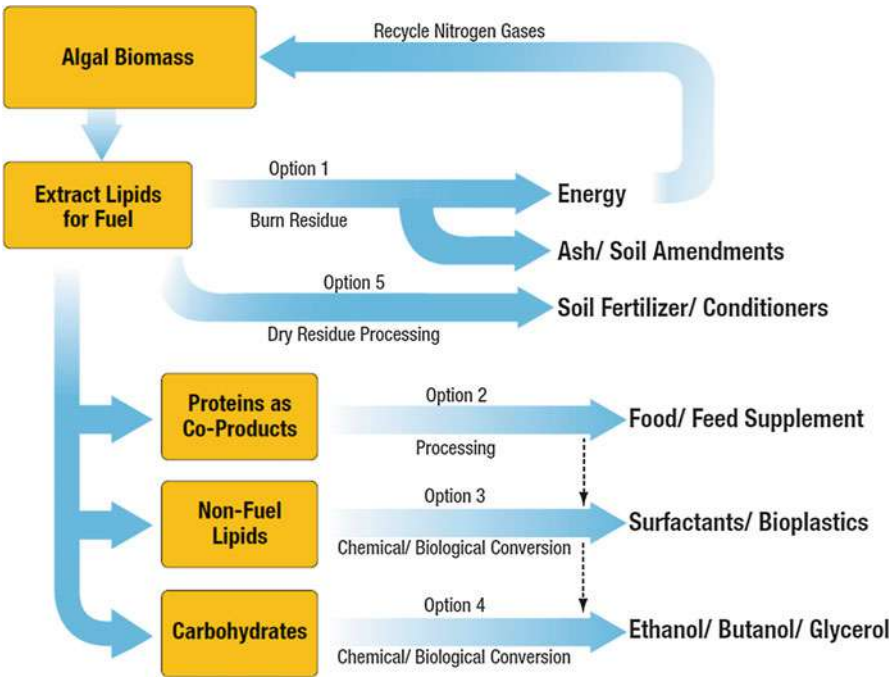

Fig. 11 Overview of the five potential options for the recovery and use of coproducts (Source: http://www1.eere.energy.gov/bioenergy/pdfs/algal_biofuels_roadmap.pdf. Accessed 4 May 2015)

The algae slurry can be anaerobically digested to biogas. Also, thermal methods such as pyrolysis and gasification are available.

The algae oil can be processed to biodiesel through transesterification. For an integrated, cost-optimized production of algae oil, the coproducts need to be utilized, too, which is depicted in terms of available options in Fig. 11 below.

Five concepts to recover and use coproducts have been devised:

Option 1: Combustion for maximum energy recovery from the leftovers of lipid extraction and use of the ash to fertilize and improve soil

Option 2: Production of food and feed supplements by recovering protein from the residues

Option 3: Recovery and utilization of nonfuel lipids and chemicals, e.g., for surfactants and bioplastics

Option 4: Recovery and utilization of carbohydrates in the algae residues and use in fermentation processes

Option 5: After extraction of (only) fuel lipids: use of the residue as soil fertilizer and conditioner (http://www1.eere.energy.gov/bioenergy/pdfs/algal_biofuels_roadmap.pdf. Accessed 4 May 2015.

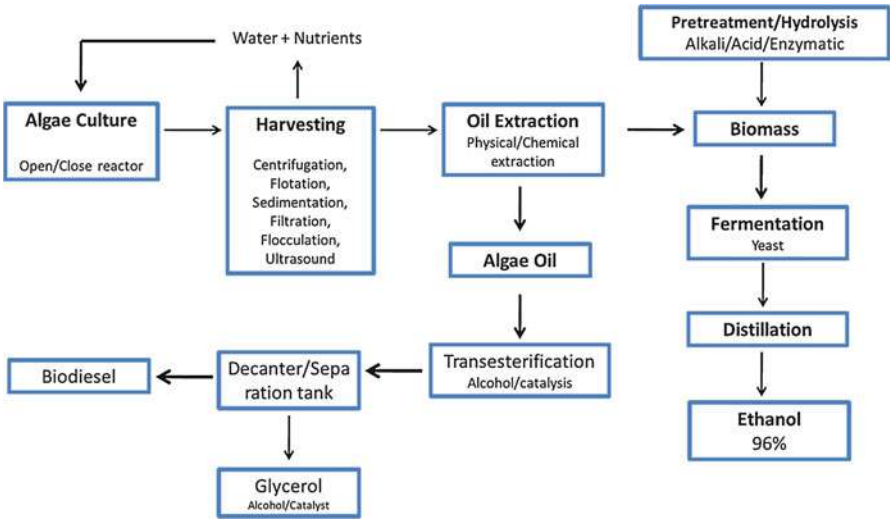

Fig. 12 Algae biofuels production approach. Biodiesel and bioethanol can be obtained from microalgal biomass, with glycerol as by-product (Source: Cuellar-Bermudez et al. in press)

In Kleinová et al. (2012), FAMEs prepared from algae oil TAG (*Nannochloropsis* and *Chlorella* microalgae) were found to meet the requirements of biodiesel standard EN 14 214. However, it was concluded that FAME from algae oil might show less oxidative stability due to higher level of unsaturation (Kleinová et al. 2012).

A simplified process flow diagram of how to obtain biodiesel and bioethanol from algae is shown below in Fig. 12.

Cyanobacteria

Cyanobacteria grow fast, do not need arable land, can use CO_2, and show genetic tractability; hence, they have a strong potential as a platform for biofuel production. They have been engineered to produce various biofuels and biofuel-related compounds, e.g., ethanol and lipids. Challenges for advancing cyanobacterial fuel production are improving genetic parts, carbon fixation, metabolic flux, nutrient requirements on a large scale, and photosynthetic efficiency using natural light (see Fig. 13).

Nozzi et al. (2013) writes: *"... despite years of research, eukaryotic algae have yet to realize their industrial potential andsynthetic biologytechniques for eukaryotic systems remain elusive ... Cyanobacteria, prokaryoticorganisms, combine of the advantages of both eukaryotic algae, as a photosynthetic microorganism, and E. coli, as a tractable and naturally transformable host."*

For more information on cyanobacteria for biofuel production, see, e.g., Nozzi et al. (2013), Parmar et al. (2011), Lu (2010), Savakis and Hellingwerf (2015),

Assessment of Biofuels

Energy Return Ratios (ERRs)

In order to compare the efficiencies of energy extraction and conversion systems, net energy analysis (NEA) is carried out, yielding energy return ratios (ERRs) such as the net energy ratio (NER) or energy return(ed) on investment (EROI) that are used (Brandt and Dale 2011). Key energy metrics are shown in Table 8 below.

NEB (net energy balance) is the difference between the total energy in the biofuel (and its coproducts) and the total primary energy necessary to produce it. A positive net energy balance is needed for sustainability. EROI and NER >1 correspond to a positive energy balance. FER and BF_{en} are variants, which refer the energy output to the amount of fossil or renewable energy input, respectively.

Table 9 below shows some energy ratios for common 1G and 2G biofuels relative to gasoline.

The comparison of NER of microalgae biomass production in raceway ponds and photobioreactors in a metastudy (Slade and Bauen 2013) has revealed strong differences (see Fig. 14 below).

Table 8 Key energy metrics

Name	Abbreviation	Formal definition
Net energy balance	NEB	$\sum \text{Energy}_{\text{output}} - \sum \text{Energy}_{\text{input}}$
Energy return on investment	EROI	$\frac{\sum \text{Energy Output}}{\sum \text{Energy Input}}$
Net energy ratio	NER	$\frac{\sum \text{Energy Output}}{\sum \text{Energy Input}}$
Fossil energy ratio	FER	$\frac{\sum \text{Energy Output}}{\sum \text{Fossil Energy Input}}$
Energy breeding factor	BF_{en}	$\frac{\sum \text{Energy Output}}{\sum \text{Nonrenewable Energy Input}}$

Source: (Gupta and Tuohy 2013)

Table 9 Energy ratios for gasoline and some first- and second-generation biofuels

	Overall energy ratio (OER)	Fossil energy ratio (FER)	Petroleum energy ratio (PER)
	Liquid fuel output	*Liquid fuel output*	*Liquid fuel output*
Liquid fuel	*Fossil + biomass input*	*Fossil input*	*Petroleum input*
Gasoline (USA)	0.81	0.81	0.91
Corn ethanol (USA)	0.57	1.4	5.0
Soy biodiesel (USA)	0.45	3.2	Not available
Cellulosic ethanol (USA)	0.45	5.0	5.0
Sugarcane ethanol (Brazil)	0.30	10	10

Source: (http://unctad.org/en/docs/ditcted200710_en.pdf. Accessed 4 May 2015)

NER is defined here as the sum of the energy used for cultivation, harvesting, and drying, divided by the energy content of the dry biomass. As it can be inferred from Fig. 14, six out of the eight reported raceway pond concepts have a NER <1, whereas the NER of all PBR was found to be >1. Likewise, this study has assessed the carbon emissions, expressed in CO_{2eq}, for different microalgae growth concepts (see Fig. 15 below).

In this study, the GHG emissions associated with algal biomass production were estimated by multiplying the external energy inputs (e.g., electricity for pumps, heat energy for drying) by the default emissions factors described in the EU renewable energy directive (RED) 2009/28/EC (European Union 2009). One can see that, based on today's growth technologies, the CO_{2eq} emissions associated with algal biomass production in raceway ponds are on the same level as emissions from the cultivation and production of RME (biodiesel). By contrast, production of microalgae in PBR yields emissions that are greater than those of conventional fossil diesel.

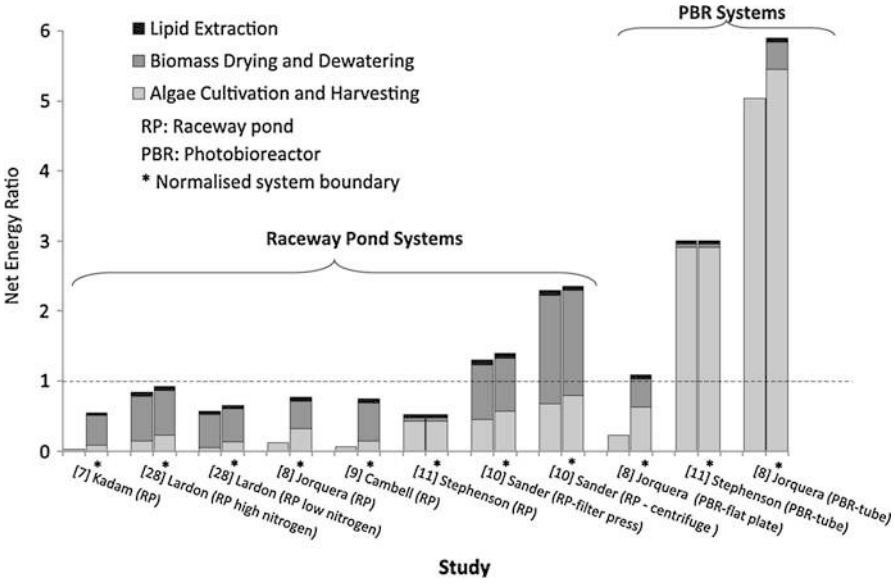

Fig. 14 Net energy ratio for microalgae biomass production: comparison of published values with normalized values (for direct comparison) (Source: Slade and Bauen 2013)

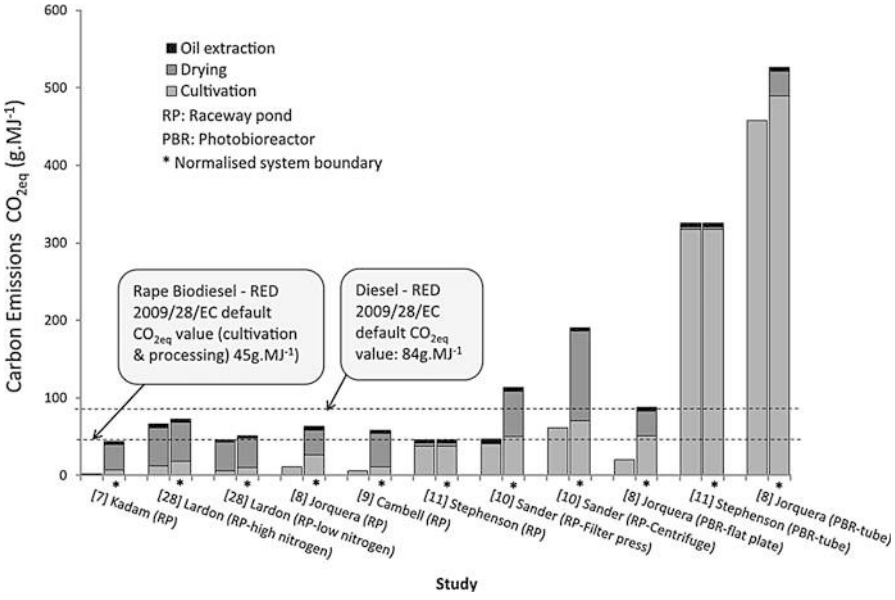

Fig. 15 Estimates for CO_2 emissions from algal biomass production in raceway ponds (The default emissions factors used to estimate carbon dioxide emissions were 83.80 g MJ/l (diesel), 91 g MJ/l (electricity), and 77 g MJ/l (heat). The emissions factor for the embodied energy in fertilizer and for production of PVC lining (in the case of raceway ponds) and PBR was assumed to be the same as for heat. Normalized system boundaries allow direct comparison of the original data (Source: Slade and Bauen 2013))

Biorefinery Concept

Petrochemical refineries are highly integrated, where the entire crude oil is being used. Cracking and other processes are used to shift the fractions of final product from fractionated distillation to the usage patterns. The biorefinery concept builds upon the same idea, where "green crude" (e.g., algae slurry) is processed into several products, high-value and low-value ones. A schematic concept is depicted below in Fig. 16.

For details on biorefineries, see, e.g., Kamm et al. (2010) and Fang (2013).

Gasoline Alternatives

In 2012, global petroleum consumption was estimated at 89 million barrels per day, and nearly half of it was for producing gasoline. Our energy demand is projected to increase by more than 50 % over the next 10 years (Arifin et al. 2014). It is estimated that in 2010, the number of 1 billion vehicles was surpassed. Today, an estimated 1.2 billion vehicles populate the world's roads, and by 2035, it will be 2 billion (Voelcker 2014). Most of them run on gasoline. The most common bio-based gasoline alternative is ethanol. Apart from ethanol, several alternative fuels can be used to replace petroleum-based gasoline and diesel; they are briefly described below (see also Table 10).

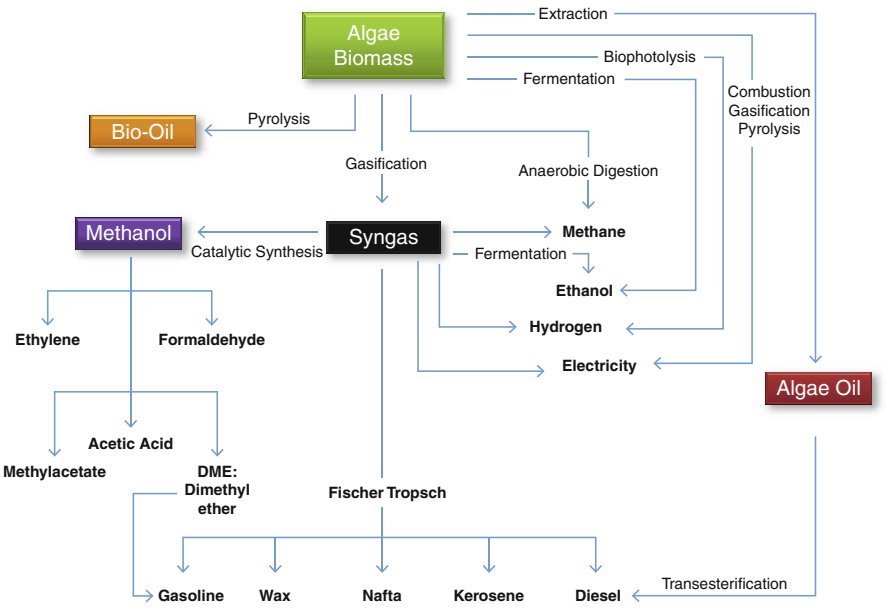

Fig. 16 Algae biorefinery concept (Source: Cuellar-Bermudez et al. in press)

Table 10 Fuel and physicochemical characteristics of petroleum-derived fuels and their potential substitutes

Sources: Akhtar et al. (2015), with [a]Linstrom and Mallard (2015), [b]Harnisch et al. (2013), [c]Weinebeck and Murrenhoff (2013), [d]Viswanath et al. (2007), [e]Peralta-Yahya et al. (2011), [f]NREL (2009), [g]Louis and Arkoudeas (2012)

Production of these alternative fuels is possible from petrochemical and renewable resources; processes can be thermal (e.g., pyrolysis and gasification with subsequent Fischer–Tropsch synthesis: BTL, biomass to liquid or, alternatively, e.g., RTP, rapid thermal processing) or enzymatic (carried out in fermenters either with enzymes or with microorganisms).

Bioethanol

Ethanol can be obtained from various carbohydrates. Starch and sugar fermentation are used industrially (1G biofuels). Ethanol production via fermentation using glycerol as carbon source was carried out ethanologenic *Escherichia coli* bacterial (Adnan et al. 2014). This process is interesting, since glycerol is a by-product of biodiesel production. Bioethanol is widely used as renewable fuel, e.g., in Brazil. Disadvantages are its lower energy density compared to gasoline and its hygroscopic nature.

BioMTBE, BioETBE

The oxygenate additives MTBE (methyl tertiary-butyl ether) and ETBE (ethyl tertiary-butyl ether) can be added to gasoline in order to increase the octane rating, improve combustion efficiency, and reduce knocking. Both additives can also be made from renewable resources. Note that MTBE is banned in several states of the USA due to possible contamination of groundwater (What is MTBE? 2015). The reason for MTBE's contamination potential is its water solubility, which makes it more mobile than other gasoline constituents.

Biomethanol

Methanol is an attractive fuel; it can be burnt or be used in fuel cells. Conversion into higher hydrocarbons is also feasible (Olah et al. 2006). Using catalysts, methane can be chemically oxidized to methanol (Fei et al. 2014). It can also be made from glycerol (BioMCN produces biomethanol from by-product glycerol 2008). Renewably produced methanol can also be used for the production of biodiesel (transesterification) and dimethyl ether (DME). For the biochemical production of bioalcohols, see also Minteer (2011).

Biobutanol

Butanol (C_4H_{10}) is comparable to gasoline in its properties (Arifin et al. 2014). It is less corrosive than ethanol and not hygroscopic. Due to its lower heat of vaporization, butanol-fuelled cars are easier to start during cold weather than ones running on ethanol.

Butanol can be mixed with gasoline in any ratio, so the existing infrastructure such as pipelines and storage facilities can be used. Butanol can be obtained petrochemically. Also, it is accessible through carbohydrate fermentation by *Clostridium acetobutylicum* in a process known as acetone–butanol–ethanol (ABE) fermentation with a product ratio of 3:6:1 (Arifin et al. 2014; Gupta and Tuohy 2013).

Bio-Propanol

Propanol can be burnt in engines (Gong et al. 2015) and fuel cells (Markiewicz and Bergens 2010). It can be obtained via metabolically engineered microorganisms from lignocellulose (Deng and Fong 2011), glucose, or glycerol (Choi et al. 2012).

Biodiesel

Diesel is used in heavy engines (trucks, ships, locomotives, construction machinery). Kerosene, which is chemically similar to diesel fuel, is deployed for aircraft propulsion in jet turbines. Table 11 below compares conventional diesel ("summer diesel," according to the standard EN 590) to three bio-based diesel substitutes, HVO (hydrotreated vegetable oil), GTL (gas to liquid) fuel, and FAME (fatty acid methyl ester, or common biodiesel). HVO is sometimes termed "renewable diesel fuel" or "green diesel" to distinguish it from biodiesel. One can see that the three substitutes are comparable in properties.

Table 11 Typical properties of HVO, European EN 590:2004 diesel fuel, GTL, and FAME. *HFRR* high-frequency reciprocating rig

	HVO	EN 590 (summer grade)	GTL	FAME (from rapeseed oil)
Density at 15 °C (kg/m^3)	775...785	≈835	770...785	≈885
Viscosity at 40 °C (mm^2/s)	2.5...3.5	≈3.5	3.2...4.5	≈4.5

Bio-Octanol

Another alternative fuel is 1-octanol (Akhtar et al. 2015). It is similar to diesel fuel (Akhtar et al. 2015). Traditional industrial production of octanol proceeds by the oligomerization of ethylene using triethylaluminium followed by oxidation. This route is known as the Ziegler alcohol synthesis. Production from renewable sources is feasible via microbial fermentation of organic compounds (Akhtar et al. 2015).

Bio-Jet Fuel

The global aviation industry aims to achieve carbon-neutral growth by 2020 and to cut its CO_2 emissions by 50 % relative to 2005 levels by 2050 (International Air Transport Association (IATA) 2009). Renewable jet fuel processes that are currently certified for use in commercial aviation include fuel produced from a hydroprocessed esters and fatty acids (HEFA) process (also known as hydrotreated renewable jet fuel) and biomass to liquid (BTL) via a Fischer–Tropsch (FT) process (Winchester et al. 2013).

For details on renewable aviation fuel, see, e.g., Cremonez et al. (2015).

Gaseous Biofuels

Apart from biogas and synthesis gas (out of the scope of this chapter), biohydrogen is an attractive option.

Biohydrogen

Hydrogen is needed by the chemical industry, e.g., for ammonia production (Haber–Bosch process) and methanol production (from CO). Today, approx. 95 % of H_2 is obtained from fossil fuels (steam reforming or partial oxidation of methane, coal gasification), with electrolysis playing a less important role.

Biohydrogen is H_2 that is produced biologically by algae, bacteria, and archaea. The carbon source can preferentially be waste. One can distinguish between dark fermentation and photofermentation. There is a great potential for improving hydrogen yield by metabolic engineering, i.e., the use of GMOs (genetically modified organisms) (see also below). Algae have been proposed for biohydrogen production (http://www1.eere.energy.gov/bioenergy/pdfs/algal_biofuels_roadmap.pdf. Accessed 4 May 2015). An advantage of biohydrogen production is energy efficiency (Kao et al. 2014). For details on biohydrogen, see, e.g., Demirbas (2011).

Gas to Liquids (GTL)

Biological Conversion of Natural Gas to Liquid Fuel (Bio-GTL)

Methane, which is the main constituent of biogas and natural gas, is the most common gaseous fuel. Attempts have been made to convert it into a liquid fuel, to meet the huge demand by the transportation sector. One approach uses certain

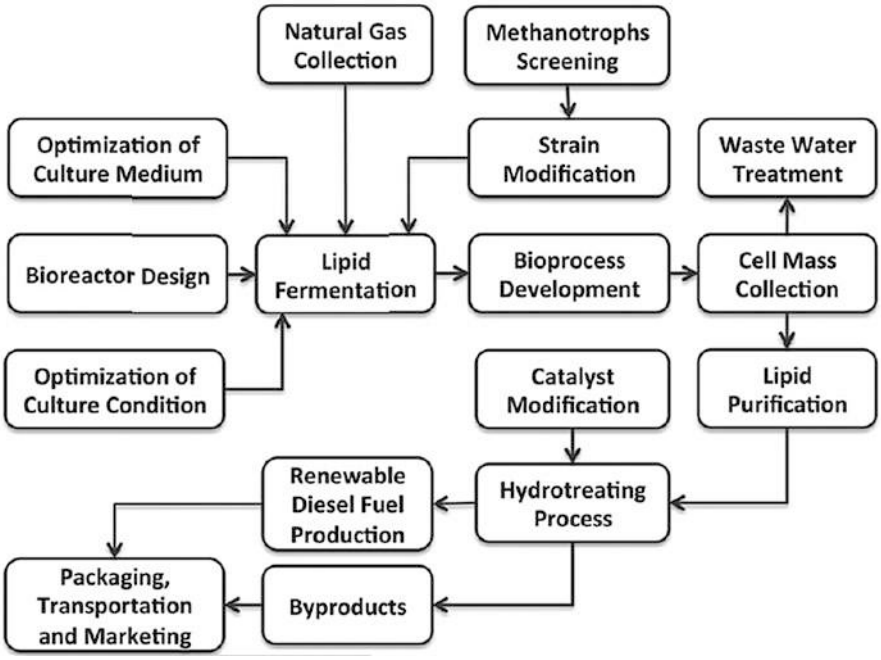

Fig. 17 Research and development map of Bio-GTL using methane as a substrate (Source: Fei et al. 2014)

bacteria, so-called **methanotrophs** (**methanophiles**). These bacteria can be grown aerobically or anaerobically, and they only feed on methane as carbon and energy source. Methanotrophs were considered for the production of vitamins, antibiotics, single-cell protein (SCP), and carboxylic acids (Fei et al. 2014). Also an important biopolymer, poly-β-hydroxybutyrate (PHB), which is a potential replacement for polypropylene (PP), can be produced by methanotrophs.

Methanotrophic bacteria are a promising concept for liquid fuel production, bypassing oil-rich crops such as rapeseed, soybean, and oil palms. A research and development roadmap for GTL with methanotrophs is shown in Fig. 17 below.

Biofuels from Biological Wastewater Treatment (BWWT) Plants

Wastewater from households or industry contains significant amounts of energetic carbon compounds. Processes in today's biological wastewater treatment (BWWT) plants are mainly based on the activated sludge process, where microorganisms oxidize organic molecules to CO_2. In municipal wastewater, lipids can represent more than 40 % of the total organic fraction, with the vast majority consisting of TAGs (triacylglycerols) (Arifin et al. 2014). Specialized oleaginous bacteria could either assimilate lipids from the wastewater or synthesize them *de novo* from other

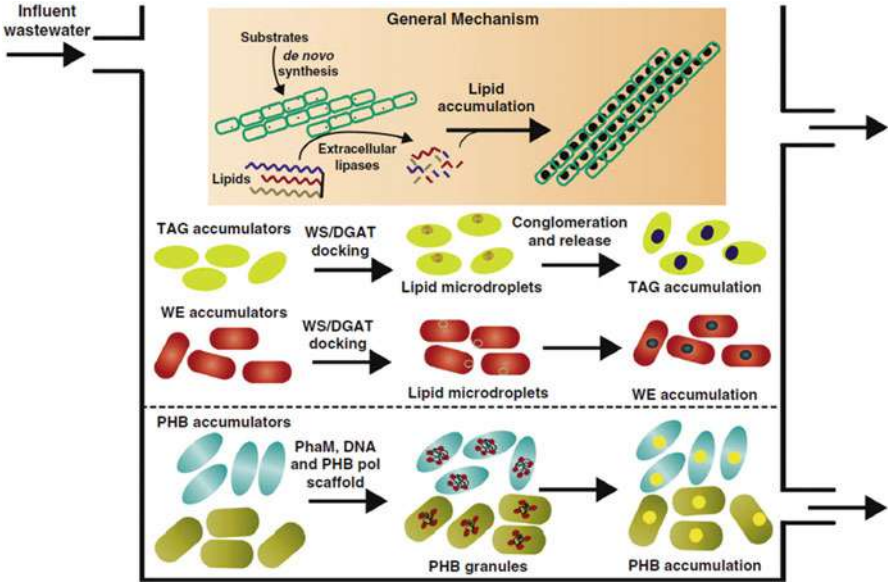

Fig. 18 Conceptual scheme of a "biorefinery column" for biofuel production from wastewater under anaerobic conditions using specifically enriched lipid accumulating bacterial populations. Abbreviations: *FAEE* fatty acid ethyl ester, *FAME* fatty acid methyl ester, *HAME* hydroxyalkanoate methyl ester, *PHB* polyhydroxybutyrate, *PHB pol* PHB polymerase, *TAG* triacylglycerol, *WE* wax ester (Source: Muller et al. 2014)

carbon sources and store them intracellularly as neutral lipids, for example, TAGs, wax esters (WEs), or polyhydroxyalkanoates (PHAs) (Arifin et al. 2014). Such a concept could be realized in a "biorefinery column" as part of a BWWT, see Fig. 18 below.

Other Technologies

Microbial Fuel Cells

A microbial fuel cell (MFC) is a device that converts chemical energy directly to electrical energy by the catalytic reaction of microorganisms (Yu et al. 2012). A configuration that derives energy directly from certain plants is known as a plant microbial fuel cell (PMFC). Potential applications for MFC lie in biosensors, bioremediation, and wastewater treatment with concurrent electricity production. **Electrohydrogenesis** can be used in microbial fuel cells.

Euglena

Euglena is a genus of single-celled flagellate protists. They live in freshwater and seawater. *Euglena* show properties like plants (photosynthesis) but also those of

animals (motion and digestion). *Euglena* were devised for jet fuel production in Japan (Alternative Jet Fuel 2015).

Archaea

Archaea are one of the three domains (kingdoms) of life, next to bacteria and eukaryota. They are single-celled microorganisms. These microbes are prokaryotes (like bacteria), meaning that they have no cell nucleus. Archaea were initially classified as bacteria, receiving the name archaebacterial. By contrast, eukaryotes are organisms whose cells contain a nucleus. Many unicellular organisms are eukaryotes, such as protozoa and algae. All multicellular organisms are eukaryotes, including animals, plants, and fungi.

Archaea could be interesting to provide special enzymes for biofuel synthesis, e.g., hyperthermophilic cellulose (Graham et al. 2011), or thermoacidophilic enzymes (Hess 2008) to break down lignocellulose.

Flue Gas Recycling

Large point sources such as power or cement plants (the latter release 8 % of anthropogenic CO_2 (Cuellar-Bermudez et al. in press)) end themselves for carbon capture and storage (CCS). For CO_2 capture from industrial sources, see, e.g., (Kuckshinrichs and Hake 2014; Romano et al. 2013). CO_2 can be captured from large point sources that burn fossil fuels, biomass can, or both. In carbon capture in processes using biomass (Bio-CCS), a negative CO_2 balance can be achieved (see Fig. 19 below).

Concepts for the integration of power plants with algae ponds are discussed in Schipper et al. (2013). For details on bio-CCS, see, e.g., Apel et al. (1994) and Zhao and Su (2014).

Metabolic Engineering

In metabolic engineering, genetic engineering is deployed to modify the metabolism of organisms. It can involve the optimization of existing biochemical pathways or the introduction of pathway components, mostly in bacteria, yeast, or plants. The goal is the high-yield production of certain metabolites (http://www.nature.com/subjects/metabolic-engineering) such as lipids for biofuel use. Anne M. Ruffing (http://cdn.intechopen.com/pdfs-wm/43693.pdf) writes: *"Metabolic engineering is a powerful tool to improve microbial fuel production, either through engineering the metabolic pathways within the native microorganism to encourage high fuel synthesis or though transferring the fuel production pathway into a model organism for optimization."*

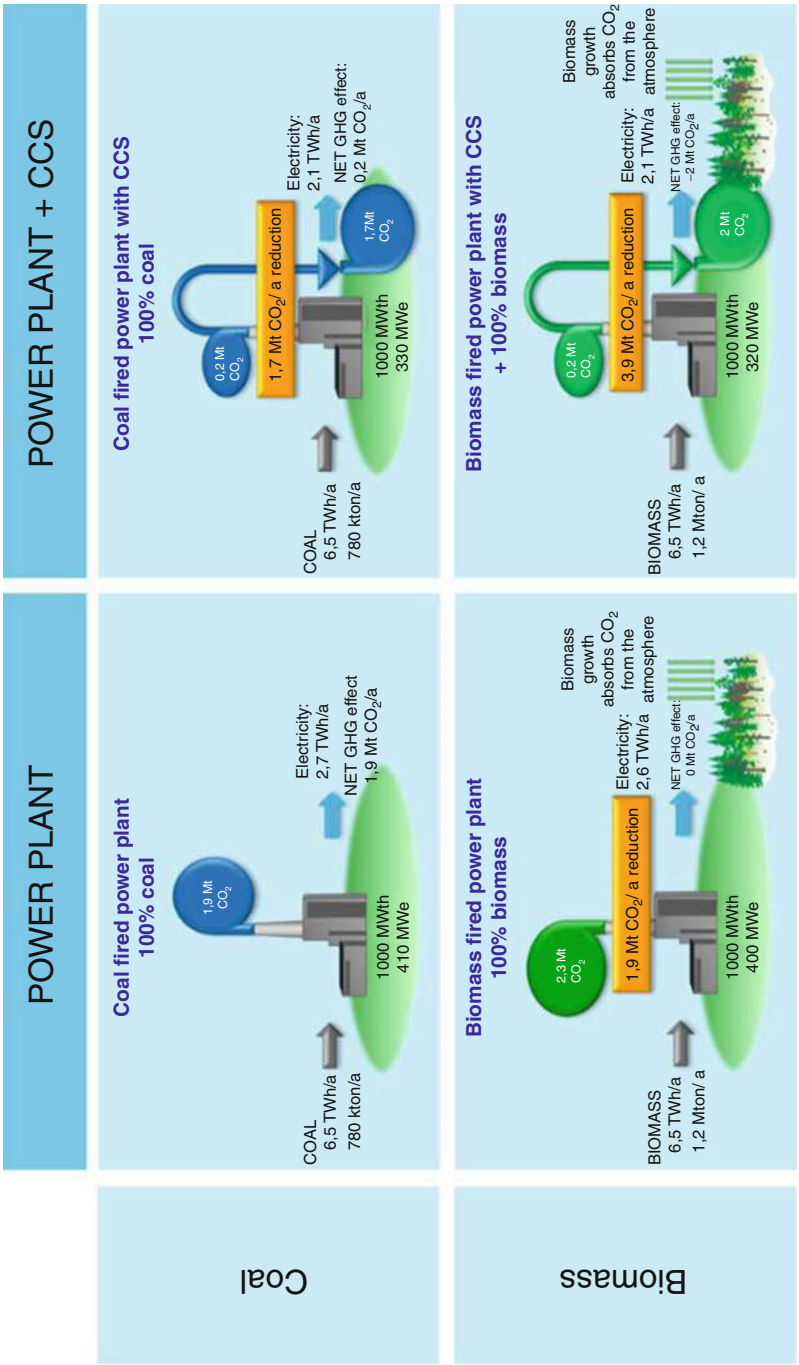

Fig. 19 Principle of carbon balance when applying Bio-CCS (Arasto et al. 2014)

Source: (Ruffing 2013)

Genetic engineering has come under criticism for foodstuff. One can argue that for biofuel production crops, the risks are lower. Table 12 provides an exemplary overview of hydrocarbons and fuel precursors by genetically modified organisms (GMOs).

2G and 3G: Development of microorganisms for cellulose-biofuel consolidated bioprocessings: metabolic engineers' tricks (Mazzoli 2012).

For a review on microbiological aspects of biofuel production, see Elshahed (2010). For details on metabolic engineering for biofuel production, see, e.g., Ruffing (2013).

The production of biofuels by **in vitro synthetic biosystems** was suggested by Zhang (2014). The concept is to achieve a high product yield, coupled with fast reaction rate, easy product separation, open process control, broad reaction condition, and tolerance to toxic substrates (Zhang 2014), as opposed to living "cell factories" of engineered microorganisms.

Enzymes from (extremophile) microorganisms for biofuel processing and production are out of the scope of this chapter.

Discussion

Biofuels are one option for renewable energy; they cannot be the only one, as Fig. 20 below suggests.

Wind energy needs less space than biomass, and renewable electricity has proven to be very efficient. Hartmut Michel writes in (http://onlinelibrary.wiley.com/doi/10.1002/anie.201200218/pdf. Accessed 4 May 2015): *"Commercially available photovoltaic cells already possess a conversion efficiency for sunlight of more than 15 %, the electric energy produced can be stored in electric batteries without major losses. This is about 150 times better than the storage of the energy from sunlight in biofuels. In addition, 80 % of the energy stored in the battery is used for the propulsion of a car by an electric engine, whereas a combustion engine uses only around 20 % of the energy of the gasoline for driving the wheels. Both facts together lead to the conclusion that the combination photovoltaic cells/electric battery/electric engine uses the available land 600 times better than the combination biomass/biofuels/combustion engine."*

The author argues that the most sensible utilization of biomass is for the generation of base chemicals for syntheses purposes. He sees the future for car propulsion

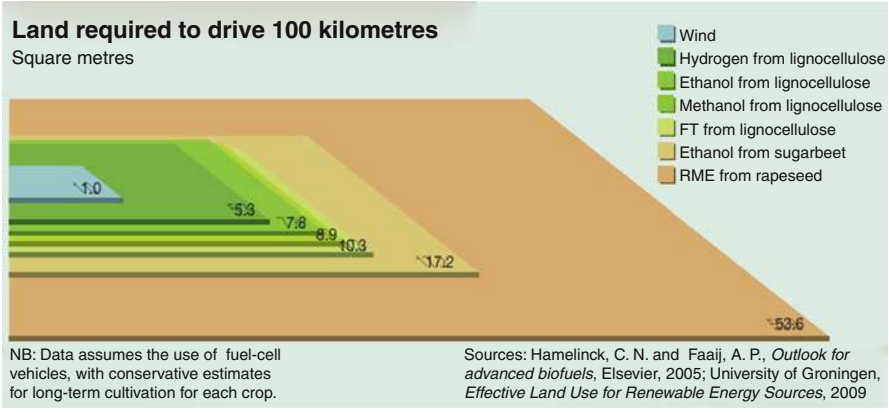

Fig. 20 Necessary land needed to generate the energy for a 100 km car trip (Source: http://www.grida.no/publications/vg/biofuels/. Accessed 4 May 2015)

in electricity. However, by replacing conventional fossil fuels with advanced biofuels in the short and medium terms, environmental benefits can be achieved.

Biofuels have their advantage in high energy densities and compatibility with existing (liquid) fuel handling systems. Hence, they are a viable option for the transportation sector, being an important "ingredient" in the mix of renewable technologies.

Conclusions

Due to rising oil prices and depleting fossil fuel reserves, interest in biofuels has increased over the last decades, with first-generation (1G) biofuels falling behind coal, oil, and gas in several performance dimensions. Advanced biofuels (2G, 3G) can contribute to sustainable transportation. Their manufacturing involves microorganisms, predominantly bacteria, yeasts, and algae. Such biofuels can replace liquid and gaseous transportation fuels. As this chapter has outlined, current challenges are the use of lignocellulosic biomass (2nd-generation biofuels), which is available abundantly, by thermal or enzymatic methods. Hopes are placed on 3rd-generation biofuels, i.e., energetic compounds obtained from microorganisms like algae or cyanobacteria from sunlight. These technologies have not yet reached commercial maturity, and metabolic engineering can support research efforts.

Outlook

Globally, biofuels now provide only 2 % of total transport fuel (http://www.cbd.int/doc/publications/cbd-ts-65-en.pdf. Accessed 4 May 2015). Most of the approx. $30*10^9$ l of biofuels that are used per year relies on 1G technologies (Ullah et al. 2014).

The IEA (International Energy Agency) predicts that biofuels will constitute approx. 27 % of the world transport fuel by 2050 (http://www.cbd.int/doc/publications/cbd-ts-65-en.pdf. Accessed 4 May 2015). In the long run, once electricity storage issues have been solved, vehicles might predominantly be powered electrically. In the meantime, replacing fossil fuels by renewable ones can help in climate change mitigation. Further research, particularly in 3G biofuel technology, is needed to bring promising concepts to commercial maturity.

Biopolymers

Maximilian Lackner

Contents

Abstract

Synthetic polymers are used extensively. Approx. 98 % of the 300 million tons of polymers manufactured each year for packaging, construction, appliances, and other technical goods are made from fossil sources, predominantly crude oil. Combustion (thermal recycling) is a preferred route of disposal, at it removes waste, however, CO_2 emissions arise. Biobased polymers, by contrast, are made from renewable resources. A second class of biopolymers for technical applications is biodegradable, being produced from conventional or renewable feedstock. Common biobased plastics are drop-in materials such as biobased PE, biobased PP, and biobased PET, and frequently used biodegradable plastics are PLA (polylactic acid), TPS (thermoplastic starch), and PHA (polyhydroxyalkanoates). Also, composites can contain natural fibers such as sisal or

hemp. Biobased polymer additives, e.g., plasticizers, are also in use. Renewable feedstock reduces the carbon footprint of the plastics produced. Hence, biopolymers can contribute to climate change mitigation. Biodegradable bioplastics avoid accumulation of the material in the environment, which has detrimental effects, e.g., on marine wildlife. The degradation of bioplastics in general does not release pollutants, and mineralization of the polymer yields CO_2 and water in case of hydrogen, carbon, and oxygen compounds. In this chapter, biobased polymers, which have a substitution potential of up to 90 %, are briefly discussed with respect to climate change mitigation.

Introduction

Construction and building materials are produced on a large scale (Smil 2013), having significant environmental impacts. According to the Cement Association of Canada, the annual global production of concrete is approx. 3.8 billion m^3. Steel production also exceeds one billion tons/year. The annual plastic production, by comparison, has reached 300 million tons. Approx. 4 % of the world's oil production is used for plastic production (Chen 2014), which by 2020, is estimated to reach 400 million tons (Biron 2014). Figure 1 shows the historic development of plastic materials.

All these materials emit CO_2 during their manufacturing and also during other stages of their life cycles. The effect of plastics on the environment, however, is mixed and diverse: at the end of their useful lifetime, which can be 100 years (e.g., for pipes) and a few minutes (e.g., for shopping bags), plastics can become a carbon sink or release CO_2 in waste incineration plants. Toxic gases can be emitted, too, in case of uncontrolled combustion. Note that there are other issues, such as littering, particularly in the marine environment, where microplastics cause harm. Such effects are out of the scope of this chapter. During their useful life, plastics can also save fuel, e.g., by less weight in cars and airplanes, hence showing a better life cycle assessment (LCA) than other materials such as steel or aluminum. Cutting a modern car's weight by 100 kg lowers fuel consumption by roughly 0.4 l/100 km and reduces CO_2 emissions by approx. 10 g/km (PlasticsEurope 2013). A weight reduction of 5 % of the bodywork of a car through the use of plastics can yield an average 3 % reduction in fuel consumption (PlasticsEurope 2014a). As a rule of thumb, 1 kg of plastics in vehicles replaces 1.5 kg of conventional materials. In Europe, for instance, the average emissions of all car models sold by one manufacturer in 1 year needs to drop from approx. 140 g CO_2 per km (fleet average 2010) to 95 g in 2020 and to 75 g (or possibly less) in 2025 and afterwards (McKinsey & Company 2012).

On average, Europe produces 25 million tons of postconsumer plastic wastes. Its fate is shown below in Fig. 2.

One can see that recycling and energy recovery are higher in countries with a landfill ban. Only a fraction of the plastic materials are being truly recycled. The highest recycling rate is generally achieved for PET (bottle material), which has a high value.

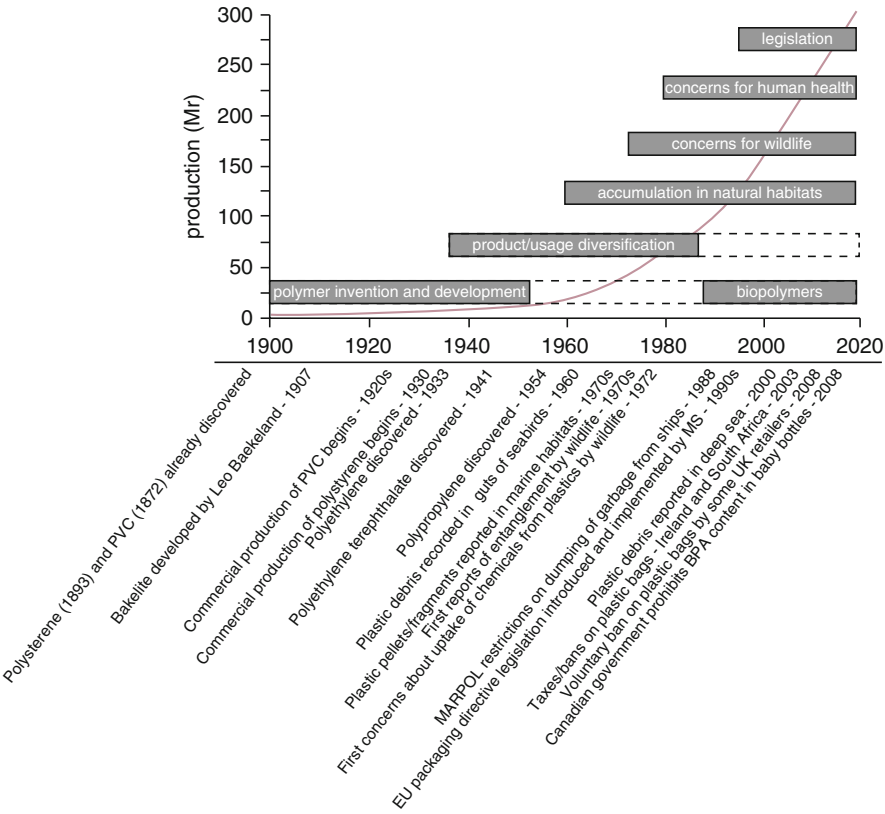

Fig. 1 Global plastic production with historical stages in the development, production, and use of plastics and associated concerns and legislative measures (Source: European Commission 2011)

Plastics in a usage cascade are also deployed in a more sustainable manner (compare Table 1).

Toxic additives in plastics can leach into the environment, which poses another concern. These general aspects are not covered here. This chapter discusses biopolymers compared to conventional plastics with a focus on climate change mitigation potential. In this chapter, the term "biopolymer" is used for technical biopolymers only (note that biopolymers are a broad, generic term).

Biobased Chemicals

Today, most chemicals are based on fossil resources. Technically, biomass can replace all fossil sources deployed for the production of materials and for generating low and medium temperature steam (Saygin et al. 2014). Cost-effective opportunities exist mainly for steam production from biomass residues and for

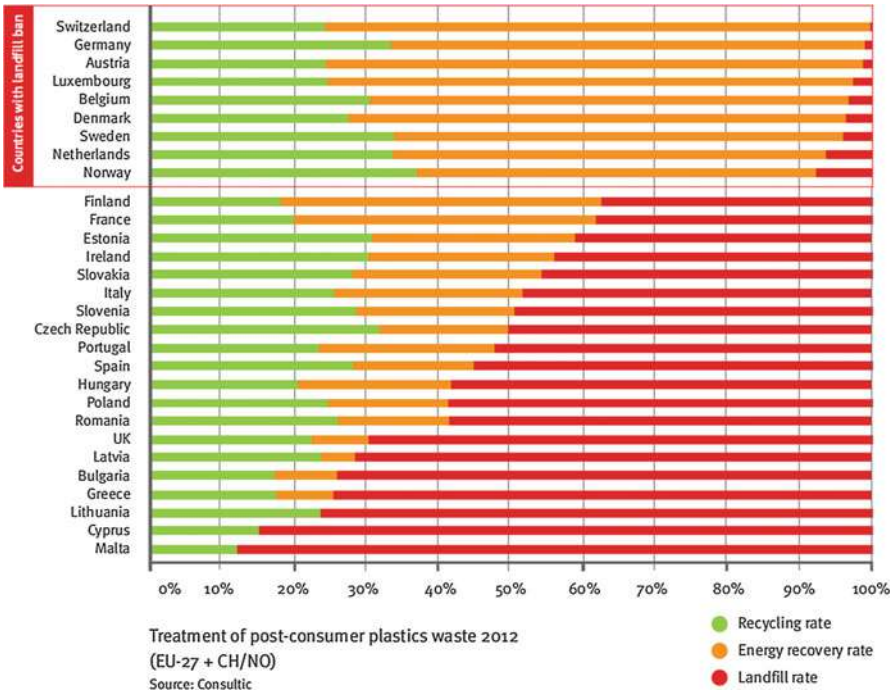

Fig. 2 Use of plastic wastes in Europe (Source: PlasticsEurope 2014b)

Table 1 "Cascade" terminology in plastic recycling (Source: European Commission 2011)

ASTM D7209 – 06 standard definitions	Equivalent ISO 15270 standard definitions	Other equivalent terms
Primary recycling	Mechanical recycling	Closed-loop recycling
Secondary recycling	Mechanical recycling	Downgrading
Tertiary recycling	Chemical recycling	Feedstock recycling
Quaternary recycling	Energy recovery	Valorization

substitution of high-value petrochemicals such as plastics (Saygin et al. 2014). Certain countries use coal (e.g., South Africa, Fischer-Tropsch synthesis) or natural gas (e.g., United Arab Emirates for PE and PP production) instead of crude oil. Natural resources are also used to some extent, with Brazil's bioethanol from sugarcane being a prominent example. In Fig. 3 below, the global organic chemical industry's mass balance and consumption of the renewable raw materials are shown (2007 data):

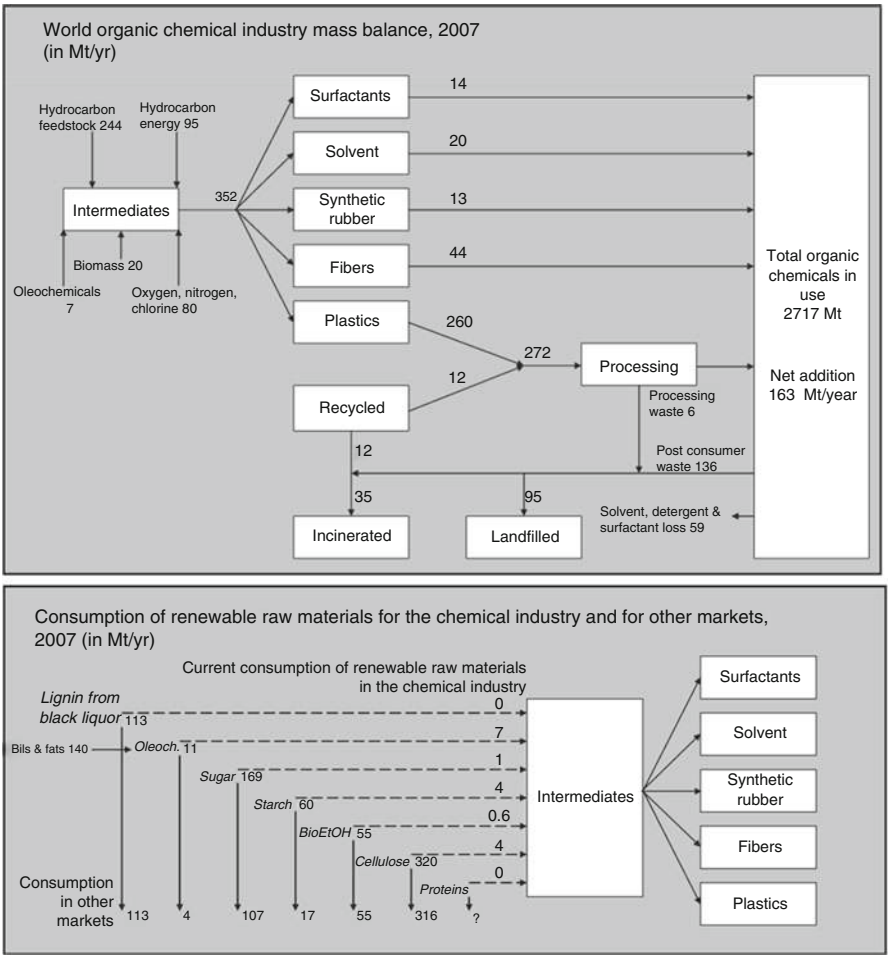

Fig. 3 World organic chemical industry mass balance and current consumption of the renewable raw materials for the chemical industry and for other markets (2007). Net addition is the total production of surfactants, solvents, synthetic rubber, fibers, and processed plastics minus the total of postconsumer waste and material loss. Total quantities of starch and sucrose consumed for bioethanol production are excluded (Source: Saygin et al. 2014)

According to a study by the US Department of Agriculture (USDA), the share of biobased chemicals in the global chemical industry will rise from currently 2 % to >22 % from 2008 (Philp et al. 2013a); see Fig. 4 below.

Biobased polymers, which currently account for approx. 1.5 % of global plastic production, are expected to gain significance in the coming years, as technology improves, consumers demand more "green products," and manufacturers want to appear "green," particularly in the area of plastics, which has a low environmental reputation.

Biobased Polymers

Synthetic (synthesized) plastics are versatile, cost-effective, and durable materials. They consist of polymers and additives, and applications range from packaging, the automotive industry, and various appliances to the healthcare industry.

75 % of the volume of plastics is filled by polyethylene (PE), polypropylene (PP), polyvinylchloride (PVC), polystyrene (PS), and polyethylene terephthalate (PET) (Pei et al. 2011). Typical applications are highlighted in Fig. 5 below.

Biopolymers are polymers produced by living organisms, i.e., polymeric biomolecules, the most important ones being polysaccharides (e.g., cellulose), polynucleotides (e.g., DNA), and polypeptides. By contrast, **synthetic polymers** such as PE (polyethylene), PP (polypropylene), PVC (polyvinylchloride), and PET

Fig. 5 Typical applications of plastic materials in Europe (EU-27 + NO/CH) in 2013 (Source: Alvarenga and Dewulf 2013)

(polyethylene terephthalate) are used in technical applications as "plastics." Plastics contain polymers and additives such as plasticizers, UV stabilizers, and mineral fillers. Synthetic polymers are manufactured from fossil feedstocks: crude oil (e.g., cracked ethylene, propylene), coal (e.g., gasification and Fischer-Tropsch synthesis), or natural gas (e.g., methane dimerization and metathesis). **Biobased polymers**, or simply **biopolymers** or **bioplastics**, are plastics either made from renewable raw materials or being biodegradable (compare Fig. 6).

Hence, the definition of bioplastics is rather broad (only those plastics which are made from fossil sources and which are not biodegradable are excluded). Conventional polymers such as PE and PP can be made from renewable feedstock. For instance, sugarcane can be converted to ethanol, from which ethylene may be obtained. Such biobased PE, as manufactured by Brazilian company Braskem, is chemically identical to its petroleum-based counterpart. As "drop-in solution," such a material can most easily replace conventionally manufactured polymers. Other biopolymers are biodegradable. They can be made from both conventional and renewable feedstock.

Bioplastics like PHA can also be produced directly by plants "factories" (van Beilen and Poirier 2012) and microorganisms (Yu 2007), which can be metabolically engineered for higher yields.

The most common biobased plastics are biobased PET, bio-PE, starch blends and thermoplastic starch (TPS), polylactic acid (PLA) (Sin et al. 2013), and polyhydroxyalkanoates (PHA) (Chen et al. 2011); see Fig. 7 below. PET consists of 70 % terephthalic acid and 30 % monoethylene glycol (MEG). The latter can be made from renewable ethanol, so a partly renewable "drop-in polymer," which is identical to petrochemically produced PET, is obtained. Such bio-PET can be recycled normally. Research is ongoing for 100 % renewable PET (bottle) material.

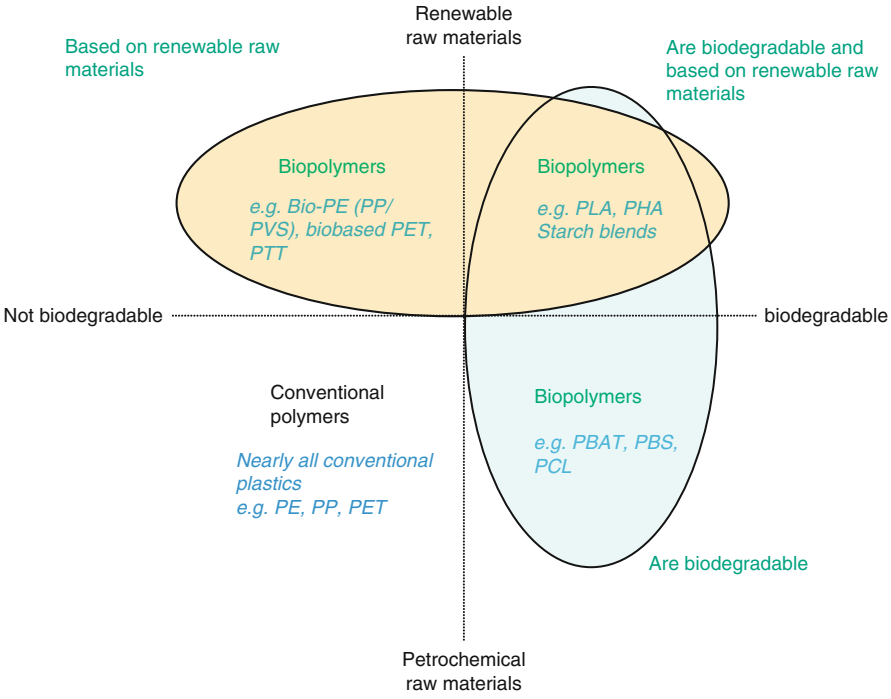

Fig. 6 Types of bioplastics, both biodegradable and nonbiodegradable (Source: Philp et al. 2013b)

The production capacity is approx. 2 % of current production volumes of conventional plastics. Compound annual growth rates for bioplastics are significantly above 10 % (PlasticsToday 2011; Globe Newswire 2013). The replacement potential for biobased polymers is estimated between 33 % and 90 % (OECD 2011). For a review on bioplastics, see, e.g., Lackner (2015), Ebnesajjad (2012), and Niaounakis (2013).

Lessons from First-Generation Biofuels

Sustainability is based in economic, social, and environmental aspects. When all three criteria are met, sustainable development is possible (compare "triple bottom line" of corporations). A balance between social and economic aspects alone is considered equitable, one between social and environmental aspects bearable and one between economic and environmental factors viable. As Fig. 8 below shows, the International Union for Conservation of Nature (IUCN) currently sees a strong imbalance toward environmental aspects of sustainable development, which is in line with common perception.

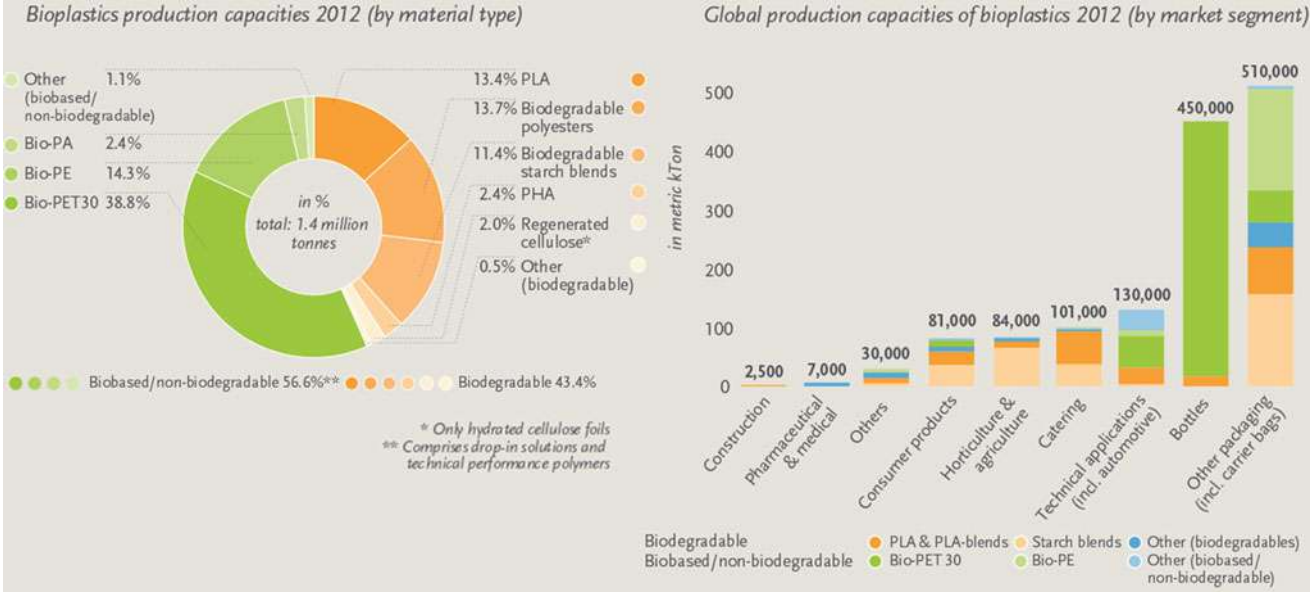

Fig. 7 Global bioplastics' production capacities in 2012 (*left*) and their use (*right*) (Source: European Bioplastics 2013)

Fig. 8 The three circles of sustainability. *Left*, theory; *middle*, current status; *right*, change needed for better balance (Source: Adams 2006)

Biofuels have been envisioned as sustainable solution for transportation, replacing petroleum-based fuels. First-generation (1G) biofuels such as sugarcane-based bioethanol or soybean-based biodiesel, however, have raised significant doubts. Lessons to be learned from 1G biofuels are discussed in Mohr and Raman (2013). Large-scale cultivation of dedicated biomass for biofuels and bioplastics is likely to affect global food prices and water scarcity (Popp et al. 2014). As agricultural commodities consume water during their production, the term "virtual water" was coined (Elena and Esther 2010). It has to be considered in environmental assessments, too.

Bioplastics or Biofuels?

Giving the limited quantity of high-value biomass available for either biofuel or bioplastic production, e.g., in case of Brazilian ethanol from sugarcane, one might ask the question which route is more environmentally sound. According to Alvarenga and Dewulf (2013), deploying ethanol to produce biobased ethylene (instead of fossil-based ethylene) for PE manufacturing would generate environmental gains in the order of 32.0 MJ of fossil energy and 1.87 kg CO_{2eq}, as opposed to the use of ethanol for transportation (instead of gasoline), where environmental gains in the order of 27.2 MJ of fossil energy and 1.82 kg CO_{2eq} were estimated. It was found that above a polymerization yield of 96 %, the bioplastics' route was better in terms of GHG emission reductions (Alvarenga and Dewulf 2013). "CO_{2eq}" stands for "CO_2 equivalent." It is that amount of CO_2 which would cause the same level of radiative forcing as a given type and amount of greenhouse gas (GHG).

According to the Bioplastics Council of the Society of the Plastics Industry (SPI), the widely held perception that the biobased plastics' industry is inextricably linked to and dependent on the emergence of a strong biorefining industry focused mainly on making biofuels is not correct (The Society of the Plastics Industry, Bioplastics Council 2013).

While conventional plastics draw their feedstock from refinery by-products, only a few selected raw materials for bioplastics such as glycerol are linked to biofuel production

(in this case, biodiesel). However, it is not necessary that bioplastics' feedstocks are coupled to biofuels (The Society of the Plastics Industry, Bioplastics Council 2013).

Biopolymers and Climate Change Mitigation

Greenhouse gases (GHG) such as CO_2, CH_4 and N_2O are emitted during feedstock production, transportation, bioplastic manufacturing, packaging, distribution, useful life, and at the end-of-life, which is considered in life cycle assessments (LCA). In a typical LCA of bioplastics, the GHG from land use change (LUC, the so-called carbon debt) for feedstock production is one of the most significant contributors to the environmental impacts (Pei et al. 2011), e.g., in case of rainforest destruction for plantations.

The system boundaries of LCA (the scope) may extend from cradle to gate, cradle to grave, or cradle to cradle; see Fig. 9 below. The cradle-to-gate (dashed lines) approach covers activities prior to usage, while cradle-to-grave approach (dashed and dotted lines) includes the product's use and end-of-life. Cradle to cradle (whole chart) is also used. Sometimes, the scope cradle to pellet is assessed.

Life cycle assessment allows the comparison of "like with like." A position paper on LCA of bioplastics by industry association European Bioplastics can be found in European Bioplastics (2008).

Guidelines for carrying out LCA are provided, e.g., by the International Organization for Standardization (ISO) 14040 series. Others were established by the US Environmental Protection Agency (EPA) and the Society for Environmental Toxicology and Chemistry (SETAC), an international NPO (Hottle et al. 2013).

In Kim and Dale (2008), it was estimated that corn-derived PHB (polyhydroxybutyrate, a potential replacement for PP) offers environmental advantages over fossil polymers, with lower nonrenewable energy consumption (95 % reduction) and lower greenhouse gas emissions (200 % reduction) compared to the petroleum-based plastics.

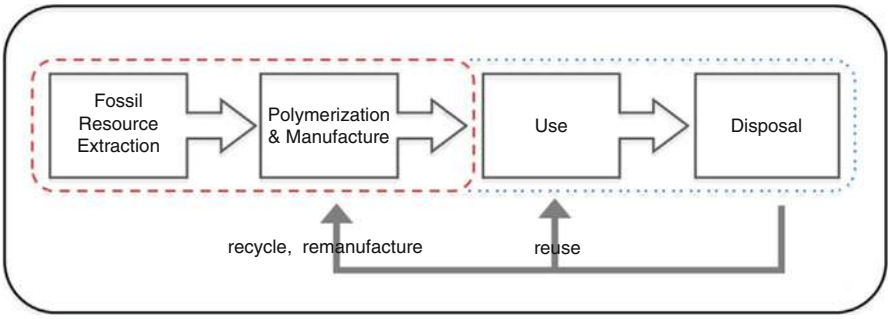

Fig. 9 Generic life cycle stages for polymers. The *dashed line* indicates a cradle-to-gate system boundaries, the dotted line is an extension of that system boundary to cradle to grave, and the entire figure is indicative of a cradle-to-cradle assessment (Source: Hottle et al. 2013)

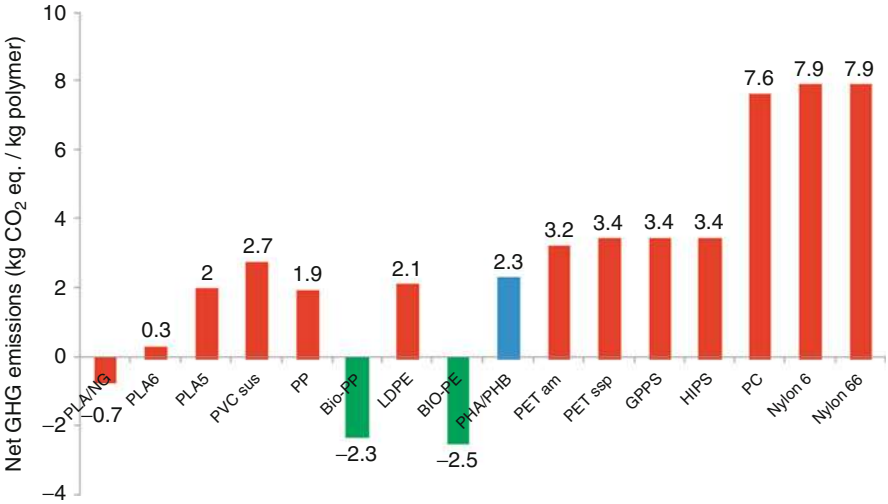

Fig. 10 GHG emissions in plastic production (From various sources: *PLA/NG* NatureWorks™ PLA next generation, *PLA5* NatureWorks™ PLA in 2005, *PLA6* NatureWorks™ in 2006, *PLA* polylactic acid, *PVC sus* PVC suspension, *HIPS* high impact polystyrene, *PC* polycarbonate, *GPPS* general purpose polystyrene, *PET am* PET amorph, *PET ssp* PET solid-state polycondensation, *Bio-PP* Braskem biobased polypropylene, *Bio-PE* Braskem biobased polyethylene (Source: Philp et al. 2013b)

Figure 10 below compares net GHG emissions, expressed in kg CO_{2eq} per kg of polymer, for conventional and biobased materials.

According to Tsiropoulos et al. (2014), a similar study, biobased polyethylene, results in greenhouse gas emissions of around 0.75 kg CO_{2eq}/kg polyethylene, i.e., 1.4 times lower than petrochemical PE, yet more than the −2.5 kg CO_{2eq}/kg found by Philp et al. (2013b). Savings of nonrenewable energy use for bio-PE were found to be roughly 65 % (Tsiropoulos et al. 2014). Such discrepancies in various studies will be discussed below.

PHB, which belongs to the class of PHA, is a biodegradable biopolymer which can be produced by bacteria and plants. Bio-PE and bio-PP are chemically identical to PE and PP, since they share the same feedstock, only of different provenience. They show significant CO_{2eq} savings compared to their traditional counterparts.

Yates and Barlow (2013) wrote that "*Biopolymers are generally considered an eco-friendly alternative to petrochemical polymers due to the renewable feedstock used to produce them and their biodegradability. However, the farming practices used to grow these feedstocks often carry significant environmental burdens, and the production energy can be higher than for petrochemical polymers.*"

They studied polylactic acid (PLA), polyhydroxyalkanoates (PHAs), and starch-based polymers, with some of the results shown in Figs. 11 (PLA) and 12 (PHA).

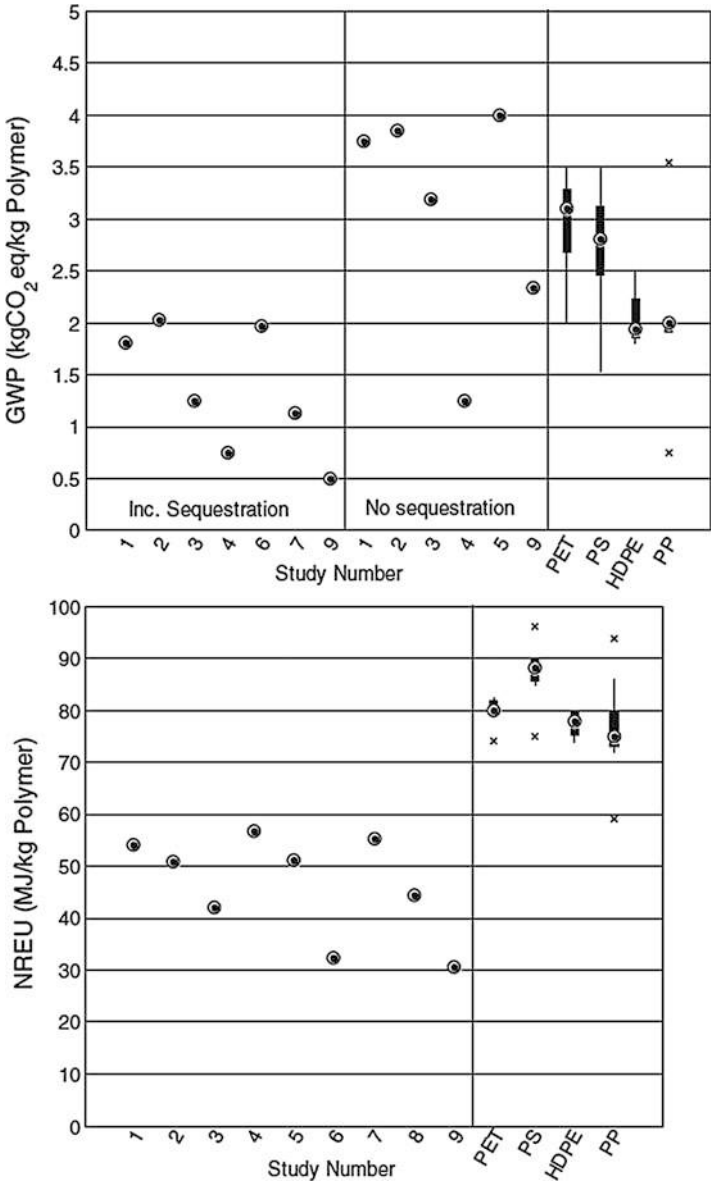

Fig. 11 GWP and NREU for **PLA** studies and petrochemical polymers. Sequestration refers to CO_2 uptake by plants used as the feedstock. Ranges for petrochemical polymers cover values reported in various comparative LCA studies and those provided by PlasticsEurope (Source: Yates and Barlow 2013)

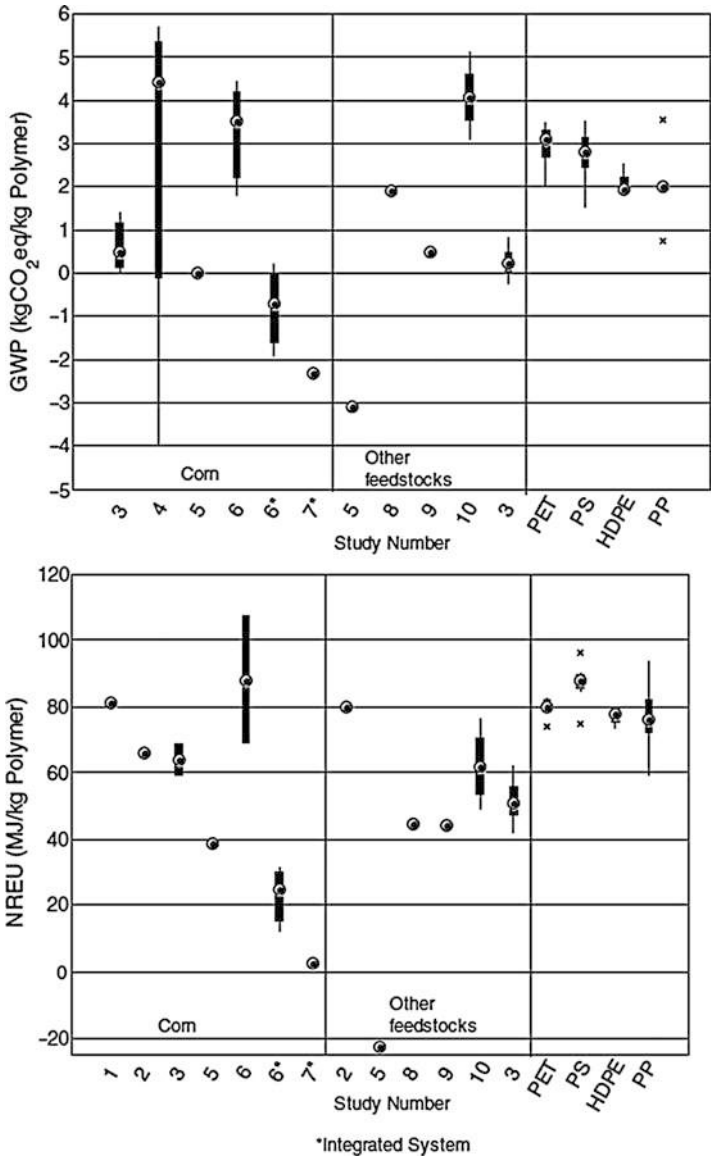

Fig. 12 GWP and NREU for **PHA** studies and petrochemical polymers. Ranges for petrochemical polymers cover values reported in various comparative LCA studies and those provided by PlasticsEurope (Source: Yates and Barlow 2013)

The LCA studies focused on nonrenewable energy use (NREU) and global warming potential (GWP). GWP is expressed in kg CO_{2eq} per kg of polymer.

As Fig. 11 shows, several studies found that GWP levels of PLA production are below those of competing conventional polymers, particularly in case of CO_2

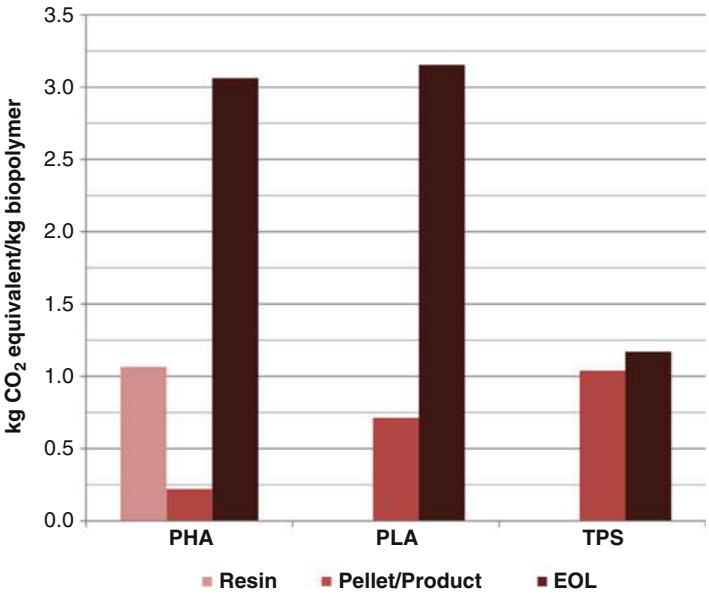

Fig. 13 Average global warming potential of biopolymers based on the extent of the system boundaries of fifteen different LCAs. *EOL* end of life (Source: Hottle et al. 2013)

sequestration, while other studies found just the opposite. Carbon sequestration stands for the long-term removal of CO_2 from the system, e.g., by landfilling.

In case of PHA, there is also disagreement in the literature on whether the biobased polymer has a lower GWP than its petrochemical counterparts. One needs to acknowledge that biobased plastics have not yet reached the same level of technological maturity as conventional plastics and that their currently smaller manufacturing units cannot be as efficient as a few 100,000 t/year standard polymerization plants. The higher GWP results, e.g., from energy consumption during production. Also, it needs to be highlighted that the outcome of life cycle assessments depends on the system boundaries as shown below in Fig. 13.

End-of-life assessment is more comprehensive. However, it depends on the chosen disposal route, which varies from country to country. For instance, in Europe incineration is used more than in the United States, where landfilling prevails, so other approaches such as "cradle to pellet" as mentioned above might be more meaningful.

Composite Materials

Apart from biobased polymers, additives and fillers can also be biobased (Lackner 2015). An example of biobased PVC plasticizers are glucose esters (Yin et al. 2014). Examples of compounds and composites with biobased fillers are

plastic wood composites (PWC), for which also recycled plastics can be used (Najafi 2013). Biobased fibers for use in plastics (both conventional and biobased) are, e.g., hemp fibers (Dhakal and Zhang 2015), cellulose fibers (González-Sánchez et al. 2014), flax fibers (El-Sabbagh et al. 2014), sisal, kenaf, jute, and coir (Wambua et al. 2003). Such fillers improve properties and can reduce both weight and costs. For a review on bionanocomposites, see, e.g., (Reddy et al. 2013).

Composite materials with biobased ingredients and recycling of bioplastics (Niaounakis 2013; Soroudi and Jakubowicz 2013) are not covered in this chapter. It only has to be stated that recycling of bioplastics would require a separate infrastructure, as some bioplastics are not compatible with regular recycling schemes (e.g., PHB in PET will degrade properties strongly; (Lackner 2015)).

Discussion

From what was depicted above, bioplastics are a "hot" topic for researchers, entrepreneurs, and customers/consumers alike, where the avoidance on crude oil dependency is a main driver and climate change mitigation a welcome side effect. Generally speaking, materials sell by properties (i.e., performance), not by price (only). The costs of bioplastics are typically higher than those of conventional polymers, which is partly due to more expensive feedstock and lack of economies of scale. Since the main barrier to market penetration of bioplastics is their price compared to that of oil-based plastics, a brief cost overview is shown here in Table 2.

Biobased plastics will play a vital role in a bioeconomy (Philp et al. 2013c). Some biobased plastics have a slightly higher density than petrochemical plastics

Table 2 Prices of bioplastics in 09/2012. Reference pellet prices (EUR per kg) – PE = 1.58; PP = 1.54; PET = 1.73 (Source: OECD 2014)

Product	Company	Location	Capacity (tones)	Price (EUR per kg)
PLA	Nature Works	United States	140,000	1.5–2.0
PLA	Hisun	China	5000	2.1
PHAs	Metabolix	United States	300/50,000	4.3–4.6
PHBV	Tianan	China	2000	4.1–4.3
Mater-Bi	Novamont	EU	75,000	3.4–5.1
Cereplast	Cereplast	United States	25,000	2.6–3.4
HDPE/LDPE/PP	Braskem	Brazil	200,000	1.3–1.7
Other	DuPont Plantic Innovia Arkema, others	Global	2000	2.5–6.9

such as PE and PP, so when being used in transportation applications, they will not result in the same fuel savings over the packagings' or vehicles' lifetime.

The IPCC writes in its Fourth Assessment Report (2007):

> It is theoretically possible to increase carbon storage in long-lived agricultural products (e.g., strawboards, wool, leather, bio-plastics) but the carbon held in these products has only increased from 37 to 83 MtC per year over the past 40 years. Assuming a first order decay rate of 10 to 20 % per year, this is estimated to be a global net annual removal of 3 to 7 $MtCO_2$ from the atmosphere, which is negligible compared to other mitigation measures. (IPCC Fourth Assessment Report: Climate Change 2007)

Hence, the main contribution to climate change mitigation of bioplastics comes from a reduction of fossil fuel use for their production.

Conclusions

Bioplastics were shown in this chapter to offer the potential for reduced GHG emissions compared to fossil plastics, rendering the same service level. Biopolymers show some unfavorable results in several LCA studies; however, the immature nature of these technologies needs to be considered (future optimization and efficiency improvements will come). Both drop-in replacements (e.g., biobased PE, biobased PP, bio-PET) and novel bioplastics (e.g., PLA, TPS, PHA) can contribute to climate change mitigation; however, a profound life cycle assessment including potential land use change has to be carried out to have a clear picture about the net effect. Further improvements in energy efficiency of feedstock production and reduction of fossil fuel use in the process are needed.

Gerngross and Slater wrote that "*any manufacturing process, not just those for plastics, would benefit from the use of renewable energy*" (Gerngross and Slater 2000), so it seems worthwhile to foster bioplastics from a climate change mitigation perspective.

The second major advantage of bioplastics, which is not related to climate change mitigation, is biodegradability as shown by some grades. Whereas the lifetime of conventional plastic materials can be hundreds of years (Harvey 2012), biodegradable plastics are mineralized to CO_2 and H_2O. They generally do not produce harmful pollutants during degradation. In landfills, nondegradable plastics act as carbon sink. However, a significant fraction of plastic wastes ends up in the oceans, where attrition leads to the formation of microplastics (Barboza and Gimenez 2015). There particles accumulate toxic substances and enter the food chain. Microplastics have become a major issue for the marine environment, and biodegradable materials can be a solution here.

Hence, it can be concluded that biobased polymers can contribute to climate change mitigation by avoiding fossil feedstock and, in case of nonbiodegradable grades, by acting as carbon sink.

Outlook

Plastics are a virtually impossible-to-replace class of materials, used from cost-effective packaging to high-end applications in health care. Biobased plastics, an emerging trend, can contribute to climate change mitigation with lower GHG emissions over their entire life cycle (Yates and Barlow 2013), European Bioplastics (2008) compared to conventional plastics. Sustainable feedstock production, alongside a decoupling from the biofuel industry, will be two major R&D topics for biobased plastics in the upcoming years. It is expected that the first huge market for biobased polymers is in packaging (Cooper 2013), which will gradually move toward higher-end applications, as performance increases (Chen 2014).

Glossary

Maximilian Lackner

This glossary is composed of entries based on terms supplied by the chapter authors of this Handbook and taken from the following sources:

- US Environmental Protection Agency (EPA)
- Intergovernmental Panel on Climate Change (IPCC)
- United Nations Framework Convention on Climate Change (UNFCCC)
- British Broadcasting Corporation (BBC)
- Agricultural Marketing Resource Center (AgMRC)
- National Oceanic and Atmospheric Administration (NOAA))

AAU See "Assigned amount unit"

Abatement Reduction of degree or intensity of greenhouse-gas emissions.

Abrupt Climate Change Sudden (on the order of decades), large change in some major component of the climate system, with rapid, widespread effects.

AC See "Adaptation Committee"

Accession An act whereby a state becomes a party to a treaty already negotiated and signed by other states; It has the same legal effect as ratification. See also "Ratification."

Acclimatization Adaptation by people to higher or lower ambient temperatures.

Acid Rain Program (ARP) A cap-and-trade emissions trading program undertaken in the USA in 1990 to control emissions of sulfur dioxide from electric utilities. This was the first significant regulatory use of the cap-and-trade mechanism for pollution control.

Active modes Walking and cycling. See also "Nonmotorized travel."

Activities implemented jointly (AIJ) Activities carried out under the Convention (UNFCCC) to mitigate climate change through partnerships between an investor from a developed country and a counterpart in a host country under a pilot phase

M. Lackner
Institute of Advanced Engineering Technologies, University of Applied Sciences FH Technikum Wien, Vienna, Austria
e-mail: maximilian.lackner@technikum-wien.at

W.-Y. Chen et al. (eds.), *Handbook of Climate Change Mitigation and Adaptation*,
DOI 10.1007/978-3-319-14409-2

that ended in the year 2000. The purpose was to involve private-sector money in the transfer of technology and know-how. See also "Joint Implementation and United Nations Framework Convention on Climate Change (UNFCCC)."

Adaptation Adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities.

Adaptive capacity The ability of a system to adjust to climate change (including climate variability and extremes) to moderate potential damages, to take advantage of opportunities, or to cope with the consequences.

Adaptation Committee (AC) A body that was established by the Conference of the Parties (COP) as part of the Cancun Agreements to promote the implementation of enhanced action on adaptation in a coherent manner under the Convention, inter alia, through various functions. See also "United Nations Framework Convention on Climate Change (UNFCCC) and Cancun Adaptation Framework."

Adaptation Fund Established to finance concrete adaptation projects and programs in developing countries that are particularly vulnerable and which are Parties to the Kyoto Protocol. The Fund is to be financed with a share of proceeds from clean development mechanism (CDM) project activities and receive funds from other sources. It is operated by the Adaptation Fund Board.

Additionality The property of a GHG reduction which ensures that it is surplus to regulation and beyond what would have happened in the absence of the project (or in the business-as-usual scenario).

Ad Hoc Working Group on Long-term Cooperative Action under the Convention (AWG-LCA) Established as a subsidiary body under the Convention by decision 1/CP.13 (the Bali Action Plan) to conduct a comprehensive process to enable the full, effective, and sustained implementation of the Convention through long-term cooperative action, now, up to and beyond 2012, in order to reach an agreed outcome to be presented to the COP for adoption.

Adjustment time See "Response time"

Aerosols Small particles or liquid droplets in the atmosphere that can absorb or reflect sunlight depending on their composition. Erroneously, the term has also become associated with the propellant used in "aerosol sprays."

Aerosol sprays Pressurized cans containing liquids and a propellant. Today, often propane, butane, air, nitrogen, or dimethylether are used as propellants. Previously, hydrofluorocarbons (strong GHG) were used.

Afforestation Planting of new forests on lands that historically have not contained forests. See also "Reforestation."

AGE See "Applied general equilibrium"

AIJ See "Activities implemented jointly"

Albedo The amount of solar radiation reflected from an object or surface, often expressed as a percentage.

Alternative energy Energy derived from nontraditional sources (e.g., compressed natural gas, solar, hydroelectric, wind). See also "Renewable energy" and "Unconventional oil."

Alliance of Small Island States (AOSIS) An ad hoc coalition of low-lying and island countries. These nations are particularly vulnerable to rising sea levels and share common positions on climate change. The 43 members and observers are American Samoa, Antigua and Barbuda, Bahamas, Barbados, Belize, Cape Verde, Comoros, Cook Islands, Cuba, Dominica, Dominican Republic, Federated States of Micronesia, Fiji, Grenada, Guam, Guinea-Bissau, Guyana, Haiti, Jamaica, Kiribati, Maldives, Marshall Islands, Mauritius, Nauru, Netherlands Antilles, Niue, Palau, Papua New Guinea, Samoa, Sao Tome and Principe, Seychelles, Singapore, Solomon Islands, St. Kitts & Nevis, St. Lucia, St. Vincent and the Grenadines, Suriname, Timor-Leste, Tonga, Trinidad and Tobago, Tuvalu, US Virgin Islands, and Vanuatu.

Amendment A modification by the COP to the text of the Convention. If consensus cannot be reached, an amendment must win three-quarters of the votes of all parties present and casting ballots.

Annex I Parties The industrialized countries listed in Annex I to the Convention, which committed to returning their greenhouse-gas emissions to 1990 levels by the year 2000 as per Article 4.2 (a) and (b). They have also accepted emissions targets for the period 2008–2012 as per Article 3 and Annex B of the Kyoto Protocol. They include the 24 original OECD members, the European Union, and 14 countries with economies in transition (Croatia, Liechtenstein, Monaco, and Slovenia joined Annex 1 at COP; the Czech Republic and Slovakia replaced Czechoslovakia.)

Annex II Parties The countries listed in Annex II to the Convention which have a special obligation to provide financial resources and facilitate technology transfer to developing countries. Annex II Parties include the 24 original OECD members plus the European Union.

Annex I Countries See "Annex I Parties"

Annex II Countries See "Annex II Parties"

Countries which have a special obligation under the Kyoto Protocol to provide financial resources and transfer technology to developing countries. This group is a subsection of the Annex I countries, excluding those that, in 1992, were in transition from centrally planned to a free market economy.

Anthropogenic Caused or produced by human activity, as opposed to natural. An example is the release of pollutants into the environment by human activities.

Anthropogenic greenhouse emissions Greenhouse-gas emissions resulting from human activities.

Anthropogenic climate change Man-made climate change, i.e., climate change caused by human activity as opposed to natural processes.

AOGCM See "Atmosphere-ocean General Circulation Model"

AOSIS See "Alliance of Small Island States"

Applied general equilibrium (AGE) Another term for computable general equilibrium (CGE), a class of economic models that use actual economic data to estimate how an economy might react to changes in policy, technology, or other external factors.

ARP See "Acid Rain Program"

AR4 IPCC Fourth Assessment Report (AR4). The Fourth Assessment Report produced by the Intergovernmental Panel on Climate Change (IPCC) published in 2007. The report assessed and summarized the climate change situation worldwide. It concluded that it was at least 90 % likely that the increase of the global average temperature since the mid-twentieth century was mainly due to man's activity. See also "IPCC" and "AR5."

AR5 See "IPCC Fifth Assessment Report"

Assigned amount unit (AAU) A Kyoto Protocol unit equal to 1 metric ton of CO_2 equivalent. Each Annex I Party issues AAUs up to the level of its assigned amount, established pursuant to Article 3, paragraphs 7 and 8, of the Kyoto Protocol. Assigned amount units may be exchanged through emissions trading.

Atmosphere The gaseous envelope surrounding the Earth. The dry atmosphere consists almost entirely of nitrogen (78.1 % by volume) and oxygen (20.9 % by volume), together with a number of trace gases, such as argon (0.93 % by volume), helium, radiatively active greenhouse gases such as carbon dioxide (0.04 % by volume), and ozone. In addition, the atmosphere contains water vapor, the amount of which is highly variable but typically 1 % by volume. The atmosphere also contains clouds and aerosols.

Atmosphere-ocean General Circulation Model (AOGCM) A numerical representation of the climate system based on the physical, chemical, and biological properties of its components, their interactions and feedback processes, and accounting for all or some of its known properties. The atmosphere and ocean general circulation model components are three-dimensional, time-dependent models that include a representation of the equations of motion on a sphere. In addition to atmosphere and ocean components, the term AOGCM is often applied to computer models that include land surface and sea ice model components. The model components are coupled, in the sense that fluxes are regularly exchanged between the different model components as they march forward in time. AOGCMs provide a relatively comprehensive representation of the climate system. AOGCM models are applied, as a research tool, to study and simulate the climate, but also for operational purposes, including monthly, seasonal, and interannual climate predictions.

Atmospheric lifetime The average time that a molecule resides in the atmosphere before it is removed by chemical reaction or deposition. This can also be thought of as the time that it takes after the human-caused emission of a gas for the concentrations of that gas in the atmosphere to return to natural levels. Greenhouse gas lifetimes can range from a few years to a few thousand years.

Atmospheric aerosols Microscopic particles suspended in the lower atmosphere that reflect sunlight back to space. They generally have a cooling effect on the planet and can mask global warming. They play a key role in the formation of clouds, fog, precipitation, and ozone depletion in the atmosphere.

AWG-LCA See "Ad Hoc Working Group on Long-term Cooperative Action under the Convention"

Backloading A measure undertaken by the EU ETS postponing the auctioning of allowances in order to give an opportunity for demand to increase.

Bali action plan (BAP) A plan drawn up at the UN Climate Change Conference in Bali, in December 2007, forming part of the Bali roadmap. The action plan established a working group to define a long-term global goal for reduction of greenhouse-gas emissions, and a "shared vision for long-term co-operative action" in the areas of mitigation, adaptation, finance, and technology. See also "Bali Road Map."

BAP See "Bali Action Plan"

Bali Road Map The Bali Road Map was adopted at the 13th Conference of the Parties and the 3rd Meeting of the Parties in Bali in December 2007. The Road Map is a set of forward-looking decisions that represent the work needed to be done under various negotiating "tracks" essential to reach a secure climate future. The roadmap gave deadlines to two working groups, one working on the Bali action plan and another discussing proposed emission reductions by Annex I countries after 2012.

Baseline-and-credit An emissions trading approach first introduced in the USA in the mid-1970s in which firms that reduced emissions below required command-and-control limits (i.e., the baseline) could earn "credits" that they could then sell to others who needed them in order to comply with regulations. Such schemes were subsequently adopted in the Kyoto Protocol under CDM and JI.

Baseline for cuts The year against which countries measure their target decrease of emissions. The Kyoto Protocol uses a baseline year of 1990. Some countries prefer to use later baselines. Climate change legislation in the USA, for example, uses a 2005 baseline.

BAU See "Business as usual"

BC See "Black carbon"

Berlin Mandate Adopted at COP-1, the mandate that launched negotiations leading to the adoption of the Kyoto Protocol.

BINGO Business and industry nongovernmental organizations. Civil society engages with the UNFCCC process through representative nongovernmental observer organizations. Since the early days of the UNFCCC, nongovernmental organizations (NGOs) have been actively involved, attending sessions and exchanging views with other participants, including government negotiators and delegates. There are currently nine NGO constituencies: BINGO (Business and Industry NGOs), ENGO (Environmental NGOs), TUNGO (Trade Union NGOs), IPO (Indigenous Peoples' Organizations), LGMA (Local Government and Municipal Authorities), RINGO (Research-oriented and Independent Organizations), YUNGO (Youth NGOs), Faith (Faith-based NGOs), Gender (Gender-based NGOs).

Biochar Slow-pyrolysis of biomass yields biochar, a stable carbon-rich solid product. See also "Hydrochar."

Biodiversity The existence of a wide variety of plant and animal species in their natural environments.

Biofuel A fuel derived from renewable sources, including crops such as maize and sugar cane, and some forms of waste. One can distinguish between 1st, 2nd, and 3rd generation (1G, 2G, and 3G) of biofuels, with increasing sustainability.

Biomass Materials of biological origin, including organic material (both living and dead) from above and below ground, for example, trees, crops, grasses, tree litter, roots, and animals and animal waste.

Biomass fuel See "Biofuel"

Biogeochemical cycle Movements through the Earth system of key chemical constituents essential to life, such as carbon, nitrogen, oxygen, and phosphorus.

Biome A naturally occurring community of flora and fauna (or the region occupied by such a community) adapted to the particular conditions in which they occur, e.g., tundra, grasslands, or deserts.
http://www.ucmp.berkeley.edu/glossary/gloss5/biome/

Biosphere The part of the Earth system comprising all ecosystems and living organisms, in the atmosphere, on land (terrestrial biosphere), or in the oceans (marine biosphere), including derived dead organic matter, such as soil organic matter and oceanic detritus.

Black carbon (BC) The soot that results from the incomplete combustion of fossil fuels, biofuels, and biomass (wood, animal dung, etc.). It is the most potent climate-warming aerosol. Unlike greenhouse gases, which trap infrared radiation that is already in the Earth's atmosphere, these particles absorb all wavelengths of sunlight and then reemit this energy as infrared radiation.

Black Carbon Aerosol See "Black carbon"

Bonn agreements Informal term for a political deal reached at COP-6 in Bonn, Germany, in 2001, by which governments agreed on the most politically controversial issues under the Buenos Aires Plan of Action. The Bonn agreements paved the way for the Marrakech Accords later in the same year.

Bonn convention See "Convention on the Conservation of Migratory Species of Wild Animals"

Bonn fund A special UNFCCC fund for contributions from the Government of Germany to cover costs of UNFCCC events held in Bonn.

Borehole Any exploratory hole drilled into the Earth or ice to gather geophysical data. Climate researchers often take ice core samples, a type of borehole, to predict atmospheric composition in earlier years. See also "Ice core."

bp-k Billion passenger-km, a unit deployed in the logistics industry.

Brazilian proposal A proposal by the delegation of Brazil made in May 1997 as part of the negotiations on the Kyoto Protocol. It included a formula to set differentiated emission reduction targets for parties based on the cumulative impact of parties' historic emissions on the global average surface temperature.

Bunker fuels Fuels consumed for international marine transport. Often, they are of inferior quality, containing higher amounts of sulphur than regular liquid transportation fuels.

Bureau A body responsible for directing the work of the COP. Its 10 members are delegates elected by each of five regional groups. The Bureau includes the COP President, six Vice Presidents, the Chairs of SBI and SBSTA, and a rapporteur. Each of the Convention's subsidiary bodies also has a Bureau.

Business as usual (BAU) A scenario used for projections of future emissions assuming no action, or no new action, is taken for mitigation. Some countries are pledging not to reduce their emissions but to make reductions compared to a business as usual scenario. Their emissions, therefore, would increase but to a lesser degree.

CACAM Negotiating coalition of countries of Central Asia and the Caucasus, Albania, and the Republic of Moldova.

Cancun Adaptation Framework (CAF) Parties adopted the Cancun Adaptation Framework (CAF) as part of the Cancun Agreements at the 2010 Climate Change Conference in Cancun, Mexico (COP 16/CMP 6). In the Agreements, Parties affirmed that adaptation must be addressed with the same level of priority as mitigation. The CAF is the result of 3 years of negotiations on adaptation under the AWG-LCA that had followed the adoption of the Bali Action Plan at the 2007 Climate Change Conference in Bali, Indonesia (COP 13/CMP 3).

Cap and trade An emission trading scheme whereby businesses or countries can buy or sell allowances to emit greenhouse gases via an exchange. The individual polluters can buy and/or sell these allowances in a market, thereby achieving the emissions target at lowest cost. The volume of allowances issued adds up to the limit, or cap, imposed by the authorities.

Capacity building In the context of climate change, the process of developing the technical skills and institutional capability in developing countries and economies in transition to enable them to address effectively the causes and results of climate change.

Carbonaceous Containing carbon.

Carbonaceous aerosol Aerosol consisting predominantly of organic substances and various forms of black carbon.

Carbon capture and sequestration (CCS) A set of technologies that can greatly reduce carbon dioxide emissions from new and existing coal- and gas-fired power plants, industrial processes, and other stationary sources of carbon dioxide. It is a three-step process that includes capture of carbon dioxide from power plants or industrial sources; transport of the captured and compressed carbon dioxide (usually in pipelines); and underground injection and geologic sequestration, or permanent storage, of that carbon dioxide in deep underground reservoirs such as rock formations that contain tiny openings or pores that trap and hold the carbon dioxide. Carbon capture is sometimes referred to as geological sequestration.

Carbon capture and storage See "Carbon capture and sequestration (CCS)"

Carbon cycle All parts (reservoirs) and fluxes of carbon. The cycle is usually thought of as four main reservoirs of carbon interconnected by pathways of exchange. The reservoirs are the atmosphere, terrestrial biosphere (usually includes freshwater systems), oceans, and sediments (includes fossil fuels). The annual movements of carbon, the carbon exchanges between reservoirs, occur because of various chemical, physical, geological, and biological processes. The ocean contains the largest pool of carbon near the surface of the Earth, but most of that pool is not involved with rapid exchange with the atmosphere.

Carbon dioxide (CO_2) A naturally occurring gas with approx. 400 ppm in the atmosphere and a by-product of burning carbonaceous fuels. It is the main anthropogenic greenhouse gas that affects Earth's radiative balance. It is the reference gas against which other greenhouse gases are measured and therefore it has a Global Warming Potential (GWP) of 1.

Carbon dioxide equivalent (CDE) A measure used to compare the effect of various greenhouse gases based upon their global warming potential (GWP). CDE is the quantity that describes, for a given amount of greenhouse gases, the amount of CO_2 that would have the same global warming potential (GWP), when measured over a specified timescale (generally, 100 years). Carbon dioxide equivalency thus reflects the time-integrated radiative forcing of a quantity of *emissions* or rate of greenhouse-gas emission – a *flow* into the atmosphere – rather than the instantaneous value of the radiative forcing of the *stock* (concentration) of greenhouse gases *in the atmosphere* described by equivalent CO_2 (CO_2e). The CDE for a gas is obtained by multiplying the mass and the GWP of the gas. The following units are commonly used:

- By the UN climate change panel IPCC: billion metric tons of CO_2 equivalent ($GtCO_2eq$)
- In industry: million metric tons of carbon dioxide equivalents (MMTCDE)
- For vehicles: g of carbon dioxide equivalents/km (gCDE/km)
- By contrast, equivalent CO_2 (CO_2e) is the concentration of CO_2 that would cause the same level of radiative forcing as a given type and concentration of greenhouse gas. Examples of such greenhouse gases are methane, perfluorocarbons, and nitrous oxide. CO_2e is expressed as parts per million by volume, ppmv.

Carbon dioxide fertilization The enhancement of the growth of plants by increasing the level of CO_2, e.g., in a greenhouse. Depending on their mechanism of photosynthesis, certain types of plants are more sensitive to changes in atmospheric CO_2 concentration.

Carbon dioxide removal (CDR) A set of concepts to moderate or retard global warming by removing CO_2 from the atmosphere on a large scale. See also "Climate engineering."

Carbon dioxide sequestration The process of removing carbon from the atmosphere and depositing it in a reservoir, also termed carbon sequestration.

Carbon equivalent See "Carbon dioxide equivalent (CDE)" and "Equivalent carbon dioxide (CO_2e)."

Carbon flux The rate of exchange of carbon between reservoirs.

Carbon footprint The total amount of greenhouse gases emitted into the atmosphere each year by a person, family, building, or organization. A person's carbon footprint includes greenhouse-gas emissions from fuel that an individual burns directly, such as by heating a home or riding in a car. It also includes greenhouse gases that come from producing the goods or services that the individual uses, including emissions from power plants that make electricity, factories that make

products, and landfills where trash is sent. For a product, the carbon footprint is the amount of carbon emitted during manufacturing.

Carbon intensity The relative amount of carbon emitted per unit of an underlying variable, often per unit of energy, quantity of fuel consumed, or per unit of GDP. See also "GDP."

Carbon leakage The part of emissions reductions that may be offset by an increase of the emissions in the nonconstrained countries above their baseline levels. See also "Emissions Trading."

Carbon market A popular (but misleading) term for a trading system through which countries may buy or sell units of greenhouse-gas emissions in an effort to meet their national limits on emissions, either under the Kyoto Protocol or under other agreements, such as that among member states of the European Union. The term comes from the fact that carbon dioxide is the predominant greenhouse gas, and other gases are measured in units called "carbon-dioxide equivalents."

Carbon negative A process where a net sink of CO_2 is realized. See also "Carbon neutral."

Carbon neutral A process where there is no net release of CO_2. For example, growing biomass removes CO_2 from the atmosphere, while burning it releases the CO_2 again. The process would be carbon neutral if the amount taken out and the amount released were identical. A company or country can also achieve carbon neutrality by means of carbon offsetting. See also "Carbon offsetting."

Carbon offset An investment in a project that will lead to the prevention or removal of carbon dioxide from the atmosphere (e.g., planting trees or building renewable energy power stations to avoid the construction of coal-fired ones).

Carbon offsetting A way of compensating for emissions of CO_2 by participating in, or funding, efforts to take CO_2 out of the atmosphere. Offsetting often involves paying another party, somewhere else, to save emissions equivalent to those produced by one's own activity.

Carbon pool Carbon pools are above-ground biomass, below-ground biomass, litter, dead wood, and soil organic carbon.

Carbon price The price placed on greenhouse-gas emissions to create a disincentive for their release (and incentive to capture or avoid them). A carbon price can be imposed, e.g., through a carbon tax, an emissions trading scheme (which fixes emission levels and allows prices to vary).

Carbon sequestration The process of storing carbon dioxide. Terrestrial, or biologic, carbon sequestration is the process by which trees and plants absorb carbon dioxide, release the oxygen, and store the carbon. Geologic sequestration is one step in the process of carbon capture and sequestration (CCS), and involves injecting carbon dioxide deep underground where it stays permanently. So one can distinguish between natural and industrial carbon sequestration.

Carbon sinks Carbon reservoirs and conditions that take-in and store more carbon (i.e., carbon sequestration) than they release. Carbon sinks can partially offset greenhouse-gas emissions. Forests and oceans are large carbon sinks.

Carboxylation A chemical reaction in which a carboxylic acid group is introduced in a substrate.

Cartagena Dialogue A collection of around 40 countries working towards an ambitious legally binding agreement under the UNFCCC, and who are committed to becoming or remaining low carbon domestically. Participates include: Antigua and Barbuda, Australia, Bangladesh, Barbados, Burundi, Chile, Colombia, Costa Rica, Denmark, Dominican Republic, Ethiopia, European Union, France, Gambia, Georgia, Germany, Ghana, Grenada, Guatemala, Indonesia, Kenya, Lebanon, Malawi, Maldives, Marshall Islands, México, Netherlands, New Zealand, Norway, Panama, Peru, Rwanda, Samoa, Spain, Swaziland, Sweden, Switzerland, Tajikistan, Tanzania, Uganda, UAE, and the UK.

Cartesian paradigm A world view in which Man is totally independent of his environment, where both body and mind are perceived as distinct and separate and not part of a unified whole. The name Cartesian is derived from the French philosopher Rene Descartes.

Cation Exchange Capacity (CEC) The capacity of soil to hold positively charged ions such as calcium (Ca^{2+}), magnesium (Mg^{2+}), and potassium (K^{+}).

Cavitation The formation of vapor cavities, consisting mainly of bubbles or voids in a liquid. As a consequence of cavitation, (strong) forces acting upon the liquid and vessel walls. It usually occurs when a liquid is subjected to rapid changes of pressure that cause the formation of cavities where the pressure is relatively low.

CBD Convention on Biological Diversity.

CCC See "UNFCCC"

CCERs See "Chinese certified emission reductions"

CC:TRAIN Training methodology for assessing vulnerability to climate change.

CDM Help Desk A support initiative for project participants, developers, coordinating and/or managing entities (CMEs), designated national authorities (DNAs), and designated operational entities (DOEs) to get reliable and timely information from the secretariat on issues regarding their CDM projects. It is only available to stakeholders in Africa, least developed countries (LDCs), small island developing states (SIDS), and countries that had 10 or fewer registered CDM projects as of 31 December 2010, as long as the project is in the process of validation or verification.

CDM Loan Scheme An interest-free loan initiative that provides funding to projects for development of PDD, validation, and first verification. It applies to projects located in host countries with less than 10 CDM project activities registered with the UNFCCC (as of 1 January of the year of submission), with a high probability of registration with the UNFCCC and generating at least 7,500 CERs/year for projects in least developed countries (LDCs), and 15,000 CERs/year in non-LDCs. Available at http://cdmloanscheme.org/

CCN See "Cloud condensation nuclei (CCN)"

CCS See "Carbon capture and sequestration"

CDM See "Clean Development Mechanism"

CDR See "Carbon dioxide removal"

CEC See "Cation Exchange Capacity"

CER See "Certified Emission Reduction"

Certified Emission Reduction (CER) A greenhouse gas trading credit, under the UN Clean Development Mechanism (CDMI) program. A CER may be earned by participating in emission reduction programs – installing green technology, or planting forests – in developing countries. Each CER is equivalent to one ton of carbon dioxide. Two special types of CERs called temporary certified emission reduction (tCERs) and long-term certified emission reductions (lCERs) are issued for emission removals from afforestation and reforestation CDM projects.

Central Group Formerly CG-11, a negotiating coalition of Central European Annex I Parties, now called the Central Group.

CFC Chlorofluorocarbon.

CFC See "Chlorofluorocarbons"

CGE See "Computable General Equilibrium"

CG-11 Central Group 11 (negotiating coalition of Central European Annex I Parties).

CH_4 Methane.

Chair National delegates elected by participating governments to lead the deliberations of the Convention's subsidiary bodies. Different chairs may be elected for other informal groups. The Chair is responsible for facilitating progress towards an agreement and serves during the intersessional period until the next COP.

Chairman See "Chair"

Chairperson See "Chair"

Chinese certified emission reductions (CCERs) Emission reduction credits certified for use in China's domestic emissions trading markets. Procedures for creating and using these credits closely follow those employed in the CDM.

Chlorofluorocarbons (CFC) Gases covered under the 1987 Montreal Protocol and used, e.g., for refrigeration, air conditioning, packaging, insulation, solvents, or aerosol propellants. Since they are not destroyed in the lower atmosphere, CFCs drift into the upper atmosphere where, given suitable conditions, they break down ozone. These gases are being replaced by other compounds: hydrochlorofluorocarbons, an interim replacement for CFCs that are also covered under the Montreal Protocol, and hydrofluorocarbons, which are covered under the Kyoto Protocol. All these substances are also greenhouse gases. See also "Hydrochlorofluorocarbons," "Hydrofluorocarbons," "Perfluorocarbons," and "Ozone depleting substance."

Clean coal technology Technology that enables coal to be burned without emitting CO_2. Some systems currently being developed remove the CO_2 before combustion, others remove it afterwards. Clean coal technology is unlikely to be widely available for at least a decade.

Clean Development Mechanism (CDM) A program that enables developed countries or companies to earn credits by investing in greenhouse-gas emission reduction or removal projects in developing countries. These credits can be used to offset emissions and bring the country or company below its mandatory target.

Clean Power Plan (CPP) A proposed rule introduced by the US EPA on June 2, 2014 to regulate GHG emissions from existing power plants in the USA.

Climate Climate in a narrow sense is usually defined as the "average weather," or more rigorously, as the statistical description in terms of the mean and variability of relevant quantities over a period of time ranging from months to thousands of years. The classical period is three decades, as defined by the World Meteorological Organization (WMO). These quantities are most often surface variables such as temperature, precipitation, and wind. Climate in a wider sense is the state, including a statistical description, of the climate system. See also "Weather."

Climate change

FCCC definition: A change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods.

IPCC usage definition: Climate change as referred to in the observational record of climate occurs because of internal changes within the climate system or in the interaction between its components, or because of changes in external forcing either for natural reasons or because of human activities. It is generally not possible clearly to make attribution between these causes. Projections of future climate change reported by IPCC generally consider only the influence on climate of anthropogenic increases in greenhouse gases and other human-related factors.

Climate Change Convention See "UNFCCC"

Climate-carbon cycle coupling Future climate change induced by atmospheric emissions of greenhouse gases will impact on the global carbon cycle. Changes in the global carbon cycle in turn will influence the fraction of anthropogenic greenhouse gases that remains in the atmosphere, and hence the atmospheric concentrations of greenhouse gases, resulting in further climate change. This feedback is called climate-carbon cycle coupling. The first generation coupled climate-carbon cycle models indicates that global warming will increase the fraction of anthropogenic CO_2 that remains in the atmosphere.

Climate engineering Engineering the climate by means of carbon dioxide removal (CDR), earth radiation management (ERM), and/or solar radiation management (SRM) is a set of concepts and tools to deliberately, and on a large scale, moderate or retard global warming.

Climate feedback A process that acts to amplify or reduce direct warming or cooling effects.

Climate forcing See "Radiative forcing"

Climate lag The delay that occurs in climate change as a result of some factor that changes only very slowly. For example, the effects of releasing more carbon dioxide into the atmosphere occur gradually over time because the ocean takes a long time to warm up in response to a change in radiation. See "Climate and climate change."

Climate model A quantitative way of representing the interactions of the atmosphere, oceans, land surface, and ice. Models can range from relatively simple to quite comprehensive. See "General Circulation Model."

Climate sensitivity In IPCC reports, equilibrium climate sensitivity refers to the equilibrium change in global mean surface temperature following a doubling of the atmospheric (equivalent) CO_2 concentration. More generally, equilibrium climate sensitivity refers to the equilibrium change in surface air temperature following a unit change in radiative forcing (degrees Celsius, per watts per square meter, $^{\circ}CW^{-1}\ m^{-2}$). One method of evaluating the equilibrium climate sensitivity requires very long simulations with Coupled General Circulation Models (Climate model). The effective climate sensitivity is a related measure that circumvents this requirement. It is evaluated from model output for evolving nonequilibrium conditions. It is a measure of the strengths of the feedbacks at a particular time and may vary with forcing history and climate state. See also "Climate" and "Radiative forcing."

Climate system The five physical components (atmosphere, hydrosphere, cryosphere, lithosphere, and biosphere) that are responsible for the climate and its variations. Also called Earth system.

Cloud condensation nuclei (CCN) Airborne particles that serve as initial sites for the condensation of liquid water and which can lead to the formation of cloud droplets, e.g., soot or sea salt. Also known as cloud seeds.

Cloud seeds See "Cloud condensation nuclei"

Clean Development Mechanism (CDM) A mechanism under the Kyoto Protocol through which developed countries may finance greenhouse-gas emission reduction or removal projects in developing countries, and receive credits for doing so which they may apply towards meeting mandatory limits on their own emissions.

Clearing house A service which facilitates and simplifies transactions among multiple parties.

CMP See "Conference of the Parties serving as the Meeting of the Parties to the Kyoto Protocol."

CMS See "Convention on the Conservation of Migratory Species of Wild Animals."

CNG See "Compressed natural gas"

Coalbed methane Methane contained in coal seams. It is often referred to as virgin coalbed methane, or coal seam gas.

Coal mine methane Coal mine methane is the subset of coalbed methane that is released from the coal seams during the process of coal mining.

Coalition for Rainforest Nations A voluntary grouping of largely developing nations with rainforests which addresses issues surrounding environmental sustainability specific to tropical rainforests. Participation does not necessarily imply that countries adhere to any specific domestic policies or negotiating positions within the international context. In September 2011, the group included Argentina, Bangladesh, Belize, Cameroon, Central African Republic, Chile, Congo, Costa Rica, Cote d'Ivoire, DR Congo, Dominica, Dominican Republic, Ecuador, Equatorial Guinea, El Salvador, Fiji, Gabon, Ghana, Guatemala, Guyana, Honduras, Indonesia, Jamaica, Kenya, Lesotho, Liberia, Madagascar, Malaysia, Nicaragua, Nigeria, Pakistan, Panama, Papua New Guinea, Paraguay, Samoa, Sierra

Leone, Solomon Islands, Suriname, Thailand, Uruguay, Uganda, Vanuatu, and Vietnam. Countries participate on a voluntarily basis primarily through unified negotiating positions, workshops, and collaborative programs.

Co-Benefit The benefits of policies that are implemented for various reasons at the same time including climate change mitigation acknowledging that most policies designed to address greenhouse gas mitigation also have other, often at least equally important, rationales (e.g., related to objectives of development or sustainability).

Compressed natural gas (CNG) Methane stored at high pressure (typically 20–25 MPa or 2,900–3,600 psi) and used in place of gasoline (petrol), Diesel fuel and propane/LPG. The volumetric energy density of CNG is approx. 42 % that of liquefied natural gas (because it is not liquefied), and 25 % that of diesel fuel. See also "Liquefied natural gas (LNG)."

Computable General Equilibrium (CGE) A class of economic models that use actual economic data to estimate how an economy might react to changes in policy, technology, or other external factors. CGE models are also referred to as AGE (applied general equilibrium) models.

Concentration Amount of a chemical in a particular volume or weight of air, water, soil, or other medium. See also "Parts per billion (ppb)" and "Parts per million (ppm)."

Conference of the Parties (COP) The supreme body of the United Nations Framework Convention on Climate Change (UNFCCC). It comprises more than 180 nations that have ratified the Convention. Its first session was held in Berlin, Germany, in 1995 and it is expected to continue meeting on a yearly basis. The COP's role is to promote and review the implementation of the Convention. It will periodically review existing commitments in light of the Convention's objective, new scientific findings, and the effectiveness of national climate change programs. See also "United Nations Framework Convention on Climate Change (UNFCCC)."

Conference of the Parties serving as the Meeting of the Parties to the Kyoto Protocol (CMP) The UNFCCC's COP also serves as the meeting of the Parties to the Kyoto Protocol. The sessions of the COP and the CMP are held during the same period in order to reduce costs and improve coordination.

Consumerism The concept that an ever-expanding consumption of goods is advantageous to the economy.

Convention on the Conservation of Migratory Species of Wild Animals The Convention on Migratory Species, also known as the Bonn Convention, aims to conserve terrestrial, aquatic, and avian migratory species throughout their range. http://www.cms.int/

Convention See "United Nations Framework Convention on Climate Change"

COP See "Conference of the Parties"

Copenhagen Accord A political agreement reached at COP 15 which calls on participating countries to pledge specific actions they will undertake to mitigate

greenhouse-gas emissions. At the conclusion of the COP, however, delegates only voted to "take note of" the document.

Co-pollutant A pollutant that is produced by the same processes that produce carbon dioxide, and where changes in carbon dioxide emissions also influence emissions of the co-pollutant.

Coral bleaching The process in which a coral colony under environmental stress expels the microscopic algae (zooxanthellae) that live in symbiosis with their host organisms (polyps). The affected coral colony appears whitened.

Cost-benefit analysis A process by which you weigh expected costs against expected benefits to determine the best (or most profitable) course of action

Cost of Illness The total cost to society of a person's illness, including health care, lost worker productivity, additional insurance costs, and lost work days.

Coercive measures Policies which are not left to the discretion of the public, e.g., lower speed limits.

Commercialization The sequence of actions to achieve market entry and general market competitiveness of new innovative technologies, processes, and products.

Committee of the Whole Often created by a COP to aid in negotiating text. It consists of the same membership as the COP. When the Committee has finished its work, it turns the text over to the COP, which finalizes and then adopts the text during a plenary session.

Compliance Committee A committee that helps facilitate, promote and enforce compliance with the provisions of the Kyoto Protocol. It has 20 members with representation spread among various regions, small-island developing states, Annex I Parties, and non-Annex I Parties, and functions through a plenary, a bureau, a facilitative branch, and an enforcement branch.

Common Reporting Format (CRF) Standardized format for reporting estimates of greenhouse-gas emissions and removals and other relevant information by Annex I Parties.

Compliance Fulfillment by countries/businesses/individuals of emission reduction and reporting commitments under the UNFCCC and the Kyoto Protocol.

Conference of the Parties (COP) The supreme body of the Convention. It currently meets once a year to review the Convention's progress. The word "conference" is not used here in the sense of "meeting" but rather of "association." The "Conference" meets in sessional periods, for example, the "fourth session of the Conference of the Parties."

Conference of the Parties serving as the Meeting of the Parties to the Kyoto Protocol (CMP) The Convention's supreme body is the COP, which serves as the meeting of the Parties to the Kyoto Protocol. The sessions of the COP and the CMP are held during the same period to reduce costs and improve coordination between the Convention and the Protocol.

Conference room papers (CRPs) A category of in-session documents containing new proposals or outcomes of in-session work. CRPs are for use only during the session concerned.

Consultative Group of Experts on National Communications from non-Annex I Parties (CGE) A panel established to improve the preparation of national communications from developing countries. National communications are an obligation of Parties to the Climate Change Convention.

Contact group An open-ended meeting that may be established by the COP, a subsidiary body or a Committee of the Whole wherein Parties may negotiate before forwarding agreed text to a plenary for formal adoption. Observers generally may attend contact group sessions.

Convention on Biological Diversity (CBD) Signed by 150 government leaders at the 1992 Rio Earth Summit, the Convention on Biological Diversity is dedicated to promoting sustainable development. Conceived as a practical tool for translating the principles of Agenda 21 into reality, the Convention recognizes that biological diversity is about more than plants, animals, and microorganisms and their ecosystems – it is about people and our need for food security, medicines, fresh air and water, shelter, and a clean and healthy environment in which to live. https://www.cbd.int/

Countries with Economies in Transition (EIT) Central and East European countries and former republics of the Soviet Union in transition from state-controlled to market economies. At the time the Kyoto Protocol was adopted in 1997, these countries were on the path from a Communist planned economy to a market economy. Many of them would now be categorised as market economies. Countries in transition to a market economy are grouped with industrialized countries in Annex I of the Kyoto Protocol, so they have emission reduction commitments to meet in the 2008–2012 period. In some cases their industrial base collapsed to such a degree in the early 1990s that they will have no difficulty meeting these commitments.

Countries in transition See "Countries with Economies in Transition"

CO_2 See "Carbon dioxide."

CO_{2e} See "Equivalent CO_2"

CPP See "Clean Power Plan"

CRF See "Common Reporting Format"

Cross-sectional data Observations of units, such as households, firms, persons, or geographical units, at the same point in time.

Crop yield The amount of crop harvested per area unit of land, for instance tons of crop per hectare.

Cryotic soil See "Permafrost"

Cryosphere One of the interrelated components of the Earth's system. The cryosphere is frozen water in the form of snow, permanently frozen ground (permafrost), floating ice, and glaciers, i.e., all global snow, ice, and permafrost. Fluctuations in the volume of the cryosphere cause changes in ocean sea level, which directly impact the atmosphere and biosphere.

CSD See "United Nations Commission on Sustainable Development."

Currently realizable potential See "Market potential"

Damage function The relation between changes in the climate and reductions in economic activity relative to the rate that would be possible in an unaltered climate.

Dangerous climate change Severe climate change with a negative effect on societies, economies, and the environment as a whole. The phrase was introduced by the 1992 UN Framework Convention on Climate Change (UNFCCC), which aims at preventing "dangerous" human interference with the climate system.

Decadal-to-centennial variability See "Deccen"

Decarbonization The reduction in carbon dioxide emissions per unit GDP, thereby reducing the carbon intensity of the economy. See also "GDP" and "Carbon intensity."

Deccen (decadal-to-centennial variability) A term used to describe variations and changes in climatic elements occurring on time scale ranging from decades to centuries. These temporal variations may be induced by changes in forcing agents arising from either human activities (e.g., increasing levels of atmospheric greenhouse gases) or natural causes (e.g., volcanic aerosols or solar irradiance). Some deccen climate variability is unforced, in that it can be the product of internally generated climate system fluctuations.

Decoupling A process in which economic growth is created without increasing carbon dioxide emissions, so the economy and emissions can proceed along different paths.

Declaration A nonbinding political statement made by ministers attending a major meeting (e.g., the Marrakesh Ministerial Declaration of COP-7).

Deforestation The permanent removal of standing forests. Deforestation contributes to increasing carbon dioxide concentrations for two reasons: (1) the burning or decomposition of the wood releases carbon dioxide; and (2) trees that once removed carbon dioxide from the atmosphere in the process of photosynthesis are no longer present.

Desertification Land degradation in arid, semiarid, and dry subhumid areas resulting from various factors, including climatic variations and human activities.

Designated National Authority (DNA) An office, ministry, or other official entity appointed by a Party to the Kyoto Protocol to review and give national approval to projects proposed under the Clean Development Mechanism.

Designated operational entity (DOE) An entity designated by the CMP (based on a recommendation by the EB) as qualified to validate proposed CDM project activities and PoAs; thus DOEs serve as auditors in the CDM process.

Discounting A standard technique used for making intertemporal decisions in which the future costs and benefits are given less weight than the present. The process of converting monetary values backward in time to an equivalent amount is called discounting. The social discount rate is the rate at which society as a whole is willing to trade off present for future benefits.

Diurnal temperature range The difference between maximum and minimum temperature over a period of 24 h.

DNA See "Designated National Authority"

DNA Help Desk A support initiative for Designated National Authorities (DNAs) to provide advice, support, and assistance with the submission of proposals for standardized baselines, recommendations of microscale renewable energy technologies for automatic additionality, or grid emission factors. It targets DNAs from

least developed countries (LDCs), small island developing states (SIDS), African countries, or Parties with less than 10 registered projects as of 31 December 2010. It is possible for project participants and designated operational entities (DOEs) to liaise with a DNA to submit a request on their behalf.

Documents In this context, official documents are available to everyone and feature the logos of the United Nations and the Climate Change Convention. They carry a reference number, such as FCCC/CP/1998/1. Pre-session documents are available before a meeting, often in all six UN languages. In-session documents are distributed on-site (CRPs, L docs, Misc. docs, Inf. docs, and nonpapers).

DOE See "Designated operational entity"

Drafting group A smaller group established by the President or a Chair of a Convention body to meet separately and in private to prepare draft text (text that still has to be formally approved later in a plenary session). Observers generally may not attend drafting group meetings.

Dryland farming A technique that uses soil moisture conservation and seed selection to optimize production under dry conditions.

Dubinin-Radushkevich (DR) Model This model expressed in the DR equation is used to describe the adsorption of subcritical fluids in microporous solids such as activated carbon (biochar). The equation has the form

$$\frac{w}{w_0} = \exp\left[-\left(A/\beta E_o\right)^2\right], \qquad A = RTIn\left({}^{P}/_{P_o}\right)$$

where w and w_o are the amount of adsorption at a relative pressure (P/P_o) and the saturated amount of adsorption, respectively, E_o is a characteristic adsorption energy, and the parameter A is Polanyi's adsorption potential. The parameter β is the affinity coefficient, and is related to the adsorbate-adsorbent interaction. The equation provides macroscopic information of the fraction of the total microscopic volume occupied by the adsorbate.

Earth radiation management (ERM) A set of concepts to moderate or retard global warming by altering, on a large scale, the radiation sent back from Earth into space. See also "Climate engineering."

Earth Summit See "United Nations Conference on Environment and Development"

Earth system See "Climate system"

EB See "Executive Board of the CDM"

Eccentricity The extent to which the Earth's orbit around the Sun departs from a perfect circle.

Ecological economics A growing transdisciplinary field that aims to improve and expand economic theory to integrate the earth's natural systems, human values, and human health and well-being.

Ecology The study of the relationships between living organisms and their environment.

Economic growth An increase in the capacity of an economy to produce goods and services, compared from one period of time to another.

Economic potential The fraction of the technical potential for GHG emissions reductions or energy-efficiency improvements that could be achieved cost-effectively in the absence of market barriers. The achievement of the economic potential requires additional policies and measures to remove market barriers. See also "Market barriers."

Economic and Social Commission for Asia and the Pacific (ESCAP) The regional development arm of the United Nations for the Asia-Pacific region. Made up of 53 member states and 9 associate members, the region is home to 4.1 billion people, or two thirds of the world's population. This makes ESCAP the most comprehensive of the United Nations five regional commissions, and the largest United Nations body serving the Asia-Pacific region with over 600 staff. Established in 1947 with its headquarters in Bangkok, Thailand, ESCAP works to overcome some of the region's greatest challenges by providing results oriented projects, technical assistance, and capacity building to member states.
http://www.unescap.org/about

Economic and Social Council (ECOSOC) The United Nations' central platform for reflection, debate, and innovative thinking on sustainable development. It is one of the six main organs of the United Nations established by the UN Charter in 1946.
http://www.un.org/en/ecosoc/

Ecosystem Any natural unit or entity including living and nonliving parts that interact to produce a stable system through cyclic exchange of materials.

ECSOC See "Economic and Social Council"

Eddy mixing Mixing due to small scale turbulent processes (eddies). Such processes cannot be explicitly resolved by even the finest resolution Atmosphere-ocean General Circulation Models (AOGCM) currently in use. Therefore, their effects must be related to the larger scale conditions. See also "Atmosphere-ocean General Circulation Model (AOGCM)."

EGTT See "Expert Group on Technology Transfer"

EIA See "Energy Information Administration (US)"

EJ Exajoule (10^{18} J). Joule is the SI unit of energy. 1 J is the work required to produce one watt of power for one second, or one "watt second" (W · s) (compare kilowatt hour (kWh); 1 kWh = 3.6 MJ).

El Niño – Southern Oscillation (ENSO) El Niño, in its original sense, is a warm water current that periodically flows along the coast of Ecuador and Peru, disrupting the local fishery. This oceanic event is associated with a fluctuation of the intertropical surface pressure pattern and circulation in the Indian and Pacific Oceans, called the Southern Oscillation. This coupled atmosphere-ocean phenomenon is collectively known as El Niño-Southern Oscillation. During an El Niño event, the prevailing trade winds weaken and the equatorial countercurrent strengthens, causing warm surface waters in the Indonesian area to flow eastward to overlie the cold waters of the Peru current. This event has great impact on the wind, sea surface temperature, and precipitation patterns in the tropical Pacific. It has climatic effects throughout the Pacific region and in many other parts of the world. The opposite of an El Niño event is called La Niña.

Embodied energy The energy used to produce a material substance (such as processed metals or building materials), taking into account energy used at the manufacturing facility (zero order), energy used in producing the materials that are used in the manufacturing facility (first order), and so on.

Emissions The release of a substance (usually a gas when referring to the subject of climate change) into the atmosphere.

Emission Trading Scheme (ETS) A scheme set up to allow the trading of emissions permits between business and/or countries as part of a cap and trade approach to limiting greenhouse gas emissions. The best-developed example is the EU's trading scheme, launched in 2005. See "Cap and trade."

Emissions factor A unique value for scaling emissions to activity data in terms of a standard rate of emissions per unit of activity (e.g., grams of carbon dioxide emitted per barrel of fossil fuel consumed, or per gram of product produced).

Emission permit An allocation of entitlements by a government to an individual organization to emit a specified amount of a substance, e.g., CO_2. Emission permits can be nontransferable or tradable.

Emission quota The fractions of total allowable emissions assigned to a country or group of countries within a framework of maximum total emissions and mandatory allocations of resources or assessments.

Emission reduction unit (ERU) A Kyoto Protocol unit equal to 1 metric ton of CO_2 equivalent. ERUs are generated for emission reductions or emission removals from joint implementation projects.

Emission standard A level of emission that under the law must not be exceeded. An example is the EURO 6 emission standard for trucks.

Emissions trading One of the three Kyoto mechanisms, by which an Annex I Party may transfer Kyoto Protocol units to, or acquire units from, another Annex I Party. An Annex I Party must meet specific eligibility requirements to participate in emissions trading. The process allows market incumbents to either reduce emissions or pay for the right to pollute (with the money paid being used to reduce emissions elsewhere).

Emission trajectories These are projections of future emission pathways, or observed emission patterns.

Energy The amount of work or heat delivered. Energy is classified in a variety of types and becomes useful to human ends when it flows from one place to another or is converted from one type into another. The SI-derived unit of energy is Joule ($1\ \mathrm{J} = 1\ \mathrm{kg} \cdot \mathrm{m}^2/\mathrm{s}^2$).

Energy balance Averaged over the globe and over longer time periods, the energy budget of the climate system must be in balance. Because the climate system derives all its energy from the Sun, this balance implies that, globally, the amount of incoming solar radiation must on average be equal to the sum of the outgoing reflected solar radiation and the outgoing infrared radiation emitted by the climate system. A perturbation of this global radiation balance, be it human-induced or natural, is called radiative forcing. See also "Radiative forcing."

Energy efficiency Using less energy to provide the same service

Energy Information Administration (EIA) The US Energy Information Administration (EIA) collects, analyzes, and disseminates independent and impartial energy information to promote sound policymaking, efficient markets, and public understanding of energy and its interaction with the economy and the environment.
http://www.eia.gov/

Energy intensity Ratio of energy consumption to economic or physical output. At the national level, energy intensity is the ratio of total domestic primary energy consumption or final energy consumption to gross domestic product (GDP) or physical output.

Energy performance rating (EPR) A metric to assess the overall energy efficiency of a building (measured in kWh/m^2 per year), either using actual or modeled energy use data.

ENERGY STAR™ A US Environmental Protection Agency (EPA) voluntary program that helps businesses and individuals save money and protect our climate through superior energy efficiency.
https://www.energystar.gov/

Enhanced Greenhouse Effect The concept that the natural greenhouse effect has been enhanced by increased atmospheric concentrations of greenhouse gases (such as CO_2 and methane) emitted as a result of human activities. These added greenhouse gases cause the earth to warm.

Enteric fermentation Livestock, especially cattle, produce methane as part of their digestion. This process is called enteric fermentation, and it represents one third of the emissions from the agriculture sector.

Entry into force The point at which an intergovernmental agreement becomes legally binding – occurring at a prestated interval after a prestated and required number of ratifications by countries has been achieved. The Climate Change Convention required 50 ratifications to enter into force. It now enters into force for each new Party 90 days after that Party ratifies the Convention. See also "UNFCCC."

Environmental economics Environmental and natural resource economics is a subdiscipline of economics and deals with the study of how environmental and natural resources are developed and managed.

Environmental Integrity Group A coalition or negotiating alliance consisting of Mexico, the Republic of Korea, Switzerland, Lichtenstein, and Monaco.

Environmentally friendly modes Active travel modes plus public transport.

Environmental Protection Agency (EPA) An agency of the US federal government which was created for the purpose of protecting human health and the environment by writing and enforcing regulations based on laws passed by Congress. The EPA began operation in 1970.
http://www.epa.gov/

EPA See "Environmental Protection Agency"

EPR See "Energy performance rating"

Equilibrium response The steady state response of the climate system (or a climate model) to an imposed radiative forcing.

Equilibrium vapor pressure See "Vapor pressure"

Equivalent carbon dioxide See "Equivalent CO_2 (CO_2e)"

Equivalent CO_2 (CO_2e) The concentration of CO_2 that would cause the same level of radiative forcing as a given type and concentration of greenhouse gas. Examples of such greenhouse gases are methane, perfluorocarbons, and nitrous oxide. CO_{2e} is expressed as parts per million by volume, ppmv. See also "Carbon dioxide equivalent (CDE)."

ERM See "Earth radiation management"

ERU See "Emission reduction unit"

ESCAP See "Economic and Social Commission for Asia and the Pacific"

ETS See "Emission Trading Scheme"

EU See "European Union"

European Union (EU) As a regional economic integration organization, the EU is a Party to both the Convention and the Kyoto Protocol. However, it does not have a separate vote from its member states. Because the EU signed the Convention when it was known as the EEC (European Economic Community), the EU retains this name for all formal Convention-related purposes. Members are Austria, Belgium, Bulgaria, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, the Netherlands, Poland, Portugal, Romania, Slovakia, Slovenia, Spain, Sweden, and the UK. http://europa.eu/index_en.htm

EUA See "European Union Allowances"

EU Burden-sharing agreement A political agreement that was reached to help the EU reach its emission reduction targets under the Kyoto Protocol (a reduction of 8 % during the period 2008–2012, on average, compared with 1990 levels). The 1998 agreement divided the burden unequally amongst member states, taking into account national conditions, including greenhouse-gas emissions at the time, the opportunity for reducing them, and countries' levels of economic development.

EU ETS (European Union Emissions Trading Scheme) An emissions trading scheme developed by the European Union, designed to help European countries meet their Kyoto Protocol commitments. The EU ETS has been the principal source of demand in the international carbon market.

European Union Allowances (EUA) Quantity-based emissions instruments employed within the EU ETS. Facilities included in the EU ETS must surrender an EUA for each ton of CO_2 emitted.

Evaporation The process by which water changes from a liquid to a gas or vapor.

Evapotranspiration The combined process of evaporation from the Earth's surface and transpiration from vegetation.

Executive Board of the CDM (EB) A 10-member panel which supervises the CDM (Clean Development Mechanism).
See also "CDM."

Exfoliation A chemical or thermal approach for individual separation of carbon sheets to produce single-layered graphene nanosheets.

Expert Group on Technology Transfer (EGTT) An expert group established at COP 7 with the objective of enhancing the implementation of Article 4.5 of the Convention, by analyzing and identifying ways to facilitate and advance technology transfer activities under the Convention. The EGTT completed its work in 2010.

Expert review teams Groups of experts, nominated by Parties, who review national reports submitted by Annex I Parties to the UNFCCC and the Kyoto Protocol.

External costs Costs, such as industrial air pollution, which are involuntarily imposed upon others.
See also "Externalities."

External impacts See "Externalities"

Externalities By-products of activities that affect the well-being of people or damage the environment, where those impacts are not reflected in market prices. The costs (or benefits) associated with externalities do not enter standard cost accounting schemes. For instance, car drivers do not need to pay for the damage caused by car emissions (e.g., acidic rain, climate change).

Falsifiability rule In science, there is no way to prove the absolute truth of any hypothesis or model, since it is always possible that a different explanation might account for the same observations. In this sense, even the most well established physical laws are "conditional." Hence, with scientific methodology it is never possible to prove conclusively that a hypothesis is true, it is only possible to prove that it is false.

Fast-start Finance (FSF) At COP 15 in Copenhagen in 2009, developed countries pledged to provide new and additional resources, including forestry and investments, approaching USD 30 billion for the period 2010–2012 and with balanced allocation between mitigation and adaptation. This collective commitment has come to be known as "Fast-start Finance."

FAR IPCC First Assessment Report (FAR), 1990. See also "IPCC" and "AR5."

FAO See "Food and Agriculture Organization of the United Nations."

FCCC See "United Nations Framework Convention on Climate Change"

Feedback When one variable in a system triggers changes in a second variable that in turn ultimately affects the original variable; a positive feedback intensifies the effect, and a negative feedback reduces the effect.

Feedback loop In a feedback loop, rising temperatures on the Earth change the environment in ways that affect the rate of warming. Feedback loops can be positive (adding to the rate of warming), or negative (reducing it). The melting of Arctic ice provides an example of a positive feedback process. As the ice on the surface of the Arctic Ocean melts away, there is a smaller area of white ice to reflect the Sun's heat back into space and more open, dark water to absorb it. The less ice there is, the more the water heats up, and the faster the remaining ice melts.

Feedback mechanisms Factors which increase or amplify (positive feedback) or decrease (negative feedback) the rate of a process. An example of positive climatic feedback is the ice-albedo feedback.

Final Energy Energy supplied that is available to the consumer to be converted into useful energy (e.g., electricity at the socket). See also "Primary energy."

Financial mechanism Developed country Parties (Annex II Parties) are required to provide financial resources to assist developing country Parties implement the Convention (UNFCCC). To facilitate this, the Convention established a financial mechanism to provide funds to developing country Parties. The Parties to the Convention assigned operation of the financial mechanism to the Global Environment Facility (GEF) on an on-going basis, subject to review every 4 years. The financial mechanism is accountable to the COP. See also "UNFCCC."

Flexible mechanism Instruments that help countries and companies meet emission reduction targets by paying others to reduce emissions for them. The mechanism in widest use is emissions trading, where companies or countries buy and sell permits to pollute. The Kyoto Protocol establishes two flexible mechanisms enabling rich countries to fund emission reduction projects in developing countries – Joint Implementation (JI) and the Clean Development Mechanism (CDM).

Fluorinated gases Powerful synthetic greenhouse gases such as hydrofluorocarbons, perfluorocarbons, and sulfur hexafluoride that are emitted from a variety of industrial processes. Fluorinated gases are sometimes used as substitutes for stratospheric ozone-depleting substances (e.g., chlorofluorocarbons, hydrochlorofluorocarbons, and halons) and are often used in coolants, foaming agents, fire extinguishers, solvents, pesticides, and aerosol propellants. These gases are emitted in small quantities compared to carbon dioxide (CO_2), methane (CH_4), or nitrous oxide (N_2O), but because they are potent greenhouse gases, they are sometimes referred to as High Global Warming Potential gases (High GWP gases).

Fluorocarbons Carbon-fluorine compounds that often contain other elements such as hydrogen, chlorine, or bromine. Common fluorocarbons include chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs), and perfluorocarbons (PFCs). See "Chlorofluorocarbons," "Hydrochlorofluorocarbons," "Hydrofluorocarbons," "Perfluorocarbons," and "Ozone depleting substance."

Food and Agriculture Organization of the United Nations (FAO) The FAO aims at "*achieving food security for all is at the heart of FAO's efforts – to make sure people have regular access to enough high-quality food to lead active, healthy lives. Our three main goals are: the eradication of hunger, food insecurity and malnutrition; the elimination of poverty and the driving forward of economic and social progress for all; and, the sustainable management and utilization of natural resources, including land, water, air, climate and genetic resources for the benefit of present and future generations*."
http://www.fao.org/

Food miles The distance an item of food travels from point of growth to point of final consumption.

Forcing mechanism A process that alters the energy balance of the climate system, i.e., changes the relative balance between incoming solar radiation and outgoing

infrared radiation from Earth. Such mechanisms include changes in solar irradiance, volcanic eruptions, and enhancement of the natural greenhouse effect by emissions of greenhouse gases. See "Radiation," "Infrared radiation," and "Radiative forcing."

Fossil fuel A general term for organic materials formed from decayed plants and animals that have been converted to crude oil, coal, natural gas, or heavy oils by exposure to heat and pressure in the earth's crust over hundreds of millions of years.

Fossil fuels Natural resources, such as coal, oil, and natural gas, containing hydrocarbons. These fuels are formed in the Earth over millions of years and produce carbon dioxide when burnt.

Fossil fuel reserves The quantity of a fossil fuel that is known to exist, based on geological and engineering evidence, and that can be recovered under current economic conditions and operating capabilities.

Fossil fuel resources See "Fossil fuel reserves"

Freundlich Model A model that expresses an empirical relationship between the concentration of a solute on the surface of an adsorbent and the concentration of the solute in the liquid with which it is in contact. The Freundlich Adsorption Isotherm is mathematically expressed as:

$$\frac{x}{m} = KP^{1/n}$$

It is also written as

$$\frac{x}{m} = Kc^{1/n},$$

where, x = mass of adsorbate
m = mass of adsorbent
p = equilibrium pressure of adsorbate
c = equilibrium concentration of adsorbate in solution
K and n are constants for a given adsorbate and adsorbent at a particular temperature

Friends of the Chair Delegates called upon by the Chair (who takes into account the need for political balance among various interests) to assist in carrying out specific tasks.

FSF See "Fast-start Finance"

Fuel switching In general, this is substituting one type of fuel for another. In the climate-change discussion it is implicit that the substituted fuel produces lower carbon emissions per unit of energy produced than the original fuel, e.g., natural gas for coal.

Fugitive fuel emissions Greenhouse-gas emissions as by-products or waste or loss in the process of fuel production, storage, or transport, such as methane given off during oil and gas drilling and refining, or leakage of natural gas from pipelines.

Full-cost pricing The pricing of commercial goods – such as electric power – that would include in the final prices faced by the end user not only the private costs of inputs, but also the costs of the externalities created by their production and use.

Gasification Noncombustion process of converting organic or fossil fuel based carbonaceous materials into carbon monoxide, hydrogen, and carbon dioxide at elevated temperatures under controlled addition of air/oxygen and/or steam.

GATT See "General Agreement on Tariffs and Trade"

GCF See "Green Climate Fund"

GCOS See "Global Climate Observing System"

GDP See "Gross domestic product"

GEF See "Global Environment Facility"

General Agreement on Tariffs and Trade (GATT) The GATT was a multilateral agreement regulating international trade with the purpose of a "substantial reduction of tariffs and other trade barriers and the elimination of preferences, on a reciprocal and mutually advantageous basis." It took effect on January 1, 1948 and lasted until April 14, 1994 (Uruguay Round Agreements, which established the World Trade Organization (WTO) on January 1, 1995). https://www.wto.org/english/docs_e/legal_e/gatt47_e.pdf

General circulation model (GCM) A general circulation model (GCM), a type of climate model, is a mathematical model of the general circulation of a planetary atmosphere or ocean and based on the Navier–Stokes equations on a rotating sphere with thermodynamic terms for various energy sources (radiation, latent heat). These equations are the basis for complex computer programs commonly used for simulating the atmosphere or ocean of the Earth. Atmospheric and oceanic GCMs (AGCM and OGCM) are key components of global climate models. Atmosphere-ocean General Circulation Models (AOGCM) encompass both land and sea masses. See also "Climate modeling."

Geoengineering See "Climate engineering"

Geosphere The soils, sediments, and rock layers of the Earth's crust, both continental and beneath the ocean floors.

Geological sequestration The injection of carbon dioxide into underground geological formations. When CO_2 is injected into declining oil fields it can help to recover more of the oil.

GHG See "Greenhouse gases"

GHG Reduction Potential Possible reductions in emissions of greenhouse gases (quantified in terms of absolute reductions or in percentages of baseline emissions) that can be achieved through the use of technologies and measures.

Glacier A multiyear surplus accumulation of snowfall in excess of snowmelt on land and resulting in a mass of ice at least 0.1 km^2 in area that shows some evidence of movement in response to gravity. A glacier may terminate on land or in water. Glacier ice is the largest reservoir of fresh water on Earth, and second only to the oceans as the largest reservoir of total water. Glaciers are found on every continent except Australia. See also "Snowpack."

Global Average Temperature The mean surface temperature of the Earth measured from three main sources: satellites, monthly readings from a network of over 3,000 surface temperature observation stations, and sea surface temperature measurements taken mainly from the fleet of merchant ships, naval ships, and data buoys.

GCOS See "Global Climate Observing System"

Global Climate Observing System (GCOS) A joint undertaking of the World Meteorological Organization (WMO), the Intergovernmental Oceanographic Commission (IOC) of the United Nations Educational Scientific and Cultural Organization (UNESCO), the United Nations Environment Programme (UNEP), and the International Council for Science (ICSU). Its goal is to provide comprehensive information on the total climate system, involving a multidisciplinary range of physical, chemical, and biological properties, and atmospheric, oceanic, hydrological, cryospheric, and terrestrial processes.
http://www.wmo.int/pages/prog/gcos/index.php?name=News

Global dimming An observed widespread reduction in sunlight at the surface of the Earth, which varies significantly between regions. The most likely cause of global dimming is an interaction between sunlight and microscopic aerosol particles from human activities. In some regions, such as Europe, global dimming no longer occurs, thanks to clean air regulations.

Global energy budget The balance between the Earth's incoming and outgoing energy. The current global climate system must adjust to rising greenhouse gas levels and, in the very long term, the Earth must get rid of energy at the same rate at which it receives energy from the sun.

Global Environment Facility (GEF) The GEF is an independent financial organization that provides grants to developing countries for projects that benefit the global environment and promote sustainable livelihoods in local communities. The Parties to the Convention assigned operation of the financial mechanism to the GEF on an on-going basis, subject to review every 4 years. The financial mechanism is accountable to the COP.
https://www.thegef.org/gef/

Global Ocean Observing System (GOOS) A permanent global system for observations, modelling, and analysis of marine and ocean variables to support operational ocean services worldwide. GOOS provides accurate descriptions of the present state of the oceans, including living resources; continuous forecasts of the future conditions of the sea for as far ahead as possible, and the basis for forecasts of climate change.
http://www.ioc-goos.org/

Global Trade Analysis Project (GTAP) A global network of researchers and policy makers conducting quantitative analysis of international policy issues. GTAP is coordinated by the Center for Global Trade Analysis in Purdue University's Department of Agricultural Economics.
https://www.gtap.agecon.purdue.edu/

Global Warming The recent and ongoing global average increase in temperature near the Earth's surface.

Global Warming Potential (GWP) A measure of the total energy that a gas absorbs over a particular period of time (usually 100 years), compared to carbon dioxide. The GWP depends on the absorption of infrared radiation spectrum by a given species and its atmospheric lifetime. For instance, the GWP of methane (AR5) is 34. See also "AR5."

GOOS See 'Global Ocean Observing System"

Greenhouse effect Trapping and build-up of heat in the atmosphere (troposphere) near the Earth's surface. Some of the heat flowing back toward space from the Earth's surface is absorbed by water vapor, carbon dioxide, ozone, and several other gases in the atmosphere and then reradiated back toward the Earth's surface. If the atmospheric concentrations of these greenhouse gases rise, the average temperature of the lower atmosphere will gradually increase. See also "Greenhouse gas," "Anthropogenic," "Climate," and "Global warming."

Green Climate Fund (GCF) At COP 16 in Cancun in 2010, Governments established a Green Climate Fund as an operating entity of the financial mechanism of the Convention under Article 11. The GCF will support projects, programs, policies, and other activities in developing country Parties. The Fund will be governed by the GCF Board.

Greenhouse effect The insulating effect of certain gases in the atmosphere, which allow solar radiation to warm the earth and then prevent some of the heat from escaping. See also "Natural greenhouse effect."

Greenhouse gases (GHGs) A gas that absorbs radiation at specific wavelengths within the spectrum of infrared radiation emitted by the Earth's surface. The gas in turn emits infrared radiation from a level where the temperature is colder than the surface. The net effect is a local trapping of part of the absorbed energy and a tendency to warm the planetary surface. Water vapour (H_2O), carbon dioxide (CO_2), nitrous oxide (N_2O), methane (CH_4), and ozone (O_3) are the primary greenhouse gases in the Earth's atmosphere.

The atmospheric gases (natural and industrial) responsible for causing global warming and climate change. The major GHGs, which are restricted by the Kyoto protocol, are carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O). Less prevalent, but very powerful, greenhouse gases are hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulphur hexafluoride (SF_6).

Gross Domestic Product (GDP) The value of all goods and services produced (or consumed) within a nation's borders.

Group of 77 (G-77) and China A large negotiating alliance of developing countries that focuses on numerous international topics, including climate change. The G-77 was founded in 1967 under the auspices of the United Nations Conference on Trade and Development (UNCTAD). It seeks to harmonize the negotiating positions of its 131 member states.

Group of Mountain Landlocked Developing Countries Negotiating group formally established in June 2010 by the governments of Armenia, Kyrgyzstan, and

Tajikstan, focused issues faced by landlocked mountain developing countries specifically vulnerable to transportation costs and food insecurity, with a view towards expanding the group to include other interested countries.

GRULAC Group of Latin American and Caribbean States.

GTAP See "Global Trade Analysis Project"

GTOS Global Terrestrial Observing System.

GWP See "Global Warming Potential"

G77 The main negotiating bloc for developing countries, allied with China (G77 +China). The G77 comprises 130 countries, including India and Brazil, most African countries, the grouping of small island states (AOSIS), the Gulf states, and many others.

Habitat fragmentation A process during which larger areas of habitat are broken into a number of smaller patches of smaller total area, isolated from each other by a matrix of habitats unlike the original habitat.

Halocarbons Compounds containing chlorine, bromine or fluorine and carbon. The carbon backbone can be fully halogenated or contain hydrogen, too. Halocarbons can act as powerful greenhouse gases (GHG) in the atmosphere. The chlorine and bromine containing halocarbons are also involved in the depletion of the ozone layer.

HCT See "Hydrothermal carbonization"

Heat island An urban area characterized by temperatures higher than those of the surrounding nonurban area. As urban areas develop, buildings, roads, and other infrastructure replace open land and vegetation. These surfaces absorb more solar energy, which can create higher temperatures in urban areas.

Heat wave A prolonged period of excessive heat, often combined with excessive humidity.

HFC Hydrofluorocarbons.

High GWP gases See "Fluorinated gases"

Hockey stick The name given to a graph with characteristic pattern. In this context, a figure plotting the average temperature in the Northern hemisphere over the last 1,000 years. The line remains roughly flat until the last 100 years, when it bends sharply upwards. The graph has been cited as evidence to support the idea that global warming is a man-made phenomenon, but some scientists have challenged the data and methodology used to estimate historical temperatures. (It is also known as MBH98 after its creators, Michael E. Mann, Raymond S. Bradley and Malcolm K. Hughes, in 1998)

Holistic thinking See "Systems thinking"

"Hot air" Refers to the concern that some governments will be able to meet their targets for greenhouse-gas emissions under the Kyoto Protocol with minimal effort and could then flood the market with emissions credits, reducing the incentive for other countries to cut their own domestic emissions.

HOV High occupancy vehicle.

Hydrocarbons Substances containing only hydrogen and carbon. Fossil fuels are made up of hydrocarbons.

HTC See "Hydrothermal carbonization"

Hydrochar An alternative to slow-pyrolysis of biomass (which yields biochar) is a process called hydrothermal carbonization (HTC) of biomass, where the biomass is treated with hot compressed water instead of drying to yield hydrochar (HTC char). See also "Biochar."

Hydrochlorofluorocarbons (HCFCs) Compounds containing hydrogen, fluorine, chlorine, and carbon atoms. Although ozone depleting substances, they are less potent at destroying stratospheric ozone than chlorofluorocarbons (CFCs). They have been introduced as temporary replacements for CFCs and are also greenhouse gases. See also "Ozone depleting substance."

Hydrofluorocarbons (HFCs) Compounds containing only hydrogen, fluorine, and carbon atoms. They were introduced as alternatives to ozone depleting substances in serving many industrial, commercial, and personal needs. HFCs are emitted as by-products of industrial processes and are also used in manufacturing. They do not significantly deplete the stratospheric ozone layer, but they are powerful greenhouse gases with global warming potentials (GWP) ranging from approx. 140 (HFC-152a) to 11,700 (HFC-23). See also "Global Warming Potential."

Hydrogen bond Chemical bond formed by the electrostatic attraction between polar molecules that occurs when a hydrogen (H) atom bound to a highly electronegative atom such as nitrogen (N), oxygen (O), or fluorine (F) experiences attraction to some other nearby highly electronegative atom.

Hydrologic cycle The process of evaporation, vertical and horizontal transport of vapor, condensation, precipitation, and the flow of water from continents to oceans. It is a major factor in determining climate through its influence on surface vegetation, the clouds, snow and ice, and soil moisture. The hydrologic cycle is responsible for 25–30 % of the mid-latitudes' heat transport from the equatorial to polar regions.

Hydrophilic Surface A surface that has affinity for water.

Hydrophobic Surface A surface that repels water.

Hydrosphere The component of the climate system comprising liquid surface and subterranean water, such as: oceans, seas, rivers, fresh water lakes, underground water, etc.

Hydrothermal carbonization (HCT) An exothermic process in which wet biomass is converted in aqueous suspensions at moderate temperatures (180–250 °C) and medium pressure conditions into highly carbonaceous hydrochars. The HTC process offers several advantages over conventional pyrolysis, e.g., use of wet feedstock without the need for predrying. The obtained char (hydrochar) can be used for carbon sequestration, soil amelioration, bioenergy production, and wastewater pollution remediation. See also "Biochar" and "Hydrochar."

Hydrothermal carbonization (HTC) Biomass is treated with hot compressed water.

IAR See "Independent Assessment Report"

ICA See "International consultation and analysis"

ICAO See "International Civil Aviation Organization."

ICCP See "International Climate Change Partnership"

Ice Core A cylindrical section of ice removed from a glacier or an ice sheet in order to study climate patterns of the past. By performing chemical analyses on the air trapped in the ice, scientists can estimate the percentage of carbon dioxide and other trace gases in the atmosphere at a given time. Analysis of the ice itself can give some indication of historic temperatures.

ICLEI See "International Council of Local Environmental Initiatives"

International Council of Local Environmental Initiatives (ICLEI) An international association of local governments and national and regional local government organizations that have made a commitment to sustainable development. It was founded in 1990.
http://www.iclei.org/

IDR See "In-depth review"

IEA See "International Energy Agency"

IET See "International Emissions Trading"

IGO See "Intergovernmental organization"

IMF See "International Monetary Fund"

IMO See "International Maritime Organization"

Implementation Actions (legislation or regulations, judicial decrees, or other actions) that governments take to translate international accords into domestic law and policy.

INC Intergovernmental Negotiating Committee for the UNFCCC (1990–1995). A committee created to draft the Convention. The INC met in five sessions between February 1991 and May 1992. After the text of the Convention was adopted in 1992, the INC met six further times to prepare for COP-1. It completed its work in February 1995.

INDC See "Intended Nationally Determined Contributions"

Independent Assessment Report (IAR) The output of an independent assessment of each Annex I Party's International Transaction Log, which in turn is part of the Party's reporting requirements to the UNFCCC. IAR is forwarded to expert review teams for consideration as part of the review of national registries under Article 8 of the Kyoto Protocol. The procedure to produce the IAR is designed to provide independent assessment of each national registry.

In-depth review (IDR) A process by which an Annex I Party's implementation of the Convention and/or the Kyoto Protocol is technically assessed by international teams of experts.

Indirect emissions Indirect emissions from a building, home, or business are those emissions of greenhouse gases that occur as a result of the generation of electricity used in that building. These emissions are called "indirect" because the actual emissions occur at the power plant which generates the electricity, not at the building using the electricity.

Industrial revolution A period of rapid industrial growth with far-reaching social and economic consequences, beginning in England during the second half of the eighteenth century and spreading to Europe and later to other countries including

the USA. The industrial revolution marks the beginning of a strong increase in combustion of fossil fuels and related emissions of carbon dioxide.

Infrared radiation Infrared radiation consists of light whose wavelength is longer than the red color in the visible part of the spectrum, but shorter than microwave radiation. Infrared radiation can be perceived as heat. The Earth's surface, the atmosphere, and clouds all emit infrared radiation, which is also known as terrestrial or long-wave radiation. In contrast, solar radiation is mainly short-wave radiation because of the temperature of the Sun. See "Radiation," "Greenhouse effect," "Enhanced greenhouse effect," "Global warming."

INF document Denotes an Information document. These documents are not translated and are available in the original language of issue.

Informal contact group A group of delegates instructed by the President or a Chair to meet in private to discuss a specific matter in an effort to consolidate different views, reach a compromise, and produce an agreed proposal, often in the form of a written text.

Information and Education Measures Actions that provide information, training or encouragement, or help to develop understanding. Such measures may provide information about the availability, performance, and other characteristics of technologies, practices, and measures.

Infrared radiation Radiation between approx. 0.8 and 25 μm. In the context of climate change, it is emitted by the Earth's surface, the atmosphere, and by clouds and also known as terrestrial (long-wave) radiation. Infrared radiation has a distinctive spectrum (i.e., range of wavelengths) governed by the temperature of the Earth-atmosphere system (Planck's law).

Intended Nationally Determined Contributions (INDC) Established at COP 20 in Lima, Peru, INDCs identify the actions that individual countries will take (recognizing differences in national priorities, circumstances, and capabilities) in order to collectively limit the average global temperature rise to 2 °C.

Intergenerational equity/justice Intergenerational equity in economic, psychological, and sociological contexts, is the concept or idea of fairness or justice in relationships between children, youth, adults, and seniors, particularly in terms of treatment and interactions. It has been studied in environmental and sociological settings.

Intergovernmental organization (IGO) An organization composed primarily of sovereign states (referred to as member states), or of other intergovernmental organizations. They are often called international organizations, although that term may also include international nongovernmental organization such as international nonprofit organizations (NPO) or multinational corporations.

Integrated assessment A method of analysis that combines results and models from the physical, biological, economic, and social sciences, and the interactions between these components, in a consistent framework, to project the consequences of climate change and the policy responses to it.

Intergovernmental Oceanographic Commission (IOC) of UNESCO Established in 1960 as a body with functional autonomy within UNESCO, it is the only competent organization for marine science within the UN system.

The purpose of the Commission is to promote international cooperation and to coordinate programs in research, services, and capacity-building, in order to learn more about the nature and resources of the ocean and coastal areas and to apply that knowledge for the improvement of management, sustainable development, the protection of the marine environment, and the decision-making processes of its member states.
http://www.ioc-unesco.org/

Intergovernmental Panel on climate Change (IPCC) The leading international body for the assessment of climate change. The IPCC was established jointly by the United Nations Environment Programme (UNEP) and the World Meteorological Organization (WMO) in 1988. The purpose of the IPCC is to assess information in the scientific and technical literature related to all significant components of the issue of climate change. The IPCC draws upon hundreds of the world's expert scientists as authors and thousands as expert reviewers. Leading experts on climate change and environmental, social, and economic sciences from some 60 nations have helped the IPCC to prepare periodic assessments of the scientific underpinnings for understanding global climate change and its consequences. With its capacity for reporting on climate change, its consequences, and the viability of adaptation and mitigation measures, the IPCC is also looked to as the official advisory body to the world's governments on the state of the science of the climate change issue. For example, the IPCC organized the development of internationally accepted methods for conducting national greenhouse-gas emission inventories. The IPCC work is shared among three Working Groups, a Task Force and a Task Group. The activities of each Working Group and of the Task Force are coordinated and administrated by a Technical Support Unit (TSU). The IPCC was honored with the 2007 Nobel Peace Prize.
http://www.ipcc.ch/

International Civil Aviation Organization (ICAO) A UN specialized agency, created in 1944 upon the signing of the Convention on International Civil Aviation (Chicago Convention). ICAO works with the Convention's 191 member states and global aviation organizations to develop international Standards and Recommended Practices (SARPs) which states reference when developing their legally-enforceable national civil aviation regulations. Today, the global air transport operates close to 100,000 daily flights.
http://www.icao.int/

International Climate Change Partnership (ICCP) A global coalition of companies and trade associations committed to constructive participation in international policy making on climate change.

International consultation and analysis (ICA) A form of review currently being negotiated and designed in the UNFCCC intergovernmental process.

International Emissions Trading (IET) One of the three Kyoto Protocol flexibility mechanisms, by which an Annex I Party may transfer AAUs to (or acquire AAUs from) another Annex I Party.

International Energy Agency (IEA) The IEA is an autonomous organization which works to ensure reliable, affordable, and clean energy for its 29 member

countries and beyond. The IEA has four main areas of focus: energy security, economic development, environmental awareness, and engagement worldwide. The IEA was founded in 1974 to help countries coordinate a collective response to major disruptions in the supply of oil. While this remains a key aspect of its work, the IEA has evolved and expanded. It is at the heart of global dialogue on energy, providing authoritative statistics and analysis.
http://www.iea.org/

International governmental organization See "Intergovernmental organization (IGO)"

International Monetary Fund (IMF) An organization of 188 countries, working to foster global monetary cooperation, secure financial stability, facilitate international trade, promote high employment and sustainable economic growth, and reduce poverty around the world. The IMF was founded in 1945.
http://www.imf.org/

International Organization for Standardization See "International Standards Organization"

International Standards Organization (ISO) The International Organization for Standardization is an independent, nongovernmental membership organization and the world's largest developer of voluntary International Standards.
http://www.iso.org/iso/home.html

International Union for Conservation of Nature (IUCN) The world's oldest and largest global environmental organization, with more than 1,200 government and NGO Members and almost 11,000 volunteer experts in some 160 countries. IUCN's mission is to "*influence, encourage and assist societies throughout the world to conserve nature and to ensure that any use of natural resources is equitable and ecologically sustainable*."
http://www.iucn.org/

Inundation The submergence of land by water, particularly in a coastal setting.

Involuntary environmentalists People, usually from lower-income households, who have little choice but to consume less energy or nonrenewable materials.

IOC See "Intergovernmental Oceanographic Commission"

IOC-UNESCO See "Intergovernmental Oceanographic Commission (IOC)"

IPCC See "Intergovernmental Panel on Climate Change"

IPCC Fifth Assessment Report (AR5) The Fifth Assessment Report (AR5) is the most comprehensive assessment of scientific knowledge on climate change since 2007 when the Fourth Assessment Report (AR4) was released by IPCC in four parts between September 2013 and November 2014. AR5 is made up of the full reports prepared by the Working Groups (I, II, and III) and their Summaries for Policymakers as well as the Synthesis Report. The Fifth Assessment report says scientists are 95 % certain that humans are the "dominant cause" of global warming since the 1950s. See also "IPCC."

IPCC Working Group I (WG I) The IPCC Working Group I (WG I) assesses the physical scientific aspects of the climate system and climate change. The main topics assessed by WG I include: changes in greenhouse gases and aerosols in the

atmosphere; observed changes in air, land, and ocean temperatures, rainfall, glaciers and ice sheets, oceans and sea level; historical and paleoclimatic perspective on climate change; biogeochemistry, carbon cycle, gases, and aerosols; satellite data and other data; climate models; and climate projections, causes, and attribution of climate change.

IPCC Working Group II (WG II) The IPCC Working Group II (WG II) assesses the vulnerability of socioeconomic and natural systems to climate change, negative and positive consequences of climate change, and options for adapting to it. It also takes into consideration the interrelationship between vulnerability, adaptation, and sustainable development. The assessed information is considered by sectors (water resources, ecosystems, food and forests, coastal systems, industry, human health) and regions (Africa, Asia, Australia and New Zealand, Europe, Latin America, North America, Polar Regions, Small Islands).

IPCC Working Group III (WG III) The IPCC Working Group III (WG III) assesses options for mitigating climate change through limiting or preventing greenhouse-gas emissions and enhancing activities that remove them from the atmosphere. The main economic sectors are taken into account, both in a near-term and in a long-term perspective. The sectors include energy, transport, buildings, industry, agriculture, forestry, and waste management. The WG analyses the costs and benefits of the different approaches to mitigation, considering also the available instruments and policy measures. The approach is more and more solution-oriented.

ISO See "International Standards Organization"

IUCN See "International Union for Conservation of Nature"

Jevons paradox A paradox in ecological economics that occurs when technological progress increases the efficiency with which a resource is used (reducing the amount necessary for any one use), but the rate of consumption of that resource rises because of increasing demand. Also termed Jevons effect.

JI See "Joint implementation"

JISC See "Joint Implementation Supervisory Committee"

JLG See "Joint Liaison Group"

Joint Liaison Group (JLG) Group of representatives of UNFCCC, CBD, and UNCCD Secretariats set up to explore common activities to confront problems related to climate change, biodiversity and desertification. See also "UNFCCC," "BCD," and "UNCCD."

Joint implementation (JI) An agreement between two parties whereby one party struggling to meet its emission reductions under the Kyoto Protocol earns emission reduction units from another party's emission removal project. The JI is a flexible and cost-efficient way of fulfilling Kyoto agreements while also encouraging foreign investment and technology transfer. An Annex I Party must meet specific eligibility requirements to participate in joint implementation.

Joint Implementation Supervisory Committee (JISC) This body, under the authority and guidance of the CMP, inter alia, supervises the verification procedure for Joint Implementation projects.

JUSSCANNZ An acronym representing non-EU industrialized countries which occasionally meet to discuss various issues related to climate change. The members are Japan, the USA, Switzerland, Canada, Australia, Norway, and New Zealand. Iceland, Mexico, and the Republic of Korea may also attend JUSSCANZ meetings.

JWG Joint working group.

Karman-Gabreilli law The idea that the energy efficiency of a transport mode decreases with increasing travel speed.

KP See "Kyoto Protocol"

Kyoto "flexibility" mechanisms See "Kyoto mechanisms"

Kyoto mechanisms Three procedures established under the Kyoto Protocol to increase the flexibility and reduce the costs of making greenhouse-gas emissions cuts. They are the Clean Development Mechanism, Emissions Trading, and Joint Implementation.

Kyoto Protocol (KP) An international agreement standing on its own, and requiring separate ratification by governments, but linked to the UNFCCC. The Kyoto Protocol, among other things, sets binding targets for the reduction of greenhouse-gas emissions by industrialized countries. It has been ratified by 192 of the UNFCCC Parties. The ultimate objective of the treaty is to stabilize greenhouse gas concentrations in the atmosphere at a level that will prevent dangerous human interference with the climate system. Industrialized countries agreed to reduce their combined emissions to 5.2 % below 1990 levels during the 5-year period 2008–2012. It was agreed by governments at a 1997 UN conference in Kyoto, Japan, but did not legally come into force until 2005. A different set of countries agreed a second commitment period in 2013 that will run until 2020. See also "United Nations Framework Convention on Climate Change (UNFCCC)."

LAI See "Leaf Area Index"

Landfill Land waste disposal site in which waste is generally spread in thin layers, compacted, and covered with soil. An alternative to landfilling, depending on waste type, is waste incineration – or recycling.

Land use The total of arrangements, activities, and inputs undertaken in a certain land cover type (a set of human actions). The term land use is also used in the sense of the social and economic purposes for which land is managed (e.g., grazing, timber extraction, and conservation).

Land-use change A change in the use or management of land by humans, which may lead to a change in land cover. Land cover and landuse change may have an impact on the surface albedo, evapotranspiration, sources and sinks of greenhouse gases, or other properties of the climate system and may thus have a radiative forcing and/or other impacts on climate, locally or globally.

Land use, land-use change, and forestry (LULUCF) A greenhouse gas inventory sector that covers emissions and removals of greenhouse gases resulting from direct human-induced land use, land-use change, and forestry activities.

Langmuir Model A model that explains adsorption on the assumption that an adsorbate behaves as an ideal gas at isothermal conditions. At these conditions,

the adsorbate's partial pressure, P_A, is related to the volume of it, V, adsorbed onto a solid adsorbent. The adsorbate binding is treated as a chemical reaction between the adsorbate molecule A_g and an empty site, S. This reaction yields an adsorbed complex A_{ad} with an associated equilibrium constant K_{eq}:

$$A_g + S \longleftrightarrow A_{ad}$$

From these assumptions the Langmuir isotherm can be derived, which states that:

$$\theta_A = \frac{V}{V_m} = \frac{K_{eq}^A P_A}{1 + K_{eq}^A P_A}$$

Latent heat The heat that is either released or absorbed by a unit mass of a substance when it undergoes a change of state such as during evaporation, condensation, or sublimation. Energy released or absorbed when water changes state (melts, freezes, vaporizes, or condenses). The latent heat of evaporation is often represented by the symbol "LE".

Latitude The location north or south in reference to the equator, which is designated at zero (0) degrees. Lines of latitude are parallel to the equator and circle the globe. The North and South poles are at 90° North and South latitude.

LDC See "Least Developed Countries"

LDCF See "Least Developed Country Fund (LDCF)"

Leaf Area Index (LAI) The area of foliage per unit area of ground. Conventionally this refers to the ratio of the area of the upper side of the leaves in a canopy projected onto a flat surface to the area of the surface under the canopy. This has also been called single-sided LAI or projected LAI. Occasionally, LAI has been used in reference to the total surface area of leaves, sometimes referred to as double-sided LAI. If a leaf is flat, the double-sided LAI is about twice that of the single-sided LAI. If the leaf is cylindrical, the double-sided LAI will be more than twice the single-sided LAI.

Leakage That portion of cuts in greenhouse-gas emissions by developed countries – countries trying to meet mandatory limits under the Kyoto Protocol – that may reappear in other countries not bound by such limits. For example, multinational corporations may shift factories from developed countries to developing countries to escape restrictions on emissions.

Least Developed Countries (LDCs) The world's poorest countries. The criteria currently used by the Economic and Social Council (ECOSOC) for designation as an LDC include low income, human resource weakness, and economic vulnerability. Approximately 50 countries have been designated by the UN General Assembly as LDCs.

Least Developed Country Fund (LDCF) The LDCF is a fund established to support a work program to assist Least Developed Country Parties to carry out, inter alia, the preparation and implementation of national adaptation programs of action (NAPAs). The Global Environment Facility, as the entity that operates the financial mechanism of the Convention, has been entrusted to operate this fund.

Least Developed Countries Expert Group (LEG) A panel of 13 experts which provides advice to LDCs on the preparation and implementation of national adaptation programs of action (NAPAs) – plans for addressing the urgent and immediate needs of those countries to adapt to climate change.

LEG See "Least Developed Countries Expert Group"

Level of scientific understanding (LOSU) This is an index on a four-step scale (high, medium, low, and very low) designed to characterize the degree of scientific understanding of the radiative forcing agents that affect climate change. For each agent, the index represents a subjective judgment about the reliability of the estimate of its forcing, involving such factors as the assumptions necessary to evaluate the forcing, the degree of knowledge of the physical/chemical mechanisms determining the forcing, and the uncertainties surrounding the quantitative estimate.

L. docs In-session documents that contain draft reports and texts for adoption by the COP or its subsidiary bodies. Usually such documents are available in all six UN languages.

Lifetime The average length of time that an atom or molecule spends in a given reservoir, such as the atmosphere or oceans.

Lignin A structural substance in a plant that is very resistant to decomposition.

Linking Directive A 2004 Directive of the European Parliament linking the EU ETS with the flexibility mechanisms of the Kyoto Protocol.

Liquefied natural gas (LNG) Natural gas (predominantly methane, CH_4) that has been converted to liquid form for ease of storage or transport. See also "Compressed natural gas (CNG)."

Lithosphere The upper layer of the solid Earth, both continental and oceanic, which is composed of all crustal rocks and the cold, mainly elastic, part of the uppermost mantle. Volcanic activity, although part of the lithosphere, is not considered as part of the climate system, but acts as an external forcing factor.

Livelihood Main source of income or food for sustaining one's household.

LNG See "Liquefied natural gas"

Longwave radiation Radiation emitted in the spectral wavelength greater than about 4 μm, corresponding to the radiation emitted from the Earth and atmosphere. It is sometimes referred to as "terrestrial radiation" or "infrared radiation," although somewhat imprecisely. See also "Infrared radiation."

Loss and damage At COP 16 in Cancun in 2010, Governments established a work program in order to consider approaches to address loss and damage associated with climate change impacts in developing countries that are particularly vulnerable to the adverse effects of climate change as part of the Cancun Adaptation Framework.

LOSU See "Level of scientific understanding"

LULUCF See "Land Use, Land-Use Change, and Forestry"

MAC See "Marginal abatement cost"

MAGICC Climate model that calculates average atmospheric temperatures and sea levels. It is used by IPCC for the construction of the SRES (Special Report on Emissions Scenarios).

Maintenance Respiration Respiration in which energy is used to maintain living biomass.

Major Economies Forum on Energy and Climate A forum established in 2009 by US President Barack Obama to discuss elements of the agreement that will be negotiated at Copenhagen. Its members – Australia, Brazil, Canada, China, the European Union, France, Germany, India, Indonesia, Italy, Japan, Mexico, Russia, South Africa, South Korea, the UK, and the US – account for 80 % of greenhouse-gas emissions. The forum is a modification of the Major Economies Meeting started by the former President George Bush, which was seen by some countries as an attempt to undermine UN negotiations.

Marginal abatement cost (MAC) Marginal abatement costs identify the incremental (or "marginal") costs associated with taking the next step in pollution control.

Marginal cost The cost on one additional unit of effort. In terms of reducing emissions, it represents the cost of reducing emissions by one more unit.

Marginal social benefit (MSB) Marginal social benefits identify the incremental (or "marginal") benefits accruing to society when an incremental action (such as taking the next step in pollution control, or producing one more nonpolluting good) is undertaken.

Marine biosphere All living marine organisms.

Market barriers In this context, conditions that prevent or impede the diffusion of cost-effective technologies or practices that could mitigate GHG emissions.

Market-based incentives Measures intended to directly change relative prices of energy services and overcome market barriers.

Market damages The value of damages generated by climate change (or some other environmental change) and evaluated based on information available to and usable by a competitive market.

Market penetration The share of a given market that is provided by a particular good or service at a given time.

Market potential The portion of the economic potential for GHG emissions reductions or energy-efficiency improvements that could be achieved under existing market conditions, assuming no new policies and measures. Also termed currently realizable potential.

Market Stability Reserve (MSR) A mechanism employed by the EU ETS which triggers adjustments in annual auction volumes of allowances in situations where the total number of allowances in circulation is outside a certain predefined range.

Marrakesh Accords Agreements reached at COP-7 which set various rules for "operating" the more complex provisions of the Kyoto Protocol. Among other

things, the accords include details for establishing a greenhouse-gas emissions trading system, implementing and monitoring the Protocol's Clean Development Mechanism, and setting up and operating three funds to support efforts to adapt to climate change.

MBH98 See "Hockey stick"

Mean sea level (MSL) MSL is normally defined as the average relative sea level (RSL) over a period, such as a month or a year, long enough to average out transients such as waves.

Measures Actions that can be taken by a government or a group of governments, often in conjunction with the private sector, to accelerate the use of technologies or other practices that reduce GHG emissions.

Megacities Cities with populations over 10 million.

Methane (CH_4) A hydrocarbon that is a greenhouse gas with a global warming potential most recently (AR4) estimated at 25 times that of carbon dioxide (CO_2). Methane is produced through anaerobic (without oxygen) decomposition of waste in landfills, animal digestion, decomposition of animal wastes, production and distribution of natural gas and petroleum, coal production, and incomplete fossil fuel combustion. Methane is the second most important man-made greenhouse gas.

Metric Ton Common international measurement for the quantity of greenhouse-gas emissions. A metric ton is equal to 1000 kg, 2205 lbs, or 1.1 short tons. See also "Short ton."

MISC documents Denotes a Miscellaneous document. These documents are not translated and are issued on plain paper with no United Nations masthead. In the UNFCCC process, submissions by Parties are normally issued as miscellaneous documents. They generally contain views or comments published as received from a delegation without formal editing. See also "UNFCCC."

Mitigation In the context of climate change, a human intervention to reduce the sources or enhance the sinks of greenhouse gases. Examples include using fossil fuels more efficiently for industrial processes or electricity generation, switching to solar energy or wind power, improving the insulation of buildings, and expanding forests and other "sinks" to remove greater amounts of carbon dioxide from the atmosphere.

Mitigation marginal cost function The relation between the total quantity of emissions reduced and the marginal cost of the last unit reduced. The marginal cost of mitigation generally increases with the total quantity of emissions reduced.

Montreal Protocol The Montreal Protocol on Substances that Deplete the Ozone Layer, an international agreement adopted in Montreal in 1987.

Moral licensing In energy efficiency, the off-setting of energy-efficient behavior in one area by increased use in another. See also "Jevons paradox."

Mount Pinatubo A volcano in the Philippine Islands that erupted in 1991. The eruption of Mount Pinatubo ejected enough particulate and sulfate aerosol matter into the atmosphere to block some of the incoming solar radiation from reaching Earth's atmosphere. This effectively cooled the planet from 1992 to 1994, masking the warming that had been occurring for most of the 1980s and 1990s.

MRV (Monitoring, reporting, and verification) Measurable, reportable and verifiable. A process/concept that potentially supports greater transparency in the climate change regime.

MSB See "Marginal social benefit"

MSR See "Market Stability Reserve"

MSL See "Mean sea level"

MSW See "Municipal solid waste"

Municipal solid waste (MSW) Residential solid waste and some nonhazardous commercial, institutional, and industrial wastes. This material is generally sent to municipal landfills for disposal. See "Landfill."

Multifunctionalism (agriculture) The argument that in addition to food production, farming can also contribute to ecosystem management, landscape protection, rural employment, etc.

Multiplier The amount by which the impact of a climate policy or project changes the direct economic costs and benefits as a result of interconnections between sectors of an economy.

NAP See "National Allocation Plan"

NAPA See "National adaptation programs of action"

NAMAs See "Nationally appropriate mitigation actions"

National Allocation Plan (NAP) National plans developed in early stages of the EU ETS that specified the allocation of emissions reduction targets within individual countries, and the distribution of allowances for trading.

National adaptation programs of action (NAPAs) Documents prepared by least developed countries (LDCs) identifying urgent and immediate needs for adapting to climate change.

National communication A document submitted in accordance with the Convention (and the Protocol) by which a Party informs other Parties of activities undertaken to address climate change. Most developed countries have now submitted their fifth national communications; most developing countries have completed their first national communication and are in the process of preparing their second.

National delegation One or more officials empowered to represent and negotiate on behalf of a government.

Nationally appropriate mitigation actions (NAMAs) At COP 16 in Cancun in 2010, Governments decided to set up a registry to record nationally appropriate mitigation actions seeking international support, to facilitate the matching of finance, technology, and capacity-building support with these actions, and to recognize other NAMAs.

Natural capital The world's stocks of natural assets which include geology, soil, air, water, and all living things. It is from this Natural Capital that humans derive a wide range of services, often called ecosystem services, which make human life possible.

Natural Gas Underground deposits of gases consisting of 50–90 % of methane (CH_4) and small amounts of heavier gaseous hydrocarbon compounds such as

propane (C_3H_8) and butane (C_4H_{10}). It can be transported in pipelines or aboard ship as LNG (liquefied natural gas).

Natural greenhouse effect The natural level of greenhouse gases in our atmosphere, which keeps the planet about 30 °C warmer than it would otherwise be – essential for life as we know it. Water vapor is the most important component of the natural greenhouse effect.

Natural variability Variations in the mean state and other statistics (such as standard deviations or statistics of extremes) of the climate on all time and space scales beyond that of individual weather events. Natural variations in climate over time are caused by internal processes of the climate system, such as El Niño, as well as changes in external influences, such as volcanic activity and variations in the output of the sun.

New Market Mechanisms (NMM) New market-based mechanisms were defined in COP17/CMP7 at Durban to be those mechanisms operating under the guidance and authority of the COP to enhance the cost-effectiveness of, and to promote, mitigation actions, bearing in mind different circumstances of developed and developing countries.

NG See "Natural gas"

NGO See "Nongovernmental organization"

Nitrogen cycle The natural circulation of nitrogen among the atmosphere, plants, animals, and microorganisms that live in soil and water. Nitrogen takes on a variety of chemical forms throughout the nitrogen cycle, including nitrous oxide (N_2O) and nitrogen oxides (NOx).

Nitrogen fertilization Enhancement of plant growth through the deposition of nitrogen compounds. In IPCC reports, this typically refers to fertilization from anthropogenic sources of nitrogen such as man-made fertilizers and nitrogen oxides released from burning of fossil fuels.

Nitrogen oxides (NOx) Gases consisting of nitrogen and oxygen. Nitrogen oxides are produced in the emissions of vehicle exhausts and from power stations. In the atmosphere, nitrogen oxides can contribute to formation of photochemical ozone (smog), can impair visibility, and have health consequences; they are thus considered pollutants.

Nitrous oxide (N_2O) A powerful greenhouse gas with a global warming potential of 298 times that of carbon dioxide (CO_2) (AR4). Major sources of nitrous oxide include soil cultivation practices, especially the use of commercial and organic fertilizers, fossil fuel combustion, nitric acid production, and biomass burning. Natural emissions of N_2O are mainly from bacteria breaking down nitrogen in soils and the oceans. Nitrous oxide is mainly removed from the atmosphere through destruction in the stratosphere by ultraviolet radiation and associated chemical reactions, but it can also be consumed by certain types of bacteria in soils.

NMM See "New Market Mechanisms"

NMVOC See "Nonmethane Volatile Organic Compounds"

Non-Annex I Parties Refers to countries that have ratified or acceded to the United Nations Framework Convention on Climate Change that are not included in Annex I of the Convention.

Non-Annex I countries The group of developing countries that have signed and ratified the Kyoto Protocol. They do not have binding emission reduction targets.

Nongovernmental organizations (NGOs) Organizations that are not part of a governmental structure. They include environmental groups, research institutions, business groups, and associations of urban and local governments. Many NGOs attend climate talks as observers. To be accredited to attend meetings under the Convention, NGOs must be nonprofit.

Nonmotorized travel See "Active modes."

Nonmarket damages Damages generated by climate change (or some other environmental change) and that cannot be evaluated by a competitive market because of a lack of information and/or the inability to act on that information.

Nonmethane Volatile Organic Compounds (NMVOC) Organic compounds, other than methane, that participate in atmospheric photochemical reactions.

Nonpaper An in-session document issued informally to facilitate negotiations. A nonpaper does not have an official document symbol. It may have an identifying number or carry the name of its author.

Nonparty A state that has not ratified the Convention but attends meetings as an observer.

"No-regrets" mitigation options See "No-regrets options"

"No-regrets options" Technology for reducing greenhouse-gas emissions whose other benefits (in terms of efficiency or reduced energy costs) are so extensive that the investment is worth it for those reasons alone. For example, combined-cycle gas turbines – in which the heat from the burning fuel drives steam turbines while the thermal expansion of the exhaust gases drives gas turbines – may boost the efficiency of electricity generating plants by 70 %. They are sometimes known as "measures worth doing anyway."

NOx See "Nitrogen oxides"

N_2O See "Nitrous oxide"

Observers Agencies, nongovernmental organizations, and Governments not Parties to the Convention which are permitted to attend, but not vote, at meetings of the COP, the CMP, and the subsidiary bodies. Observers may include the United Nations and its specialized agencies, other intergovernmental organizations such as the International Atomic Energy Agency, and accredited nongovernmental organizations (NGOs).

Ocean acidification The ocean absorbs approximately one-fourth of man-made CO_2 from the atmosphere, which helps to reduce adverse climate change effects. However, when the CO_2 dissolves in seawater, carbonic acid is formed. Carbon emissions in the industrial era have already lowered the pH of seawater by 0.1. Ocean acidification can decrease the ability of calcifying marine organisms to build their shells and skeletal structures and kill off coral reefs, with serious

effects for people who rely on them as fishing grounds. Amongst others, corals, mollusks, algae, and crustaceans are affected.

ODS See "Ozone depleting substance"

OECD See "Organization for Economic Cooperation and Development"

Omitted variable bias Omitting one or more variables from an econometric model, where the omitted variable is both a determinant of the dependent variable and correlated with at least one independent variable in the model. This causes the ordinary least squares estimator to be biased and inconsistent.

OPEC See "Organization of Petroleum Exporting Countries"

Organization for Economic Cooperation and Development (OECD) An international economic organization of 34 countries, founded in 1961 to stimulate economic progress and world trade. Its mission is to "*to promote policies that will improve the economic and social well-being of people around the world.*" http://www.oecd.org/

Organization of the Petroleum Exporting Countries (OPEC) An intergovernmental organization of 14 nations which account for approx. 43% of global oil production (2015). OPEC was founded in 1960 and is headquartered in Vienna. OPEC's stated mission is "to coordinate and unify the petroleum policies of its member countries and ensure the stabilization of oil markets, in order to secure an efficient, economic and regular supply of petroleum to consumers, a steady income to producers, and a fair return on capital for those investing in the petroleum industry."

OPEC See "Organization of the Petroleum Exporting Countries"
An intergovernmental organization, created at the Baghdad Conference on September 10–14, 1960, by Iran, Iraq, Kuwait, Saudi Arabia, and Venezuela. The five Founding Members were later joined by nine other Members: Qatar (1961); Indonesia (1962) – suspended its membership from January 2009; Libya (1962); United Arab Emirates (1967); Algeria (1969); Nigeria (1971); Ecuador (1973) – suspended its membership from December 1992 to October 2007; Angola (2007); and Gabon (1975–1994). OPEC has its headquarters in Vienna, Austria. OPEC's objective is to coordinate and unify petroleum policies among Member Countries.
http://www.opec.org

Opportunity cost A benefit, profit, or value of something that must be given up to acquire or achieve something else. Since every resource (land, money, time, etc.) can be put to alternative uses, every action, choice, or decision has an associated opportunity cost.

Ozone Ozone, the triatomic form of oxygen (O_3), is a gaseous atmospheric constituent. In the troposphere, it is created by photochemical reactions involving gases resulting both from natural sources and from human activities (photochemical smog). In high concentrations, tropospheric ozone can be harmful to a wide range of living organisms. Tropospheric ozone acts as a greenhouse gas. In the stratosphere, ozone is created by the interaction between solar ultraviolet radiation and molecular oxygen (O_2). Stratospheric ozone plays a decisive role in the

stratospheric radiative balance. Depletion of stratospheric ozone, due to chemical reactions that may be enhanced by climate change, results in an increased ground-level flux of ultraviolet (UV-) B radiation. See also "Atmosphere" and "Ultraviolet radiation."

Ozone depleting substance (ODS) A family of man-made compounds that includes, but are not limited to, chlorofluorocarbons (CFCs), bromofluorocarbons (halons), methyl chloroform, carbon tetrachloride, methyl bromide, and hydrochlorofluorocarbons (HCFCs). These compounds have been shown to deplete stratospheric ozone, and therefore are typically referred to as ODSs. See "Ozone."

Ozone layer The layer of ozone that begins approximately 15 km above Earth and thins to an almost negligible amount at about 50 km, shields the Earth from harmful ultraviolet radiation from the sun. The highest natural concentration of ozone (approximately 10 parts per million by volume) occurs in the stratosphere at approximately 25 km above Earth. The stratospheric ozone concentration changes throughout the year as stratospheric circulation changes with the seasons. Natural events such as volcanoes and solar flares can produce changes in ozone concentration, but man-made changes are of the greatest concern. See also "Stratosphere" and "Ultraviolet radiation."

Ozone precursors Chemical compounds, such as carbon monoxide, methane, nonmethane hydrocarbons, and nitrogen oxides, which in the presence of solar radiation react with other chemical compounds to form ozone, mainly in the troposphere. See also "Troposphere."

PAH See "Polycyclic aromatic hydrocarbons"

PAM See "Policies and measures"

Panel data Repeated observations of the same units, such as households, firms, persons, or geographical units, over several periods of time

Parametrization In climate modeling, this term refers to the technique of representing processes that cannot be explicitly resolved at the resolution of the model (subgrid scale processes) by relationships between the area averaged effect of such subgrid scale processes and the larger scale flow.

Passive solar energy Use of the sun to heat, cool, or illuminate buildings, without the use of energy conversion devices such as solar cells.

Particulate matter (PM) Very small pieces of solid or liquid matter such as particles of soot, dust, fumes, mists, or aerosols. The physical characteristics of particles, and how they combine with other particles, are part of the feedback mechanisms of the atmosphere. See also "Aerosol" and "Sulfate aerosols."

Parts Per Billion (ppb) Number of parts of a chemical found in one billion parts of a particular gas, liquid, or solid mixture. See also "Concentration."

Parts Per Million by Volume (ppmv) Number of parts of a chemical found in one million parts of a particular gas, liquid, or solid. See also "Concentration."

Parts Per Trillion (ppt) Number of parts of a chemical found in one trillion parts of a particular gas, liquid, or solid. See also "Concentration."

Party A state (or regional economic integration organization such as the European Union) that agrees to be bound by a treaty and for which the treaty has entered into force.

PCT See "Personal carbon trading"

PDD See "Project design document"

PEB Pro-environmental behavior

Per-capita emissions The total amount of greenhouse gas emitted by a country per unit of population.

Permafrost Soil at or below the freezing point of water 0 °C (32 °F) for 2 or more years perennially (continually) frozen. Also known as cryotic soil.

Personal carbon trading (PCT) A proposed quantity-based policy instrument for reducing the carbon emissions emitted by individuals. The aim of the scheme would be to deliver guaranteed levels of carbon savings in successive years in an equitable way. A PCT scheme would set a total cap on all carbon emissions generated from the fossil fuel energy used by individuals. Individuals would use their allowance when purchasing fossil fuel based energy for home energy and transport. If an individual exceeds his or her allowance then additional carbon units would need to be bought from the market and if an individual has surplus carbon units these can be sold. The scheme would be mandatory and administered electronically.
http://www.eci.ox.ac.uk/research/energy/downloads/pct/pct-transport.pdf

Perfluorocarbons (PFCs) A group of chemicals composed of carbon and fluorine only. These chemicals (predominantly CF_4 and C_2F_6) were introduced as alternatives, along with hydrofluorocarbons, to the ozone depleting substances. In addition, PFCs are emitted as by-products of industrial processes and are also used in manufacturing. PFCs do not harm the stratospheric ozone layer, but they are powerful greenhouse gases: CF_4 has a global warming potential (GWP) of 7,390 and C_2F_6 has a GWP of 12,200. The GWP is from the IPCC's Fourth Assessment Report (AR4). These chemicals are predominantly human-made, though there is a small natural source of CF_4. See also "Ozone depleting substance."

Performance criteria See "Standards"

Petroleum A fossil hydrocarbon fuel. The name petroleum covers both naturally occurring unprocessed crude oil and petroleum products that are made up of refined crude oil.

PFC See "Perfluorocarbons"

Phenology The timing of natural events, such as flower blooms and animal migration, which is influenced by changes in climate. Phenology is the study of such important seasonal events. Phenological events are influenced by a combination of climate factors, including light, temperature, rainfall, and humidity.

Photosynthesis The process by which plants take CO_2 from the air (or bicarbonate in water) to build carbohydrates, releasing O_2 in the process. There are several pathways of photosynthesis with different responses to atmospheric CO_2 concentrations. See also "Carbon sequestration" and "Carbon dioxide fertilization."

Phytostabilization Inhibition of metal mobility by plant roots through absorption and accumulation process. Phytostabilization minimizes the metal availability to plants and metal leaching into ground water.

Plenary A formal meeting of the entire COP, CMP, or one of the subsidiary bodies. Formal decisions or conclusions may only be taken during plenary sessions.

PoA See "Program of Activities of CDM"

Point of Zero Charge (PZC) Concentration of charge determining ions corresponding to a neutral or zero-charged surface. When the pH is lower than the pzc value, the system is said to be "below the pzc." Below the pzc, acidic water donates more protons than hydroxide groups, and so the adsorbent surface is positively charged (attracting anions). Conversely, above pzc the surface is negatively charged (attracting cations/repelling anions).

Policies Procedures developed and implemented by government(s) regarding the goal of mitigating climate change through the use of technologies and measures.

Policies and measures (PAM) A frequently used phrase – sometimes abbreviated as PAMs – referring to the steps taken or to be taken by countries to reduce greenhouse-gas emissions under the UNFCCC and the Kyoto Protocol. Some possible policies and measures are listed in the Protocol and could offer opportunities for intergovernmental cooperation.

Polycyclic aromatic hydrocarbons (PAH) A diverse group of organic environmental pollutants consisting of two or more fused aromatic rings and are produced by natural and anthropogenic sources. Examples include acenapthene, acenaphthalene, napthalene, chrysene, phenanthrene, and benzo(a)pyrene.

Pool A component of the climate system that has the capacity to store, accumulate, or release a substance of concern, e.g., atmosphere, oceans, soils, and forests. See also "Reservoir."

ppm (350/450) An abbreviation for parts per million, usually used as short for ppmv (parts per million by volume). The Intergovernmental Panel on Climate Change (IPCC) suggested in 2007 that the world should aim to stabilise greenhouse gas levels at 450 ppm CO_2 equivalent in order to avert dangerous climate change. Some scientists, and many of the countries most vulnerable to climate change, argue that the safe upper limit is 350 ppm. Current levels of CO_2 only are about 400 ppm.

Preindustrial levels of carbon dioxide The levels of carbon dioxide in the atmosphere prior to the start of the Industrial Revolution. These levels are estimated to be about 280 parts per million (by volume). The current level is around 400 ppm.

President The official of a member government elected by the Parties to preside over the COP and the CMP. The President is often a senior official or minister from the state or region hosting the Conference. The President may not participate in the negotiations as a representative of the member government during the term of presidency.

Precautionary principle Avoiding a solution that is irreversible, because the assumptions on which the solution is based may prove incorrect, in favour of a seemingly inferior solution that can be reversed.

Precession The wobble over thousands of years of the tilt of the Earths axis with respect to the plane of the solar system.

Primary energy Energy embodied in natural resources (e.g., coal, crude oil, sunlight, uranium) that has not undergone any anthropogenic conversion or transformation. It is transformed into secondary energy by cleaning (natural gas), refining (oil in oil products), or by conversion into electricity or heat. When the secondary energy is delivered at the end-use facilities it is called final energy (e.g., electricity at the wall outlet), where it becomes usable energy (e.g., light). Primary energy is also referred to as energy sources. See also "Final energy."

Program of Activities of CDM (PoA) A voluntary coordinated action by a private or public entity which coordinates and implements any policy/measure or stated goal (i.e., incentive schemes and voluntary programs) reducing GHGs via an unlimited number of project activities, and meeting additionality requirements.

Project design document (PDD) The document prepared by the project participant of a CDM project activity which sets out in detail, in accordance with the CDM rules and requirements, the CDM project activity which is to be undertaken.

Protocol An international agreement linked to an existing convention, but as a separate and additional agreement which must be signed and ratified by the Parties to the convention concerned. Protocols typically strengthen a convention by adding new, more detailed commitments.

p-km Passenger-km

Pyrolysis A thermochemical decomposition of organic materials at high temperatures under no-oxygen or oxygen-limited conditions.

PZC See "Point of Zero Charge"

QELRO See "Quantified Emissions Limitation and Reduction Commitments"

Quantified Emissions Limitation and Reduction Commitments (QELRO) Legally binding targets and timetables under the Kyoto Protocol for the limitation or reduction of greenhouse-gas emissions by developed countries.

Radiation Energy transfer in the form of electromagnetic waves or particles that release energy when absorbed by an object. See also "Ultraviolet radiation," "Infrared radiation," "Solar radiation," and "Longwave radiation."

Radiative damping An imposed positive radiative forcing on the Earth-atmosphere system (e.g., through the addition of greenhouse gases) represents an energy surplus. The temperature of the surface and lower atmosphere will then increase and in turn increase the amount of infrared radiation being emitted to space, thus a new energy balance will be established. The amount that emissions of infrared radiation to space increase for a given increase in temperature is known as the radiative damping.

Radiative forcing A simple measure of the importance of a potential climate change mechanism. Radiative forcing is the perturbation to the energy balance of the Earth-atmosphere system (in W/m^2) following, for example, a change in the concentration of carbon dioxide or a change in the output of the Sun; the climate system responds to the radiative forcing so as to reestablish the energy

balance. A positive radiative forcing tends to warm the surface and a negative radiative forcing tends to cool the surface. The radiative forcing is normally quoted as a global and annual mean value. A more precise definition of radiative forcing, as used in IPCC reports, is the perturbation of the energy balance of the surface-troposphere system, after allowing for the stratosphere to readjust to a state of global mean radiative equilibrium. Sometimes called "climate forcing."

Rain-fed crops Crops that rely on natural rainfall for moisture, without access to irrigation.

Ratification Formal approval, often by a Parliament or other national legislature, of a convention, protocol, or treaty, enabling a country to become a Party. Ratification is a separate process that occurs after a country has signed an agreement. The instrument of ratification must be deposited with a "depositary" (in the case of the Climate Change Convention, the UN Secretary-General) to start the countdown to becoming a Party (in the case of the Convention, the countdown is 90 days). See also "Accession."

RCP See "Representative concentration pathway"

Rebound effects See "Spill-over effects"

Recommendation A formal act of the COP or the CMP which is weaker than a decision or a resolution, and is not binding on Parties to the Convention or the Kyoto Protocol.

RECs See "Renewable Energy Certificates"

Recycling Collecting and reprocessing a resource so it can be used again. An example is collecting aluminum cans, melting them down, and using the aluminum to make new cans or other aluminum products.

REDD See "Reducing Emissions from Deforestation and forest Degradation"

REDD+ REDD activities plus additional sustainable forestry management practices, including conservation and enhancement of forestry carbon stocks.

Reducing Emissions from Deforestation and forest Degradation (REDD) A UNFCCC mechanism whose objective is to mitigate climate change by reducing net emissions of greenhouse gases through enhanced forestry management in developing countries. It provides developing countries with financial incentives to preserve forests.

Reductionism An approach to understanding the nature of complex things by reducing them to the interactions of their parts, or to simpler or more fundamental things. It can also be described as the philosophical position that a complex system is nothing but the sum of its parts, and that an account of it can be reduced to accounts of individual constituents.

Reflectivity The ability of a surface material to reflect sunlight including the visible, infrared, and ultraviolet wavelengths.

Reforestation Direct human-induced conversion of nonforested land to forested land through planting, seeding, and/or the human-induced promotion of natural seed sources, on land that was previously forested but converted to nonforested land.

REG document Regular documents have a serial number following the year. They are translated into all six official languages of the United Nations.

Regional groups Alliances of countries, in most cases sharing the same geographic region, which meet privately to discuss issues and nominate bureau members and other officials for activities under the Convention. The five regional groups are Africa, Asia, Central and Eastern Europe (CEE), Latin America and the Caribbean (GRULAC), and the Western Europe and Others Group (WEOG).

Registries, registry systems Electronic databases that track and record all transactions under the Kyoto Protocol's greenhouse-gas emissions trading system (the "carbon market") and under mechanisms such as the Clean Development Mechanism. "Registry" may also refer to current discussions on a system for inscribing nationally appropriate mitigation actions.

Regulatory measures Rules or codes enacted by governments that mandate product specifications or process performance characteristics.

Relative Sea Level Rise The increase in ocean water levels at a specific location, taking into account both global sea level rise and local factors, such as local subsidence and uplift. Relative sea level rise is measured with respect to a specified vertical datum relative to the land, which may also be changing elevation over time.

Removal unit (RMU) A Kyoto Protocol unit equal to 1 metric ton of carbon dioxide equivalent. RMUs are generated in Annex I Parties by LULUCF activities that absorb carbon dioxide.

Renewable energy Energy created from sources that can be replenished in a short period of time. The five renewable sources used most often are: biomass (such as wood and biogas), the movement of water, geothermal (heat from within the earth), wind, and solar. See also "Alternative energy."

Renewable Energy Certificates (RECs) Renewable energy certificates represent the environmental attributes of power produced from renewable energy projects. They are sold separately from the electricity itself, in markets designed to increase renewable energy services, and are sometimes called renewable energy credits, green certificates, or green tags.

Research and systematic observation An obligation of Parties to the Climate Change Convention; they are called upon to promote and cooperate in research and systematic observation of the climate system, and called upon to aid developing countries to do so.

Research, Development, and Demonstration Scientific/technical research and development of new production processes or products, coupled with analysis and measures that provide information to potential users regarding the application of the new product or process; demonstration tests the feasibility of applying these products or processes via pilot plants and other precommercial applications.

Representative concentration pathways (RCPs) The radiative forcing scenarios used by the IPCC.

Reservation An exception or concern noted for the record by a Party in the course of accepting a decision of the COP or the CMP. No reservations are allowed to the Convention itself, or to the Protocol.

Reservoir A component of the climate system, other than the atmosphere, which has the capacity to store, accumulate, or release a substance of concern, e.g.,

carbon, a greenhouse gas or a precursor. Oceans, soils, and forests are examples of reservoirs of carbon. Pool is an equivalent term (note that the definition of pool often includes the atmosphere). The absolute quantity of substance of concern, held within a reservoir at a specified time, is called the stock.

Residence Time The average time spent in a reservoir by an individual atom or molecule. With respect to greenhouse gases, residence time usually refers to how long a particular molecule remains in the atmosphere. For most gases other than methane and carbon dioxide, the residence time is approximately equal to the atmospheric lifetime.

Resilience A capability to anticipate, prepare for, respond to, and recover from significant multihazard threats with minimum damage to social well-being, the economy, and the environment.

Resolution Directives that guide the work of the COP or the CMP – opinions rather than permanent legal acts. Unlike decisions, resolutions do not generally become part of the formal body of legislation enacted by the COP or the CMP.

Respiration The process whereby living organisms convert organic matter to CO_2, releasing energy and consuming O_2.

Response time The time needed for the climate system or its components to reequilibrate to a new state, following a forcing resulting from external and internal processes or feedbacks.

It is very different for various components of the climate system. The response time of the troposphere is relatively short, from days to weeks, whereas the stratosphere comes into equilibrium on a time scale of typically a few months. Due to their large heat capacity, the oceans have a much longer response time, typically decades, but up to centuries or millennia. The response time of the strongly coupled surface troposphere system is, therefore, slow compared to that of the stratosphere, and mainly determined by the oceans. The biosphere may respond fast (e.g., to droughts), but also very slowly to imposed changes. Also called adjustment time.

Retranslocation The transport of minerals and food from the leaves of a plant to storage when the leaves senesce. The addition of a substance of concern to a reservoir. The uptake of carbon containing substances, in particular carbon dioxide, is often called (carbon) sequestration.

Review of commitments Regular scrutiny by Convention Parties of the adequacy of the treaty's Article 4.2 (a) and (b) outlining developed country commitments to limit greenhouse-gas emissions. The first review took place at COP-1 and led to a finding that progress was not "adequate" – and so to negotiations that led to the Kyoto Protocol, which has more stringent commitments for developed countries.

Risk coefficient The amount of additional incidence or severity of disease in a population produced by a unit change in ambient air concentration of a pollutant.

Rio Conventions Three environmental conventions, two of which were adopted at the 1992 "Earth Summit" in Rio de Janeiro: the United Nations Framework Convention on Climate Change (UNFCCC), and the Convention on Biodiversity (CBD), while the third, the United Nations Convention to Combat Desertification (UNCCD), was adopted in 1994. The issues addressed by the three treaties are

related – in particular, climate change can have adverse effects on desertification and biodiversity – and through a Joint Liaison Group, the secretariats of the three conventions take steps to coordinate activities to achieve common progress.

Rio+20 The United Nations Conference on Sustainable Development, to be held in Rio de Janeiro, Brazil, on June 4–6, 2012. The first UN Conference on Sustainable Development was the "Earth Summit," held in 1992, and it spawned the three "Rio Conventions" – the UNFCCC, the UNCCD, and the UNCBD.

RMU See "Removal unit"

Roster of experts Experts nominated by Parties to the Climate Change Convention to aid the Secretariat in work related to review of national reports of Annex I Parties, preparation of reports on adaptation technology, the transfer of technology to developing countries, and the development of know-how on mitigating and adapting to climate change.

Rules of procedure The parliamentary rules that govern the procedures of the COP, the CMP, and the subsidiary bodies, covering such matters as decision-making and participation. The COP has not yet formally adopted rules of procedure, but all except one (on voting) are currently being "applied." As such, they are commonly referred to as the "draft rules of procedure being applied."

Salt water intrusion Displacement of fresh or ground water by the advance of salt water due to its greater density, usually in coastal and estuarine areas.

SAR IPCC Second Assessment Report (SAR), 1995. See also "IPCC" and "AR5."

SBI See "Subsidiary Body for Implementation"

SBSTA See "Subsidiary Body for Scientific and Technological Advice"

SCC See "Social cost of carbon"

SCCF See "Special Climate Change Fund"

SDGs See "Sustainable Development Goals"

Scenario A plausible description of how the future may develop, based on a coherent and internally consistent set of assumptions about key relationships and driving forces (e.g., rate of technology changes, prices). Note that scenarios are neither predictions nor forecasts.

SCM See "Sectoral crediting mechanism"

Sea Surface Temperature The temperature in the top several feet of the ocean, measured by ships, buoys, and drifters.

Second Assessment Report (SAR) An extensive review of worldwide research on climate change compiled by the IPCC and published in 1995. Some 2,000 scientists and experts participated. The report is also known as Climate Change 1995. The SAR concluded that "the balance of evidence suggests that there is a discernible human influence on global climate." It also said "no-regrets options" and other cost-effective strategies exist for combating climate change.

Secretariat The office staffed by international civil servants responsible for "servicing" the UNFCCC Convention and ensuring its smooth operation. The secretariat makes arrangements for meetings, compiles and prepares reports, and coordinates with other relevant international bodies. The Climate Change

Secretariat, which is based in Bonn, Germany, is institutionally linked to the United Nations. See also "UNFCCC."

Sectoral crediting mechanism (SCM) A baseline-and-credit scheme rewarding GHG emission reductions from a specific sector against a predetermined threshold.

Sectoral trading mechanism (STM) A sectoral GHG reduction mechanism based upon a cap-and-trade rather than baseline-and-credit approach; depending up the design, countries might receive sectoral allowances ex-ante for trading purposes.

Sensitivity The degree to which a system is affected, either adversely or beneficially, by climate variability or change. The effect may be direct (e.g., a change in crop yield in response to a change in the mean, range, or variability of temperature) or indirect (e.g., damages caused by an increase in the frequency of coastal flooding due to sea level rise).

SF_6 See "Sulphur hexafluoride."

Short ton Common measurement for a ton in the USA. A short ton is equal to 2,000 lbs or 0.907 metric tons or 907 kg. See "Metric ton."

SIDS Small island developing states.

Sink Any process, activity, or mechanism which removes a greenhouse gas, an aerosol, or a precursor of a greenhouse gas from the atmosphere. Forests and other vegetation are considered sinks because they remove carbon dioxide through photosynthesis.

Snowpack A seasonal accumulation of slow-melting snow. See also "Glacier."

Social cost of carbon (SCC) The marginal cost of emitting an additional ton of carbon (or carbon dioxide).

Social cost of carbon dioxide See "Social cost of carbon"

Social discount rate See "Discounting"

Social efficiency The use of nontechnical means to reduce energy consumption.

Soil carbon A major component of the terrestrial biosphere pool in the carbon cycle. The amount of carbon in the soil is a function of the historical vegetative cover and productivity, which in turn is dependent in part upon climatic variables.

Solar luminosity A measure of the brightness of (i.e., the amount of solar radiation being emitted by) the Sun.

Solar radiation Radiation emitted by the Sun. It is also referred to as short-wave radiation. Solar radiation has a distinctive range of wavelengths (spectrum) determined by the temperature of the Sun. See also "Ultraviolet radiation," "Infrared radiation," and "Radiation."

Solar radiation management (SRM) A set of concepts to moderate or retard global warming by shielding part of solar radiation from Earth. See also "Climate engineering."

Sonochemistry Chemistry of understanding the application of ultrasound to chemical reactions and processes. Ultrasound is the part of sonic spectrum which ranges from about 20 kHz to 10 MHz.

Sonoluminescence Initiation of bright flashes of light caused by imposing a loud, high frequency sound on a gas bubble contained within a liquid.

Sorption A physical or chemical process by which one substance becomes attached to another.

Spatial scales Continental: 10–100 million km^2
Regional: 100 thousand–10 million km^2
Local: less than 100 thousand km^2

Special Climate Change Fund (SCCF) The SCCF was established to finance projects relating to adaptation; technology transfer and capacity building; energy, transport, industry, agriculture, forestry, and waste management; and economic diversification. This fund should complement other funding mechanisms for the implementation of the Convention. The Global Environment Facility (GEF), as the entity that operates the financial mechanism of the Convention, has been entrusted to operate this fund.

Special Report on Emissions Scenarios (SRES) A report by the Intergovernmental Panel on Climate Change (IPCC) published in 2000.

Spill-over effects Reverberations in developing countries caused by actions taken by developed countries to cut greenhouse-gas emissions. For example, emissions reductions in developed countries could lower demand for oil and thus international oil prices, leading to more use of oil and greater emissions in developing nations, partially off-setting the original cuts. Current estimates are that full-scale implementation of the Kyoto Protocol may cause 5–20 % of emissions reductions in industrialized countries to "leak" into developing countries. Also known as "rebound effects" or "take-back effects."

Spin-up "Spin-up" is a technique used to initialize an AOGCM. At present it is not possible to diagnose accurately the state of the coupled atmosphere-ocean system and therefore it is not possible to prescribe observed starting conditions for an experiment with an AOGCM. Instead, the atmosphere and ocean components of the model are run separately, forced with "observed" boundary conditions, followed perhaps by a further period of "spin-up" when the atmosphere and ocean are coupled together, until the AOGCM is near to a steady state. See also "Atmosphere-ocean General Circulation Model (AOGCM)."

SRES See "Special Report on Emissions Scenarios"

SRM See "Solar radiation management"

Standards Set of rules or codes mandating or defining product performance (e.g., grades, dimensions, characteristics, test methods, rules for use). Also termed performance criteria.

STM See "Sectoral trading mechanism"

Stern review A report on the economics of climate change led by Lord Nicholas Stern, a former World Bank economist. It was published on 30 October 2006 and argued that the cost of dealing with the consequences of climate change in the future would be higher than taking action to mitigate the problem now. http://mudancasclimaticas.cptec.inpe.br/~rmclima/pdfs/destaques/sternreview_report_complete.pdf

Storm surge An abnormal rise in sea level accompanying a hurricane or other intense storm, whose height is the difference between the observed level of the sea surface and the level that would have occurred in the absence of the cyclone.

Stratosphere Region of the atmosphere between the troposphere and mesosphere, having a lower boundary of approximately 8 km at the poles to 15 km at the equator and an upper boundary of approximately 50 km. Depending upon latitude and season, the temperature in the lower stratosphere can increase, be isothermal, or even decrease with altitude, but the temperature in the upper stratosphere generally increases with height due to absorption of solar radiation by ozone.

Stratospheric ozone See "Ozone layer."

Streamflow The volume of water that moves over a designated point over a fixed period of time. It is often expressed as cubic feet per second (ft^3/s).

Structural changes Changes, for example, in the relative share of GDP produced by the industrial, agricultural, or services sectors of an economy; or, more generally, systems transformations whereby some components are either replaced or partially substituted by other ones.

Subsidence See "Subsiding"

Subsidiary body A committee that assists the Conference of the Parties. Two permanent subsidiary bodies are created by the Convention: the Subsidiary Body for Implementation (SBI) and the Subsidiary Body for Scientific and Technological Advice (SBSTA). Two major temporary bodies that exist currently are the Ad Hoc Working Group on Further Commitments for Annex I Parties under the Kyoto Protocol (AWG-KP), established at COP 11 in Montreal, and the Ad Hoc Working Group on Long-term Cooperative Action under the Convention (AWG-LCA), established at COP 13 in Bali. Additional subsidiary bodies may be established as needed.

Subsidiary Body for Implementation (SBI) The SBI makes recommendations on policy and implementation issues to the COP and, if requested, to other bodies.

Subsidiary Body for Scientific and Technological Advice (SBSTA) The SBSTA serves as a link between information and assessments provided by expert sources (such as the IPCC) and the COP, which focuses on setting policy.

Subsiding The downward settling of the Earth's crust relative to its surroundings.

Sulfate aerosols Particulate matter that consists of compounds of sulfur formed by the interaction of sulfur dioxide and sulfur trioxide with other compounds in the atmosphere. Sulfate aerosols are injected into the atmosphere from the combustion of fossil fuels and the eruption of volcanoes like Mt. Pinatubo. Sulfate aerosols can lower the Earth's temperature by reflecting away solar radiation (negative radiative forcing). General Circulation Models which incorporate the effects of sulfate aerosols more accurately predict global temperature variations. See "Particulate matter," "Aerosol," "General Circulation Models" (United Nations Framework Convention on Climate Change [UNFCCC]).

Sulfur hexafluoride (SF_6) A colorless gas soluble in alcohol and ether, slightly soluble in water. A very powerful greenhouse gas used primarily in electrical transmission and distribution systems and as a dielectric in electronics. The global warming potential (GWP) of SF_6 is 22,800 (AR4). See "Global Warming Potential."

Supertoxicants A special category of pollutants that includes dioxins, biphenyl, furans, etc., and are quite stable in the environment and are not subject to easy chemical and biological decomposition. Less than seven drops of supertoxic chemical if given in a liquid form to a 70-kg human could be lethal.

Sustainable development Development that meets the needs of the present without compromising the ability of future generations to meet their own needs.

Sustainable Development Goals (SDG) A post-2015 development agenda, launched at the Rio+20 Conference, to replace expiring Millennium Development Goals.

Systems thinking Systems thinking involves looking at the interconnections between parts of a whole rather than concentrating just on the parts. Systems thinking or holism acknowledges that complex systems are inherently irreducible, and more than the sum of their parts, and that a holistic approach is needed to understand them.

Take-back effects See "Spill-over effects"

TAR IPCC Third Assessment Report (TAR), 2001. See also "IPCC" and "AR5."

Technical potential The amount by which it is possible to reduce GHG emissions or improve energy efficiency by using a technology or practice in all applications in which it could technically be adopted, without consideration of its costs or practical feasibility.

Technology A piece of equipment or a technique for performing a particular activity.

Technology transfer (TT) The process whereby technological advances are shared between different countries. Developed countries could, for example, share up-to-date renewable energy technologies with developing countries, in an effort to lower global greenhouse-gas emissions.

Telecommuting Replacement of the work trip by working from home or in a neighborhood center using information technology.

Teleshopping Replacement of shopping trips by on-line purchasing.

Terrestrial biosphere All living organisms on land.

Thermal expansion The increase in volume (and decrease in density) that results from warming water. A warming of the ocean leads to an expansion of the ocean volume, which leads to an increase in sea level.

Thermocline The region in the world's ocean, typically at a depth of 1 km, where the temperature decreases rapidly with depth and which marks the boundary between the surface and deep ocean.

Thermohaline circulation Large-scale density-driven circulation in the ocean caused by differences in temperature and salinity. In the North Atlantic, the thermohaline circulation consists of warm surface water flowing northward and

cold deep water flowing southward, resulting in a net poleward transport of heat. The surface water sinks in highly restricted sinking regions located in high latitudes.

Third Assessment Report (TAR) The third extensive review of global scientific research on climate change, published by the IPCC in 2001. Among other things, the report stated that "The Earth's climate system has demonstrably changed on both global and regional scales since the pre-industrial era, with some of these changes attributable to human activities. There is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities." The TAR also focused on the regional effects of climate change.

Tipping point A threshold for change, which, when reached, results in a process that is difficult to reverse. Scientists say it is urgent that policy makers halve global carbon dioxide emissions over the next 50 years or risk triggering changes that could be irreversible.

Trace gas Any one of the less common gases found in the Earth's atmosphere. Nitrogen, oxygen, and argon make up more than 99 % of the Earth's atmosphere. Other gases, such as carbon dioxide, water vapor, methane, oxides of nitrogen, ozone, and ammonia, are considered trace gases. Although relatively unimportant in terms of their absolute volume, they have significant effects on the Earth's weather and climate.

Track-two JI One of two approaches for verifying emission reductions or removals under joint implementation, whereby each JI project is subject to verification procedures established under the supervision of the Joint Implementation Supervisory Committee. Track-two procedures require that each project is reviewed by an accredited independent entity.

Transient climate response The time-dependent response of the climate system (or a climate model) to a time-varying change of forcing.

Transient climate simulation Mode of running a global climate model in which a period of time is simulated with continuously varying concentrations of greenhouse gases so that the climate of the model represents prospective changes already realized by the time of each future date in question, rather than the higher long-run equilibrium warming eventually resulting from atmospheric concentrations at each such date. The difference stems from ocean thermal lag.

Transpiration The process by which water vapor is lost from plants, evaporating from cell walls just below the surface of the leaf and diffusing into the air through small stomatal pores.

Travel demand management The attempt to reduce the volume of travel by measures such as car-pooling, lowering speed limits, parking control and pricing, etc.

Tropopause The atmospheric layer separating the stratosphere from the troposphere. It marks the transition from temperatures that decrease with increasing height within the troposphere to an atmospheric region that experiences increasing temperatures with height.

Troposphere The lowest part of the atmosphere from the surface to about 10 km in altitude in mid-latitudes (ranging from 9 km in high latitudes to 16 km in the tropics on average) where clouds and "weather" phenomena occur. In the troposphere, temperatures generally decrease with height.

Tropospheric Ozone (O_3) See "Ozone."

Tropospheric Ozone Precursors See "Ozone precursors."

Trust funds Funds earmarked for specific programs within the UN system.

TT See "Technology transfer"

TT:CLEAR Technology Transfer Information Clearing House.

Tundra A treeless, level or gently undulating plain characteristic of the Arctic and sub-Arctic regions characterized by low temperatures and short growing seasons.

TUNGO Trade related nongovernmental organizations.

Turn-over time The ratio between the mass of a reservoir (e.g., the mass of N_2O in the atmosphere) and the rate of removal from that reservoir (e.g., for N_2O, the rate of destruction by sunlight in the stratosphere).

Twenty-twenty-twenty (20-20-20) This refers to a pledge by the European Union to reach three targets by 2020: (a) a 20 % reduction in greenhouse-gas emissions from 1990 levels; (b) an increase in the use of renewable energy to 20 % of all energy consumed; and (c) a 20 % increase in energy efficiency. The EU says it will reduce emissions by 30 %, by 2020, if other developed countries also pledge tough action.

Ultraviolet (UV)-B radiation Solar radiation within a wavelength range of 280–320 nm, the greater part of which is absorbed by stratospheric ozone. Enhanced UV-B radiation suppresses the immune system and can have other adverse effects on living organisms.

Ultraviolet radiation (UV) The energy range just beyond the violet end of the visible spectrum. Although ultraviolet radiation constitutes only about 5 % of the total energy emitted from the sun, it is the major energy source for the stratosphere and mesosphere, playing a dominant role in both energy balance and chemical composition. Most ultraviolet radiation is blocked by Earth's atmosphere, but some solar ultraviolet penetrates and aids in plant photosynthesis and helps produce vitamin D in humans. Too much ultraviolet radiation can burn the skin, cause skin cancer and cataracts, and damage vegetation.

Umbrella group A loose coalition of non-European Union developed countries formed following the adoption of the Kyoto Protocol. Although there is no formal membership list, the group usually includes Australia, Canada, Iceland, Japan, New Zealand, Norway, the Russian Federation, Ukraine, and the USA.

Unconventional oil Petroleum produced or extracted using techniques other than the conventional (oil well) method. See also "Petroleum."

UN See "United Nations"

UNCCD See "United Nations Convention to Combat Desertification"

UNCED See "United Nations Conference on Environment and Development"

UN CSD See "United Nations Commission on Sustainable Development"

UNCTAD See "United Nations Conference on Trade and Development"

UNDP See "United Nations Development Programme"
UNECE See "United Nations Economic Commission for Europe"
UNEP See "United Nations Environment Programme"
UNESCAP See "Economic and Social Commission for Asia and the Pacific"
UNFCCC See "United Nations Framework Convention on Climate Change"
UNIDO See "United Nations Industrial Development Organization"
Uniform report format A standard format through which Parties submit information on activities implemented jointly under the Convention.
Unintended consequences Outcomes of an action not foreseen or intended.
United Nations An intergovernmental organization established in 1945 to promote international co-operation. It has 193 members. The headquarters of the United Nations is in Manhattan, New York City, and enjoys extraterritoriality. Further main offices are situated in Geneva, Nairobi, and Vienna. The organization is financed by assessed and voluntary contributions from its member states. Its objectives include maintaining international peace and security, promoting human rights, fostering social and economic development, protecting the environment, and providing humanitarian aid in cases of famine, natural disaster, and armed conflict.
http://www.un.org/
United Nations Commission on Sustainable Development (UN CSD) Established by the UN General Assembly in December 1992 to ensure effective follow-up of United Nations Conference on Environment and Development (UNCED), also known as the Earth Summit. From its inception, the CSD was highly participatory in structure and outlook, by engaging in its formal proceedings a wide range of official stakeholders and partners through innovative formulae. At its 11th session in 2003, the Commission decided on a multiyear work program consisting of review and policy years. Since its establishment in 1992, the Commission has greatly advanced the sustainable development agenda within the international community. At the United Nations Conference on Sustainable Development (Rio+20), member states agreed to establish a high level political forum that will subsequently replace the Commission on Sustainable Development.
https://sustainabledevelopment.un.org/csd.html
United Nations Conference on Environment and Development This was the 1992 Rio Conference (i.e., the "Earth Summit").
http://www.un.org/geninfo/bp/enviro.html
United Nations Conference on Trade and Development (UNCTAD) Governed by its 194 member states, it is the United Nations body responsible for dealing with development issues, particularly international trade – the main driver of development.
http://unctad.org/
United Nations Convention to Combat Desertification (UNCCD) Desertification, along with climate change and the loss of biodiversity, were identified as the greatest challenges to sustainable development during the 1992 Rio Earth Summit. Established in 1994, UNCCD is the sole legally binding international

agreement linking environment and development to sustainable land management. The Convention addresses specifically the arid, semiarid, and dry subhumid areas, known as the drylands, where some of the most vulnerable ecosystems and peoples can be found. In the 10-Year Strategy of the UNCCD (2008–2018) that was adopted in 2007, Parties to the Convention further specified their goals: "*to forge a global partnership to reverse and prevent desertification/land degradation and to mitigate the effects of drought in affected areas in order to support poverty reduction and environmental sustainability.*"
http://www.unccd.int

United Nations Development Programme (UNDP) The United Nations'global development network. Headquartered in New York City, UNDP advocates for change and connects countries to knowledge, experience, and resources to help people build a better life. It provides expert advice, training, and grant support to developing countries, with increasing emphasis on assistance to the least developed countries. The status of UNDP is that of an executive board within the United Nations General Assembly.
http://www.undp.org/

United Nations Economic Commission for Europe (UNECE) Set up in 1947 by ECOSOC, it is one of five regional commissions of the United Nations. The others are:

- Economic Commission for Africa (ECA)
- Economic and Social Commission for Asia and the Pacific (ESCAP)
- Economic Commission for Latin America and the Caribbean (ECLAC)
- Economic and Social Commission for Western Asia (ESCWA)

UNECE's major aim is to promote pan-European economic integration. To do so, it brings together 56 countries located in the European Union, non-EU Western and Eastern Europe, South-East Europe and Commonwealth of Independent States (CIS), and North America. All these countries dialogue and cooperate under the aegis of UNECE on economic and sectoral issues. However, all interested United Nations member states may participate in the work of UNECE. Over 70 international professional organizations and other nongovernmental organizations take part in UNECE activities. See also "ECOSOC."
http://www.unece.org/info/ece-homepage.html

United Nations Environment Programme (UNEP) The United Nations Environment Programme (UNEP) is a leading global environmental authority that promotes the coherent implementation of the environmental dimension of sustainable development within the United Nations system and serves as an authoritative advocate for the global environment. UNEP work encompasses:

- Assessing global, regional, and national environmental conditions and trends
- Developing international and national environmental instruments
- Strengthening institutions for the wise management of the environment

http://www.unep.org/

United Nations Framework Convention on Climate Change (UNFCCC) The Convention on Climate Change sets an overall framework for intergovernmental efforts to tackle the challenge posed by climate change. It recognizes that the climate system is a shared resource whose stability can be affected by industrial and other emissions of carbon dioxide and other greenhouse gases. The Convention enjoys near universal membership, with 196 countries having ratified.
Under the Convention, governments:
• Gather and share information on greenhouse-gas emissions, national policies, and best practices
• Launch national strategies for addressing greenhouse-gas emissions and adapting to expected impacts, including the provision of financial and technological support to developing countries
• Cooperate in preparing for adaptation to the impacts of climate change
The Convention entered into force on 21 March 1994.
http://newsroom.unfccc.int/

United Nations Industrial Development Organization (UNIDO) A specialized agency in the United Nations system, formed in 1966 and headquartered in Vienna, Austria. The Organization's primary objective is the promotion and acceleration of industrial development in developing countries and countries with economies in transition and the promotion of international industrial cooperation.
http://www.unido.org/

Uptake The addition of a substance of concern to a reservoir. The uptake of carbon containing substances, in particular carbon dioxide, is often called (carbon) sequestration.

Urban heat island The idea that many large cities are much warmer than the surrounding countryside because of urban heat release, impervious surfaces which restrict evaporation, etc.

USEPA See "Environmental Protection Agency"

Vapor pressure The pressure of a vapor in thermodynamic equilibrium with its condensed phases in a closed system. All liquids have a tendency to evaporate, and some solids can sublimate into a gaseous form. Vice versa, all gases have a tendency to condense back to their liquid form, or deposit back to solid form, as long as the temperature is below their critical temperature or decomposition temperature. In plain terms, a liquid evaporates at all pressures below its vapor pressure, while remaining stable at pressure above the vapor pressure. Also termed "equilibrium vapor pressure."

Vapor pressure deficit A measure of the "dryness" of the air. A high vapor pressure deficit corresponds to a low relative humidity and/or high temperature, while a low vapor pressure deficit corresponds to a high relative humidity and/or low air temperature.

VER See "Voluntary Emissions Reduction"

VOC See "Volatile Organic Compounds"

Volatile Organic Compounds (VOC) Any one of several organic compounds which are released to the atmosphere by plants or through vaporization of oil products, and which are chemically reactive and are involved in the chemistry of tropospheric ozone production. Methane, while strictly falling within the definition of a VOC, is usually considered separately.

Voluntary commitments A draft article considered during the negotiation of the Kyoto Protocol that would have permitted developing countries to voluntarily adhere to legally binding emissions targets. The proposed language was dropped in the final phase of the negotiations. The issue remains important for some delegations and continues to be discussed, currently in the context of the Bali Action Plan, in terms of what constitutes "voluntary."

Voluntary Emissions Reduction (VER) An emission reduction credit exchanged in voluntary (rather than compliance) emissions markets, and usually certified by a voluntary emission standard. VERs are sometimes referred to as verified emissions reductions.

Voluntary Measures Measures to reduce GHG emissions that are adopted by firms or other actors in the absence of government mandates. Voluntary measures help make climate-friendly products or processes more readily available or encourage consumers to incorporate environmental values in their market choices.

Vulnerability The degree to which a system is susceptible to, or unable to cope with, adverse effects of climate change, including climate variability and extremes. Vulnerability is a function of the character, magnitude, and rate of climate variation to which a system is exposed, its sensitivity, and its adaptive capacity.

Wastewater Water that has been used and contains dissolved or suspended waste materials.

Water Retention Capacity The maximum amount of water that a given soil can retain per unit quantity.

Water use efficiency (WUE) A higher water use efficiency in a plant means less water is lost while fixing a molecule of CO_2. C4 and CAM species have an enhanced ability to utilize light while restricting water loss. Although it may be defined in a number of ways, it is basically the amount of organic matter produced by a plant divided by the amount of water used by the plant in producing it.

Water vapor The most abundant greenhouse gas, it is the water present in the atmosphere in gaseous form. Water vapor is an important part of the natural greenhouse effect. While humans are not significantly increasing its concentration through direct emissions, it contributes to the enhanced greenhouse effect because the warming influence of greenhouse gases leads to a positive water vapor feedback. In addition to its role as a natural greenhouse gas, water vapor also affects the temperature of the planet because clouds form when excess water vapor in the atmosphere condenses to form ice and water droplets and precipitation. See "Greenhouse gas."

WBCSD See "World Business Council for Sustainable Development"

Wedge Theory The theory of opportunities for limiting or diminishing the greenhouse effect and global warming. Wedges include: decarbonized electricity,

decarbonized fuels, fuel displacement by alternative energy sources (e.g., solar energy, nuclear energy), methane management, and natural carbon sinks (e.g., forests).

WUE See "Water use efficiency"

Weather Atmospheric condition at any given time or place. It is measured in terms of wind, temperature, humidity, atmospheric pressure, cloudiness, and precipitation. In most places, weather can change from hour-to-hour, day-to-day, and season-to-season. Climate in a narrow sense is usually defined as the "average weather," or more rigorously, as the statistical description in terms of the mean and variability of relevant quantities over a period of time ranging from months to thousands or millions of years. The classical period is 30 years, as defined by the World Meteorological Organization (WMO). These quantities are most often surface variables such as temperature, precipitation, and wind. Climate in a wider sense is the state, including a statistical description, of the climate system. A simple way of remembering the difference is that climate is what you expect (e.g., cold winters) and "weather" is what you get (e.g., a blizzard).

Weber-Morris Model The model theorized that the rate of intraparticle diffusion varies proportionately with the half power of time (t) and is expressed as:

$$q_t = K_{id}\left(t^{1/2}\right) + c$$

where,

- q_t = adsorbate uptake at time t, (mg/g)
- K_{id} = the rate constant of intraparticle transport, (mg/g).$min^{-1/2}$
- c is the intercept and its value is related to the boundary layer thickness

WCC See "World Climate Conference"

Wedge Theory The theory of opportunities for limiting or diminishing the greenhouse effect and global warming. Wedges include: decarbonized electricity, decarbonized fuels, fuel displacement by alternative energy sources (e.g., solar energy, nuclear energy), methane management, and natural carbon sinks (e.g., forests).

WEOG Western European and Others Group (United Nations regional group).

Wet/dry deposition The removal of a substance from the atmosphere either through being washed out as rain falls (wet deposition) or through direct deposition on a surface (dry deposition).

WG I See "IPCC Working Group I"

WG II See "IPCC Working Group II"

WG III See "IPCC Working Group III"

"When" and "where" flexibility The ability to choose the time (when) or location (where) of a mitigation option or adaptation scheme in order to reduce the costs associated with climate change.

WHO World Health Organization.

WMO See "World Meteorological Organization"

World Business Council for Sustainable Development (WBCSD) The World Business Council for Sustainable Development (WBCSD) positions itself as "*a CEO-led organization of forward-thinking companies that galvanizes the global business community to create a sustainable future for business, society and the environment. Through its members, the Council applies its respected thought leadership and effective advocacy to generate constructive solutions and take shared action to drive business action on sustainability in the coming decade and beyond. The WBCSD aims to be the leading voice of business that will support companies in scaling up true value-added business solutions and in creating the conditions where more sustainable companies will succeed and be recognized. Member companies are represented on the Council by the CEO or a board level executive. Council Members drive the strategic direction of the WBCSD and of individual projects where they can join or lead Cluster boards*." http://www.wbcsd.org/

World Climate Conference (WCC) A series of international meetings, organized by the World Meteorological Organization (WMO). The First World Climate Conference was held on 12–23 February 1979 in Geneva.

World Meteorological Organization (WMO) The World Meteorological Organization (WMO) is a specialized agency of the United Nations. It is the UN system's authoritative voice on the state and behavior of the Earth's atmosphere, its interaction with the oceans, the climate it produces, and the resulting distribution of water resources. WMO has a membership of 191 member states and territories. It originated from the International Meteorological Organization (IMO), which was founded in 1873. Established in 1950, WMO became the specialized agency of the United Nations in 1951 for meteorology (weather and climate), operational hydrology, and related geophysical sciences. http://www.wmo.int

WSSD See "World Summit on Sustainable Development"

WTO See "World Trade Organization"

Zone Movement of wind or ocean waters in a direction that is roughly parallel to the lines of latitude

Zone of ablation Area of a glacier where losses of ice from melting, evaporation, and sublimation exceed additions of snow annually.

Zone of accumulation Area of a glacier where additions of snow exceed losses of ice from melting, evaporation, and sublimation.

100-Year Flood Levels Severe flood levels with a 1-in-100 likelihood of occurring in any given year.
