(CdS/TiO_2)	CdS/TiO_2 nanotubes showed greater efficiency than either material alone	Li et al. (2010)

solar cells, and quantum dot (QD) solar cells as discussed in this review have to be explored (Solanki and Beaucarne 2007). Dye-sensitized solar cells (DSSC) may be a cost-effective option, a significant limitation being dye cost and stability and corrosion of metal components of the cell due to the usage of the popular iodine–iodide-based, charge shuttling electrolyte (Toivola et al. 2009). Recombination of photogenerated charges, mainly due to irregularity in the periodicity of the materials, has to be addressed or the performance of a solar cell improved (Frank et al. 2004).

To improve the application of low-cost, high-efficiency solar cells, low-cost ink technologies need to be developed to make it possible to develop a sort of spray paint methodologies to prepare bulk high-efficiency solar cells (Hillhouse and Beard 2009). International standardization of cost for solar cell fabrication is being developed and tested (Chamberlain 1980). Organic material-based solar cells are relatively new and far from becoming *state-of-the-art* devices. However, they are gaining popularity and there is some market activity with devices offering efficiencies of 4–6 % (Hoppe and Sariciftci 2004). Due to the fact that solar systems are open to the elements and the moving nature of the sun, issues such as tracking to maintain efficiency of the system and protection against dust and minimizing the impact of cloud interference have to be considered for reliable operation of the system. One has to explore the development of new materials and applications for solar energy utilization and minimize the use of environmentally toxic materials such as Cd (Bauer 1993). Other emerging areas such as band gap engineering and multilayered systems (high-efficiency tandem cells) for solar energy utilization have to be examined as well (Khaselev and Turner 1998; Goswami et al. 2004).

Integrating Tested Concepts of Solar Energy Utilization to Produce Fuels in an Effective Way

One method to improve solar energy utilization is to develop "smart and integrated systems" that can perform several solar-driven processes that are complementary in nature. The benefits of such an approach are as follows:

Table 7 Materials for photocatalytic reduction of CO_2

Material	Reason	Refs.
TiO_2	TiO_2 anchored on glass act as active photocatalyst for reduction of CO_2 with H_2O	Anpo (1995)
	Highly dispersed anchored TiO_2 to reduce CO_2 to CH_4, Cu loading increased CH_3OH	Anpo et al. (1995)
	TiO_2 nanoparticles, found 14 nm to be optimum photocatalyst	Koci et al. (2009)
	Simple synthesis methods to form highly active nanocomposite photocatalyst	Li et al. (2008)
	TiO_2 pellets reduced CO_2 in the presence of water vapor under UV irradiation	Tan et al. (2006)
	Cu-loaded TiO_2 increases photoreduction CO_2, shown Cu(I) as primary active site	Tseng et al. (2004)
	Cu–TiO_2 optical fibers transform CO_2 to hydrocarbons at higher efficiencies	Wu et al. (2005)
	Highly dispersed TiO_2 within zeolite cavities for efficient CO_2 reduction	Yamashita et al. (1998)
	TiO_2 on a SnO_2 glass substrate to form bilayer catalyst, high photocatalytic activity	Tada et al. (2000)
	Effect of metal depositing on TiO_2, improved efficiency	Xie et al. (2001)
CdSe	CdSe/Pt/TiO_2 photocatalyst producing high yield of CH_4 with CH_3OH, H_2, and CO as minor products	Wang et al. (2010)

Ti-Si	Ti-containing silicon thin films higher reduction than powdered photocatalyst	Ikeue et al. (2002)
Titanium silicalite	UV irradiation reduction of CO_2 with H_2 to CH_4, Ti believed to provide active site	Yamagata et al. (1995)
Poly (3-alkylthiophene)	Photocatalyst in the presence of phenol to produce salicylic acid	Kawai et al. (1992)
$BiVO_4$	Photocatalytic ethanol production under visible light	Liu et al. (2009)
$CaFe_2O_4$	Nonpoisonous, cheap, p-type semiconductor with small band gap	Matsumoto et al. (1994)
Ga_2O_3	Photoreduction of CO_2 with H_2 at room temperature and ambient pressure	Teramura et al. (2008)
$InTaO_4$	Common water splitting semiconductor, now tested CO_2 reduction. Reduction potential increased by adding NiO cocatalyst	Pan and Chen (2007)
(K, Na, Li)TaO_3	Photocatalytic reduction of CO_2 to CO in presence of H_2	Teramura et al. (2010)

1. Maximizing solar energy utilization
2. A one-stop system for multiple applications
3. Improved utilization of land (this benefit can be a significant advantage in places with costly real estate and where limited land may be available for solar energy)
4. Potential for improved energy efficiency, reduced ecological impact, and greater benefits for human activity

Three examples are presented below that illustrate these aspects.

Example 1: Integrated Organic Waste Treatment and Fuel Cell System

An interesting concept that combines two traditional applications of photocatalysis, environmental remediation and energy generation, to form a photo-fuel cell device is discussed below (Antoniadou et al. 2010). Photocatalytic degradation of organic environmental waste results in the formation of hydrogen ions which can be tapped to produce hydrogen molecules in order to use them as a clean fuel. The organic "fuel" wastes can be a part of a photoelectrochemical device that is comprised of two electrodes, (1) a photoanode that essentially consists of the photocatalyst where holes oxidize the organics to liberate H^+ ions, (2) a cathode where the ions are reduced to form hydrogen, and (3) an electrolyte consisting of water, organics, and some salt (essential for ionic conductivity). A schematic of the setup and a prototype of the device are shown in Fig. 5; TiO_2 coated on a fluorine-doped tin oxide (FTO) substrate is used as a photoanode for oxidation of organics. One can expand on this concept a step further by (1) matching the pollutants in a manner that maximizes photooxidation on the basis of redox properties of the materials involved, (2) mechanism of degradation, or (3) potential for H^+ ion generation to improve the yield of hydrogen.

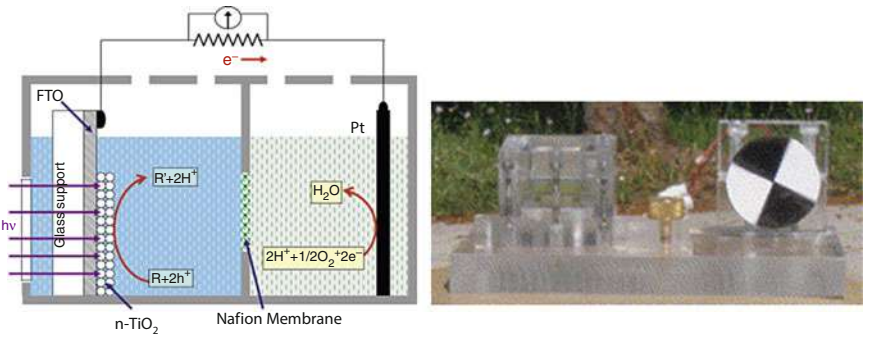

Fig. 5 Schematic representation of a two-compartment PEC cell. The openings at the *upper part* represent gas inlets and outlets. The chemical reactions shown are only indicative examples. The system can be used with other combination of pollutants to produce energy (Reprinted with permission from Elsevier)

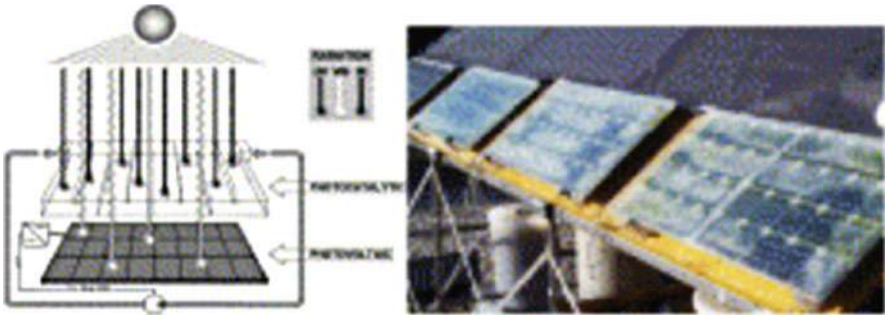

Fig. 6 Schematic representation of a hybrid photocatalytic-photovoltaic system powered using internally generated energy (Reprinted with permission from Elsevier)

Example 2: A Hybrid Photocatalytic-Photovoltaic System (HPPS)

A research group from Switzerland has pioneered the development of an autonomous eco-friendly HPPS system which utilizes solar energy to perform photodegradation of pollutants and a PV system to generate power for operating the system simultaneously (Sarria et al. 2005). This three-tiered system consists of (1) a sun-facing top layer where UV-assisted photodegradation of pollutants is performed, (2) an intermediate water layer which functions as an IR filter to regulate temperature, and (3) a visible light-absorbing PV device that produces electricity at the bottom to power a recirculation pump associated with the system. A schematic of the system is shown in Fig. 6. The system thus does not draw any external power for performing the waste treatment. The system consists of four PV modules and has an overall volume of 25 L. This is an example of a smart integrated system that utilizes UV, visible, and IR parts of the solar spectrum to combining photodegradation of pollutants and producing electricity. A possible direction to further improve the efficiency of such systems may be to focus on trying to harvesting IR photons to produce electricity using new photocatalysts.

Example 3: Bioprocesses to Convert Waste to Energy Using Algae

Man-made emissions such as CO_2 from industries have adverse effects on the environment; the realization of the negative effects of such emissions has led to international protocol and policy changes such as cap-and-trade agreements to control environmental impact (Kunjapur and Eldridge 2010; Pittman et al. 2011; Walke 2009). On the other hand, the shortage of transportation fuels has necessitated the need to develop alternate sources of energy. These two challenges can potentially be addressed simultaneously using algae.

Algae-based systems can assist in green house gas control by consuming CO_2 to produce a variety of useful products. Algae in the presence of sunlight, water, and

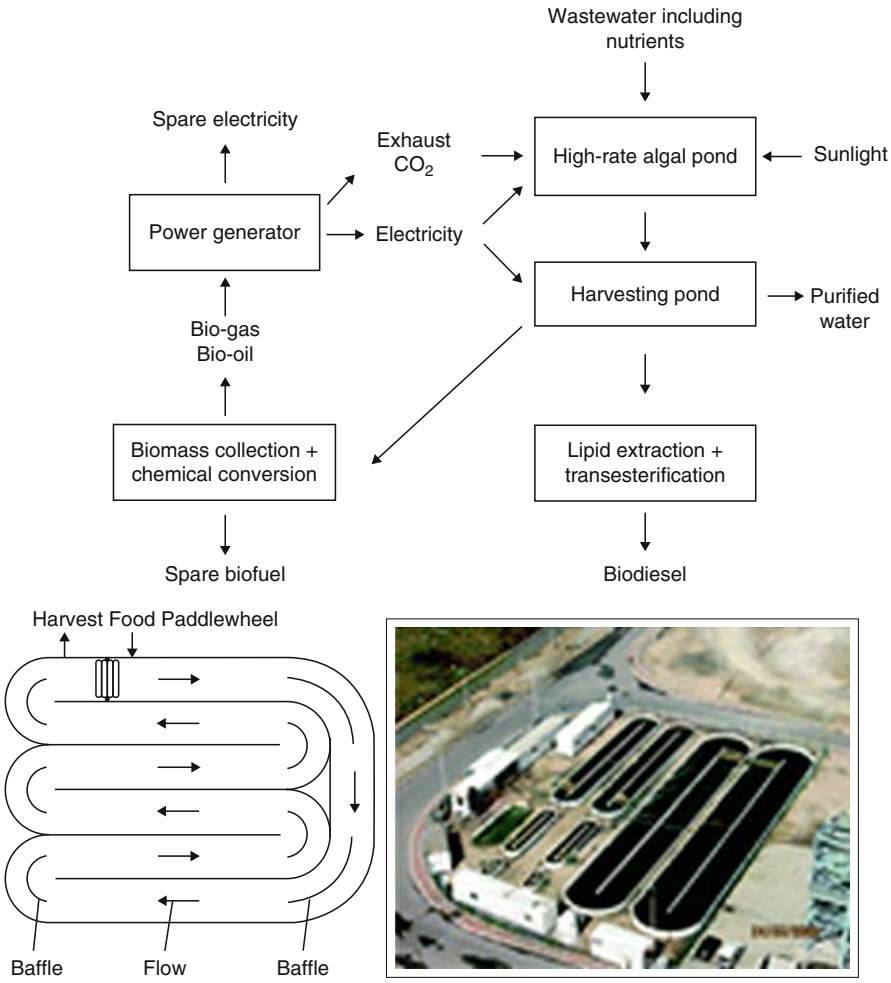

Fig. 7 The steps involved in biodiesel production using waste water, solar energy, and CO_2, and the picture of an actual raceway facility implementing about process (Top) (Reprinted with permission from Elsevier and ACS)

CO_2 nutrients produce biofuels (for transportation), solid biomass (burned to produce heat or electricity), hydrogen, or oxygen. A schematic of the pathway for some of these products is shown in Fig. 7. This approach is considered a promising solution to global environmental and energy needs. Photobioreactors or raceway ponds are two common methods to contact algae with light, CO_2, and nutrients. An example of a raceway pond is shown in Fig. 7.

In a generic parlance, these examples help reinforce the old adage – *One man's junk is another man's treasure*.

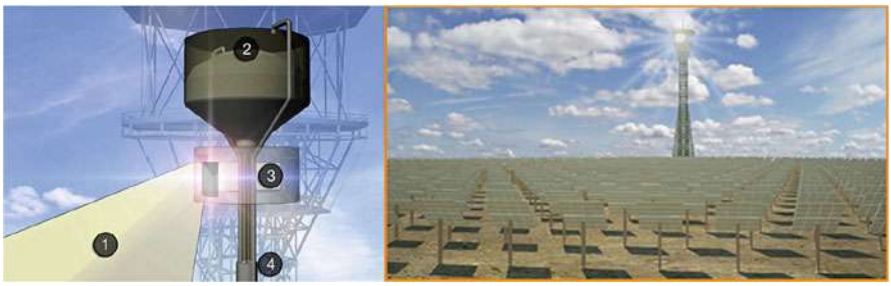

Fig. 8 Schematic of Sundrop Fuels® system to concentrate solar energy onto the thermochemical reactor for gasification and the ground view of heliostat mirrors used to concentrate solar energy

Example 4: Solar-Powered Biomass Gasification

Biomass gasification is the process of converting organic material to syngas, primarily carbon monoxide and hydrogen, which can be used to produce various forms of energy and fuels (Sundrop Fuels Inc 2010; In Biomassmaganzine.com 2010). Organic biomass is reacted at high temperatures with a specific amount of oxygen and water to produce syngas. The syngas is then purified and can be used for electricity generation, production of liquid fuels, or production of hydrogen gas. The problem with traditional gasification processes is that a large amount of energy is required to generate the high temperatures necessary for gasification. This energy is typically supplied by coal-fired power plants or by burning part of the biomass feedstock. Researchers at several Colorado universities in collaboration with the National Renewable Energy Laboratory have developed a rapid solar-thermal reactor that can be used for biomass gasification. In this process, a number of mirrors are used to concentrate solar energy to a single point producing extremely high reactor temperatures, in excess of 2,000 °C. Sundrop Fuels has applied this technology at their solar-driven biomass gasification facility in Louisville, Colorado. Sundrop Fuels uses thousands of solar heliostat mirrors on the ground to direct concentrated solar energy to a thermochemical reactor atop a high tower. Feedstock entering the reactor is converted to syngas at 1,300 °C. Figure 8 shows a schematic representation of the solar-driven gasification process. The syngas is then cleaned and processed to create "green" gasoline, diesel, and aviation fuels. Biomass gasification is a promising technology for producing a number of fuels, and the use of concentrated solar energy eliminates traditional energy losses during thermal energy generation.

Commercial Ventures

The progress in the development of materials for solar energy utilization in the last few decades has permitted a wide variety of solar cell-based commercial ventures to fulfill contemporary specific niches and markets. Furthermore, solar companies are constantly researching and refining their manufacturing processes to discover more

Table 8 Commercial companies involved in the design of solar energy conversion systems

Company	Headquarter's location	Solar cell technology	Website
Konarka Technologies	Lowell, MA	Power plastics	http://www.konaraka.com
Dyesol	Queanbeyan, NSW, Australia	High purity dye solar cell	http://www.dyesol.com
Inventux Technologies	Berlin, Germany	Solar micromorph thin-film modules	http://www.inventux.com

economical and eco-friendly solar cells that will satisfy emerging markets and cliental needs. Within this section, we will profile three solar companies: Konarka Technologies, Dyesol, and Inventux Technologies. Table 8 briefly introduces these companies.

Konarka® Technologies

Konarka Technologies is an international solar company receiving recognition worldwide for developing a third-generation organic photovoltaic technology-based solar cell (Konarka 2009). An organic photovoltaic cell utilizes conductive polymers or small carbon-based molecules for light absorption and charge transport, respectively, while traditional electronics use inorganic conductors such as copper. Konarka's chief technology, Power Plastic, was invented by the company's cofounder and Nobel Prize laureate, Dr. Alan Heeger. Power Plastic is a photoreactive polymer material and can be printed or coated inexpensively onto flexible substrates using roll-to-roll manufacturing; it is comprised of several thin layers: a photoreactive printed layer, a transparent electrode layer, a plastic substrate, and a protective packaging layer, as illustrated in Fig. 9.

Unique Features

Konarka's Power Plastic has several advantages over other organic photovoltaic technologies. These include:

- Tunable cell chemistry to absorb specific wavelengths of light as well as broad spectrum
- To capture both indoor and outdoor light and convert it into direct energy in the form of electric current
- To perform its function using all recyclable materials
- Being thin, lightweight, and flexible

Applications

Konarka's Power Plastic has four major end-product applications. These include:

- Microelectronics: powering sensors, smart cards, and low-power applications
- Portable power: solar-powered sensors, backpacks, and cell phone chargers

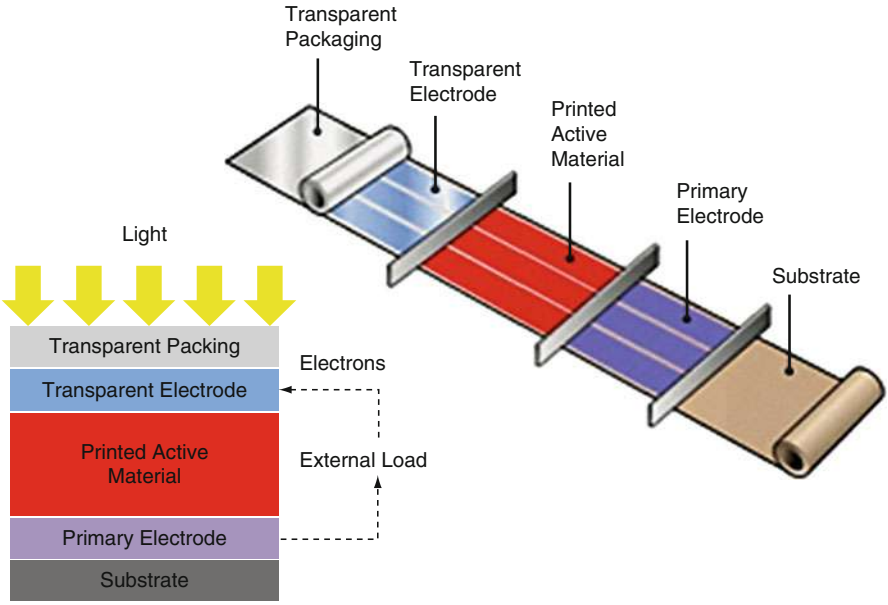

Fig. 9 Illustration of power plastic layers (modified from the Konarka® website)

- Remote power: accessing renewable power at stadiums, carports, and airports
- Building integrated applications (BIPV): custom-manufactured applications roof, windows, and walls

Cost per Watt

Konarka's Power Plastic technology has already reduced the cost of manufacturing solar cell so that it is less than $1 per watt; moreover, Konarka states that through mass production, this cost will be further reduced to approximately $0.10/W.

Future Plans

Konarka is currently developing two future applications for Power Plastic which are under development by Konarka and Arch Aluminum %26 Glass:

- Manufacturing transparent and opaque solar cells for integrated curtain walls and windows components
- The ability for this technology to work off-angle permitting the technology to expand to other niches

Konarka's ongoing research involves conducting advanced research in power fibers, bifacial cells, and tandem architecture. The resulting products of this ongoing research would permit Konarka to expand solar power technology to woven textiles

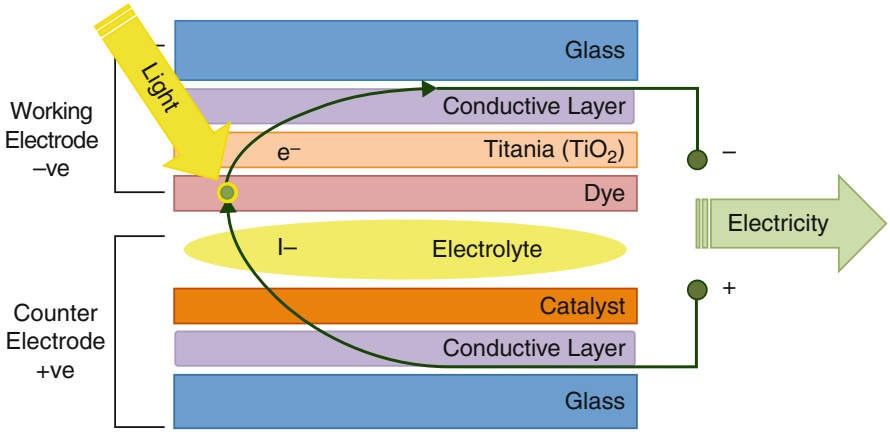

Fig. 10 The fundamental DSC structure design consideration (taken from the Dyesol® website)

via power fibers. Bifacial cells being transparent in nature would permit the solar cells to generate electricity from inside and outside light while allowing the technology to double as a see-through window. Tandem architecture would increase the efficiency of organic photovoltaic devices to 15 % through the process of stacking series-connected subcells.

Dyesol®

Dyesol manufactures and sells high purity dye solar cell (DCS) materials, titania pastes, sensitizing dyes, electrolytes, and electrode catalysts (Dyesol 2010). As seen in Fig. 10, the DSC structure consists of a layer of nanoparticulate titania (titanium dioxide) which is formed on a transparent electrically conducting substrate and photosensitized via a single ruthenium (Ru)-based dye layer. An iodide-tri-iodide-based electrolyte redox system is placed between a layer of photosensitized titania and a second electrically conducting catalytic substrate.

Unique Features

Some advantages of using DSC technology versus other contemporary silicon-based photovoltaic technology are that they:

- Are much less sensitive to angle of incidence of radiation – it is a "light sponge" soaked with dye.
- Perform over a wide range of light conditions.
- Have low sensitivity to ambient temperature changes.
- Are much less sensitive to shadowing and can be diode-free.
- Are an option for transparent modules, thus enabling wider applications.

- Are truly bifacial: They absorb light from both faces and can be inverted.
- Are versatile: DSC power can be amplified by tandem and optical techniques without the use of concentrators.

The resulting DSC panels are more versatile because they are less sensitive to the angle of the solar radiation, allowing them to be installed on vertical walls and in low-light areas; moreover, they can be transparent and can be designed in various color schemes permitting more attractive architectural integration options than those available for silicon.

Applications

Dyesol's patented products and their applications are listed below:

- Interconnected Glass Module: This design is for applications where longest lifetime is needed for exposed mounting and to be isostructural to and replacing the existing structure. Electrical interface can be typically via a short DC bus to a local area network for distribution or inversion to AC.
- SureVolt Solar Range: Maintain voltage at all light levels, having high resistance to damage through impact, bending, tension, torsion, and compression. The range is ideally suited for use in portable consumer electronics, military, and indoor applications, as well as developed landscape infrastructure.

Dyesol's dye solar cells (DSC) are marketed to low light, dappled light, and indoor light markets, a market that only DSC can address.

Cost per Watt

The *Photovoltaic World* May/June 2009 magazine stated at the anticipated 7 % Dyesol efficiency the resulting cost of DSC technology was $1.00/W.

Future Plans

Dyesol appears to have two major future goals:

1. To outsource to working in collaboration with wireless technology and tandem products
2. To enhance power out devices to direct chemical production and complete building solutions

Inventux Technologies

Inventux is a solar energy company that specializes in the development, production, and marketing of environmentally friendly, silicon-based thin-film solar (micromorph thin-film) modules (Inventux 2010). The combination of an amorphous with a microcrystalline cell is termed a micromorph cell. Micromorph cells

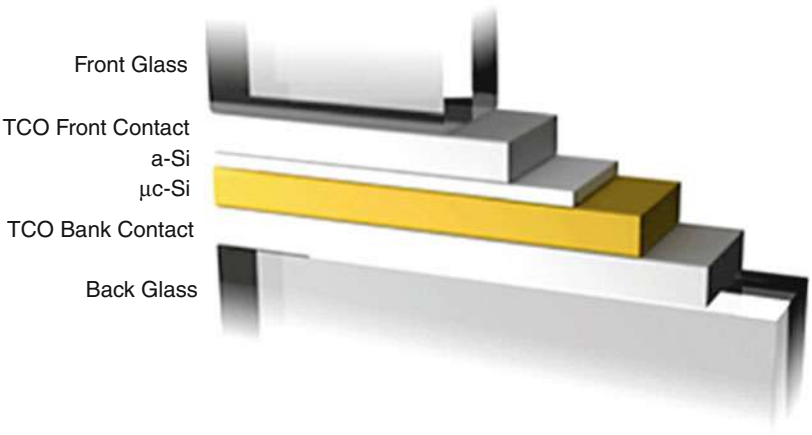

Fig. 11 Thin-film photovoltaic modules layer composition (taken from the Inventux® website)

thus represent the most consistent advancement of amorphous silicon-based tandem cell technology. Figure 11 illustrates the thin-film photovoltaic modules layer composition. The glass serves both as a substrate for the thin-film PV cell and a component of the later encapsulation of the element. The various layers are successively deposited on the front glass. To produce the absorber layers, the plasma-enhanced chemical vapor deposition (PECVD) using gaseous silicon hydrogen compounds became generally accepted. The production of the front and back contact layers (transparent conductive oxide – TCO) takes place by applying low-pressure chemical vapor deposition (LPCVD).

Unique Features

Inventux' solar modules contain absorbers made of amorphous and microcrystalline silicon. Amorphous and microcrystalline silicon are suitable to be combined in a tandem solar cell, since the different band gaps facilitate an enhanced utilization of solar radiation and manufacturing can be done using the same technology. Several of the advantages and benefits of using Inventux Solar Technologies PV modules are:

- The extremely thin 0.002-mm absorber layer requires only a minimum amount of raw material (silicon); the layer thickness is just one-hundredth of that of conventional photovoltaic technology.
- Exploitation of a broader light spectrum as well as fewer shading losses as with crystalline modules, up to 30 % higher yield during inhomogeneous light conditions compared to crystalline modules and a wider range of applications possible.
- By far better temperature behavior at good solar radiation conditions as with crystalline technology, higher yields at full load conditions.
- Monolithic module configuration, as opposed to crystalline cell configuration – with its electrically required spacing, only very little inactive module surface exists.

- Monolithic wiring during the process makes subsequent manual production steps superfluous.
- Series connection of solar cells leads to a relatively high open circuit voltage of the modules, minimized conduction losses, and reduced cabling work.
- Due to the very high spectral acceptance, they have the highest efficiency potential in the area of silicon-based thin-film photovoltaics.

Applications

Inventux thin-film photovoltaic modules are particularly suitable for large, grid-connect photovoltaic systems; moreover due to the micromorph tandem structure wide light spectrum absorption capabilities, Inventux technologies can be used during inhomogeneous light conditions and climate conditions.

Cost per Watt

Inventux Solar Technologies implements Oerlikon Solar's micromorph technology in the company's manufacturing processes. Oerlikon claims that through the incorporation of advanced fabrication designs, the company's turnkey tandem junction technology would be capable of producing modules for $0.70/W by the end of 2010.

Commercial Venture that Employs Tested Concepts of Solar Energy Utilization to Produce Fuels in an Effective Way

Algenol® (2010) is a US-based firm that proposes sequestering CO_2 from power plant exhausts and producing transportation fuel from it. The company plans to use water and sunlight to produce value ethanol (an additive to gasoline). A schematic of their proposed flow sheet is shown in Fig. 12. The firm focuses on the production of

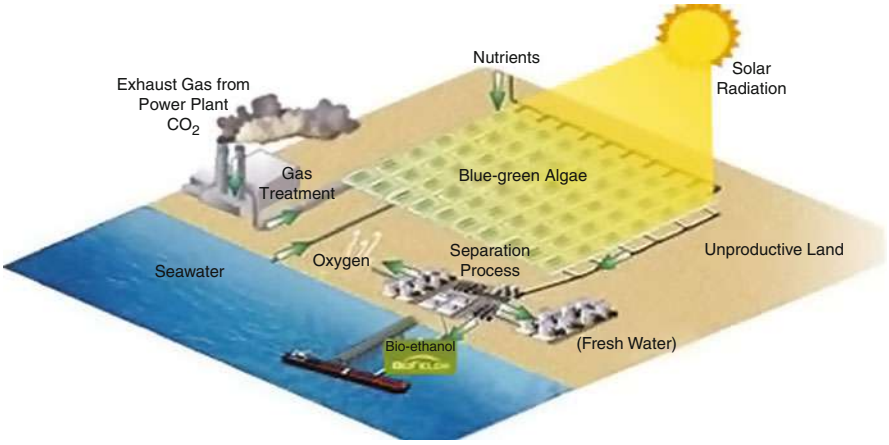

Fig. 12 An artistic rendition of a plant showing CO_2 capture from exhaust of a power plant and its utilization in a biofuel production facility. http://www.treehugger.com/files/2008/06/algenol-algae-biofuel-race-process-economics-advantage.php

ethanol from algae without destroying the algae. A unique highlight of their system is the possibility of growing the algae in land areas that may be deemed unfit for agricultural activities, for example, a desert-like environment. They are planning to build commercial facilities in the United States and Mexico in the near term for large-scale ethanol production. The company plans to sell ethanol at a price of $3.00/gal and is expected to be a major player in the value ethanol market in the near future.

Other Types of Solar Companies

A list of other solar companies from different regions around the world is provided next. These companies are involved in manufacturing products that utilize solar energy in different processes. The reader is referred to the links provided for further information.

Company	Headquarter's location	Solar cell technology	Website

Future Work

Solar research is no longer considered as a small blimp in the energy field. The last three decades of work has in fact brought it to a position where it has been accepted as a serious competitor to many traditional/nontraditional sources of energy. This is evident from the skyrocketing growth rate for solar-based technologies in the world.

However, much needs to be done. Several critical areas require further development to cement the status of solar as a reliable, large-scale, and everlasting source of energy for mankind. To make solar commercial, economical, and lasting, development has to be simultaneously realized along three fronts: scientific, pilot-scale testing and processing, and rapid evaluation and commercialization of promising technologies. A brief insight into future directions along these lines is provided. The scientific step is the most important aspect of all the three stages. Material properties, or rather constraints, are an area that clearly is the limiting factor and greatest challenge to solar energy commercialization. Since solar energy harvesting requires a close interaction of materials with elements and in some instances requires operation under extreme conditions, materials stability is of paramount importance. Solar-to-electric conversion technologies have the potential to transform mankind's energy needs. However, materials that demonstrate stable performance without undergoing chemical transformations and consisting of earth-abundant elements are urgently needed. Researchers have to focus on developing low-cost, wide-spectrum solar energy harvesters. The improvement of solar conversion or utilization efficiency is critical. To achieve efficiency improvements, fundamental understating of material properties such as charge transport, recombination dynamics, and thermal management is needed. One approach to accelerate materials identification and its testing is to employ a combinatorial analysis method. There have been some efforts in this direction, but more is needed. Past research has abundantly shown that multi-element/multi-compound systems as light harvesters are the correct way to move toward realizing efficient solar harvesters. Stacking different materials built on-site or assembling prefabricated compound(s) is required to improve light absorbance as well as efficient transformation of absorbed energy. Combinatorial techniques have to be developed to analyze libraries of possible compounds and to expedite the identification of formulations for maximizing light absorbance and its testing. In stage II, one really needs to focus on the techniques to synthesize solar energy harvesters and convertors on a large scale. Issues such as reliable scale-up material properties (identical and reproducible product) and cost competitiveness have to be addressed at the pilot scale. Approaches such as screen or ink-jet printing have been considered to be very promising techniques to reproduce lab-scale results on a commercial scale. These techniques have to be tested and perfected before further large-scale ventures. Performance data of extended use of solar energy convertors is still limited. Therefore, such data along with weather patterns and its influence on solar energy transformation has to be obtained. Realistic modeling predictions and long-term solar energy outputs have to be generated before using solar as the alternative source of energy for human activity. Stage III will require a large-scale effort on the part of governments (policy makers), green technology companies (research entities and venture capitalists), and public at large to come together to make solar energy a lasting and impacting form of alternate energy source. There are several evidences of governments getting sensitized to such needs, and short-term incentives are provided to test the people's acceptance of the technologies and market reactions. However, there is still no leading technology within the solar energy conversion technologies that can be considered as the one solution for mankind's energy needs. Therefore, the search has to go on.

Conclusion

Solar energy utilization has immense potential due to the range of applications in which it can be utilized. The core issue with solar energy is materials development. There has been significant progress in this area thanks to cutting-edge research in different parts of the world. Market penetration-driven favorable incentives now have to drive the commercialization of promising technologies. The authors are of the opinion that it is no longer necessary to follow *a wait and watch approach* for solar energy systems as many of these systems have passed that stage. One has to take concerted efforts to (1) customize systems based on geographical needs, (2) cost considerations, (3) long-term goals, and (4) institutional support. Solar energy systems are going to play a significant role in future energy portfolios regardless of the applications.

Acknowledgments The authors thank Prof. Wei-Yin Chen for the opportunity to make this contribution. Vaidyanathan Subramanian would like to thank the representatives of Konarka®, Dyesol®, and Inventux Technologies® for their time and contributions. He would also like to thank Prof. Misra and York Smith for their insights as well as the Department of Energy (Grant # DE-EE0000272) for the financial support.

Greenhouse Gas Emission Reduction Using Advanced Heat Integration Techniques

Kailiang Zheng, Helen H. Lou, and Yinlun Huang

Contents

Abstract

Consuming about 20 % of total energy annually in the USA (according to DOE in 1994), the chemical industry is a major source of greenhouse gas (GHG) emissions. It has been widely recognized that a significant reduction of energy

consumption and GHG emissions in chemical processes must implement advanced heat integration technologies in a holistic way.

Heat integration is a family of technologies for improving energy efficiency. The technologies can be applied to the design of heat exchanger networks, heat-integrated reaction-separation systems, etc. Pinch analysis is the foundation of heat integration. In this chapter, the applicability of pinch technology in GHG emission reduction is reviewed first. Furthermore, the concept of "total site," which is valuable for energy targeting and integration at regional level, is described. A "total site" includes not only traditional industrial processes but also commercial and residential energy users into the scope.

Then, more advanced concepts in heat integration are introduced. The concepts are developed based on the observation of problems arising in heat integration applications – stability of heat-integrated systems in operation. The known modeling work addressing these issues will be reviewed thoroughly. The basic principles on how the disturbance-propagation-rejection models for these major chemical processing systems can be adopted in process synthesis and analysis stages will be discussed.

The concept of "total site" has been further extended to greenhouse gas emission targeting and reduction. Carbon dioxide (CO_2) emission-focused pinch analysis methodology is reviewed, which is valuable for obtaining the optimal energy resource mix of fossil fuel and renewable energy for the regional or national energy sector.

Introduction

The chemical industry is one of the largest energy-consuming sectors in the USA. According to the US DOE's analysis, this industry consumes approximately 20 % of the total industrial energy consumption (1994) and contributes in a similar proportion to the nation's greenhouse gas (GHG) emissions. There are great potentials to reduce the energy demand and GHG emissions in chemical process systems using advanced heat integration technologies. The basic heat integration methodology was developed in the past decades under the label "Pinch Analysis." Some key points have been published at the end of 1970, but it was Linnhoff and his coworkers (1994) who developed the basis of pinch technology, which is now considered as the foundation of heat integration.

Pinch analysis was originally developed based on thermodynamic principles to identify the optimal energy recovery strategies between the matches of hot and cold streams. It provides tools that allow the users to investigate energy flows within a process and identify the most economical ways of maximizing heat recovery and of minimizing the demand for external utilities purchased elsewhere (e.g., steam and cooling water), thus contributing to GHG emission reduction. The core concept is to match the available internal heat sources (hot streams) with the appropriate heat sinks (cold streams) to maximize the energy recovery and minimize the cost of external heat sources. Some specialized software packages for implementing the

pinch point analysis are available, such as Super Target™ (KBC Energy Services), Aspen Pinch™, Hextran™ (Simsci), and Honeywell Exchangernet™. Taking the Super Target™ suite, for example, it allows the user to carry out an in-depth pinch analysis for the heat integration within processes, columns, and a large site, respectively, using the PROCESS, COLUMN, and SITE modules.

Over the past decades, pinch analysis has been successfully used to reduce energy consumption site wide (Matsuda et al. 2009) and in individual processes. The applications of pinch analysis in industrial sectors such as oil refining, chemicals, pulp and paper, etc., can typically identify opportunities for 10–35 % energy consumption savings (Natural Resources Canada 2003). Due to its powerful function, the application of pinch analysis is extended to many fields, such as wastewater treatment (Rossiter 1995; Wang and Smith 1994), hydrogen integration (El-Halwagi et al. 2003; Towler et al. 1996), emission targeting (Dhole and Linnhoff 1993a), and even financial management (Zhelev 2005).

In this chapter, the fundamentals of pinch analysis are briefly introduced first. It will cover all of the following aspects: setting energy targets by the construction of composite curves, grid diagram for developing the heat exchanger network (HEN), plus/minus principles for process modifications, appropriate placement of units, principles of data extraction, mathematical programming approach, total site concept, etc. Then, more advanced concepts about the controllability and operability issues of heat integration system are addressed. A disturbance propagation and control (DP&C) model is introduced to the HEN design approach to handle the disturbance issue. This will lead to the optimal design solution both in the criteria of economic cost and controllability. At last, a novel carbon emission pinch analysis (CEPA) methodology, which is developed from traditional pinch analysis, is introduced for emission reduction targeting and planning from industrial sites to regional or national energy sectors. It can identify the minimal usage of low carbon emission yet high-cost energy resources and obtain the optional energy resources allocation scheme.

The Basics of Pinch Analysis

Pinch analysis is a rigorous, structured approach for identifying the bottlenecks in industrial process energy use. The minimum theoretical utility requirement in a process (target) can be calculated for overall energy use, as well as for specific utilities (LP, HP steam, cooling water, etc.) ahead of any detailed heat integration system design activities. Pinch technology can be used to extend the analysis to the site-wide integration of a number of processes by means of utility systems. When considering any pinch-type problem, the same principles apply:

- A process can be defined in terms of supplies and demands (or sources and sinks) of energy.
- The optimal solution can be achieved by appropriately matching sources and sinks by following thermodynamic laws.

- The defining parameter in determining the suitability of matches is the temperature of streams.
- Inefficient transfer of resource can block identification of an optimal solution.

Energy Targets

Constructing the composite curves. The most fundamental concept in pinch analysis is the so-called composite curve. Composite curves are used to determine the minimum energy consumption target for a given process system. The curves are profiles of heat availability (demonstrated by the hot composite curve) and heat demands (shown by the cold composite curve). The degree to which the curves overlap is a measure of the potential for heat recovery, as illustrated in Fig. 1. The gray zone in Fig. 1, where two composite curves overlap (heat duty wise), is the amount of heat that can be recovered through heat integration.

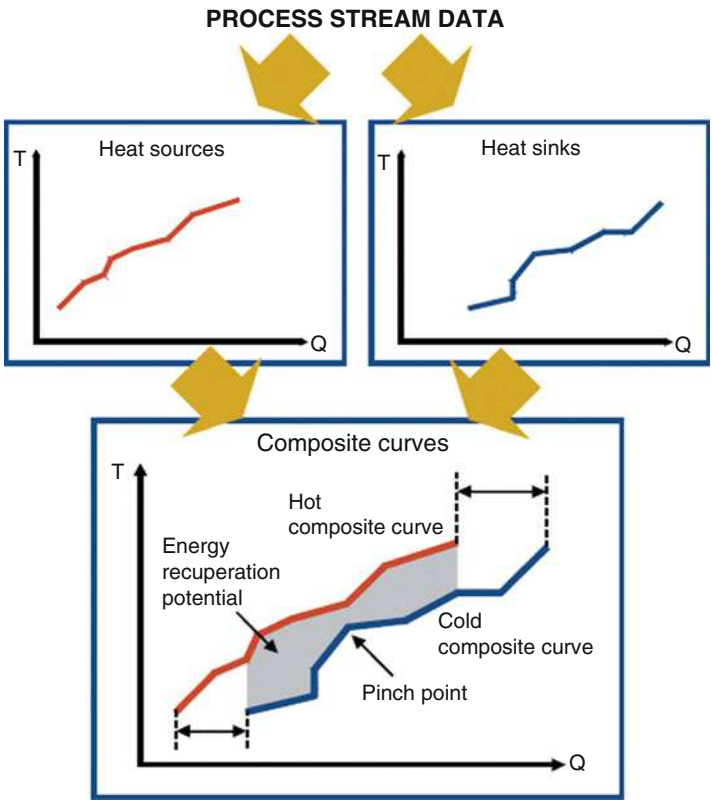

Fig. 1 The composite curves (Natural Resources Canada 2003)

Table 1 Example data for building composite curves (Natural Resources Canada 2003)

Stream	Stream type	Supply temperature (°C)	Target temperature (°C)	Heat duty (kW)	CP (kW/°C)
1	Hot	200	100	2,000	20
2	Hot	150	60	3,600	40
3	Cold	80	120	3,200	80
4	Cold	50	220	2,550	15

To construct the curves, it requires only a complete and consistent energy balance of the process. The data are used to define the process streams in terms of their temperatures, mass flow rates, as well as heat capacities and heating or cooling requirements. These data can be obtained from one or all of the following ways: plant measurements, design data, and simulation. Once identified, these process streams are then divided into sources and sinks.

A source is the stream that has a certain amount of heat to be removed, out of which a fraction or whole can be recovered. Such process streams are called hot streams. A sink corresponds to a stream that must be heated, which is called a cold stream. In pinch analysis, process streams should be identified and then divided into source and sink streams. This step is called data extraction, which is crucial for any pinch analysis. The following example explains how to do the data extraction:

Table 1 presents the stream data chosen to illustrate the construction of the composite curves. The following elements are necessary:

- Stream or segment temperatures: the supply temperature T_s and the target temperature T_t
- Heat capacity flow rate of each stream or segment, defined as $CP = \frac{\Delta H}{\Delta T}$ where ΔH is the enthalpy variation over the temperature interval ΔT and CP is defined as mass flow rate (kg/s) × heat capacity (KJ/(°C · kg)) and has a unit of kW/°C. For example, stream 2 is cooled from 150 °C to 60 °C, releasing 3,600 kW of heat. Its CP value is 40 kW/°C.

Figure 2a shows the hot streams plotted individually on a temperature-duty (or temperature-enthalpy) diagram. The slope of composite curve is the inverse of the CP value. By adding the enthalpy changes of the individual streams within each temperature interval, the hot composite cure is constructed as shown in Fig. 2b. Note that in Fig. 2b, from 150 °C to 100 °C, the slope of the composite curve in this section is reduced. In a similar way, the cold composite curve can be constructed, as illustrated in Fig. 2c and d.

Determining the energy targets. An important part of pinch analysis is the minimum energy requirement (MER) for a given process or plant. This information is used to identify the maximal potential for improvement before starting the detailed process design. To determine the minimum energy target of a process, the cold composite curve is moved left horizontally toward the hot composite curve, as shown in Fig. 3a. Please note that the enthalpy axis measures relative quantities,

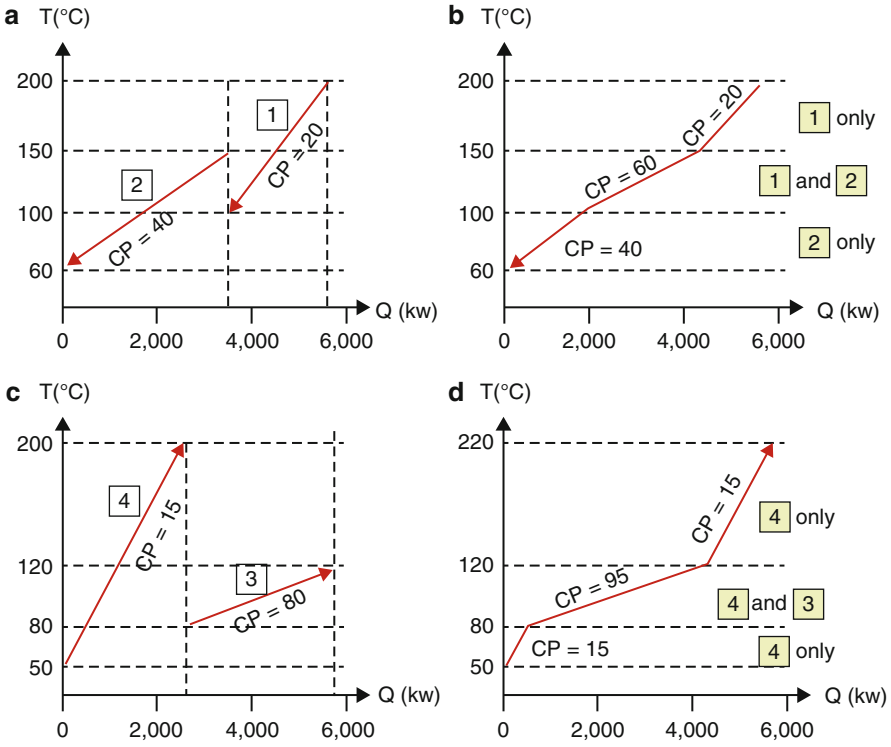

Fig. 2 Constructions of composite curves (Natural Resources Canada 2003)

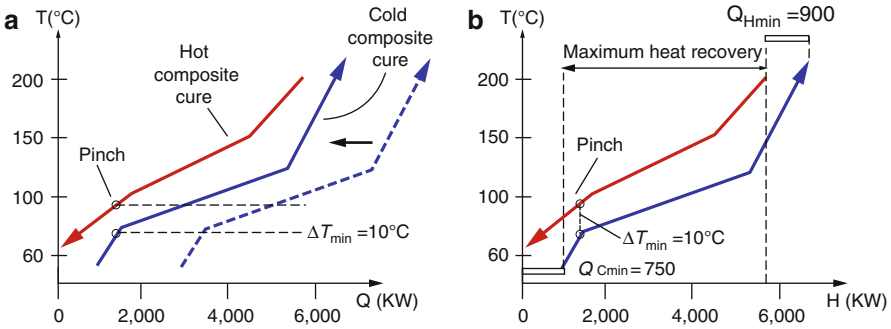

Fig. 3 Determine the energy targets by using the composite curves (Natural Resources Canada 2003)

and it only represents the enthalpy change of process streams. Moving a composite curve horizontally does not, in any way, change the stream data. The relative position of the composite curves depends on the minimum allowable temperature difference, $\Delta T_{\min}$, which is the minimum temperature difference that is allowed in a heat

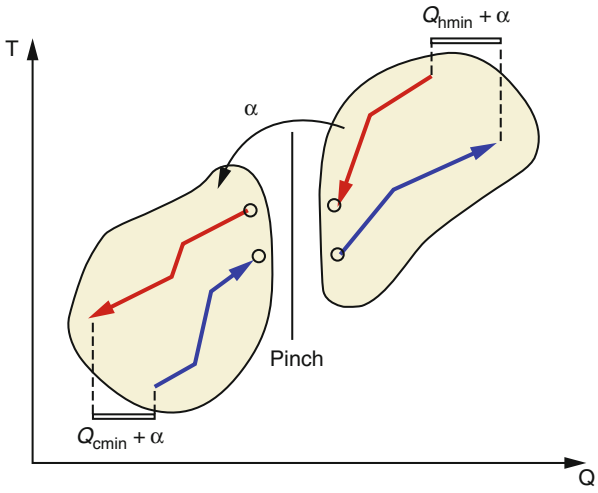

Fig. 4 Heat transfer across the pinch point (Natural Resources Canada 2003)

exchanger (note that the value of ΔT_{min} is usually given before design based on engineering experience; optimal determination of its value is a complicated problem). This also determines the pinch position where the heat transfer between the hot and cold streams is the most constrained. A value of 10 °C is used in this example.

In Fig. 3b, the overlap between the composite curves is the maximum heat recoverable between the hot and cold streams in the process; the remaining heating and cooling needs are the minimum hot utility requirement ($Q_{H\ min}$) and the minimum cold utility requirement ($Q_{C\ min}$) of the process, respectively, for the chosen ΔT_{min}. In this example, the minimum hot utility requirement ($Q_{H\ min}$) is 900 kW and the minimum cold utility requirement ($Q_{C\ min}$) is 750 kW, respectively, as indicated in Fig. 3b.

As demonstrated in the above example, pinch analysis enables the setting of targets for minimum energy consumption prior to any detailed heat exchanger network (HEN) design and allows to quickly indentify the scope of energy savings at an early stage of synthesis.

The point of the closest approach between the two composite curves, where ΔT_{min} is reached, is known as the pinch point. The pinch point is determined by the minimum temperature difference that will be accepted in any heat transfer unit. The pinch principle states that any design where heat is transferred across the pinch will require more energy than the minimum requirement. Consequently, the pinch point divides the problem into two independent subsystems, that is, the hot-end subsystem and the cold-end subsystem.

In principle, the region above the pinch only requires hot utility, while the region below the pinch only requires cooling utility (see Fig. 4). According to pinch design rules, no heat should be transferred from the hot-end subsystem to the cold-end subsystem. For example, if α amount of cross-pinch heat is transferred from the subsystem above the pinch to that below the pinch, then this cross-pinch heat needs

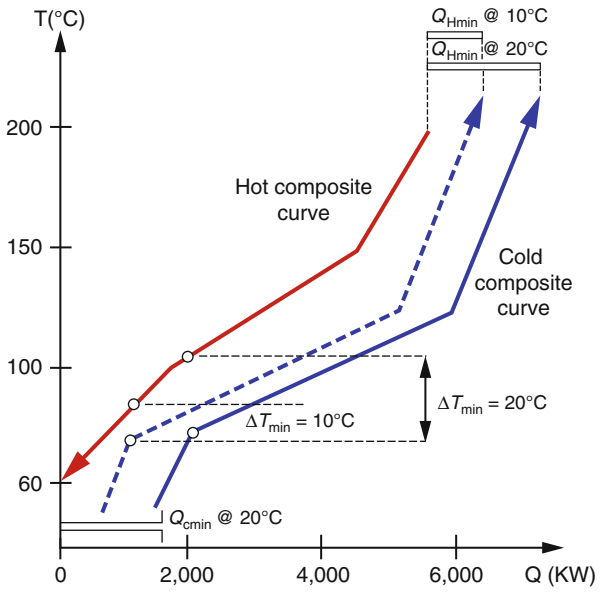

Fig. 5 Effect of ΔT_{min} (Natural Resources Canada 2003)

to be supplied by an equivalent amount of hot utility above the pinch plus the same amount of cold utility below the pinch. Needless to say, this situation should be avoided in any case.

Selection of ΔT_{min}. Generally, saving energy may increase the capital cost, and thus, often, there is a need of a trade-off between capital and energy costs. This can be demonstrated by examining the composite curves. As the separation between hot and cold composite curves (ΔT_{min}) increases, the overlap between the hot and cold streams becomes reduced, thereby decreasing opportunities for heat recovery and in turn increasing the utility cost (Fig. 5). Meanwhile, if ΔT_{min} is increased, which means the permissible minimum temperature driving force between the hot and cold streams is increased, this will allow a greater temperature difference in any heat exchanger. Then, heat exchangers would be smaller in size, thereby making the capital cost for individual heat exchanger lower. Thus, the higher energy cost may be offset by the reduced capital cost of heat exchangers.

Figure 6 shows a generalized trend of energy cost and capital cost when ΔT_{min} changes. It is very obvious that for any given plant, there exists an optimum value of ΔT_{min} which can minimize the total cost of energy and capital. If the cost of energy and the cost of heat exchangers are known for a given plant, it is possible to predict the optimum value of ΔT_{min} ahead of detailed design. In practice, ΔT_{min} for a particular process is often selected by the two factors: the shape of composite curves and the engineer's experience. For chemical processes, and where utilities are used for heat transfer, ΔT_{min} values are typically in the range of 10–20 °C. For low temperature process using refrigeration, a lower ΔT_{min} value, for example, 3–5 °C, could be used to minimize expensive power demands in a refrigeration system.

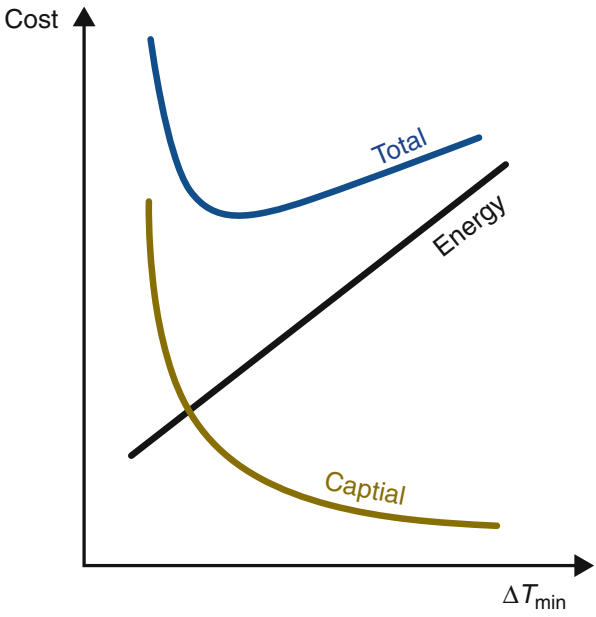

Fig. 6 Energy/capital trade-off (Natural Resources Canada 2003)

Targeting for multiple utilities: *the grand composite curve.* Most processes are heated and cooled using several different utility levels (e.g., different steam pressure levels, furnace flue gas, cold water, refrigeration levels, etc.). It is desirable to increase the use of cheap utility levels and decrease the use of expensive utility levels. For example, using low-pressure (LP) steam instead of high-pressure (HP) steam and cooling water instead of refrigeration can reduce the energy cost.

Composite curves can provide the overall energy targets. However, they do not clearly indicate the exact amount of energy needed to supply by various utility levels. The grand composite curve, which plots process energy deficit (above the pinch) and energy surplus (below the pinch) as a function of temperature, can handle this problem and determine the multiple utility targets.

To construct the grand composite curve, a small mathematical adjustment must be made to the composite curves. The hot composite curve is shifted down and the cold composite curve is shifted up separately by 1/2 ΔT_{min} each, until they touch at the pinch point. The resulting composite curves are referred as the shifted curves and have no real physical meaning. They are merely a step in the construction procedure, which ensures that the resulting grand composite curve shows the required zero-heat flow at the pinch point.

The grand composite curve is generated by plotting the heat load difference between the hot and cold composite curves as a function of temperature (Fig. 7). It provides a graphical representation of the heat flow through the process, from the hot utility to those parts of process above the pinch point, and from the process below the pinch point to the cold utility. The pinch point is where the curve intercepts the temperature axis (Fig. 7).

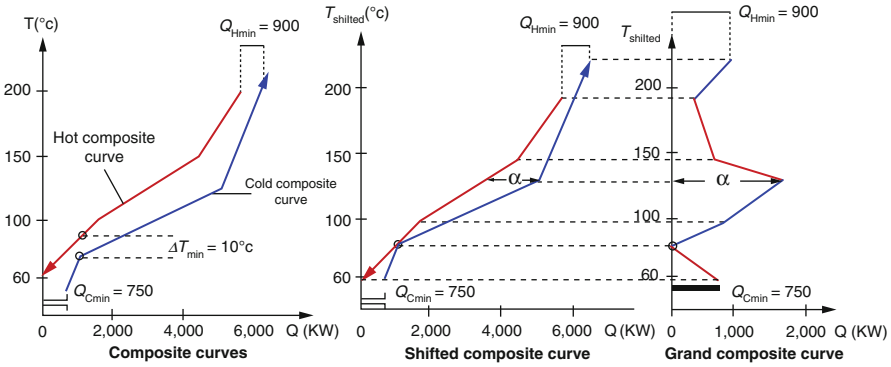

Fig. 7 Construction of the grand composite curve (Natural Resources Canada 2003)

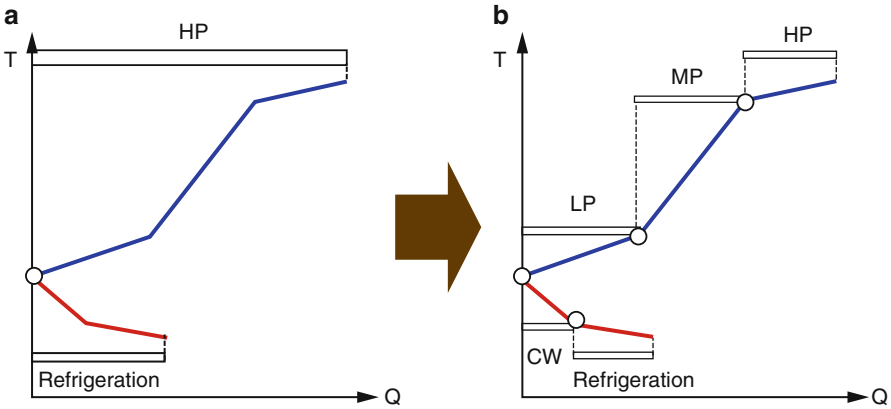

Fig. 8 The grand composite curve for multiple utilities targeting: (**a**) before targeting; and (**b**) after targeting (Natural Resources Canada 2003)

Figure 8a shows a grand composite curve where high-pressure (HP) stream is used for heating and refrigeration is used for the cooling process. In order to reduce the utility costs, some intermediate utilities, such as medium-pressure (MP) steam, low-pressure (LP) steam, and cooling water (CW), can be used as an alternative. Figure 8b shows targets for these alternative utilities.

The target for an LP steam is determined by plotting a horizontal line at the LP steam temperature from the T-axis until it intercepts the grand composite curve. The MP steam target can be obtained in a similar way. The remaining heating duty is satisfied by the HP steam. A similar procedure can be done below the pinch to determine the use of cooling water instead of refrigeration. In summary, the grand composite curve is one of the basic tools used in pinch analysis for the selection of

appropriate utility levels and for targeting optimal heat loads of various utility levels to minimize the total utility cost.

Heat Exchanger Network Design

The targeting step in a pinch analysis includes targeting for minimal energy usage, targeting for process modifications, targeting for multiple utilities, and appropriate placement of heat engines and heat pumps. The aim of targeting step is to explore various process improvement options, such as energy recovery, process modification, and utility system integration, quickly and easily without going into the detail of heat integration design. The key improvement options identified in the targeting stage need to be realized in the detailed design. The heat exchanger network (HEN) design procedure which is based on pinch principle can translate the idea of improvement option into specific detailed design. This design procedure uses the so-called grid diagram to represent the heat exchanger networks. This method will systematically lead the designer to good network design schemes that achieve the energy targets within practical limits.

Grid diagram. Figure 9 illustrates a grid diagram, which is a working frame for synthesizing a heat exchanger network (HEN). The hot streams run from left to right at the top, while the cold streams run in the opposite direction at the bottom, as illustrated in Fig. 9. The vertical line with two arrows connecting the hot stream with cold stream represents the heat exchanger between process streams. Heaters on cold steams and coolers on hot streams are shown with circles. The process pinch location is represented by a dashed line dividing the grid diagram into two parts. The pinch hot and cold temperatures obtained from composite curves by the determined $\Delta T_{\min}$ are

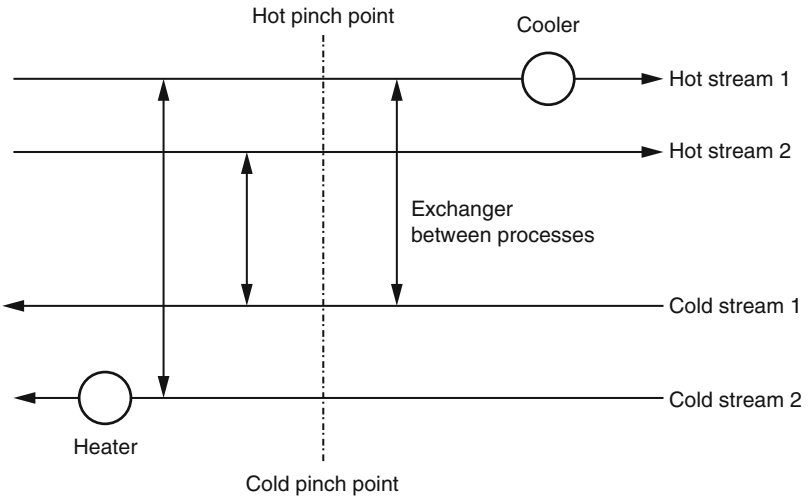

Fig. 9 Grid diagram for developing the heat exchanger network

shown at the top and bottom of the dashed line. The process above the pinch (heat sink) is on the left side of the dashed pinch line, and the process below the pinch (heat source) is on the right side. Overall, in the grid diagram, the temperatures of streams decrease from the left side (above the pinch) to the right side (below the pinch).

According to the pinch principles discussed before, the process is divided into two independent subsystems at the pinch point and any heat transfer across the pinch will require more energy than the minimum requirement. Thus, the HEN design should be conducted in two steps, above the pinch and below the pinch, respectively. The design starts at the pinch, where the heat transfer is most constrained. To determine the match of steams sequentially, heuristic feasibility rules could be used. Note that stream matching can be also determined by rigorous mathematical programming methods (Papoulias and Grossmann 1983; Yee et al. 1990; Floudas 1995; Floudas and Grossmann 1986; Ciric and Floudas 1990).

For a pinch match above the pinch (at the left side), the following heuristic rule can be followed, that is, $CP_{\text{hot}} \leq CP_{\text{cold}}$. In this context, *CP* means mass flow rate × specific heat capacity. This rule can be easily understood by the fact that only hot utility is needed above the pinch, so the *CP* value of the cold streams must be greater than the *CP* value of the hot streams.

Similarly, below the pinch (at the right side), for each pinch match, the following heuristic rule holds: $CP_{\text{hot}} \geq CP_{\text{cold}}$. The two rules above can be summarized as $CP_{\text{in}} \leq CP_{\text{out}}$. It means for a match at the pinch, the *CP* value of the stream going out of the pinch must be greater than the *CP* value of the stream coming into the pinch. For example, when considering the process above the pinch, the *CP* of hot stream, which is coming into the pinch, is smaller than the *CP* of cold stream, which is going out of the pinch.

Number of matches, paths, and loops. Linnhoff and coworkers (1994) pointed out that the minimum number of units (matches) N_E needed to recover the energy between N_s process streams using N_u utilities can be expressed by the following equation, if the synthesis problem cannot be feasibly divided into two or more energy-independent problems:

$$N_E = N_s + N_u - 1$$

If there are N_{loop} loops present in the network, this equation can be modified as:

$$N_E = N_s + N_u - 1 + N_{\text{loop}}$$

The concept of path means a physical connection through streams and heat exchangers for the transfer of energy between utilities. A path allows the modification of the temperature difference between hot and cold streams. A loop is a closed trajectory connecting several heat exchangers. These two concepts are very useful in the optimization of heat exchanger network design.

Reducing the HEN. The HEN design for minimum energy requirements based on the pinch principle ensures the maximal energy recovery, thus minimizing the energy cost. However, this design may increase the number of units needed, and thus

demanding a high equipment cost. In this case, merging some units and reducing the number of equipments may contribute more significantly to the total cost saving through trade-off between the capital and operating costs. The final optimization of the design will depend on the cost of energy and equipment in the particular case analysis. As a rule of thumb, breaking the loop including the heat exchanger with the smallest load and removing this unit in a loop can greatly reduce the total cost of the design. The loss of energy recovery capacity due to the reduction of small units can be partly compensated by increasing the heat transfer area of large units. This can be explained by the fact that for small heat exchangers, the fixed capital cost of equipment, which includes installation, instrumentation, control, supervising, and maintenance costs, is usually larger than the cost of incremental heat transfer area.

Appropriate Placement and Process Modifications

Appropriate placement of units. The appropriate placement principle determines the optimal location of individual units against the pinch. It applies to heat engines, heat pumps, distillation columns, evaporators, furnaces, and any other operating units which can be represented in terms of heat sources and sinks.

In the process industry, the use of combined heat and power systems has been increased significantly. In such cogeneration units, the heat rejected by a heat engine, such as steam turbine, gas turbine, or diesel engine, is used as hot utility and integrated into the process. If a heat engine is integrated across the pinch, as

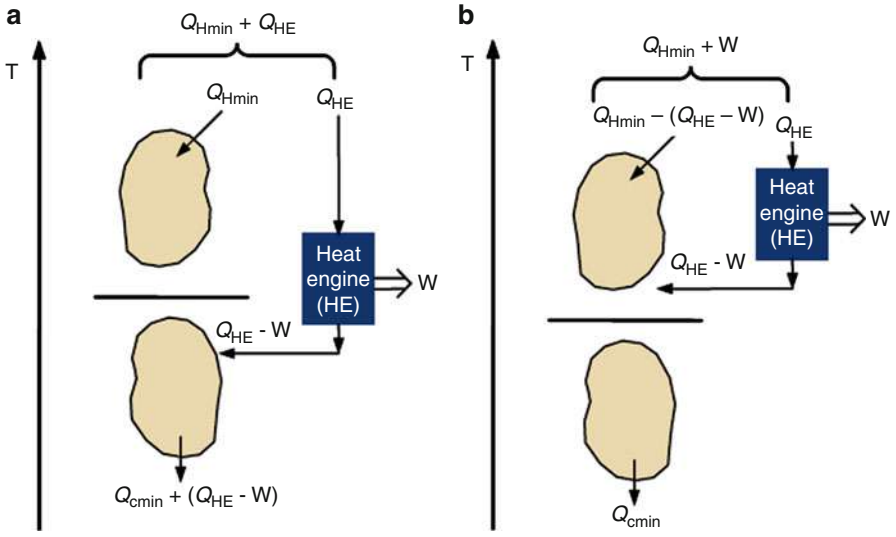

Fig. 10 Integration of heat engine exhaust: (**a**) across the pinch; and (**b**) above the pinch (Natural Resources Canada 2003)

shown in Fig. 10a, the process will still require the same amount of utilities ($Q_{H\ \mathrm{min}}$). When the heat engine is completely integrated above the pinch as shown in Fig. 10b, the heat is rejected to the heat sink region of the process, thus exploiting temperature differences between the utility and process and producing work at a very high efficiency. After integration, the import of W amount of extra energy from heat sources can produce W amount of shaft work, and the efficiency of heat to work conversion appears close to 100 %. A similar situation will arise when heat engine is completely integrated below the pinch.

Heat pumps, such as vapor compression and refrigeration, are systems that absorb heat at a low temperature in an evaporator, consume shaft work to compress the working fluid, and reject heat at a higher temperature in a condenser. If the pump is located completely above the pinch, it simply transforms power into heat, which is

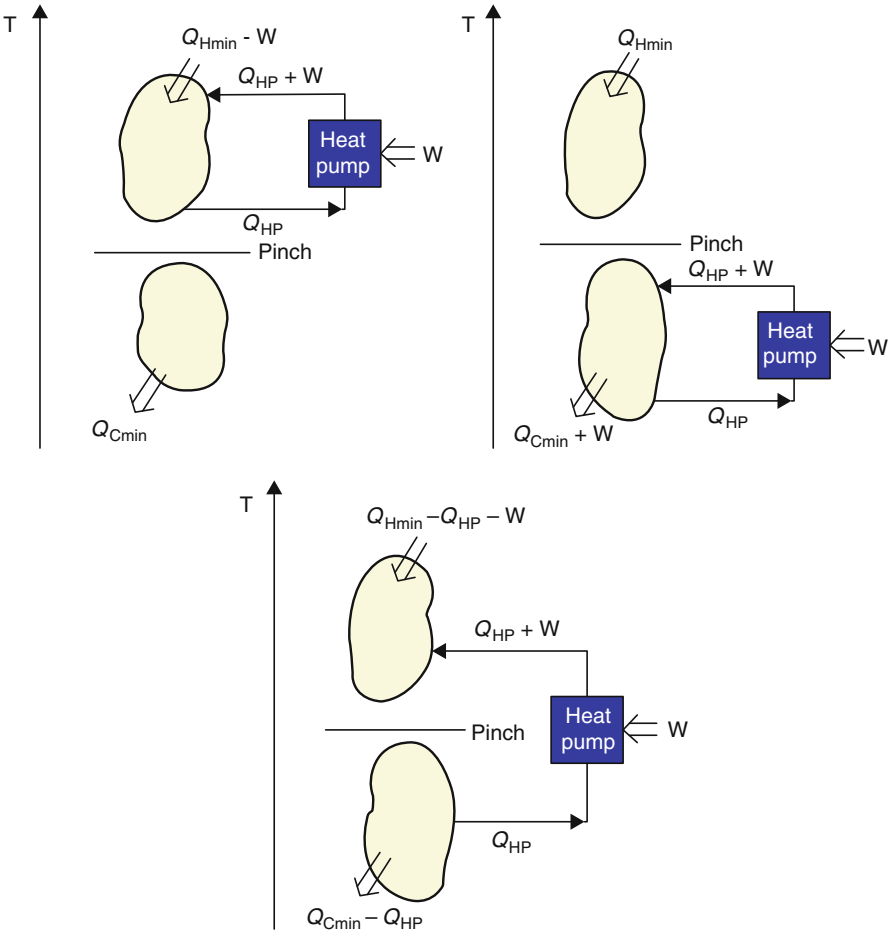

Fig. 11 Integration of a heat pump above, below, and across the process pinch (Natural Resources Canada 2003)

not economical. If it is placed completely below the pinch, the situation is even worse because work is transformed into waste heat. The only appropriate way to place a heat pump is across the pinch, where heat is absorbed below the pinch and rejected above the pinch, as shown in Fig. 11.

In fact, the principles introduced above can be concluded as the Townsend and Linnhoff heuristics (Seider et al. 2003):

1. When positioning heat engines to reduce the total utilities, place them entirely above or below the pinch.
2. When positioning heat pumps to reduce the total utilities, place them across the pinch.

Plus/minus principle in process modifications. For a process, the heat and material balance determines the shape of the composite curves and then the minimum energy requirements set by the curves. By changing the heat and material balance, the composite curves would change accordingly. Thus, it is possible to further reduce the energy requirement of the process. There are several parameters that could be changed, such as distillation column operating pressures and reflux ratios, feed vaporization pressures, etc. There are so many choices that a guide is needed to confidently predict the parameters that could be changed to reduce the energy consumption. By applying the thermodynamic rules based on pinch analysis, which is called the "plus/minus principle," it is possible to identify the appropriate process modifications that will improve the energy recovery significantly. In general, the hot utility can be reduced by (1) increasing hot stream (heat source) duty above the pinch and (2) decreasing cold stream (heat sink) duty above the pinch. Similarly, the cold utility target can be reduced by (1) decreasing hot stream duty below the pinch and (2) increasing cold stream duty below the pinch. This is termed as the plus/minus principle for process modifications. This simple principle provides a reference for any adjustment in process heat duties, such as vaporization of a recycle, etc., and indicates which modifications would be beneficial and which would be detrimental.

Often, it is possible to change temperatures rather than heat duties. It is clear from the composite curves that temperature changes confined to one side of the pinch will not have any effect on the energy targets. However, temperature changes across the pinch can change the energy targets for the process. For example, reducing the feed vaporization pressure (cold stream) may move the feed vaporization duty from above the pinch (minus) to below the pinch (plus). Hence, a reduction of vaporization duty is achieved in both hot and cold utilities. This can be considered as an application of plus/minus principle twice.

When a cold stream is removed from the region above the pinch and placed below the pinch, certainly, the shape of cold stream composite curve will change accordingly. The hot utility needed will diminish by the exact amount of cold utility moved. Similarly, moving a hot stream from the region below the pinch to above the pinch will reduce the hot utility consumption. In general, the above observations for beneficially shifting process temperatures can be summarized as follows: (1) shift hot streams from below the pinch to above and (2) shift cold streams from above the pinch to below.

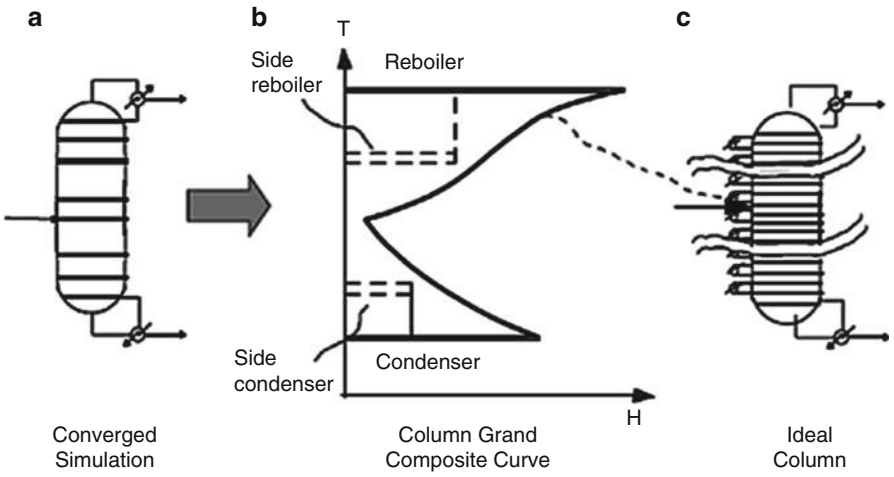

Fig. 12 Column grand composite curve (Linnhoff March 1998)

Modifications of distillation column. Distillation column unit is the basic processing step in many chemical plants. Although distillation is highly energy-intensive, consuming energy in the magnitude of several MJ/s, it has a low thermodynamic efficiency (less than 10 % for a difficult separation). Thus, it is one of the important areas for heat integration. During the retrofit or new column design, pinch analysis can be exploited to identify the targets for appropriate column modifications in order to reduce utility cost and to improve energy efficiency. Some software packages, such as Super Target™ (KBC Energy Services), Aspen Pinch™, provide advanced software tools for the implementation of column targeting and modifications.

Figure 12 shows an example of the column grand composite curve (CGCC) (Dhole and Linnhoff 1993b), a tool that is used for column pinch analysis. CGCC is based on the concept of minimum thermodynamic condition for a distillation column, which pertains to thermodynamically reversible column operation. In this ideal condition, a distillation column would operate at minimum reflux, with an infinite number of stages, and with side reboilers and side condensers placed at each stage with appropriate heat loads for the operating and equilibrium lines to coincide, as shown in Fig. 12c. In other words, the reboiling and condensing loads are distributed over the whole column. The stage-enthalpy (stage-H) or temperature-enthalpy (T-H) profiles for such an ideal column therefore can represent the theoretical minimum heating and cooling requirements of the column operation. These profiles are termed as the column grand composite curves (CGCC).

Most industrial columns have certain inevitable losses or inefficiencies. In order to set realistic targets for the column modifications, these losses must be allowed. To handle this problem, Dhole and Linnhoff (1993b) developed a practical near-minimum thermodynamic condition (PNMTC) approach, which is adopted by many software. This approach takes into account the losses or inefficiencies

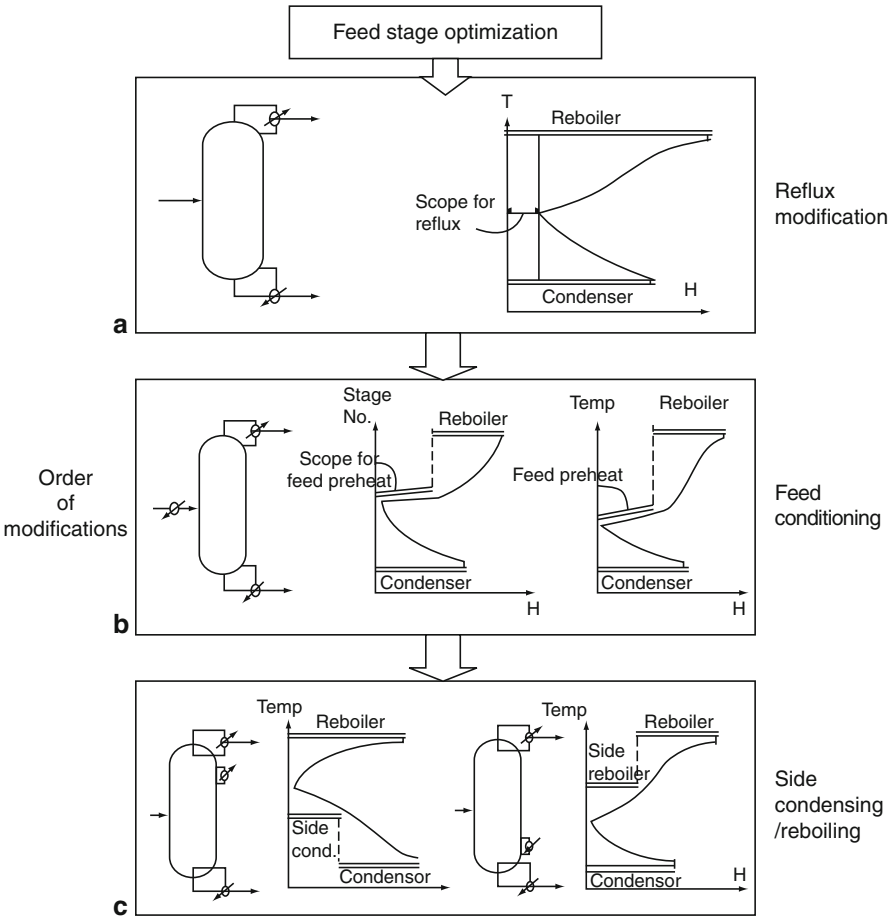

Fig. 13 Using column grand composite curve to identify column modifications (Linnhoff March 1998)

introduced through practicalities of column design, such as pressure drop, multiple side products, side strippers, sharp separations, etc. The procedure for constructing the CGCC starts from a converged column simulation. From the simulation, the necessary column information is extracted on a stage-wise basis. Then, the equations for equilibrium and operating lines are solved simultaneously at each stage for designated light-key and heavy-key components. The enthalpy deficits used in plotting the CGCC are calculated at each stage. At last, these enthalpy deficits are cascaded to construct the CGCC either in stage-H or T-H dimensions.

Like the grand composite curve for a process, the CGCC provides a thermal profile for the column and can be used for identifying the targets for potential column modifications, such as feed location, reflux ratio, feed conditioning (preheating or precooling), and side condensing or reboiling. Based on the

inspection of the CGCCs, the following order of implementation of different column modifications is recommended as shown in Fig. 13: feed location (appropriate placement), reflux ratio modification (reflux ratio vs. no. of stages), feed conditioning (preheating or precooling), and side condensing or boiling.

Feed location needs to be carried out first since it may strongly interact with other column modifications. The feed enthalpy strongly influences the shape of CGCC near the feed stage. And the CGCC usually shows a pinch point near the feed stage. Inspection of the CGCC can identify any distortions due to inappropriate feed location. Normally, this kind of distortions will be apparent since the stage-H CGCC will have significant projections at the feed location (pinch point). This is due to a need for extra local reflux to compensate for the inappropriate feed location. The optimal feed stage can be obtained by trying alternate feed locations and observing its influence on the reflux ratio. When the feed is introduced too high up in the column, there will be a sharp enthalpy change on the condenser side of the stage-H CGCC, and the feed should be moved down. Similarly, when the feed is introduced too low, there will be a sharp change on the reboiler side of the stage-H, and the feed should be moved up. The optimal feed location not only removes the distortion in the stage-H CGCC but also reduces the condenser and reboiler duties.

Out of many other column modification options, the scope of reflux improvement must be considered first since it results in direct heat load savings at both reboiler and condenser. In Fig. 13a, the horizontal gap between vertical axis and T-H CGCC pinch point indicates the scope for reduction in heat duties through reduction of reflux ratio. When the reflux ratio is reduced (while increasing the number of stages to maintain the separation), the gap will decrease, and the CGCC will move closer to the vertical axis, thus reducing the condenser and reboiler duties. It must be noted that when the reflux ratio is reduced, the number of stages will increase to maintain the desired separation. Thus, to obtain an optimal reflux ratio, the increase in the capital cost due to the increase of stages should be traded off against the savings in the operating cost due to reduced condenser and reboiler loads.

Inappropriate feed condition usually results in a sharp enthalpy change in the CGCCs near the feed location and increases the heat load of condenser or reboiler. The scope of feed conditioning can be identified from the sharp enthalpy changes on the stage-H or T-H CGCCs. Figure 13b shows an example that the feed needs to be preheated. The extent of the sharp enthalpy change on the CGCCs determines the appropriate preheating duty needed. Feed preheating not only reduces the reboiler duty but also reduces the temperature levels at which the hot utility (for the reboiler and the feed preheater) needs to be supplied. For feed precooling, the situation is similar. Changes in the heat duty of feed preheaters or precoolers will lead to similar duty changes in the reboiler or condenser loads.

After the modification of feed conditioning, side condensing/reboiling should be analyzed. An appropriate side reboiler, like the feed preheaters, not only reduces the heat loads of column reboiler but also reduces the temperature levels at which the hot utility (for the main reboiler and the side reboiler) needs to be supplied. In Fig. 13c, the two CGCCs show the potential for side condensing and reboiling, respectively.

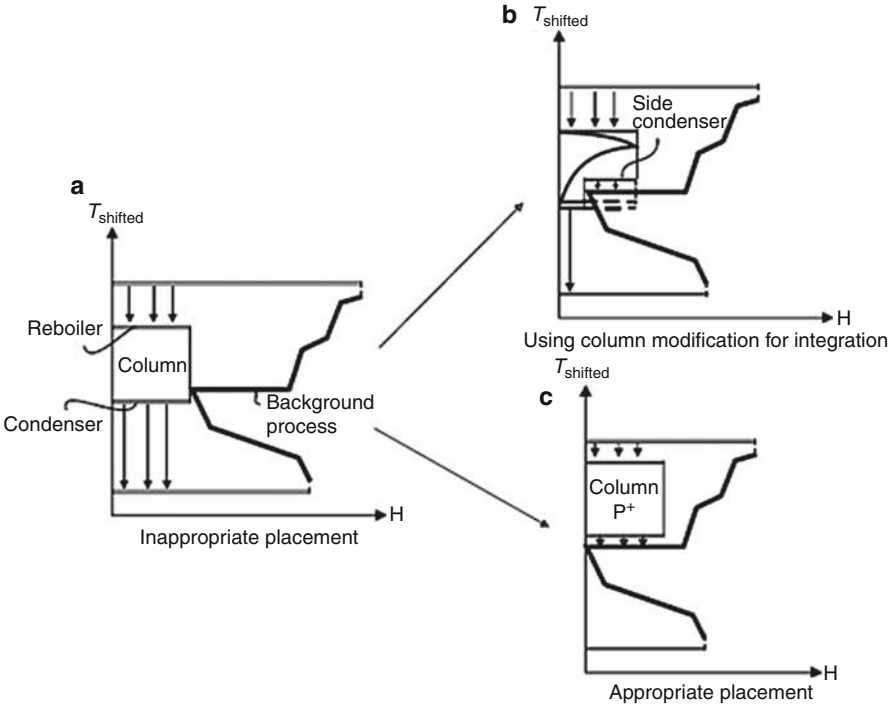

Fig. 14 Appropriate integration of a distillation column with the background process (Linnhoff March 1998)

In general, feed conditioning is preferred to side reboiling or side condensing as it offers a more moderate and convenient temperature level. Meanwhile, feed conditioning is external to the column and therefore easier to be implemented than side condensing/reboiling.

Till here, several ways of improving column thermal efficiency by stand-alone column modifications and their sequence are presented. In many cases, it is possible to further improve the overall energy efficiency of the process by appropriately integrating the column with the background process.

Figure 14 illustrates three examples of integrating the distillation column with the background process. The background process is represented by its grand composite curve. Figure 14a shows an example of an inappropriately placed column with its temperature range across the pinch temperature of the background process and without any potential for integration with the background process. Figure 14b illustrates a case that although the column temperature range still crosses the pinch temperature of the background process, a side condenser can be added to further improve the overall thermal efficiency as identified by the CGCC.

Figure 14c presents a different alternative integration scheme, which allows a complete integration between the column and the background process. In this scheme, the column pressure is increased to move the CGCC to one side of the

process pinch point instead of crossing the pinch. Thus, the overall energy consumption of this scheme is just the energy consumption of the background process.

Although appropriate column integration can provide significant energy benefits, these benefits must be considered together with the relevant issues, like the associated capital investment and difficulties in operation.

Data Extraction

Before the pinch analysis can be done, various process information is needed. Note that the amount of information available from plant measurement, data acquisition systems, and simulation models of a process can be very large, and most of the data may be of no relevance to the analysis. It is thus necessary to identify and extract only the information that truly captures the relevant sources and sinks and their interactions with the overall process. The required data involves process stream heating and cooling information, utility stream information, cost information, and some background information regarding the processes. In summary, the following data need to be collected for each process stream: mass flow rate (kg/s), specific heat capacity (kJ/kg·°C), supply and target temperature (°C), and heat related to a phase change (kJ/kg). Additionally, for the utilities and the existing heat exchangers, the following information needs to be acquired: existing heat exchanger area (m^2), heat transfer coefficient of heat exchangers ($kW/(m^2 \cdot °C)$), and utilities available in the process (water temperature, steam pressure levels, etc.).

Data extraction could be time-consuming and must be performed carefully as the results of pinch analysis strongly depend on this step. Poor data extraction can easily lead to missed opportunities for the process improvement. In extreme cases, poor data extraction can falsely show that the existing process design is already the optimal one in energy efficiency. Data extraction needs to be conducted in an appropriate way, which only accepts the critical parts of the existing design that cannot be changed. A key objective of data extraction is to recognize the parts of process that can be further modified during the analysis (e.g., adding new heat exchangers, changing the process temperatures, etc.). If during the data extraction, all the features of existing design are considered as fixed, then there will clearly be no scope for improvement. If the extraction does not consider any features of the existing design, then the pinch analysis conducted later may overestimate the potential benefits.

At the beginning of a data extraction, it is recommended that all process streams be included. The constraints, such as distance between processes, operability, and control and safety issues, can be considered later on. The experienced specialists may include some constraints at the beginning of data extraction. This can speed up the overall analysis; however, lots of experience is required to ensure that potential heat integration opportunities are not excluded by adding these constraints earlier. Hence, data extraction requires lots of experience, and there are many sector specifics for data extraction. Not all of them can be covered here; however, some important heuristic rules have been developed as guidelines over the past years.

Do not mix streams at different temperatures. In a process flow sheet, the streams at different temperatures cannot be directly mixed together, as such direct non-isothermal mixing acts as a direct contact heat exchanger. Such mixing may involve cross-pinch heat transfer and therefore increase the overall external utility requirement. It should not become a fixed feature of the data extraction. For example, if the pinch is located at 70 °C, then mixing a stream at 90 °C with a stream at 50 °C will create a cross-pinch heat transfer and increase the energy targets. To avoid this, if mixing must take place due to process reasons, then the isothermal mixing must be considered. The streams involved in mixing should be considered independently and extracted separately as being mixed at the same target temperature.

Do not carry over features of the existing solution. This rule is illustrated with the example whose process flow sheet is shown in Fig. 15. Based on the original data extraction generated from the process flow sheet in Fig. 15, a HEN design is conducted using pinch analysis. The original data extraction and corresponding HEN design are illustrated in Fig. 16. Because the HEN design from pinch analysis, consisting of one heater, one cooler, and two exchangers, is identical to the existing process flow sheet design in Fig. 15, it seems that the existing flow sheet design is already optimized and there is no opportunity for further improvement. The pinch analysis results in no benefit.

However, the original flow sheet is not an optimal design and the original data extraction is not appropriate. Figure 17 shows an appropriate method of data extraction from the existing process flow sheet and the corresponding HEN design. All the three cold streams previously extracted can be denoted as just one cold stream, and likewise, only one hot stream needs to be extracted. The improved design is much simpler and easier to control. It shows significant additional potential

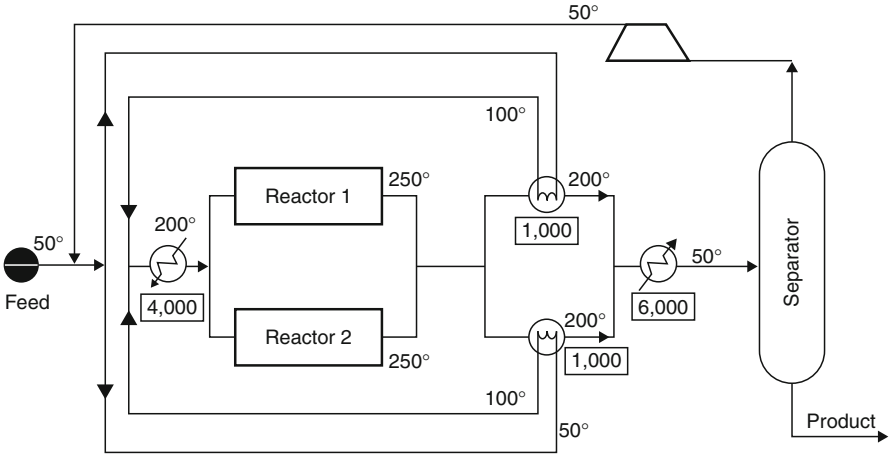

Fig. 15 Example process flow sheet for data extraction (Linnhoff March 1998)

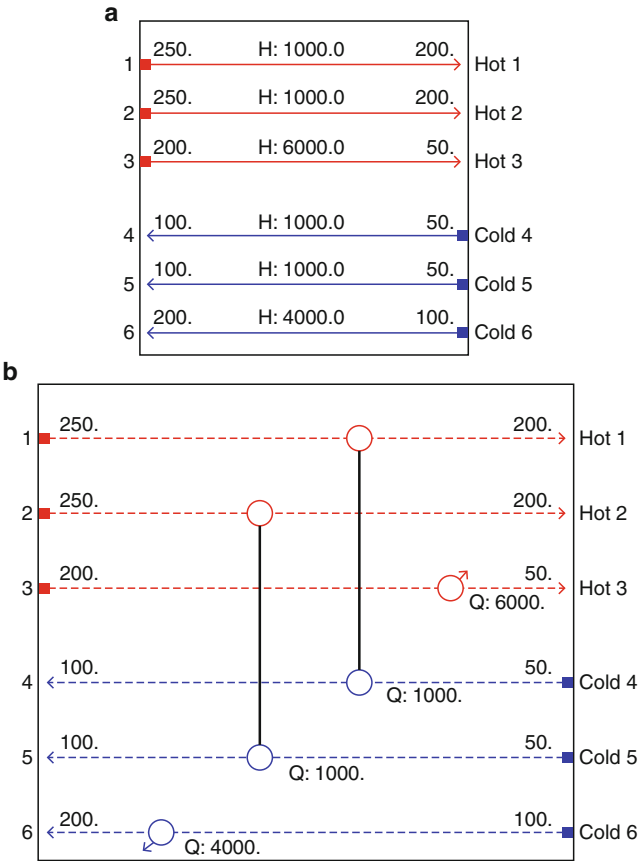

Fig. 16 Original data extraction and HEN design (Linnhoff March 1998)

for improved energy recovery and reduces both the equipment cost and energy cost. The "appropriate" data extraction does not exclude any potential energy-saving opportunities. As this example illustrates, the practitioner should be careful in separating the relevant stream data from the original process flow sheet design and should not take over features from it.

Do not consider true utility streams. A true utility stream is a utility stream (steam, flue gas, cooling water, refrigerant, cooling water, etc.) that can be replaced in principle by any other stream (process or utility) for heat recovery. One of the goals of using pinch analysis is to reduce the usage of utilities. Therefore, if utility streams are extracted in a similar way to process streams, they will be considered as fixed features and thus no opportunities of reduction in utility use will be identified. However, in some cases, it is not practical to replace the utility streams by any other form of heat recovery. The utility streams are not true utility streams and need to be extracted as process streams. This is often the case for steam dryers, ejectors, and turbine drives. For example, when steam is required in a shift reactor to enhance the

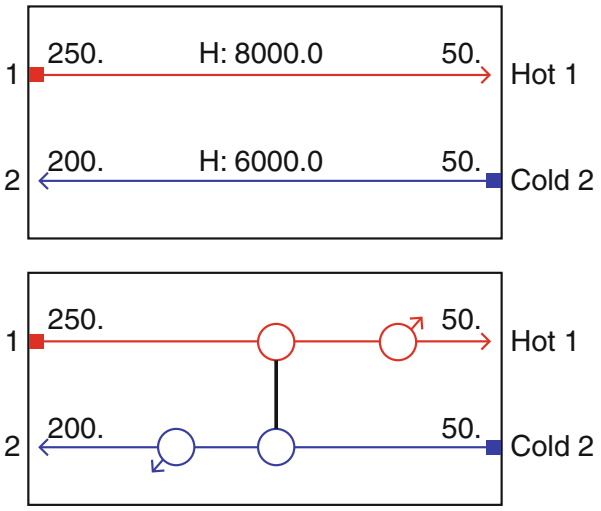

Fig. 17 Improved data extraction and HEN design (Linnhoff March 1998)

shift process, the steam is not a true utility. The steam is not just used for heating but is necessary for the reaction and cannot be replaced. In this situation, the steam must be extracted as a cold stream, to be heated and vaporized from the original feed condition to the appropriate steam temperature and pressure for the reaction.

Identify hard and soft constraints. A hard constraint would be a constraint that cannot be changed in any way, like the inlet temperature of a reactor, while a soft constraint is often open to change within certain range. An example of a soft constraint is the discharged temperature of a product stream going to storage, which is often flexible within a range. It is sometimes possible to achieve more heat recovery by changing the soft constraints, such as temperature, pressure, and enthalpy conditions of streams, at the data extraction stage. So the soft constraints should be ideally extracted and the plus/minus principle for process modifications should be applied.

Total Site Concept

In the previous part, heat and power integration for a single process has been studied. Typically, industrial processes, such as refinery and petrochemical processes, operate as parts of large sites or factories. A total site is originally defined as an industrial system consisting of several processes, whose material and energy needs are supplied by a central utility system. For example, in a large site where direct heat integration between processes (e.g., heat exchange between two streams from different processes) is difficult due to a long distance between them, indirect heat integration may be achieved through a utility system. By integrating a number of processes via the steam system, additional inter-process heat recovery can be achieved. Figure 18 shows a schematic of a typical process industry site involving several processes, A, B, and C. These individually operated processes, some with

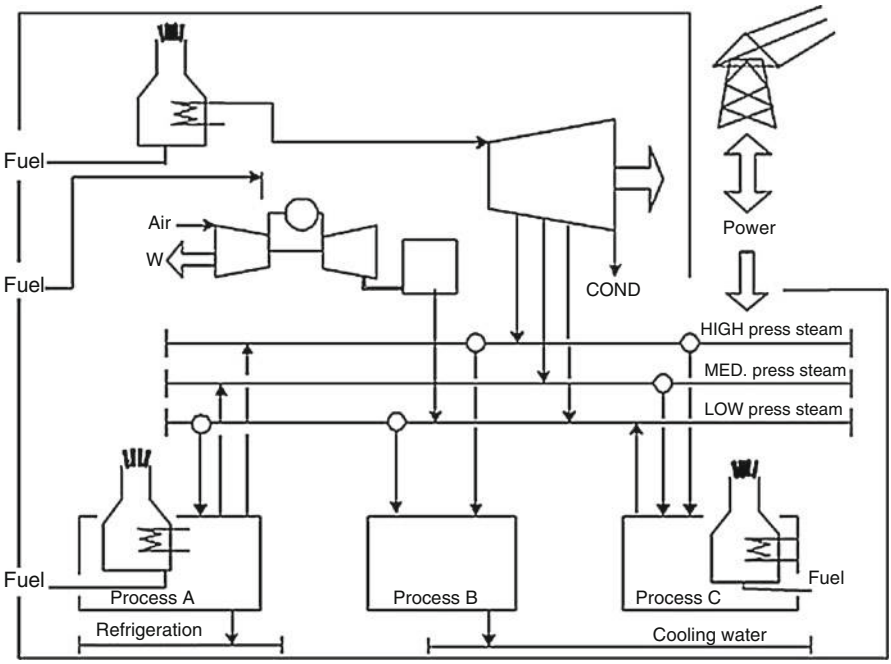

Fig. 18 Schematic of a site whose separately operated processes are linked indirectly through the utility system (Natural Resources Canada 2003)

their own utilities, are served by a central utility system. The utility system consumes fuel, generates power, and supplies the necessary steam through several steam mains. There are both consumption and recovery of process steam via the steam mains between the different processes. Usually the individual production processes and the central services are controlled by different departments and operated independently. The site infrastructure therefore usually suffers from an inadequate overview design and control. For example, in a site involving 50 production processes, the grand composite curve of each individual process will suggest different steam levels. To minimize the total energy and capital cost of the whole site, it requires an approach to consider the individual process issues along with the site-wide utility planning together to identify the correct compromise in steam levels and loads.

A graphical method, the so-called total site profiles, was first introduced by Dhole and Linnhoff in 1993 (1993a). Klemes et al. (1997) then extended this methodology to site-wide applications. This method allows a target to be set for the total site heat recovery. Site-wide analysis usually starts with a kickoff meeting to determine the detail levels each process should be studied and the scope of total site data extraction. In general, not all processes need to be analyzed at the same level. For example, some units may lack enough data for the analysis, and some processes do not need a detailed study due to their small size or low complexity.

Three models, black box, gray box, and white box, are used to represent the broad categories of detail level that may be applied to a process. Black-box processes are not to be studied in detail and only the overall utility consumption is considered. This may be because their energy consumption is very small, or heat recovery projects may be difficult to implement, or it is just not the right time for the company to invest in that area. So these processes are simply represented by their existing utility consumption profiles.

Gray-box processes only consider heat transfer that involves utilities. These processes usually have small scope of process-process heat exchange but have significant utility use. In these cases, the process streams that are heated or cooled by utility are considered; however, the process-process heat exchange matches are not considered. In this way, the process/utility interface can be optimized in a site-wide area instead of internal optimization within the process. Again, there is no need to conduct individual pinch analyses for the processes.

White-box processes need to perform a detailed pinch analysis. These are usually complex processes with significant energy consumption. For these processes, grand composite curves are constructed. The source and sink profiles of these white-box processes, together with those of black-box processes and gray-box processes, are further modified to construct the site source sink profile (SSSP) which consists of a site heat source profile and a site sink profile. The construction procedure involves selecting parts of the grand composite curves that are satisfied by the central utility system and shifting the temperature. It is not the same as simply combining all the process stream data together into a single site data set, which would allow some far from realistic scenarios. Those scenarios do not consider the realistic constraints, such as distances, controllability, flexibility, etc., which will reduce the number of integration possibilities. For the detailed construction procedure, please see reference (Linnhoff March 1998).

Figure 19 illustrates the construction site source sink profiles for a site consisting of four white-box processes (A, B, C, and D) and several other gray-box and black-box processes. In the total site profiles diagram, the site heat sources are shown on the left side and the site heat sinks are shown on the right side.

Total site analysis is used to determine the potential for maximizing indirect heat integration through central utilities. The analysis can identify the optimal balance of process steam generation via heat recovery and consumption, and also the optimum steam header pressures. After the site source profile and site heat sink profile are plotted, the composite curves of steam generation and consumption are also constructed. The heat should transfer from the heat source profile to the steam generation profile to generate steams. And also, the heat from the steam usage profile should transfer to the heat sink profile by the consumption of steam. By superimposing the current utility balance onto the site source and sink profiles, thermodynamic targets for heat and power cogeneration can be set graphically. Figure 20 shows the site source sink profiles and utility profiles for a site-wide analysis. On the left side of Fig. 20a, the gap between the process heat sources profile and the current steam generation profile shows that there is a potential to generate additional high-pressure steam through heat recovery from process heat sources.

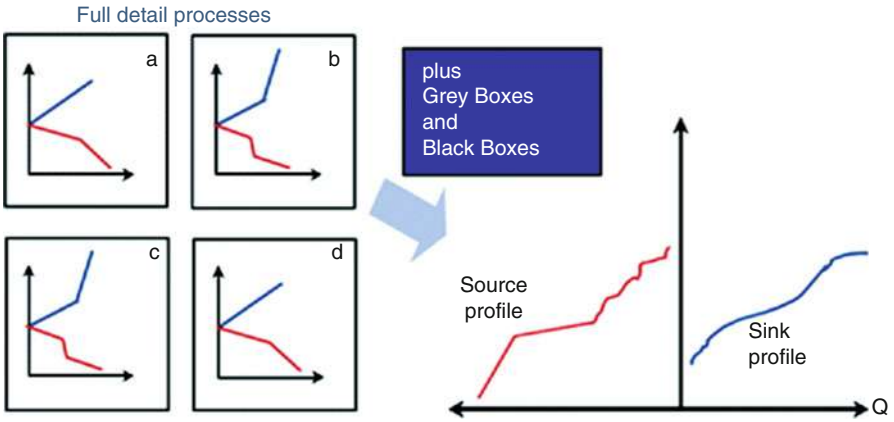

Fig. 19 Construction of the site-wide source sink profiles (Natural Resources Canada 2003)

Similarly, on the right side of Fig. 20a, the gap between the process heat sink curve and the current steam consumption curve shows that much of the medium-pressure steam usage can be substituted by low-pressure steam to reduce the steam energy consumption.

Figure 20b shows the target for optimal steam generation through heat recovery from process heat sources and the target for optimal steam consumption (heat load and pressure levels). On the left side of Fig. 20b, the optimal additional high-pressure steam generation can be identified through shifting the existing steam generation profile toward process heat sources profile. This will effectively increase the heat integration between processes indirectly through the utility system and reduce the need of external hot utility for steam generation. Similarly, on the right side of Fig. 20b, the optimal heat load and pressure levels of steam consumption can be targeted by shifting the existing steam consumption profile toward process heat sinks profile.

Typically, a site-wide pinch analysis can be carried out in two phases. The objective of the first phase is to get a reliable target for overall, site-wide savings and to identify the potential area that is likely to yield greatest benefits during the following second phase. In this way, engineering hours are minimized both in phase 1, through the judicious selection of black- and gray-box processes, and in phase 2, by not having to study every data in detail. In phase 2, further project packages need to be developed, and the strategic total site road map can be constructed. After the work of phase 1, it is possible to establish the relationship between investment and benefit of all the projects in the site. Such a representation is called the road map for the site development. The road map includes project details such as savings, investment, effect on emissions, and the compatibility of projects with each other. Each route in a road map consists of a series of mutually compatible projects. Each project package is explored for its technical and economic feasibility. The road map forms a rigorous basis for the designer or planner to plan a route or a strategy for long-term site development on all energy-related issues.

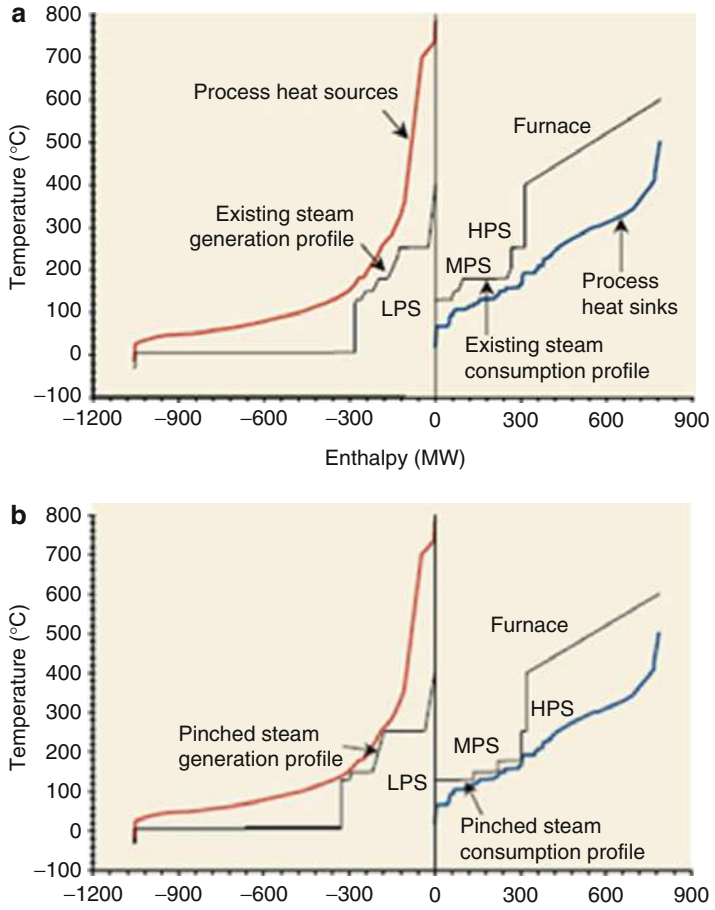

Fig. 20 (**a**) The existing total site profiles before targeting. (**b**) Total site profiles after targeting (Natural Resources Canada 2003)

As a summary, the key steps in total site pinch analysis can be listed as follows:

1. Individual process pinch analysis: Starting from heat and material balances of individual processes, pinch analysis establishes key options for process modifications, energy recovery (savings in noncentral utilities), and targets for multiple utilities. The grand composite curves are ready for use in total site analysis.
2. Total site pinch analysis: The site source sink profiles and the central utility generation and usage curves are constructed. They can help to set targets for the utility system improvements and process-wise improvements. The assumptions of steam system instep (1), such as the pressure of steam mains, need to be reset if they are changed in this step (2).

3. Identification of specific projects and construction of road map: The targets obtained through previous steps need to be further implemented in detail. Then the specific projects are put together in a coherent plan involving alternative routes of compatible projects.
4. Final selection of project alternatives from total site road map.

The site-wide analysis technique can be a very powerful approach for oil refining, petrochemical, and iron and steel plants, as well as regional energy sectors. Some software applications based on this approach are currently available. The SuperTarget software package (KBC Energy Services, UK), allows engineers to undertake total site pinch analysis using its site module. Kazuo Matsuda et al. (2009) applied the total site pinch analysis to one of the largest heavy chemical complexes in Japan which has 31 sites consisting of process industries including a petrochemical, refinery, and power company. Their study demonstrates that despite the very high efficiency of the individual process plants in the complex, the area-wide pinch technology can identify a huge amount of energy-saving potential. In their study, a large amount of energy saving, 0.9×10^6 GJ/year, was achieved by the implementation of area-wide integration projects.

An important innovation about the total site concept has been presented by Perry et al. (2008), who extended this concept. Traditionally, a total site includes only a set of industrial processes. Perry et al. made a further improvement by including commercial and residential energy users into the total site concept. The resultant process collections are termed as locally integrated energy sectors.

Mathematical Programming Approach for HEN Design

Over the past decades, heat-integrated system and HEN design have been extensively studied. Most of the contributions to this research can be classified as either a sequential or a simultaneous synthesis method (Furman and Sahinidis 2002). Generally speaking, mathematical programming represents a class of alternative techniques in spite of pinch analysis. Linear programming (LP) method and mixed integer linear programming (MILP) (Papoulias and Grossmann 1983) are both sequential methods.

The simultaneous synthesis methods are primarily mixed integer nonlinear programming (MINLP) (Yee and Grossmann 1990) formulations of HEN problems. The approach is based on a stage-wise superstructure representation that contains all possible network configurations and process stream matches. In each stage, potential heat exchange may take place between any pair of hot and cold streams. This MINLP model can simultaneously optimize and synthesize the capital and energy cost, and other structural features, as steam splitting and bypass design. While the MINLP can be formulated easily, unfortunately, it is frequently difficult to obtain converged solutions using the algorithms available today in systems like GAMS, especially when the number of streams is large and the models are complex. It is beyond the scope of this text to cover in detail the

approaches to formulating and solving MINLPs. However, in the next section of this chapter, a disturbance propagation and rejection (DPR) embedded MINLP model is introduced for HEN design.

Disturbance Propagation and Control Modeling for the Design of Highly Controllable Heat-Integrated Systems

Traditionally, in most process synthesis activities, only the cost is considered when targeting the optimal solution. This practice can give rise to the designs at the minimum total annualized investment. Process operational issues, especially structural controllability, are usually not a concern in the design procedure, while only steady-state condition is considered. As a consequence, the operational controllability of the "optimal" design solution generated by the aforementioned traditional method may be questionable. In the worst case, an (economically) optimally designed process may not be operable, as shown in Yang et al. (1996), where a real industrial example is described, where the originally designed HEN experiences various disturbances of temperatures and heat capacity flow rates in operation. Industrial practice has made it clear that process controllability should be part of the process synthesis work. This has led to the introduction of an active research area, called integration of process design and control (IPDC) (McAvoy 1987; Huang and Fan 1992; Elliott and Luyben 1995).

The analysis of disturbance propagation (DP) and disturbance rejection (DR) is conducted extensively in flexibility and controllability analysis. Flexibility is a system's capability of absorbing long-term variations appearing at the inlet of process (Papalexandri and Pistikopoulos 1994; Kotjabasakis and Linnhoff 1986). Controllability is referred to as the system's capability of withstanding short-term disturbances. Yang et al. (1996, 2000, 2005; Lou and Huang 2002) introduced a simplified, first-principle-based modeling approach to evaluate DP in HENs, MENs (Mass Exchanger Network), distillation networks, and heat-integrated reaction system design at the steady-state level. Integrating this quantitative analysis approach into traditional process synthesis can lead to the optimal design satisfying both economic and operational objectives.

Disturbance Propagation Modeling

The DP modeling approach introduced below is general, and it will be integrated into a super structure-based MINLP (mixed integer nonlinear programming) model, through a case study, to generate a cost-effective and highly controllable network.

In the process synthesis stage, the precise information of process disturbance is usually unavailable. Meanwhile, a worst-case design is usually sufficient, though may not be optimal. Thus, the estimated maximum magnitude of each disturbance can be used instead. For a HEN operated at a given normal operating condition, the known types of disturbances can be expressed as the maximum fluctuation of stream

source temperature (δT^s) and that of heat capacity flow rate (δMc_p). After propagating these disturbances of input source streams, the resulting DP model can predict the stability of the target temperature of each stream by the obtained δT^t, which stands for the largest deviation from the normal operating target points. Yang et al. (1996) developed a DP modeling methodology for a heat exchanger unit as well as a HEN that can contain any number of hot and cold streams. By neglecting the high-order differentiation terms and replacing the logarithmic mean temperature difference by an arithmetic mean term (Yan et al. 2001), the model can be simplified to a linear one and is summarized below.

Unit-based DP model. A DP model for a single heat transfer unit (HTU) can be written as follows:

$$\delta T^t = D_t \delta T^s + D_m \delta M c_p \tag{1}$$

or

$$\begin{pmatrix} \delta T_h^t \\ \delta T_c^t \end{pmatrix} = \begin{pmatrix} 1-\alpha & \alpha \\ \beta & 1-\beta \end{pmatrix} \begin{pmatrix} \delta T_h^s \\ \delta T_c^s \end{pmatrix} + \begin{pmatrix} (2-\alpha)\alpha_h & -\alpha_c \alpha \\ \beta \alpha_h & -\alpha_c (2-\beta) \end{pmatrix} \begin{pmatrix} \delta MC_{ph} \\ \delta MC_{pc} \end{pmatrix} \tag{2}$$

where

$$\alpha = \frac{T_h^s - T_h^t}{T_h^s - T_c^s}, \tag{3}$$

$$\beta = \frac{T_c^t - T_c^s}{T_h^s - T_c^s}, \tag{4}$$

$$\alpha_h = \frac{T_h^s - T_h^t}{2MC_{p_h}}, \tag{5}$$

$$\alpha_c = \frac{T_c^t - T_c^s}{2MC_{p_c}}, \tag{6}$$

where D_t and D_m are temperature and heat capacity flow rate-related disturbance propagation matrix, respectively; T and δT are the stream temperature and temperature fluctuation, respectively; Mc_p and δMc_p are the heat capacity flow rate and its fluctuation, respectively; superscripts s and t refer to source and target, respectively; and h and c refer to hot and cold streams, respectively. The above model can be used to provide a quick and accurate quantification of DP through the propagation in a heat exchanger.

System DP model. The unit-based DP model in Eq. 1 can be applied to any heat transfer unit (HTU) in a HEN. Thus, the DP model for the i-th HTU, named E_i, in a HEN can be expressed as:

$$\delta T_{E_i}^{\text{out}} = D_{t_{E_i}} \delta T_{E_i}^{\text{in}} + D_{m_{E_i}} \delta M c_{p_{E_i}} \tag{7}$$

If a HEN contains N_e heat exchangers, a system DP model can be established directly by lumping all the single unit-based models in the sequence of exchanger numbers. This procedure yields the following equation:

$$\delta T^{*\text{out}} = D_{t_E}^{*} \delta T^{*\text{in}} + D_{m_E}^{*} \delta M c_p^{*} \tag{8}$$

where

$$\delta T^{*\text{in}} = \left[\left(\delta T_{E_1}^{\text{in}} \right)^T \left(\delta T_{E_2}^{\text{in}} \right)^T - \left(\delta T_{E_{Ne}}^{\text{in}} \right)^T \right]^T, \tag{9}$$

$$\delta T^{*\text{out}} = \left[\left(\delta T_{E_1}^{\text{out}} \right)^T \left(\delta T_{E_2}^{\text{out}} \right)^T - \left(\delta T_{E_{Ne}}^{\text{out}} \right)^T \right]^T, \tag{10}$$

$$\delta M_{c_p}^{*} = \left[\left(\delta M c_{P_{E_1}} \right)^T \left(\delta M c_{P_{E_2}} \right)^T - \left(\delta M c_{P_{E_1^e}} \right)^T \right]^T, \tag{11}$$

$$D_{t_E}^{*} = \text{diag}\left\{ D_{t_{E_1}}, D_{t_{E_2}}, \cdots, D_{t_{E_{Ne}}} \right\}, \tag{12}$$

$$D_{m_E}^{*} = \text{diag}\left\{ D_{m_{E_1}}, D_{m_{E_2}}, \cdots, D_{m_{E_{Ne}}} \right\}, \tag{13}$$

The superscript Tin equations designate the transpose operation of corresponding matrix, which interchanges the rows and columns of matrix. The "diag" in Eqs. 12 and 13 means the matrix $D_{t_E}^{*}$ and $D_{m_E}^{*}$ are diagonal matrices, which is a square matrix whose elements outside the main diagonal are all zero. The dimensions of vectors $\delta T^{*\text{in}}$, $T^{*\text{out}}$, and $\delta M C_p^{*}$ are all $2\,N_e \times 1$, and the $D_{t_E}^{*}$ and $D_{m_E}^{*}$ are both $2\,N_e \times 2\,N_e$ matrices. It is needed to point out that $\delta T^{*\text{ in}}$ and $\delta T^{*\text{ out}}$ contain a number of N_m intermediate temperatures. An intermediate temperature is the temperature of a stream between two adjacent heat transfer units (HTUs). N_m can be calculated by the following Eq. 14:

$$N_m = 2N_e - N_s - N_{\text{split}}, \tag{14}$$

where N_e is the number of HTUs; N_s is the total number of hot streams and cold streams; and N_{split} is the total number of stream branches after splitting.

After several steps of mathematical processing, a general system DP model can be derived as bellow:

$$\delta T^{t} = \underline{D_t} \delta T^{s} + \underline{D_m} \delta M c_p \tag{15}$$

where

$$\underline{D_t} = D_{t11} + D_{t12}(I - D_{t22})^{-1} D_{t21}, \tag{16}$$

$$\underline{D_m} = D_{m1} + D_{t12}(I - D_{t22})^{-1} D_{m2}. \tag{17}$$

Those underbars in the equations do not have any mathematical meaning and are just symbols to differentiate from other matrix variables. For the detailed deduction of this model, please refer to the work of Yang et al. (2006).

DP-based network structure representation. To derive those matrices in the DP model, a structural matrix S, whose dimension is $(2\ N_e - N_{\text{split}}) \times 2\ N_e$, should be constructed. Matrix S can be decomposed into two sub-matrices, $S_1(N_s \times 2\ N_e)$ and $S_2(N_m \times 2\ N_e)$, whose definitions are given below.

In sub-matrix S_1, each row is designed for a hot or cold stream, and the columns are divided into N_e pairs. Each pair is assigned for a specific heat transfer unit (HTU). In each pair, the left column corresponds to the hot stream going through the HTU, and the right column corresponds to the cold stream through the unit. A stream may be split into a number of branches, going through different HTUs and mixing together. In this case, the splitting ratios are reflected by the matrix elements corresponding to the streams. Each element has a value between 0 and 1, where 0 represents streams not going through the units – a fraction represents the splitting portion going through the unit – and 1 means the stream going through units without splitting.

In sub-matrix S_2, each row represents the intermediate streams between two adjacent HTUs. The definition of columns is the same as sub-matrix S_1. Each element of matrix S_2 represents the connection modes of the intermediate stream with an HTU. [1], [1], or 0 is assigned to the element to represent an intermediate stream entering, leaving, or not going through an HTU, respectively.

DP model-embedded HEN synthesis approach. HEN synthesis can be fulfilled by mixed integer nonlinear programming (MINLP) method, following the procedures of network representation, mathematical optimization model formulation, and optimal solution identification. The DP model introduced above can be integrated in the optimization model to take account of controllability issues in HEN design.

Problem statement. In an HEN synthesis problem, there are a set I of hot process streams, a set J of cold process streams, and a set K of superstructure stages. Each hot or cold process stream has a specified heat capacity flow rate, and their inlet and outlet temperatures are also specified exactly or given as inequalities. A set of hot and cold utilities, along with their temperatures, are also known. Meanwhile, the predicted max-min source temperature disturbance and flow rate fluctuations are also given along with the permissible target temperature fluctuations. The objective of the synthesis is to determine a network structure with the minimum total annual cost (TAC) satisfying the permissible target temperature fluctuation requirement.

Stream-based superstructure. The first step of the synthesis is constructing a stream-based superstructure. An HEN superstructure can be developed by a graph-theoretical approach (Floudas 1995). Figure 21 shows a two-stage superstructure for a two hot and **two** cold stream synthesis problems, which will be studied in this case. All units and their inputs and outputs are represented as a set of nodes in the graph, where all possible connections are linked between pairs of units. The key elements of

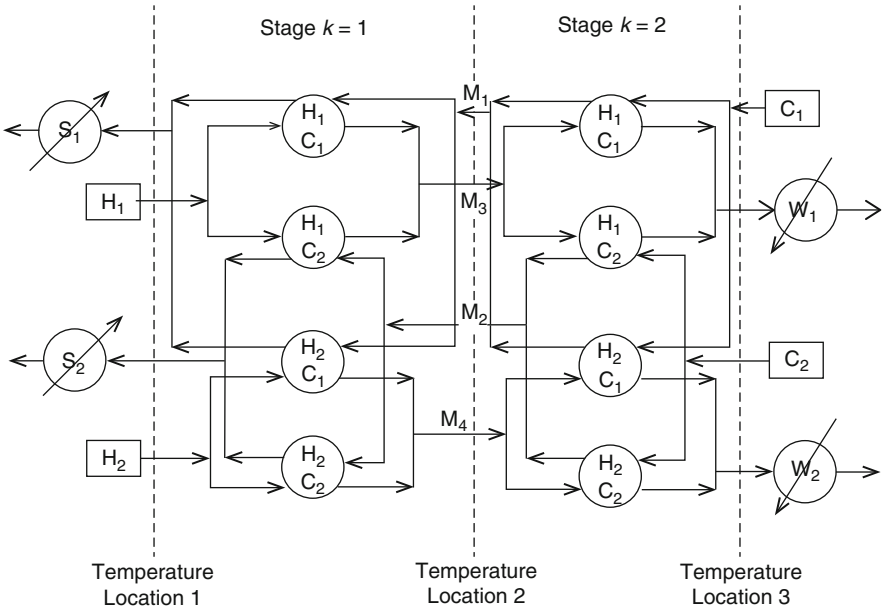

Fig. 21 Two-stage superstructure for two hot streams and two cold streams (Yan et al. 2006)

a superstructure are HTUs, mixers, and splitters. An HTU is denoted as a large circle, while a mixer or splitter is denoted as a small dot. Each HTU has a splitter at its inlet and a mixer at its outlet.

Problem formulation. After the construction of HEN superstructure, the next step is to formulate the synthesis problem with mathematical equations.

Objective function. The total annual cost (TAC) is the combination of the utility cost and heat exchangers' related cost, such as the cold utility cost, hot utility cost, fixed charges, and area cost for heat exchangers between streams. TAC should be minimized and can be formulated as (Yan et al. 2006):

$$\begin{aligned}
&\min \sum_{i\in I} C_{CU} Q_{cu,i} + \sum_{j\in J} C_{HU} Q_{hu,j} + \sum_{i\in I}\sum_{j\in J}\sum_{k\in K} CF_{i,j} y_{i,j,k} \\
&+ \sum_{i\in I} CF_{cu,i} y_{cu,i} + \sum_{j\in J} CF_{hu,j} y_{hu,j} \\
&+ \sum_{i\in I}\sum_{j\in J}\sum_{k\in K} C_{i,j}\left(\frac{Q_{i,j,k}}{U_{i,j}\left[\Delta T_{i,j,k}\Delta T_{i,j,k+1}\left(\Delta T_{i,j,k}+\Delta T_{i,j,k+1}\right)/2\right]^{1/3}}\right)^{0.6} \\
&\quad + \sum_{i\in I} C_{i,cu} + \left(\frac{Q_{cu,i}}{U_{cu,i}\left[\Delta T_{cu,i}\left(T_i^t - T_{cu}^s\right)\left(\Delta T_{cu,i} + T_i^t - T_{cu}^s\right)/2\right]^{1/3}}\right)^{0.6} \\
&\quad \sum_{j\in J} C_{j,cu} + \left(\frac{Q_{hu,j}}{U_{hu,j}\left[\Delta T_{hu,j}\left(T_{hu}^s - T_j^t\right)\left(\Delta T_{hu,j} + T_{hu}^s - T_j^t\right)/2\right]^{1/3}}\right)^{0.6},
\end{aligned} \tag{18}$$

where C_{CU} is the per-unit cost of cold utility; $Q_{cu,\ i}$ stands for the heat exchanged between hot stream i and the cold utility; C_{HU} is the per-unit cost of hot utility; $Q_{hu,\ j}$ stands for the heat exchanged between cold stream j and the hot utility; CF is the fixed charge for heat exchangers; C is the area cost coefficient; the exponent 0.6 in this equation is a constant used by many researchers to analyze the area cost of heat exchangers; T^s and T^t are inlet and outlet temperatures, respectively; U is the heat transfer coefficient; $Q_{i,\ j,\ k}$ is the heat exchanged between hot process stream i and cold process stream j in stage k; $\Delta T_{i,\ j,\ k}$, is the temperature approach for the match of hot stream i and cold process stream j in stage k; $\Delta T_{cu,\ i}$ is the temperature approach for the match of hot stream i and the cold utility; $\Delta T_{hu,j}$ is the temperature approach for the match of cold process stream j and hot utility; variable $y_{i,\ j,\ k}$ stands for the existence of a match between hot process stream i and cold process stream j in stage k; $y_{cu,\ i}$ stands for the existence of a match between hot stream process i and cold utility; and $y_{hu,\ j}$ stands for the existence of a match between cold stream process j and hot utility. The binary variables represent the existence of unit for a match and the values are either 1 or 0.

$$y_{i,j,k}, y_{cu,i}, y_{hu,j} \in \{0,1\}, \quad \forall i \in I, \forall j \in J, \forall k \in K \tag{19}$$

Constraints. This MINLP problem should be subject to the following constraints.

Energy balance constraints. The overall energy balance for each process streams should be observed. For example, the amount of energy each hot (cold) process stream releases (obtains) by the difference of source and target stream temperature should be equal to the sum of heat transferred between process streams and heat transferred to (from) cold utilities (hot utilities).

Also, the energy balance for each stream is each superstructure stage and the energy balance for the utility streams should be respected.

Temperature feasibility constraints. The temperature of each stream should decrease monotonically along with the temperature locations.

Logical constraints. The temperature approach between the streams that exchanged heat should not exceed the maximum temperature difference. Meanwhile, the exchanged heat of process streams and utilities cannot exceed an upper limit.

System controllability constraints. Besides the above constraints, the target temperature fluctuations of streams should be limited in permissible ranges, which are the controllability-related constraints.

$$\delta T_{\max}^{t(-)} \leq \delta \underline{T}^t \leq \delta T_{\max}^{t(+)} \tag{20}$$

where $\delta \underline{T}^t$ is the vector for target temperature fluctuations and $\delta T_{\max}^{t(-)}$ and $\delta T_{\max}^{t(+)}$ are vectors for the maximum negative and positive target temperature fluctuations, respectively.

The DP-based network structure matrix S can be constructed according to the approach introduced in the previous section. Then, based on this structure matrix S

and the binary variables, an HEN system DP model can be constructed as introduced before. Through the system DP model, the target temperature fluctuations $\delta \underline{T}^t$ can be obtained from the source temperature disturbances $\delta \underline{T}^s$ and source heat capacity flow rate disturbances Mc_p.

Optimal solution identification. After the formulation of objective function and various constraints, the last step in this synthesis approach is the optimization of the model. This DP-embedded MINLP model can be solved using the general algebraic modeling system (GAMS).

Case application of DP-embedded HEN synthesis approach. Yan et al. (2006) studied the case of Yee and Grossmann (1990) for the incorporation of DP into the HEN design procedure. This design problem has two hot streams and two cold streams. The design data including the disturbance information are listed in Table 2. The stage-wise superstructure is already shown in Fig. 21. There are 12 possible matches and therefore 12 binary variables. According to this superstructure, a structure matrix S is also generated and listed in Table 3. The "M" labeled stream in Table 3 stands for the intermediate stream between two adjacent heat transfer units. In this case, three scenarios are studied and each has a different control requirement. In each scenario, the control requirements, which are the maximum negative and positive target temperature fluctuations $\delta T^{t(-)}_{\max}$ and $\delta T^{t(+)}_{\max}$ act as one of the constraints. The optimal HEN of this scenario can be obtained by solving the DP-embedded MINLP problem using GAMS.

For further detailed calculations, please refer to the work of Yan et al. because only the results are provided here. Table 2 listed the control requirements, the actual temperature fluctuations, and the TAC of each scenario. Figures 22, 23, and 24 give the optimal HEN solution of each scenario under different control specifications. The symbol "E" in these figures represents the heat exchangers.

Comparing the three optimal solutions, it is obvious that solution A in scenario I has the simplest HEN structure (Fig. 22) and the minimum TAC ($ 450,072 in Table 2). This is because in scenario I, there are no constraints imposed on the maximum negative and positive target temperature fluctuations $\delta T^{t(-)}_{\max}$ and $\delta T^{t(+)}_{\max}$, and actually, this is the traditional synthesis case where no control issues are considered. However, when the strict control requirements are specified, this optimal solution

Table 2 Stream data for the synthesis problem (Yan et al. 2006)

Stream	T^s (°C)	T^t (°C)	Mc_p (kW/°C)	$\delta T^{s(+)}$ (°C)	$\delta T^{s(-)}$ (°C)

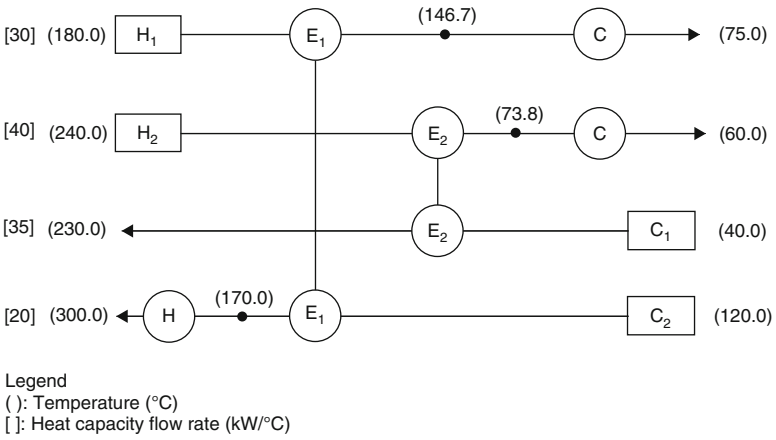

Fig. 22 Solution A for the HEN synthesis problem in scenario I (Yan et al. 2006)

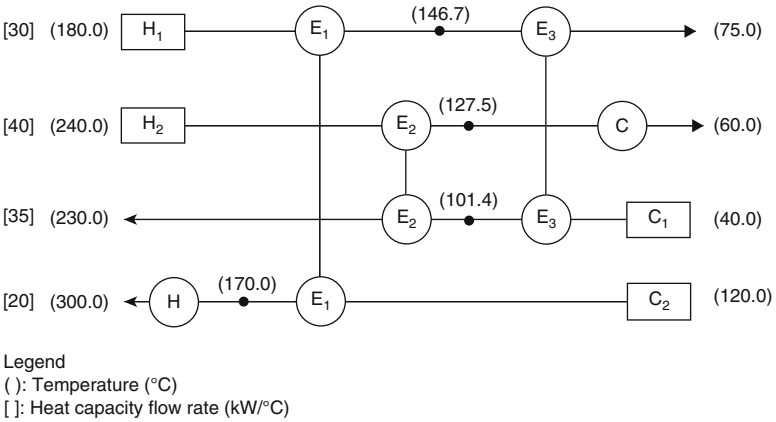

Fig. 23 Solution C for the HEN synthesis problem in scenario III (Yan et al. 2006)

may not qualify. For example, in scenario III, the control requirement $\delta T_{\max}^{t(-^{+})}$ of cold stream 2 is within the range of ± 1 °C, which is far beyond the actual temperature fluctuations of $(-3.3, 6.6)$°C in scenario I. This indicates solution A will not meet the control requirements of scenario III, and this indicates that integrating DP model into the HEN design procedure can generate the optimal result which meets the control requirements. Plus, different control specifications can be imposed on the synthesis problem according to the real process. Comparing scenarios II and III, stricter control requirements are imposed on cold stream 2 and hot stream 1, and a higher TAC is needed in scenario III. The higher TAC is kind of the trade-off for stricter control requirements (Table 4).

Disturbance Propagation and Control (DP&C) Model-Embedded Synthesis Approach

The DP model introduced above can be used to quickly estimate the maximum deviation of system outputs under various types of disturbances. However, the DP models do not consider any control actions for disturbance rejection (DR). This can lead to a conservative network design. In operation, a HEN is always controlled through regulating bypass flow rates associated with heat exchangers. Thus, Yan et al. (2001) further extend Yang's DP model to a disturbance propagation and control (DP&C) model where control actions are taken into account. This model can be embedded into a HEN design procedure to optimally select the locations and nominal fractions of bypasses with the minimum penalty on capital cost.

The system DP&C model is expressed below. For the detailed derivations, please refer to the work of Yan et al. (2001).

$$\delta \underline{T}^{t} = \underline{B}\underline{\delta f} + \underline{D_t}\underline{\delta T}^{s} + \underline{D_m}\underline{\delta M c_p} \tag{21}$$

where

$$\underline{B} = B_1 + D_{t_{12}}(\mathrm{I} - D_{t_{22}})^{-1}B_2 \tag{22}$$

$$\underline{D_t} = D_{t_{11}} + D_{t_{12}}(\mathrm{I} - D_{t_{22}})^{-1}D_{t_{21}} = \left(\underline{D_{t_h}}^T \underline{D_{t_c}}^T\right)^T; \tag{23}$$

$$\underline{D_m} = D_{m_1} + D_{t_{12}}(\mathrm{I} - D_{t_{22}})^{-1}D_{m_2} = \left(\underline{D_{m_h}}^T \underline{D_{m_c}}^T\right)^T; \tag{24}$$

$\delta\underline{T}^t$ and $\delta\underline{T}^s$ are vectors of maximum stream temperature deviation for the target and source temperature, respectively; $\underline{B}$ is the process-gain matrix; $\delta\underline{f}$ is the vector of maximum fluctuations of bypass nominal fractions; and $\underline{D_t}, \underline{D_m}, B_1, B_2$, etc. are relative matrices.

Disturbance rejection with minimum economic penalty. While a bypass of a heat exchanger can help to reject disturbances, its installation must cause an increment of heat transfer area and the capital cost. A trade-off between the DR and cost must be made in the bypass selection. Figure 25 illustrates how the stream target temperature fluctuation (δT^t) and the increment heat transfer area ($\Delta A_E/A_E$) are related to the nominal fraction of a bypass (f_E). The nominal fraction of a bypass (f_E), can be

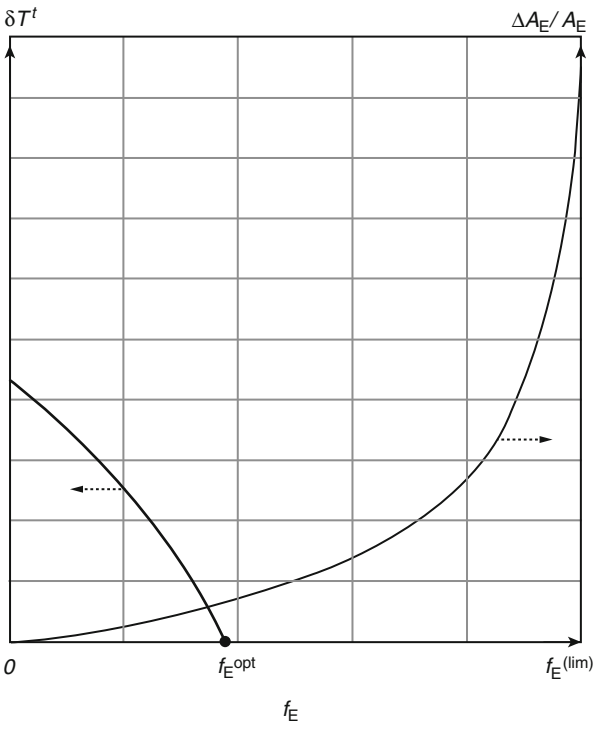

Fig. 25 Relationship of target temperature, heat transfer area, and bypass fraction (Yan et al. 2001)

selected from 0 (no bypass) to the upper limit $f_E^{(lim)}$. As shown in Fig. 25, when f_E increases, δT^t will decrease, while $\Delta A_E/A_E$ will increase. In this study, the optimal solution is defined as the one realizing complete disturbance rejection at the steady state and with minimum increment of heat transfer areas. Any nominal fraction value below the optimal value f_E^{opt} will not realize complete DR. Meanwhile, any value above f_E^{opt} will have more area increment with the same complete DR level, and this is certainly not desirable.

Case study: design of bypasses and control loops for a four-stream HEN. Yan et al. (2001) developed an iterative design procedure to determine the optimal locations and nominal fractions of bypasses in a HEN design and applied this method to a four-stream HEN design case previously studied by Yee and Grossmann (1990). For simplicity, only the problem statement and the solution are provided here to demonstrate the efficacy of this approach.

Table 5 and Fig. 26 show the steady-state design data as well as source disturbance information and control requirements of the selected case.

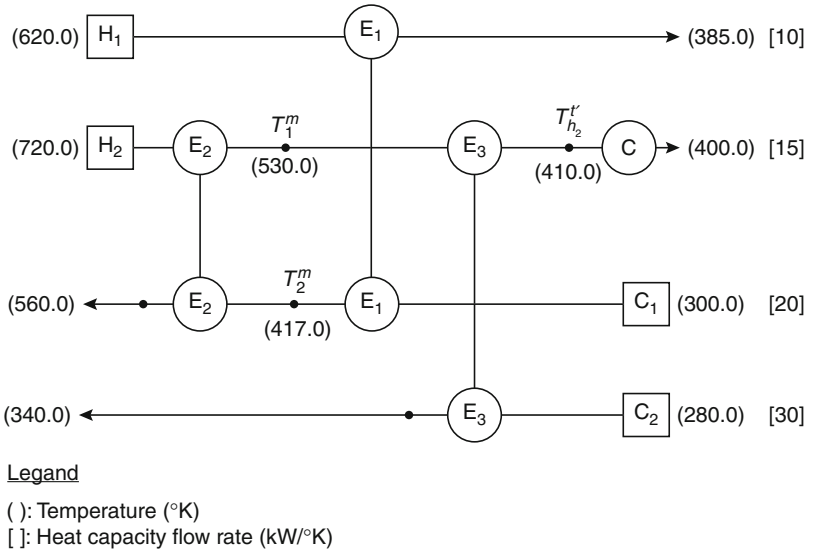

Fig. 26 Original four-stream HEN design (Uzturk and Akman 1997)

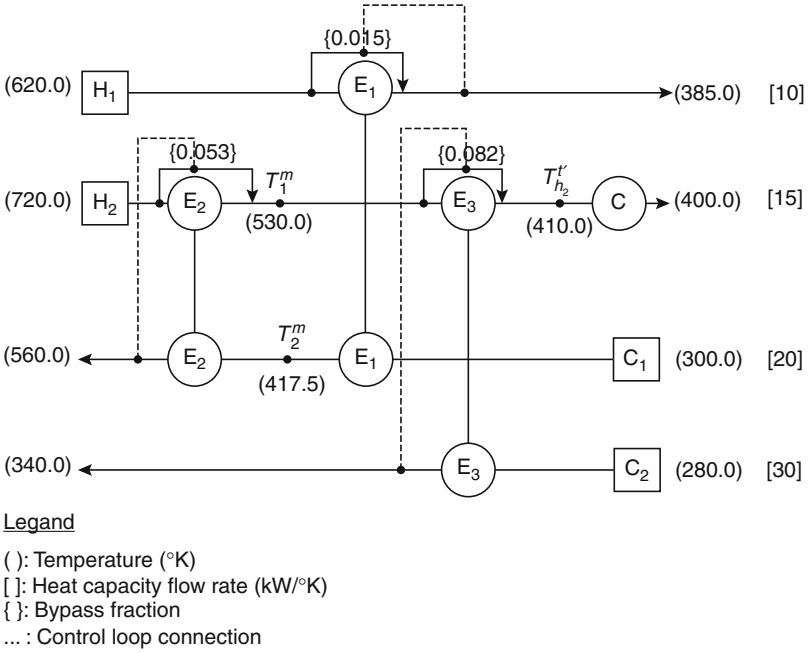

Fig. 27 Optimal bypass design for the HEN by the DP&C approach (Yan et al. 2001)

The resulting optimal bypass design with control loops by the DP&C approach is shown in Fig. 27. Uzturk and Akman (1997) also studied the same problem and their result is shown in Fig. 28. Table 6 compares the different design results in total costs. The design solution by DP&C model is 6 % cheaper than that by Uzturk and Akman. In addition, the RGA (relative gain array) analysis reveals that the solution by DP&C method has no system interaction among loops at steady state. By contrast, the design in Fig. 28 has considerable interactions among loops.

To sum up, the disturbance propagation and control (DP&C) method can quantify the disturbance propagation and disturbance rejection by using bypasses in the HEN design process. It can help to design the fewest bypasses with their nominal fractions for complete disturbance rejection with minimum economic penalty. The application strongly demonstrates the robustness and efficacy of this DP&C-based HEN design approach.

Emissions Targeting and Planning: CO_2 Emissions Pinch Analysis (CEPA)

Emission targeting by pinch analysis has been reported by Linnhoff and Dhole (1993a) using the total site analysis concept. Total site in their work refers to industrial systems incorporating several processes, which are serviced by a central

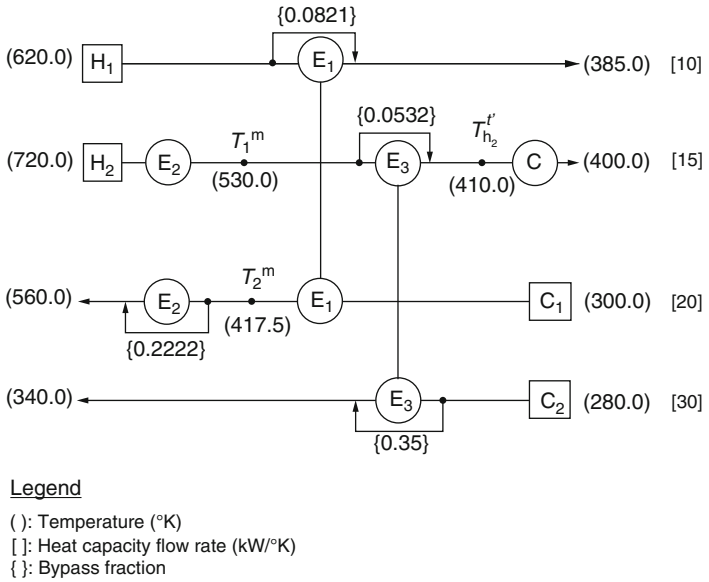

Fig. 28 Bypass design for the same HEN by Uzturk and Akman (1997)

Table 6 Comparison of different design results (Yan et al. 2001)

Heat exchanger	Original design (no bypass), area (m^2)	DP&C design (with bypass), area (m^2)	Uzturk and Akman design (with bypass), area (m^2)
E_1	34.7	35.4	39.1
E_2	42.3	44.3	49.2
E_3	22.8	23.7	25.8
ΣE_i	99.8	103.4	114.1
Cost	$24,386	$24,905	$26,408

energy-utility system. Although emission targeting by pinch analysis was introduced in those studies, the early applications were limited to within industrial facilities. Tan and Foo (2007) reformulated the traditional "total site" concept (Dhole and Linnhoff 1993a; Klemes et al. 1997; Linnhoff and Dhole 1993) and presented a novel application of pinch analysis for the preliminary planning of a country's energy sector. The carbon emissions pinch analysis (CEPA) was first developed by Tan and Foo and coworkers (2007; Foo et al. 2008; Lee et al. 2009) for emission targeting and reduction from industrial sites to macroscales (e.g., regional or national energy sectors).

Crilly and Zhelev utilized the CEPA method to analyze the Irish electricity sector (Crilly and Zhelev 2008). Detailed description of the procedure for implementing the CEPA methodology can be found in Crilly and Zhelev (2008). The following is a brief illustration of the novel method.

When planning energy sectors, it occurs very often that emission constraints will present. This is especially common in the industrialized countries such as Germany and Ireland where CO_2 emission limits are applied during the Kyoto/post-Kyoto setting. Thus, the problem arises when considering how to identify energy allocation schemes to meet the specified emission limits. If only environmental issues are considered, it is naturally desirable to maximize the use of low-carbon or zero-carbon energy sources, such as wind, hydroelectric, solar, biomass energy, etc. However, in real-world planning scenarios, economic issues need to be considered. Due to the high cost of renewable energy sources mentioned above, it is often desirable to determine the minimum amount of low-carbon or zero-carbon energy sources required to meet the national or regional emission limits and energy demand, which is known as the defined pinch point. The CEPA method can be used to determine the minimum quantity of low-carbon or zero-carbon energy sources needed and the energy allocation scheme among different energy resources in order to meet the specified emission limits and energy demand.

Ireland's electricity sector. In Ireland, GHG emissions come from various industrial sectors, including electricity generation, transportation, other manufacturing and service industries, as well as agricultural and waste-treatment sectors. The emissions in 2005 have an overall 25.48 % increase as compared with the 1990 level. This amount is far above Ireland's permissible 13 % increase in overall GHG emissions under the European Union (EU)'s Burden-Sharing Agreement on the Kyoto Protocol. For Ireland's electricity sector, it contributed a 23.33 % share of Ireland's overall GHG emissions in 2005 (21.40 % in 1990) and took a substantial 32.66 % of Ireland's total primary energy requirement (TPER), according to the publications from the government. In 2005, the TPER can be classified using the following actual energy resource (AER) mix (Crilly and Zhelev 2008):

1. Fossil fuel: natural gas (NG) ∼40.09 %, coal (C) ∼27.77 %, oil (O) ∼15.16 %, and peat (P) ∼10.02 %
2. Electricity: imported electricity (IE) from Scotland ∼3.45 %
3. Renewable energy sources (RESs): landfill gas, biomass, and other biogas ∼0.57 %, hydro ∼1.06 %, and wind ∼1.88 %

In the short-to-medium future of Ireland's electricity sector, a well-designed optimal energy resource (OER) mix is required to satisfy both the energy needs and emission limit. The renewable energy source-electricity (RES-E) has its disadvantages, such as high cost, limited public acceptability, inherent intermittency/variability, lack of predictability and poor reliability, etc. Thus, only the absolute minimum amount of RES-E should be employed in the optimal energy resource (OER) mix for the sector.

Application of CEPA. The basis of the approach is the construction of the composite curves of both the demand and the supply. These composite curves are then manipulated and shifted depending on the desired objectives. Crilly and Zhelev applied the CEPA to the electricity sector based on the data sources from the Sustainable Energy Authority of Ireland (SEAI), which is set up by the Ireland

Table 7 The past and forecasted AER mixes and OER mixes for the sector in 2005 and 2010, respectively (Crilly and Zhelev 2008)

	RESs	NG	Oil	Coal	Peat	IE	Total
EF$\left(\mathrm{t}\frac{\mathrm{CO_{2(e)}}}{\mathrm{TJ}}\right)$	0	56.8	75.6	94.6	116.7	120.0	–

government as its national energy authority. The data for the actual energy resource (AER) mix in 2005 is shown in Table 7. The energy demand (consumption) and resource (supply) composite curves (CC) before shifting are plotted in Fig. 29. More specifically, the figure depicts a correlation between the amount of CO_2 or $CO_{2\,(\mathrm{equivalent})}$ per unit time and the amount of energy per unit time. It shows a slope of the amount of CO_2 per unit energy for any line segments, which is also the emission factor. The resource composite curve is constructed by plotting cumulatively the quantity of electricity generated for the several fuel resources against total emissions from those resources. The emission factor (EF) (i.e., the amount of emissions produced per unit of electricity, $\left(\mathrm{t}\frac{\mathrm{CO_{2(e)}}}{\mathrm{TJ}}\right)$ for each energy resources is also provided in Table 7. The fuel source with the lowest emission factor is plotted first, followed by the next lowest and so on. In this resource composite curve, the renewable energy source is plotted first, followed by natural gas, oil, coal, peat, and imported electricity. The slope of each line segment is equal to the emission factor of corresponding energy resource. All emissions factors are expressed as carbon equivalent and include all relevant greenhouse gases.

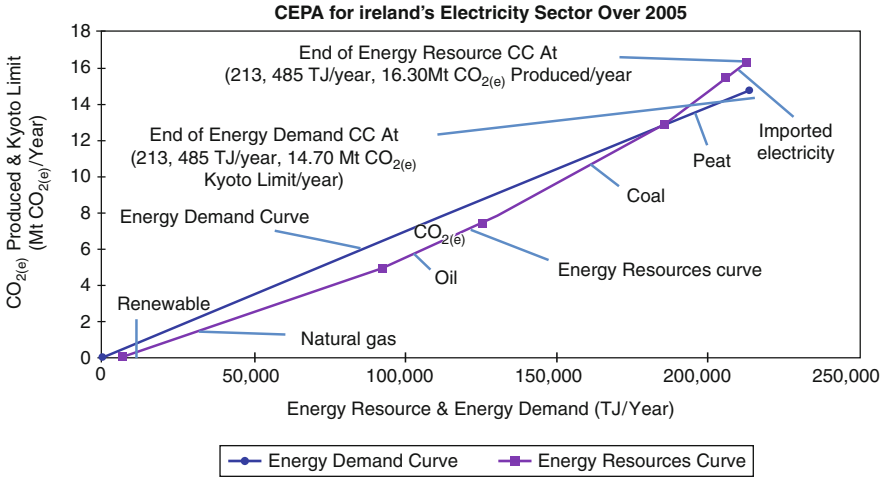

Fig. 29 CEPA applied to Ireland's electricity sector over 2005: before shifting of energy resource CC (Crilly and Zhelev 2008)

Ireland permitted an increase of its overall GHG emissions by no more than 13 % per year during 2008–2012, as compared to the baseline year of 1990, which is 55.75 Mt $CO_{2(e)}$. Thus, Ireland's environmental protection agency determined a leveled-out Kyoto limit (KL) of 62.99 Mt $CO_{2(e)}$ for each year between 2008 and 2012. The Kyoto limit KL_{2005} for 2005 is 61.78 Mt $CO_{2(e)}$ by the principle of interpolation. Because the electricity sector had a 23.79 % share of the actual overall GHG emissions of 69.63 Mt $CO_{2(e)}$ in 2005, this sector should be allocated the same percentage of the KL_{2005}, which equated to 14.70 Mt $CO_{2(e)}$. This value is the vertical ordinate for the top end of the energy demand curve as shown in Figs. 29 and 30.

The energy demand composite curve is also constructed using the same method as the energy resource composite curve. It is assumed that the emissions from various demand sectors are proportional to the electricity usage and therefore will produce a straight line from the origin to the end of the demand composite curve. The horizontal ordinate for the top end of both the energy demand curve and energy resource composite curve should share the same value because the demand (or consumption) should match the resource (or supply) in any given year. The slope of the demand line is known as the grid emission factor (GEF), which is simply the average emission factor for the entire system. In this case, the EF for the energy demand curve is 69.0 $\mathrm{t}\frac{CO_{2(e)}}{TJ}$.

In Fig. 29, it is easy to find that the top end of the resource curve is above the top end of the energy demand curve, which shows the AER mix led to more emissions than the permitted KL of the electricity sector. Thus, the energy resource composite curve needs to be shifted horizontally to the right to get rid of the excess emissions. Figure 30 shows a shifted energy resource composite curve that meets the Kyoto limit for the sector. The energy resource CC is shifted horizontally to the right until it intersects with the top end of energy demand CC, and this is the CO_2 emission pinch

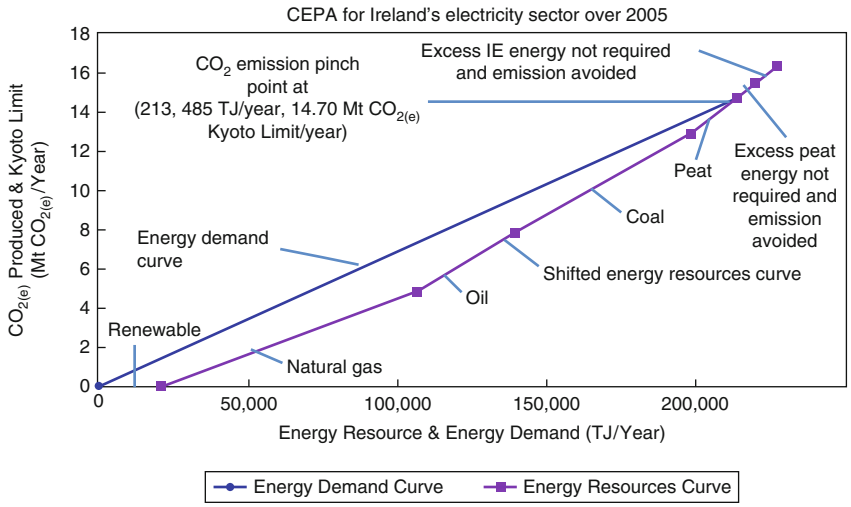

Fig. 30 CEPA applied to Ireland's electricity sector over 2005: after shifting of energy resource CC (Crilly and Zhelev 2008)

point. At this pinch point, the energy resources not only provide a total amount of 213,485 TJ energy per year (meeting the annual energy demand) but also release 14.70 Mt $CO_{2(e)}$ emissions (meeting the Kyoto limit of emission). In this way, the amount that the resource CC has been shifted then becomes the minimal amount of renewable energy that needs to be added in order to meet the emission target. The overhang of the resource CC to the right of the pinch point represents the amount and type of energy resources that need to be substituted by renewable energy. In this case, the renewable energy portion of the energy resource CC increases, the portion of imported electricity is totally substituted, and the portion of electricity from peat generation decreases as illustrated in Fig. 30. By increasing the energy resources with low-emission factors and decreasing energy resources with high-emission factors, the shifting procedure achieved the desired objective, that is, the emissions produced by the resources equal to the Kyoto limit of the demand. Meanwhile, the other objective of using the minimum amount of renewable energies due to their disadvantages is also achieved by this horizontal shift procedure. Each of the line segments of the shifted energy resource CC is measured off in order to get the optimal energy resource (OER) mix in 2005, which is also the optimal energy resource allocation scheme of the sector. The corresponding emissions produced by each of these optimal amounts are also measured. All of the measured data are listed in Table 7.

Further adaptations to CEPA. Crilly and Zhelev made a forecasting adaptation to the CEPA methodology, which is briefly introduced here. If the optimal energy resource (OER) mix in the future can be predicted, then the sector's policymakers can use this information to guide the future development plan of the sector. For example, in the near future, Ireland will close old and inefficient power plants and

create new power generation plants. The ahead-of-time knowledge of the future OER mix will be particularly useful for the policymakers to decide which form of power generation plant should be constructed. As long as the future actual energy resource (AER) mix is available, the future OER mix can be obtained using the same CEPA procedure described in the proceeding section. The future AER mix can be projected based on the energy model linked with macroeconomic model together with many key forecast parameters, such as GDP growth, population growth, fuel prices, etc. In 2006, the Sustainable Energy Authority of Ireland (SEAI), Ireland's national energy authority, published the projected AER mix for the electricity sector in 2010, which is shown in Table 7. Crilly and Zhelev used that information to forecast the OER mix that the energy sector in 2010 should have. Their forecast is also listed in Table 7. Analyzing those data, the OER mix in 2010 will need to have the input of RESs rising from 7.2 % of the AER mix to 8.2 %. This important and invaluable information will give the relevant policymakers and stakeholders 3 years time in advance to make up for this forecasted shortfall of renewable energies in 2010 for the analysis made in 2007.

Future Trends

Heat integration is one branch of process integration technologies. In the authors' view, there are several directions that can be considered as potentially promising for the future of process integration.

Process integration, especially the newer development, has not been used as widely as it could be. It is likely to see a wider range of application in process integration. Still, there is much work to be carried out in the research of integrating heat-integrated network with separation systems and reactor designs and the consideration of operational issues as well. Heat integration is closely related to mass integration by nature. Although extension of pinch analysis to mass integration field, such as water pinch and hydrogen pinch, has already been applied to industries successfully, systematic methods in this area are still in development. Utilizing advanced optimization techniques to solve process integration problems is very promising.

With the advancement of computer technology, a new generation of more powerful software tools for process integration may emerge. Comparing to the process simulation software, which is relatively mature, the process integration software is at its infancy. Process integration problems are generally complex tasks at considerable scales and involve comprehensive interactions. The development of powerful commercial software for process integration is instrumental for its wider application.

Climate change has recently become a major focus of industry and government. Pinch analysis has been extended to solve emissions and energy footprint problems to meet the environmental goals with technical and economic constraints simultaneously. Several methodological (graphical and numerical) approaches have been developed to handle problems such as energy allocation, segregated targeting, and retrofit planning. Meanwhile, similar approaches for considering energy, land, and

water footprint issues in energy and biofuel systems have been developed. Regarding the increasing concerns on climate change, more methodologies and applications are expected in this area.

Conclusion

Heat integration is a family of methodologies that can be used to improve energy efficiency, reduce energy consumption, and minimize GHG emissions. Pinch analysis can be considered as the foundation of heat integration. It can identify the maximal heat recovery and minimal external utility needs for the system before any detailed design. As a powerful tool, pinch analysis extends its application to many other fields, such as waste reduction, wastewater treatment, refinery hydrogen management, emission targeting, etc.

In spite of the total annualized cost, the HEN design must always consider the operability and controllability issues as well. During operations, various disturbances of temperatures and heat capacity flow rates always present. The disturbance propagation and control (DP&C) model-embedded HEN design approach can estimate the disturbance propagation and reject the severe disturbances through bypass design. This method can generate an optimal design solution satisfying both the economic and control objectives, thereby ensuring the achievement of high energy efficiency and low emissions.

The novel carbon emission pinch analysis (CEPA) methodology, developed based on traditional pinch analysis, can identify the minimal quantity of low-carbon-emission energy resources needed to meet both the emission limit and energy requirement and the optimal energy allocation scheme, for a regional or national energy sector. It can provide invaluable information for the decision-makers and stakeholders.

Modern Power Plant Control for Energy Conservation, Efficiency Increase, and Financial Benefit

Pal Szentannai

Contents

Abstract

Process control takes place in all power plants. The main task of all automatic controllers is to assure the optimal values of their controlled variables under all circumstances. The quality of operation of these controllers has evidently a crucial effect on the way of operation of the entire power plant. Whether a power plant – based on either renewable resources or fossil fuels – is operated in a highly effective way, or is a rather resource-consuming one, is evidently of

very high importance regarding emissions and other ecological aspects. This fact is the reason for discussing in this chapter the possible ways for increasing the level of control quality in power plants.

An overview will be given at the beginning about the ways and tools the advanced control methods offer – in case of their more intensive applications in power plants – for protecting the environment and for mitigating the climate change. It will be followed by a concise but goal-oriented introduction of the most relevant control methods together with their evaluations regarding the aspects of their applicabilities in power plants. Because the way toward obtaining the environmental benefits offered by the advanced control methods is not a trivial one, some considerations, aspects, and hints will be given on this issue in the next part. A few successful power plant applications will be introduced afterward, and the actual main development directions will be outlined at the very end of this chapter.

Nomenclature

$A(q)$	Polynomial in the ARX model
$a_1 \ldots a_5$	Free parameters of the cost function
$B_1\ (q)$	Polynomial in the two-input ARX model
$B_2\ (q)$	Polynomial in the two-input ARX model
$b_1 \ldots b_5$	Free parameters of the cost function
C_{CO} mol/m^3	Molar concentration of CO in the flue gas
C_{NO} mol/m^3	Molar concentration of NO in the flue gas
e	Control error
$e(t)$	Equation error of the ARX model
K	Cost function
q	Time shift operator
r	Air distribution: ratio of primary air to total air
r	Reference signal (set point)
t s	Time
u	Control signal (process input)
$\dot{V}_A$ m^3/s	Total air flow
$\dot{V}_P$ m^3/s	Primary air flow
$\dot{V}_S$ m^3/s	Secondary air flow
y	Controlled variable
y_M	Controlled variable modeled
ϑ, T K	Bed temperature

Introduction

The practically exclusively used control method in power plants is currently the PID (proportional-integral-derivative (Evans 1954)) algorithm. The well-known, clear-sighted effects of its three parameters, the easy and uniform methods for setting

them, and the multiply proofed, stable operation assure its widespread success in many industrial branches, including the energy industry (Åström and Hägglund 1995; Datta et al. 2000; Visioli 2006; O'Dwyer 2009; Smith 2009; Yu 2006). Besides these clear advantages, the PID controller does have its limitations (which will be discussed later in this chapter), and parallel, modern control theory offers a wide range of advanced control methods. The basic ideas of the most important such methods will be briefly introduced in this chapter, together with the conclusions in the special aspect of their applicabilities in power plants. These introductions will be extended with practical hints regarding their realizations in new or existing power plants of any type, and some practical examples will be introduced too.

The problem discussed in this chapter is a rather unusual one! No compromise must, namely, be made between economical and ecological interests, because the benefits of applying advanced control methods in power plants serve both in the same time. It is evident, namely, that increasing the efficiency or decreasing the resource-consuming manner of operation (referring to any sorts of fuel, water, air, or even valuable components under decreased thermal stress) serves both of those goals in parallel. In spite of the limited number of advanced control applications in power plants, the published results show clear, numerically expressible benefits, an overview of which will also be given in this chapter.

The total number of industrial applications of advanced control techniques has increased rapidly worldwide, but the distribution of these applications among industry branches is considerably unequal. While chemical industry alone had more than 7,000 running applications of the most popular solution (Model Predictive Control, MPC) in 2005, the number of similar applications in power plants at that time was definitely below 100 (Dittmar and Pfeiffer 2006). Interesting is also the dynamic rate of increase of those applications in the chemical industry: their number has been doubled practically every 5 years since 1995.

The goal of this chapter is nothing else but to encourage operators and owners of power plants together with decision makers for applying advanced control methods also in power plants in order to contribute to both global climate change mitigation and local financial benefits.

For building a basis, some elementary ideas and notational practice of the control theory will be outlined here for those readers who are unfamiliar with this area.

The central element of a control system is always the *process* (or *plant*, P) to be controlled as shown in Fig. 1. The process can be affected by its input signal u (*plant input* or *control signal*), and its response is its output signal y (*controlled variable*). The process is often affected by *disturbances* (d) too, which may be either measurable or unmeasurable. In the classical control theory, all the above signals are considered as scalars, but throughout this chapter, they will be handled as vector variables – without any extra markings like boldfaced or underlined letters. It means that the current discussions may also refer to systems having multiple input and multiple output signals. In most cases of the following discussion, several signals (several real measuring points) can be handled jointly as components of one variable, which will be handled as a multidimensional vector variable (like in the algebra).

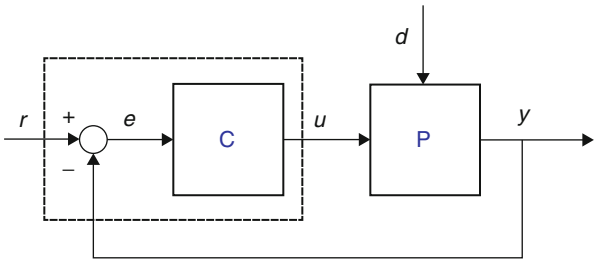

Fig. 1 Basic elements of a closed loop control system – introduction of the notation used throughout the discussion of advanced control methods. Each variable may represent several physical variables joined as a multidimensional vector variable

The *process* to be controlled is generally not an entire system (e.g., a whole power plant or a boiler), much rather only a subprocess of it. In some books, papers, and theoretical discussions, the borders and list of inputs and outputs of the *process* are considered as predefined characteristics of the system. A definitely differing approach will be followed throughout this chapter. The theoretical and practical considerations on defining the borders of the process P are, namely, a key toward successful control, and a high level of knowledge of both power engineering and control sciences is required in this essential step.

Another important element of a control system is the *controller* (C) itself. In the classical approach, its input is the *control error* (e), which is the deviation between *controlled variable* (y) and *reference signal* (or *set point*, r). In some advanced control methods, both *controlled variable* and *reference signal* will be considered, not only their actual difference. In the case of multi-output processes, also the reference signals must be multidimensional vector variables, of course.

The goal of controller design is to set the internal behavior of the controller C so that the process output y could keep or follow the value prescribed by the reference signal r. Throughout this design procedure, the instationary behavior of the process also must be considered. The goal of the science of control theory is to develop such design procedures for many different plant types. The modern control theory has reached a really high amount of very useful results throughout its theoretical work; however, these results are still rarely utilized in power plants. The possible utilizations of these results and their environmental (and also financial) benefits will be discussed throughout the rest of this chapter.

Environmental Benefits Offered by Advanced Control Methods in Power Plants

Energy conservation and efficiency increase of power plants are important goals to be considered throughout their basic design efforts. But how can these goals be supported by the real-time controllers? The next figure shows just one example. According to this example, a better control may keep the superheated steam

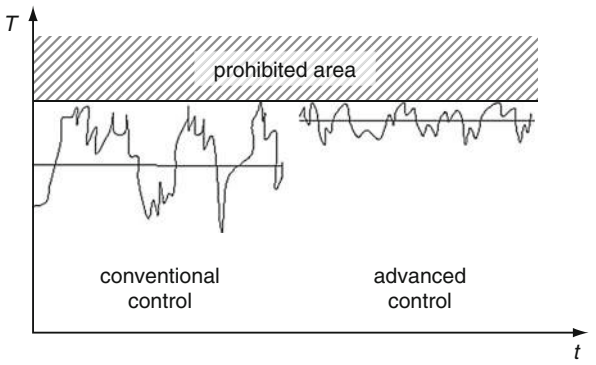

Fig. 2 Environmental benefit from applying advanced control. Narrower band of fluctuation allows higher average live steam temperature, which directly results in higher plant efficiency

temperature of a thermal power plant within a narrower band (Fig. 2). This decreased fluctuation in turn allows a higher set point of the same temperature, since the properties of the steel material used determine the maximum permissible steam temperature. And a higher average live steam temperature directly increases the efficiency of the plant, which means a direct decrease in fuel consumption. As a further consequence, the amount of emitted pollutants (including CO_2) will be significantly decreased while producing the unchanged amount of electricity and heat. It is important to mention here that this positive effect is valid not only for fossil-fueled power plants but in an identical fashion also for biomass fueled or other ones. Similarly, an increased efficiency of wind mills, photovoltaic power plants, or hydroelectric power stations will reduce the energy demand to be produced from fossil resources.

An obvious case of obtaining direct environmental benefit in the steady-state operation was discussed in this simple example only. It is important to mention already here that modern control techniques offer a much wider range of areas where direct environmental and economic benefits can be expected. The most important such benefits can be listed as follows:

- Reaching higher efficiency in steady states (which directly results in lower fuel consumption and emission – as introduced in the example above)
- Making load changes smoother and less resource consuming (by means of considering and limiting thermal stresses which in turn results in increased lifetimes)
- Making the start-up periods faster (which directly results in savings in fuel consumption)
- Increasing the level of supply by making the power plant a more flexible one in the energy market (which increases the potential of thermal power plants for compensating the uneven supply of wind farms)

Besides the steam temperature control discussed in the above example, a number of further control tasks exist in power plants. An excellent overall summary of their specific goals and classical solutions can be found in Klefenz (1986, 1991). The basic components of power plants are often extended nowadays with different subprocesses

in order to fulfill some specific or newly set requirements. These subprocesses require in most cases some own control tasks like the minimization of the ammonia slip in the flue gas in DENOX facilities. It is important to emphasize that advanced control techniques discussed in this chapter can be applied for all abovementioned groups of power plant control tasks, and in all cases, similar direct economic and environmental benefits are expected due to their higher level of intelligence.

What is the secret behind advanced control techniques that allows them to offer such benefits? Let us answer this question using the example of one of the most frequently used techniques, model predictive control (MPC). Its most important properties are as follows:

- Its control actions are *based on future values* calculated by an integrated process model.
- It can inherently *consider constraints* regarding, e.g., allowed operating areas and actuator positions, speed limits.
- *Multivariable* control is naturally handled allowing an integrated compensation of cross effects.

This chapter and its approach are definitely not against the traditional PID (proportional-integral-derivative) controller! There are the definite reasons for the worldwide and branchwide success and high proliferation of the PID controller technique. It is also certain that the PID controller technique has had a nearly exclusive role in all branches of the industry from the nineteenth century onward, and it will keep its role in the future as well. However, it is also obvious that the PID control technique does have its limitations. The most important cases – together with just a few power plant examples – for which the efficient application of the PID control technique is strongly limited, can be given as follows:

- For MIMO (multi-input, multi-output) systems with significant couplings (e.g., heat and power controls of turbogenerator groups)
- For strongly nonlinear processes (e.g., engines and turbines)
- For time-variant processes (e.g., waste incinerators)
- For cases where better control performance is required

The examples given in brackets behind the above bullets could be extended with a really high number of cases from the power generation industry. This makes it an evidence that power plants are typical applications where it is definitely advisable to apply advanced controllers.

Introduction of the Advanced Control Methods of Highest Potentials in Power Plants

Which are the most important advanced control methods? What are their basic ideas? In which cases are they advantageous and where are their limits? These questions will be discussed in this section – but from the special aspect of their possible

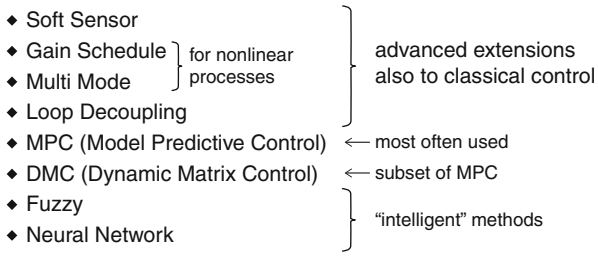

Fig. 3 The most important advanced control methods from the aspect of their applicabilities in power plants

applications in power plants. Figure 3 gives a schematic overview of those advanced control methods that seem to be of the highest potential regarding their applications in power plants or have proven already their successful applicabilities in the energy industry. This figure will be used as a road map throughout this section.

It will be seen – after studying the basic ideas of the above methods – that most of them use process models for reaching a better control quality. A wide variety of model structures, depths, and approaches is available, and their presences seem to be general characteristics of the advanced control methods. The reason for it can be understood easily, and it can be summarized as follows: *the better the process is known by its controller, the higher control quality can be expected*. According to this, the efforts in process modeling and simulation are of the highest importance. And further on this statement seems to be true also for the person who intends to design the control system of an entire energy technology system like a power plant. According to this, a deep knowledge of the power plant, its subprocesses, thermal, chemical, and practical engineering aspects, operation environment, etc., must be well known for realizing a successful, high-quality (advanced) control system. A mathematical description of the selected process may not be enough, since just the procedure of drawing the borders of the subprocesses requires all the above theoretical and practical knowledge and experiences, and this beginning step is crucial regarding the later success.

The basics of the most important advanced control methods will be discussed in the next subsections. However, their detailed theoretical analyses are no goals of the current chapter, since these aspects (e.g., stability issues) are discussed in detail for numerous particular cases in the original research articles and textbooks. In spite of this, a special care will be taken throughout the current discussions on the aspects of their possible roles, advantages, and limiting characteristics regarding their possible applications in power plants for reaching environmental benefits and financial results.

Soft Sensor

In some cases, a significant difficulty in building effective control loops is the lack of a measured variable characterizing well the actual state of the process. A wide variety of theoretical and simple practical reasons may cause this situation like a significant

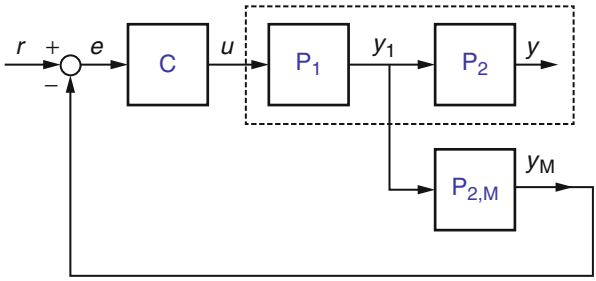

Fig. 4 Soft sensor is practically a model ($P_{2,M}$) of a subprocess (P_2). The calculated version (y_M) of an unmeasurable process variable (y) can be used for control on the basis of the measurement of another "primary" variable (y_1)

time delay between the core process and its measurable output signal, a signal being very difficult or expensive to measure accurately, a signal burdened with significant noise or other inaccuracies, and so on.

Soft sensor may be a good solution for these cases. Its basic idea (see Fig. 4) is to measure other, easily accessible process variables being in strong relationship with the required one, and the later one will be deduced from the measured one. For doing this deduction, a model will be used in all cases.

Some special cases of the approach of *soft sensor* are known in the literature under their own names. *Kalman filter* is a broad set of tools for the cases where the measured data contains significant noise and other inaccuracies, while the *Smith predictor* gives a very interesting theoretical solution for processes with pure time delays. A significant technical relevance has in this field the so-called state optimal control. This advanced technique was applied successfully in several power plants in classical control environments in the 1990s, and it was mostly used for controlling the superheated steam temperature. This process can be, namely, characterized by a significant time delay being dependent also upon the actual plant load; however, modeling this SISO (single-input, single-output) system is not too difficult. Determining the actual rate of combustion in a boiler can be mentioned as a further example, because an accurate measurement on the steam or hot water side indicates any changes significantly later than the primary processes that originated them.

Gain Schedule and Multimode Control

A practical extension of all linear controller design methods toward nonlinear processes are *gain schedule* and *multimode* control. The idea behind both of them is to choose always among a number of predefined control configurations depending upon the actual operating point.

The first step in designing such a control system is to identify an appropriate variable to be used as *scheduling variable*, which may be the plant load signal in most power plant applications. Thereafter, a set of operating points will be chosen within the whole range of the scheduling variable, and any (advanced or classical) simple control design methods will be applied to each. During the online operation of the system, always one control configuration will be activated according to the actual value of the scheduling variable. The only difference between the two

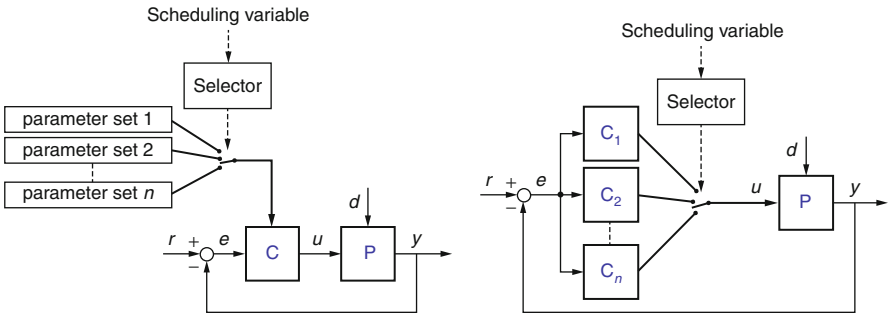

Fig. 5 Basic ideas of gain schedule (*left*) and multimode control (*right*)

subjected methods is that while in the case of *gain scheduling*, only the parameter settings of an unchanged controller will be updated according to the actual values of the scheduling variable, in the case of *multimode* control, the whole controller itself – as visible in Fig. 5.

As an evident advantage of these approaches, well-known linear control methods can be used also for nonlinear processes. However, only slight nonlinearities can be handled on this way, because otherwise the frequent switches between the actually used controllers or control parameters would result in unpredictable behaviors. This phenomenon indicates also a drawback of this method: the switches may result in unsmooth operation.

Regarding the applicabilities of these two similar control methods in power plants, it can be stated that they can be effectively applied, because the main nonlinearities in these applications can be easily characterized by the plant load signal as the scheduling variable. The nonlinearities caused by the varying actual load is in most cases exactly in the range where an unchanged linear controller cannot be used effectively anymore, but these nonlinearities still allow the applications of these simple methods. An advantage of the first subjected method is its simplicity, while the later one allows its application also in such cases where the use of different control algorithms at different operating points is necessary.

Loop Decoupling

In many practical cases, the control loops are not really independent from each other. This fact can easily be observed very often in power plants when a change in one control loop affects the other. The reason is, of course, that because of the presence of strong couplings (dashed lines in Fig. 6) inside the entire process, it cannot be considered as a set of independent one-dimensional (SISO) subsystems. It is in reality a coupled multidimensional process, which should be handled by the methods developed for multidimensional control problems, since the methods and tools developed for one-dimensional cases (e.g., the PID controller) cannot satisfactory solve the multidimensional problems. Control engineers often try to smooth out the

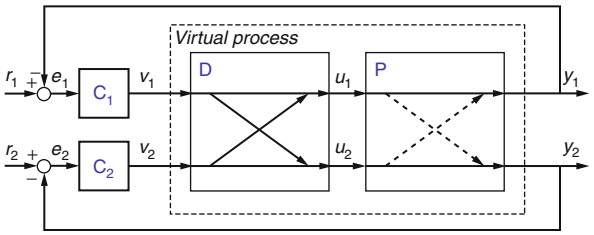

Fig. 6 Inserting a well-designed decoupler (D) between controllers (C_1, C_2) and process (P) results in a virtual process having no internal cross couplings. This virtual process can be controlled by means of independent, one-dimensional controllers designed according to any (e.g., classical) control design methods

most disturbing cross effects by means of several empirical tools. However, a relatively simple overall theoretical solution exists for tracing back the multidimensional problem to a set of one-dimensional problems, and these one-dimensional control tasks can already be solved by means of common (advanced or classical) controller design methods.

A so-called decoupler (D in Fig. 6) will be designed and applied according to well-known, relatively simple design procedures, the details of which will not be discussed here. The goal of such a *decoupler* is to build a virtual process, the inputs of which are the inputs of the decoupler and the outputs are the outputs of the real process. The control loops of this resultant virtual process are independent from each other already.

Loop decoupling can easily be realized also in the existing control system of an existing power plant; since most DCS (digital control system) software allows the insertion of extra multiplier blocks, the decoupler is built up in most cases. Their actual values shall be determined off-line by well-known standard procedures, which require also a process model. The controllers C_1 and C_2 will be designed afterward, also off-line, by considering the dynamic characteristics of the resultant virtual process *decoupler + process* (the inputs of which are v_1 *and* v_2, the outputs, y_1 *and* y_2 in Fig. 6).

Model Predictive Control

The control method having the highest potential regarding industrial applications (including power plant applications as well) and also the highest number of successfully running industrial realizations is *model predictive control* (*MPC*). This is already a complete control method, which cannot be considered as a simple extension to the classical ones. This is a model-based method, which entirely handles also multidimensional processes. A further practical advantage of MPC regarding its industrial realization is its entire capability for handling constraints like maximal and minimal possible flow rates, valve positions, and other technological prescriptions. Model predictive control has several variations and development directions; its

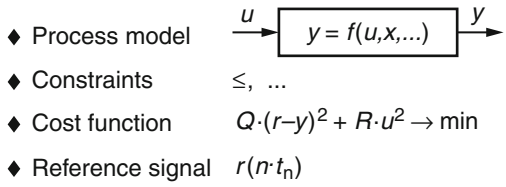

Fig. 7 A priory requirements of the MPC method

common basic idea will be summarized below – with special respect to its power plant applications for energy conservation and efficiency increase.

The initial requirements of this control method are a *process model*, a set of *constraints*, a *cost function*, and the future values of the *reference signal* up to a certain horizon as shown in Fig. 7.

A *process model* can be used theoretically in any programmed form. In practical applications, empirical models (black box models) are often used because they can be generated relatively easily by means of available identification procedures based on pure input, output measurements. Nevertheless, physical modeling (or at least using semiempirical models) is rather advisable, because a deep understanding of the controlled process (represented in such a model) gives definitely a great help in controlling it successfully. Processes, where identification-based empirical models are practically unusable, are the ones characterized by long-term conservation behaviors. It is important to emphasize here, because this is a frequent case in power plant processes! The long-term fuel and bed material accumulation in fluidized bed combustors (FBC) is a typical case, but grate firing and some other power plant processes are of very similar characteristics.

The mathematical procedure of MPC does inherently handle also constraints, which should be given as relational operators referred to any available variables of the model or the control structure. This characteristic of MPC makes it a very practice-oriented one in case of its application in power plants, as discussed above. An interesting utilization of this property of MPC is the inclusion of some technological constraints (e.g., thermal stresses) which cannot be considered directly in the case of most other control methods.

A very clear formulation of the goal of the control is the *cost function* (or *target function*), which gives the weighting between two opposite interests. A very low control error can, namely, be achieved at the expense of a very intensive actuator operation and vice versa. In Fig. 7, Q and R are the weightings, which are matrices in the general, multidimensional case. They represent the relative importances of these two aspects, where the matrix elements refer to the individual physical control errors (differences between set points and measured outputs) and actuator activities.

The reference signal can be either a constant set point or a function of time. Because the basic version of MPC is a timely discrete one, the future values of the reference signal should be available in the time steps $n \cdot t_n$.

The task the controller has to execute online at each time step is to solve the quadratic optimization problem with constraints. Because this problem is a well-

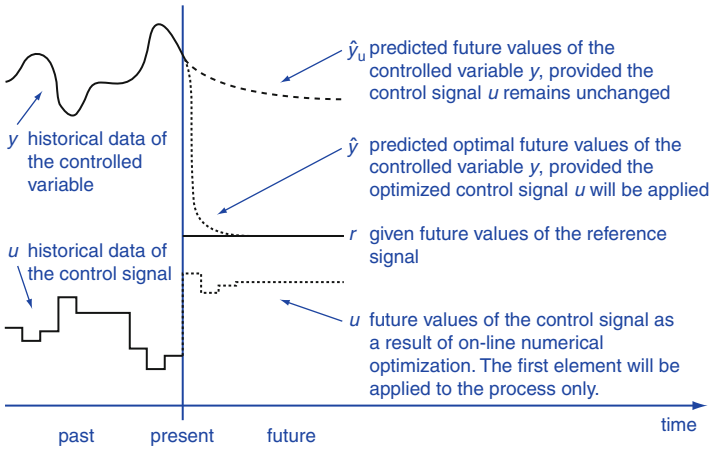

Fig. 8 Way of operation of the model predictive control. This method inherently handles also multidimensional processes and timely changing reference signals; however, for a better visibility, the much simpler single-input single-output case is indicated here. The inherent consideration of constraints is also not visible in this figure

known one for a longer while, numerous effective solver algorithms are available in the literature of mathematics. They will be adapted and used in the model predictive controllers, the operational procedure of which is the following.

In each time step, the optimization problem formulated above will be solved numerically, and its result is the optimal future time series of the control signal u (Fig. 8). Not the whole time series but only its first element will be applied to the system, because in the next time step, the same optimization procedure will deliver a newer, updated control signal. In this way, the actually applied control signal will consider also the latest measured process data, which behavior acts as an effective tool against model inaccuracies being present of necessity.

As a summary to MPC, it can be stated that this advanced control method offers excellent properties that can be utilized well also in power plants. That is why an increasing number of its applications in any types of power plants would be definitely a very effective tool for energy conservation, efficiency increase, and emission reduction. However, for realizing such applications, expert knowledge is required covering both power engineering and advanced control engineering.

Dynamic Matrix Control

A rather simple version of model predictive control (MPC) is dynamic matrix control (DMC). Simplicity means here a procedure of significantly less online computational demand, which is an advantage regarding its applications in power plants.

This early version of MPC can use the process model in a predefined simple form only, which is the so-called dynamic matrix. A drawback of this simplicity is, of

course, the higher inaccuracy of the model in most cases. As a further difference compared to the basic MPC approach, DMC does not handle constraints entirely, which fact may also be either an advantage or disadvantage depending upon the specific application.

Fuzzy Control

Both *fuzzy control* and *neural network control* came from the direction of artificial intelligence research, and that is why they are often called *intelligent* control methods (although this naming does not mean any rank differences compared to other advanced techniques).

Fuzzy logic is an alternative direction of the set theory. According to the approach of the classical set theory, a point may either belong to a set or definitely not. In the fuzzy set theory, a membership function will be used instead, which is ranged from 0 to 1. It is important to mention at this point that human thinking seems to be much closer to the later approach, since nobody could clearly define the borders of the set "youth." The unsharp borders of this set are indicated in Fig. 9, which shows them as an example on fuzzy membership functions.

All measured data in fuzzy control will be classified into fuzzy sets, and this initial step of fuzzy control is called *fuzzification*. A given actual value of a measurement may belong to more sets in the same time. According to the basic idea of fuzzy logic introduced above, several sets will be defined by their membership functions like "very low," "low," "medium," etc., and these membership functions are usually overlapped.

The next step does no more deal with exact measured data; it uses the fuzzified states only (like "pressure is low"). In this second step, decisions will be made according to some rules implemented during the design process of the fuzzy controller. These rules are rather simple ones like "IF pressure is *low* THEN set discharge valve position to *somewhat open.*"

The final step in fuzzy control is called *defuzzification.* Output values will be formed here from the resulted decisions by means of output membership functions in such a

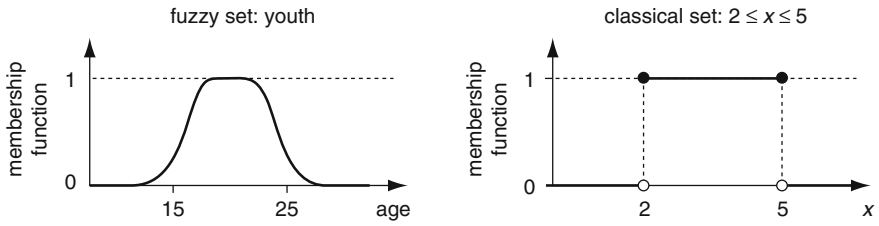

Fig. 9 A fuzzy membership function to the fuzzy set described by the human expression "youth" (*left*). Membership functions can be used also in the classical set theory, but their borders are "crisp" (*right*)

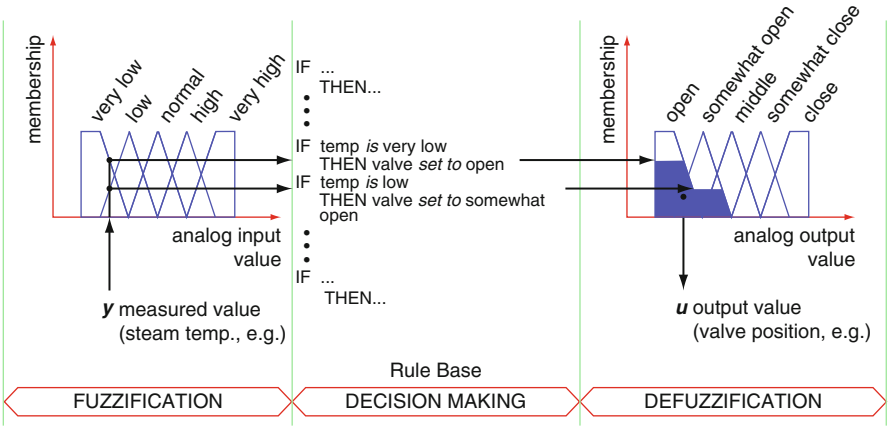

Fig. 10 Internal structure of the fuzzy controller. Extension toward multivariable and dynamic control is possible

way that the parallel decisions will be weighted by those membership values which resulted from them. The whole procedure is indicated in Fig. 10 in a simplified manner.

Regarding its usability in power plants, fuzzy control can be characterized by the next advantages (+) and disadvantages (−):

- + Easy realization of human/expert knowledge, because the way of representation of the operational requirements is very close to the human thinking.
- + Low-cost realization is possible, because fuzzification and defuzzification may be realized by means of low-cost sensors and actuators, respectively, and decision making is a procedure requiring relatively low computational capacities.
- − Unsmooth output signals may be resulted by the discretized way of operation of the decision-making procedure.
- − The overall stability of the control system can rarely be guaranteed because of the heuristic setup of the controller.

Neural Network

Neurons are the basic elements of the nervous system. Many of them work in parallel, and the interactions between them determine the way of operation of the entire system. The junctions where these interactions take place are called synapses, and the magnitude of transferring signals from one neuron to another one through a certain synapse can be changed throughout the normal biological learning process. One neuron may receive several input signals from others, but it generates only one output signal.

The above (general and simplified) description is the basis of the artificial neural networks (NN), which can be used also as controllers (Fig. 11).

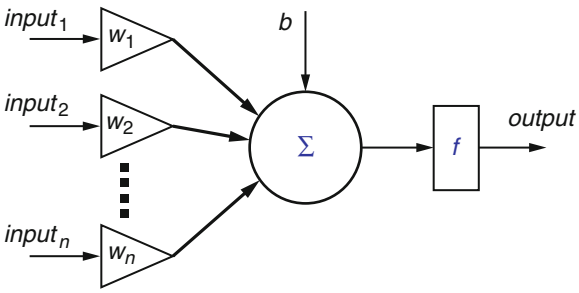

Fig. 11 One artificial neuron. In a layer of a neural network, several neurons act in parallel. In a neural network, some layers will be applied. w_i represents the weighting factors and b is an additive, the actual settings of which is the result of the learning process

A very important characteristic of neural networks is their abilities for learning. It practically means certain procedures for finding the optimal set of the weighting factors w_i and additive constants b so that in case of a set of inputs, the network would result in its desired set of outputs. Several search procedures are known, which depend also upon the actual form of the neuron output function f.

The application of this theoretical background for the purposes of controlling a process still has a number of different approaches.

If, for example, the neural network learns the inverse behavior of the process, applying the desired process output on the neural network input, its output will result the process input necessary for that desired process output. Beyond this theoretically simple application, many further successful ways of industrial applications are known. Also several combinations of fuzzy control and neural networks are applied, and both of these "intelligent" methods are often used as value-added extensions to other control solutions.

Proposed Ways of the Introduction of Advanced Control into Power Plants

The introduction of advanced control methods offers a number of ecological and economical benefits as discussed above; however, the way of their implementation is not an evident one (Szentannai 2010). One must be aware of the special requirements of modern control techniques compared to those of the traditional, PID-based ones. As a general and strongly simplified observation, it can be stated that modern techniques are based on more detailed calculations. This is the reason for their requiring significantly higher computational capacities. Computers capable of such performance became commercially available low-cost standard ones in recent years, and many people use equipment of that capacity in everyday life. However, the reliability of these computers is definitely below the level expected in power plants. Moreover, most industrial control systems were designed for lower computational capacities only. A further problem can result from the fact that only a few digital control systems (DCSs) are equipped with standard software tools required to program an advanced control application.

In this actual situation, one must distinguish between two different cases: application *in a new power plant* or application *in an existing power plant* equipped with traditional controllers.

The first case seems to be easier, since the new control system of a new power plant can be designed according to the special needs of the selected advanced control method. This first means the appropriate selection of the hardware and software structure of the DCS to be applied: a system capable of these control methods should be installed.

In spite of this theoretically simple and straightforward method, a more conservative approach will be proposed here to realize the benefits of advanced control strategies in new power plants. During the construction of a new power plant, it may be more advantageous and secure to program and use traditional control loops in the commissioning period of the whole power plant technology and to set up advanced controllers in a second phase only after reaching stable and secure operation. In most cases, commissioning in any case is followed by a longer period of fine-tuning the entire power generation technology, which should be used also for setting up, fine-tuning, and testing the final, modern control system as software changes in the unchanged DCS. This approach also allows a final comparison between traditional and advanced controls.

In the second case, an existing power plant is running with its complete, proved, and stable traditional control system. In this case, the purpose of the introduction of an advanced control technique is to achieve and utilize its benefits outlined above. While doing this, one should not forget that the existing stable operation is of much higher actual importance than any advantages the new controller may offer. In other words, the benefits of the introduction of the advanced controller must be achieved in such a way that stability of the existing control system will by no means be lost. A good practice for this is to retain the existing control system as a supervisor above the new one. The supervisor should stay idle as long as the difference between the outputs of new and advanced controllers remains below a given threshold. This limit may be increased stepwise by the control engineer after appropriate periods of reliable operation of the new control technique, allowing more and more effective utilization of its benefits.

Another question in this case is the choice of hardware on which to run the new control algorithm. Since the existing control system is generally not capable of doing this, an external platform is required. A rather general configuration is proposed in Fig. 12, which indicates both hardware and software structure, together with the necessary communication pathway.

This scheme should be considered as a typical arrangement only and must be modified according to the actual environment in each particular case. Positioners are, e.g., in many cases realized outside the DCS (digital control system), sometimes as distributed local ones. Some device border lines must be actualized in this case; however, even in such a case, no change is proposed to the general concept of keeping the positioners outside the advanced controller.

As visible on the above figure, the high-level parts (the traditional, one-dimensional PID controllers) of the existing control loops will be replaced by

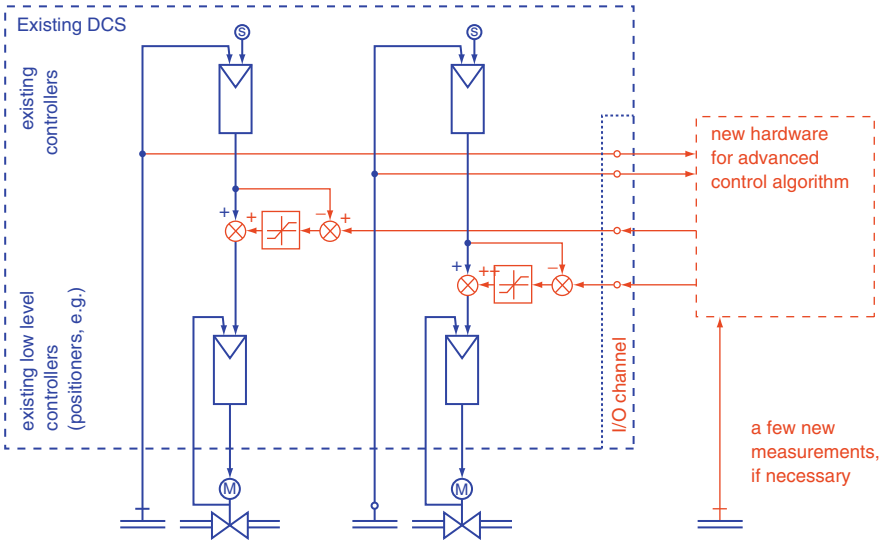

Fig. 12 Proposed typical hardware and software configuration for applying advanced control in a power plant originally equipped with a traditional control system. Benefits of the modern control will be utilized while the proven and secure operation of the original control system will be retained (*Thick lines*, existing system; *thin lines*, advanced control extension)

the advanced controller, but the replaced elements will become effective again if and when the new control outputs show an unlikely degree of variance from those of the original control system. This proposed method of implementation assures a secure way to realizing the benefits of advanced control techniques.

This scheme may also be applicable in the case of a new power plant, the only difference being that the communication channel between old and new hardware can be omitted since the capacity of the DCS can be chosen to satisfy the higher computation needs of an integrated implementation of the advanced algorithm also. This is possible nowadays without any remarkable surplus in the DCS price.

Successful Applications of Advanced Control in Power Plants

Applying the latest results of the control theory also in power plants is not only a theoretical possibility! A number of applications are known from the literature; some of them will be introduced in this section. A general, interesting characteristics of these applications is that they serve the ecological goals not only through increasing the plant efficiency (which directly results in energy conservation and reduced total flue gas emission including CO_2), but most of them also bring about further environmental benefits.

After the literature overview, a case study will be given where not only the basic idea and the results will be shown but also the complete solution in detail. For those

who want to go deeper or want to have a broader overview of advanced control applications in different types of power plants, a recently published book can be proposed (Szentannai 2010).

Some Published Applications

Ruusunen (2010) applied the *soft sensor* technique on two grate-fired combustors based on solid biomass (wood chips, wood pellets, and fuel peat) of 30 and 300 kW thermal capacities. His goal was to compensate the combustion power fluctuations being present in these small-scale biomass fired boilers due to inhomogeneous fuel quality and unequal feeding capacity. The stabilized and accurate combustion power is, namely, critical for maintaining low emissions and stable operating conditions.

Based on the model-based approach, fuel power changes could be compensated by the controller before they affected the heat output of the boiler, enabling continuous and delay-free monitoring of disturbances. As inputs of the soft sensor, some temperature measurements were used, the locations of which were found to be critical.

Operational experiences have shown that through the applied advanced control strategy, the standard deviations of the heat output and CO reduced by 40 %. Also 25 % reduction of CO concentration was measured during the test period, and the fluctuation of the oxygen concentration was reduced by 45 % in the same time. The increase in boiler efficiency is also very attractive: 1–2.4 % points!

Havlena and Pachner (2010) reported a successful application of multivariable Model Predictive Control (MPC). Their goal was to improve stability key process variables, effectiveness of limestone use, and boiler combustion efficiency under emission limits. Two circulating fluidized bed (CFB) boilers were originally operated with standard PID control strategy. As the fluidized bed combustion process shows strong interactions between process variables, standard PID control did not fully meet the operational requirements. The boilers are fueled by a mixture of coal and coke, and the nominal steam production is 310 t/h each.

A very simple, half-empirical (gray box) model was set up including also the long-term storage characteristics of this combustor type.

The bed temperatures were originally manually kept between 860 °C and 900 °C by the operators. After the introduction of the model-based advanced control technique, these temperatures are automatically maintained with standard deviation below 1 °C at a given reference value, which is optimal for in situ SO_2 removal. The SO_2 emissions, originally only monitored, are now controlled and held within a very narrow band (<25 mg/m^3). As further environmental benefits of this application of the MPC technique, reduction of the flue gas O_2 emission to 2.5 % resulted in boiler efficiency increase by 0.25–0.5 % point. Another important result was the improved boiler responsiveness to load demand changes, which is very important for compensating the unpredictable load balance changes of the electricity system, caused by changes in the wind power intensities, for example.

Franke and Doppelhamer (2006) applied the nonlinear MPC technique on a 700 MW coal-fired power plant, which has to perform full start-up and shutdown processes very often. A special characteristics of this application is that not only ordinary process variables are considered by the controller but also new measured data being important regarding lifetimes of valuable boiler components.

During start-up, fast temperature changes cause intensive spatial temperature differences in thick-walled parts, in particular, headers behind the superheaters and spherical fittings in the live steam pipe. These spatial temperature differences cause thermal stress, which cause fatigue up to destruction. This is why the thermal differences in the mostly exposed places will be measured and considered in the current application of MPC, which advanced control technique is able to handle such constraints inherently.

After taking into operation this new control method, the overall start-up time could be reduced by about 20 min and the start-up costs by about 10 % in the 700 MW power plant. It is of very high environmental importance also in case of its being a coal-fired power plant, because the CO_2 emission was reduced accordingly, and this increased flexibility increases in turn the possible share of wind power in the electricity network.

An Optimum Control Application Discussed in Detail

After the above literature overview, a selected advanced control solution will be introduced as a detailed example. A new combustion control strategy for fluidized bed combustors (FBCs) will be discussed in this section.

The basic goal of combustion control is always identical, regardless of the actual combustion technique or control strategy, namely, setting the air flow rate so that optimal combustion conditions can be assured under the actual fuel feed, fuel composition, and other circumstances. Despite this strong similarity, significant differences appear between the FBCs and other combustion technologies, since in case of fluidized bed combustion,

- The combustion air must assure not only optimal combustion but also appropriate fluidization.
- The combustion air must be set with respect to the actual fuel inventory, not to the actual fuel feed rate.
- The air distribution between primary and secondary air is a supplementary task of high importance.

The proposed approach in setting up the control strategy follows the traditional way of formulating a *cost function* (also called *target function*) to be minimized, but the significant differences listed above will be considered as well. While the traditional combustion control has one control variable only (the air flow), the new one is two-dimensional, since the optimal flow rates of both primary and secondary air

must be controlled. While the traditional combustion control considers a few losses only (basically, incomplete combustion loss because of too low air flow and heat loss by exhaust gas because of too high air flow), the new one must consider also some others of significant influences. The list of aspects proposed to be built into the new cost function is as follows:

- Satisfactory fluidization must be assured in the lower section of the combustion chamber (below the secondary air inlet).
- Satisfactory fluidization must be assured in the upper section of the combustion chamber (above the secondary air inlet).
- The characteristic bed temperature must not be too high.
- Total CO emission must not be too high (or it must not exceed its threshold).
- Total NO emission must not be too high (or it must not exceed its threshold).

This list of terms was found to be sufficient in practical cases. Limiting the bed temperature also from below was found to be unnecessary, for example, because other terms of the list assure already that this deviation cannot happen. As a mathematical representation of this set of terms, exponential functions are proposed because of their easy-to-handle ability both numerically and analytically and also because of their abilities for being parameterized so that different limiting shapes can be realized from a nearly linear manner up to a practically sharp threshold. According to this, the proposed form of the cost function K (which is to be minimized by the combustion control) is the following:

$$\begin{aligned} K = &\exp\left(a_1 \cdot \dot{V}_\mathrm{P} + b_1\right) \\ &+\exp\left(a_2 \cdot \left(\dot{V}_\mathrm{P} + \dot{V}_\mathrm{S}\right) + b_2\right) \\ &+\exp\left(a_3 \cdot \vartheta + b_3\right) \\ &+\exp\left(a_4 \cdot C_\mathrm{CO} \cdot \left(\dot{V}_\mathrm{P} + \dot{V}_\mathrm{S}\right) + b_4\right) \\ &+\exp\left(a_5 \cdot C_\mathrm{NO} \cdot \left(\dot{V}_\mathrm{P} + \dot{V}_\mathrm{S}\right) + b_5\right) \end{aligned} \tag{1}$$

The proposed control concept allows other cost functions as well, of course. Its parameters should be set according to the actual local needs dictated by the technology (e.g., temperature, fluidization), environmental goals (e.g., emission limits), and any further economical circumstances (e.g., prices of losses). In the actual case, the next set of parameters was found to be the best, and this one was used throughout the further investigations:

$$\begin{aligned} &a_1 = -0.24\ \mathrm{s/m^3}; a_2 = -0.11\ \mathrm{s/m^3}; a_3 = \ 0.018\ \mathrm{1/K}; \\ &a_4 = \ 0.15\ \mathrm{s/(m^3 \cdot ppm)}; a_5 = \ 0.015\ \mathrm{s/(m^3 \cdot ppm)}; \\ &b_1 = \ 5.4; b_2 = \ 7.91; b_3 = -19.4; b_4 = -3; b_5 = -3. \end{aligned}$$

The task formulated previously (to minimize the cost function) should be realized by an appropriately designed controller. Furthermore, it is believed that better control performance can be reached on the basis of better knowledge of the process to be

controlled. While in case of the traditional PID controller the whole information about the process is represented by only three parameters, advanced control theories use more detailed models.

In the investigated case, a comprehensive mathematical model of the fluidized bed combustion will be used for setting up and testing the advanced control scheme. This model was developed and validated by means of measurements on a 300 MW_{th} industrial FBC unit by the author, and it was published elsewhere (Szentannai 1998).

The actual control task is not the most general one: the minimum place of a calculated variable should be found in this case, and not a given set point of the controlled variable should be followed as generally. Different approaches are known for a controller configuration to solve the model-based optimum control problem outlined above; some of them are listed here:

- Off-line optimum seeking algorithms can be run on the programmed model and cost function while simulating a high variety of operating conditions. The found optimal settings can then be stored in a real-time (online) controller.
- An online optimum seeking algorithm can be realized in the real-time controller.
- The above closed loop optimum seeking controller can be supported by initial guesses coming from either the off-line optimum search (first bullet above) or learned previous results of the online search (second bullet).
- Further model-based online optimum seeking procedures can be developed based on the results of the advanced control theory.

The second approach will be discussed here in detail, since this one can be considered as a basis for further enhancements either upstairs or downstairs.

The idea of the proposed control structure is simple; it traces back the optimum control task to an ordinary control task. According to this, the gradient of the actual value of the cost function should be controlled to zero (Fig. 13) according to the principle of the extremum-seeking control philosophy (Blackman 1962; Zhanga and Ordóñez 2009).

All process variables of the fluidized bed combustor involved in the cost function will be continuously measured, of course. Their actual values will be forwarded to the block that calculates the actual scalar value of the cost function, the minimum of which should be found and set by the remaining elements of the control structure. Its gradient should be estimated in the next block. The space of search is two-dimensional spanned by the manipulated variables $\dot{V}_P$ and $\dot{V}_S$, but in practice it often seems to be better to handle to use another space defined by the coordinate transformation $\dot{V}_A = \dot{V}_P + \dot{V}_S$, $r = \dot{V}_P/\dot{V}_A$ where $\dot{V}_A$ is *total air* and r is *air distribution*.

In the gradient estimator, a known identification method will be used first. A two-dimensional, discrete-time ARX model will be identified online, which standard method delivers the model in the following form:

$$A(q) \cdot \Delta y(t) = B_1(q) \cdot \Delta u_1(t) + B_2(q) \cdot \Delta u_2(t) + e(t), \tag{2}$$

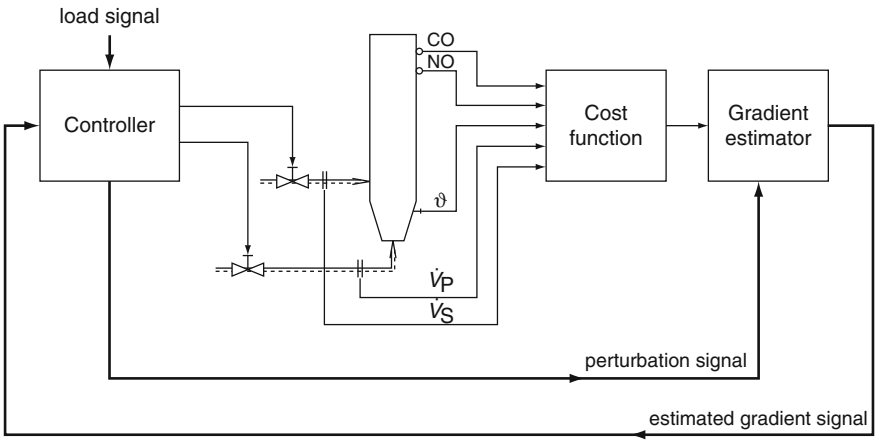

Fig. 13 The proposed structure of combustion control using extremum seeking control developed for fluidized bed combustors

where q is the time shift operator, $y(t)$ is the process output (which is the K value in the actual case), and Δu_1 and Δu_2 are the process inputs ($\dot{V}_P$ and $\dot{V}_S$ in the actual case). This procedure needs to know also the perturbation signal, which will be defined and added to the inputs by the controller block. The results of the identification procedure are in this case the coefficients of the polynomials $A(q)$, $B_1(q)$, and $B_2(q)$. The final output of this block (the gradient estimates) can be calculated according to

$$\frac{\partial K}{\partial \dot{V}_A} = \left.\frac{B_1(q)}{A(q)}\right|_{q=1} \tag{3}$$

$$\frac{\partial K}{\partial r} = \left.\frac{B_2(q)}{A(q)}\right|_{q=1}. \tag{4}$$

The controller block in the proposed control structure (Fig. 13) can be any traditional controller. The set point is zero, and the process variable to be controlled is the estimated gradient delivered by the block described above. In the actual, first implementation of the scheme, a rather simple, conservative control law was built in: the (two-dimensional) controller step will be set always proportional to the negative gradient received. A flat sawtooth signal of very low amplitude compared to the effective outputs added to a random binary signal (of low amplitude as well) was chosen as perturbation signal needed for the ARX identification. It is generated within the control block, it is added to the calculated control output, and it is forwarded extra to the ARX identifier located in the *gradient estimator* block. The load signal of the block is introduced to the controller block for further developments only, as an additional information for learning the optimum values once found.

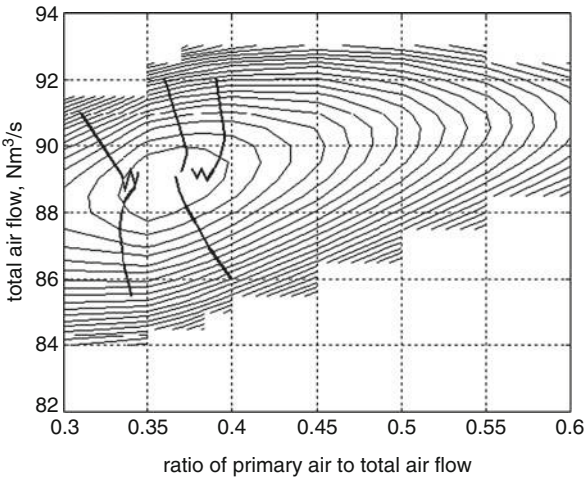

Fig. 14 Trajectories of the extremum seeking control from different starting points

The control strategy was realized in the simulation environment Matlab-Simulink©. The model described above was used throughout the simulation tests and also for plotting the surface of the cost function over the $\dot{V}_A - r$ space. (The surface of this function is not visible for the online controller, of course.) Figure 14 shows the paths of some simulated searches that started from different initial guesses far from the optimum. The results are satisfactory, and the controller succeeded in shifting the fluidized bed combustion system close to its optimum in all cases.

Based on the current results, further tests of the new control strategy are planned after implementing it on an industrial-sized fluidized bed combustor. The model-based control development allows also a number of further investigations. The optimal primary and secondary air flows as functions of the actual boiler load were calculated, for example, and the resulted functions were rather similar to those found by others experimentally to be the best (Bunzemeier 1992; Edelmann 1992). Further research will focus on the application of the programmed mathematical model in other model-based control procedures offered by the advanced control theory according to the bulleted list at the beginning of this section.

Future Directions

Actual trends and successful examples of numerous applications of advanced control techniques in power plants indicate their significant benefits both ecologically and economically. This double positive effect predicts their dissemination in the

upcoming years, in spite of their current time lag compared to similar applications in other industry branches.

Besides the somewhat higher computational capacities required by these methods, the most significant bottleneck in their dissemination seems to be the lack of technicians familiar with both power engineering and modern control theory. This aspect should be considered in the education already, where besides the theoretical background, the application-oriented issues together with the available controller realizations and software packages should also be introduced to the future engineers.

All advanced control methods have really good outlooks for successful applications in power plants; however, the model-based ones seem to be more advantageous and prosperous in this area. The explanation is simple: if a controller has more information about the process (e.g., in form of a model), it has better chances for a successful control. This statement explains also the handicap of the traditional PID controller, its whole knowledge about the process is, namely, only three digits, its three parameters. Model predictive control (MPC) is that model-based control technique which has really good inherent properties for its power plant applications and which seems to be the mostly used one. Very good commercial packages are available for its linear version, and theoretical and practical extensions toward strongly nonlinear cases can also be built up. The realization of these methods requires nowadays generally a computational platform outside of the standard digital control system (DCS) of the plant, but in the near future the commercial DCSs will be hopefully equipped with all the hardware and software components required for their integrated realizations. Some steps toward this direction can be observed already at the most significant DCS suppliers worldwide, and this further development will be warmly welcome by those who are interested in the environmental and financial optimization of the energy industry.

Regarding the model types to be built into the model-based controllers, gray box models and mathematical models seem to be more advantageous and successful contrary to black box models, because the later types generally do not consider long-term storage effects, which are typical in some combustion processes. But not only because of this significant advantage can be predicted a more intensive dissemination of gray box models and mathematical models in the near future. The needed amount of work of power engineers for setting up such models is, namely, not so high in the control enhancement project, and their presence is needed by all means because drawing the borders of the multivariable process is a key, and it cannot be done without their technological knowledges.

Acknowledgments The author is grateful to ProcessEng Engineering GmbH, Vienna, Austria, and to Periodica Polytechnika Civil Engineering, Budapest, Hungary, for permitting to use some materials published by the author earlier in Szentannai (2010, 2011).

Abstract

This chapter discusses mobile and area sources of carbon dioxide (CO_2) and other greenhouse gas (GHG) emissions. The CO_2 emissions from mobile sources are accounted globally for 23 % of world energy-related GHG emissions in 2004. In the United States, the CO_2 emissions in 2004 from mobile sources included 28 % of all anthropogenic GHG emissions, and the missions from mobile sources grew 29 % between 1990 and 2004. The CO_2 emissions for several megacities, the carbon footprint expressed in CO_2, and the CO_2 per capita used as a sustainability scale are also reviewed. Traffic congestion and gridlock in most urban areas and cities have grown substantially worse over the years, causing commuters to waste millions of hours in traffic jams. The resulting vehicle emissions have adverse impacts on the environment, both in air quality degradation and increases in GHG. Examples are presented on contributions of built environment and transportation-related air pollution and GHG emissions from mobile sources, cities, and other populated areas.

The heat island effect causes an increase in surface temperature and air temperature in the built-up areas of a city. Urban sprawl and associated transportation-related emissions also tend to increase area temperature. An increase in air temperature results in a higher rate of photochemical reactions that form ground-level ozone and smog during hot summer days. Additionally, it requires extra electricity to cool down buildings in summer days, resulting in increased energy demands, larger air-conditioning bills, and elevated emissions of GHG and ozone precursors.

Sustainable multimodal transportation network and urban infrastructure facilities are warranted to support urban communities in view of the demand of energy, reduce public health hazards resulting from air pollution and urban smog, and mitigate adverse impacts of GHG emissions on the environment. Innovative geospatial applications of high-resolution satellite imageries are presented to estimate built-up area and traffic volume. Real-time intelligent transportation system technologies can also improve traffic flow, reduce congestion and air pollution, and decrease GHG emissions. Government agencies and cities worldwide can use CO_2 emission per capita sustainability scale for evaluating effectiveness of sustainable transportation and development policies. Country laws and regulations to reduce transport-related emissions and international accords on global responsibility for CO_2 reductions are reviewed.

Introduction

Overview

A well-maintained network of transportation infrastructure and an adequate supply of energy are two indispensable pillars of any economy as they support the transport and mobility needs of the public, industries, agriculture and other businesses, and quality of life. The highway network of a country forms the backbone of its transportation infrastructure by providing connectivity needs that allow for the safe and efficient mobility of people and goods. It also represents investments of billions of dollars in every country. Figure 1 illustrates world ranking in road length, and Fig. 2 shows vehicle stocks of selected countries (ORNL 2003). The United States (USA) leads the world in automobile ownership with approximately 137 million registered cars as of 2008 that is 0.74 % up from 136 million cars in 2007 (DOT 2007, 2008). The proportion of cars in the vehicle fleet is much higher in the United States compared to most industrialized and developing countries. Approximately 25 % of all world petroleum produced, which is a primary source of carbon emissions, is consumed in the United States (ORNL 2004). About 66.5 % of this is used by the transportation sector in the United States to provide safe and efficient mobility.

As of 2007, the transportation sector includes over 254 million road transport vehicles which comprise of 93.3 % cars and other automobiles, 2.8 % motorcycles, 0.3 % buses, and 3.6 % trucks (DOT 2007). However, trucks travel almost twice as

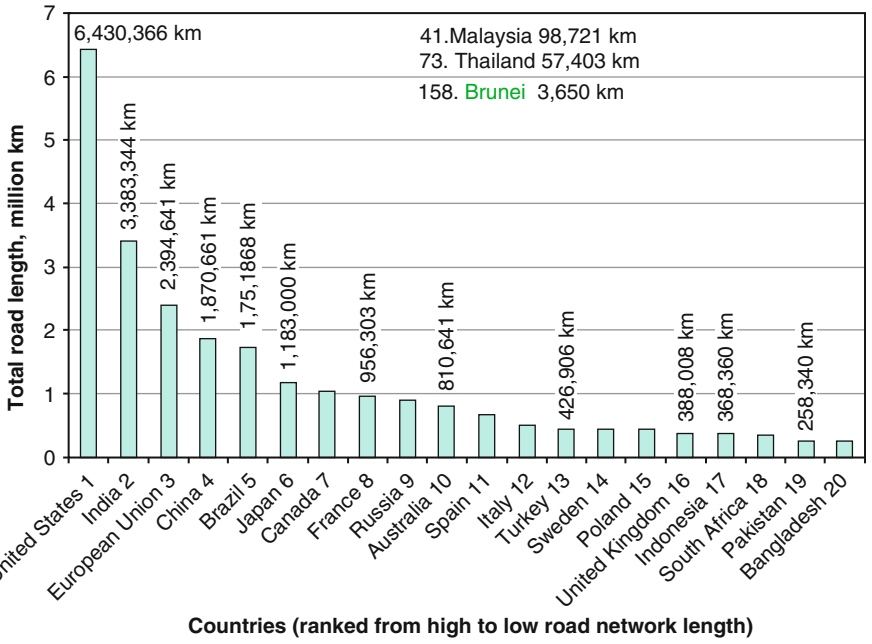

Fig. 1 World ranking in road length

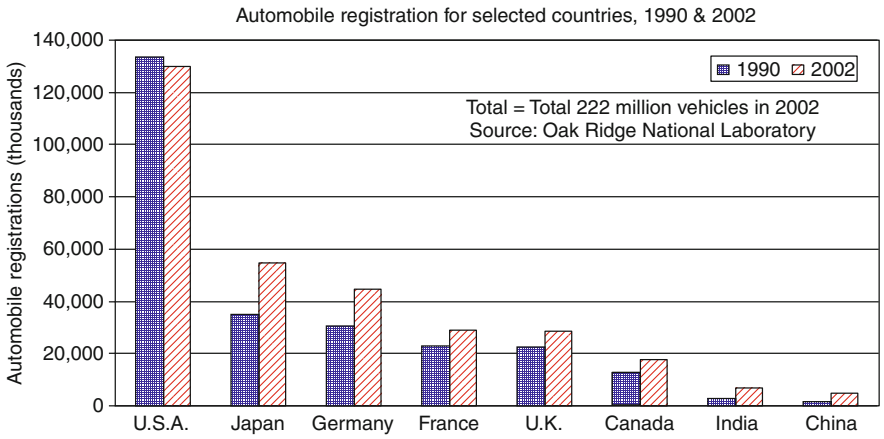

Fig. 2 Car ownership trends in selected countries

much as cars per vehicle per year and consume 3.5 times more fuel than cars per vehicle. Travel demand has been increasing consistently in the United States since the construction of the interstate highway system causing congestion, gridlock, air pollution, GHG emissions, and physical deterioration of pavements from the higher proportion of truck traffic on the national highway system (GAO 2002a, b; EPA 2005a). Additionally, aircraft, trains, and ships provide vital links in the transportation infrastructure network of the United States. In 2009, 704 million passengers were enplaned on US airlines domestically and internationally, which is expected to reach one billion passengers a year by 2023 (FAA 2010). Worldwide, 2.4 billion passengers are expected to depart on scheduled airline flights in 2010, compared to 2.1 billion passengers reported in 2006 (IATA 2007, 2010). Growth in urban areas and cities (Auch et al. 2004) contributes to area and mobile GHG emissions resulting from consumption by buildings, industries, and roads (EPA 2005a; EIA 2000).

According to the IPCC report, 33 billion tons of anthropogenic CO_2 is emitted annually, 7.3 billion tons is absorbed by the ocean, 7.3 billions of tons is absorbed by the forests, and 18.3 billon tons accumulated in the atmosphere (IPCC 2007). The industrialized countries contain 20 % of the population and produce 46 % of the greenhouse gases. Anthropogenic carbon emissions from transportation and populated areas are estimated to be 77 % globally (IPCC 2007), in addition to the industrial emission from coal- and fossil fuel-based power-generating plants and industries. The CO_2 emissions from mobile transportation sources are accounted globally for 23 % of the world energy-related GHG emissions in 2004 and 28 % in the United States. Between 1990 and 2007, the US inventory of anthropogenic GHG emission includes electricity, transportation, industrial, agriculture, and residential and commercial sectors (Fig. 3). The transportation sector accounts for 28 % of all anthropogenic GHG emissions in the United States, trailing the electricity sector at 34 % (EPA 2005a). Over 600 coal fire-powered plants contribute to electricity generation and GHG emissions in the United States, and coal remains the source

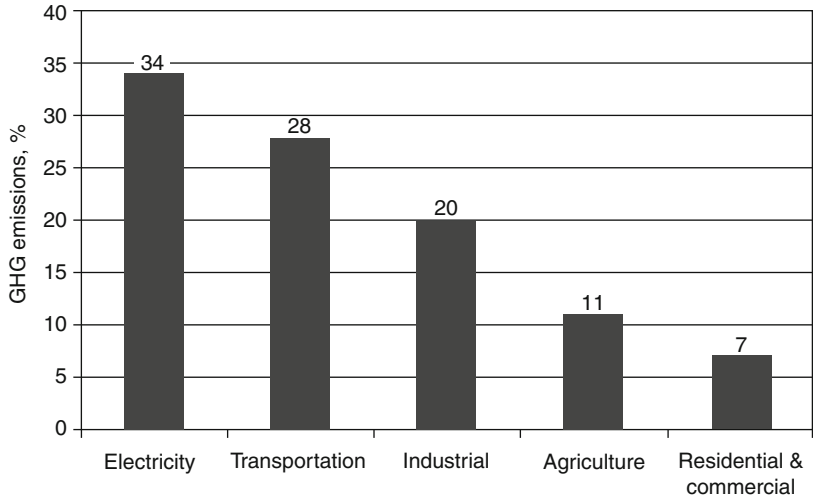

Fig. 3 Inventory of US greenhouse gas emissions

of 50–70 % of electricity in the United Kingdom, India, and China. Worldwide, the number of vehicles has grown tenfold since 1950, and the present number is estimated to be about 630 million vehicles. Worldwide, vehicle inventory will continue increasing sharply as the world population migrates to urban areas, energy demand grows, and air quality degrades in cities (United Nations 1999; WHO/UNEP 1992, 2009; WBCSD 2004; EEA 2008; WHO 2009a).

Travel demands over the past two decades already surpassed capacity limits of the road infrastructure, not only in the United States but also in most urban areas worldwide. This growth in travel demand and congestion directly contributes to increases in air pollution and greenhouse gases, mobility costs, user operation costs, public health costs, and other societal costs. The resulting vehicle emissions and demand on energy (due to the increased built areas and population migration from rural areas) have had adverse impacts on the environment, both in air quality degradation and increases in GHG (WHO/UNEP 1992; WHO 2009a; Uddin and Boriboonsomsin 2005, 2006; Uddin et al. 2005; 2009a, b; Osborne 2009; Headrick 2010; Uddin 2006; 2007, 2009, 2010a, b; Uddin and Uddin 2010). The GHG emissions are well-known contributors to global warming, rising sea levels and temperatures, and climate change mechanisms. This chapter focuses on traditional uses of petroleum-based gasoline and diesel which fuel the transportation sectors.

Objectives

The objectives are to:

1. Review the current and future trends of emission contributions from transportation and area sources, including built-up urbanized areas and their adverse

impacts on global warming and climate change indicators, ground-level air quality, and public health.
2. Discuss abatement strategies for greenhouse gas emissions by implementing sustainable transport and traffic management, smart growth and mixed use urban planning, mass transit multimodal solutions, alternative fuel, and vehicle fuel efficiency technologies.
3. Present best practices and use of geospatial analysis, life cycle costs and benefits, and value engineering to evaluate effectiveness of abatement strategies for sustainable transportation infrastructure and urban growth to reduce their contributions of air pollution and greenhouse gases.

Environmental Sustainability Challenges

Sustainability Definition

Sustainability has been defined in different variations. The following definition is used in this chapter: "to meet the current needs without depleting natural resources and compromising the ability of future generations to meet their own needs for sustaining a comfortable quality of life."

A "sustainability scale" is defined as carbon footprint in terms of carbon dioxide per capita. Sustainable transportation and development policies strive to minimize adverse impacts on the environment while conserving natural resources.

Environment, Energy, and GHG Emissions

Environment and energy are greatly impacted by transportation system planning and operation, urban growth and land-use practices, and travel modes available to and used by the population. After the Clean Air Act of 1970, the EPA's federal environmental regulations and vehicle technology innovations (such as catalytic converter) in the United States have resulted in the removal of lead from the fuel and vehicle emissions (Uddin and Boriboonsomsin 2005). Other vehicle emissions affect the ground-level air quality and greenhouse gases. This creates significant changes in the ecocycle involving water, oxygen, and carbon dioxide, all essential in sustaining human, animal, and plant life. The following six criteria pollutants have been recognized as the most damaging to the public health and the environment for which the US EPA established the National Ambient Air Quality Standards (NAAQS) (Uddin and Boriboonsomsin 2005; Bernow and Marron 1990): ground-level ozone (O_3), carbon monoxide (CO), oxides of nitrogen (NOx), sulfur dioxide (SO_2), particulate matter (PM_{10} and $PM_{2.5}$), and lead (Pb). The notation PM_{10} is used to describe particles of aerodynamic diameter 10 μm or less, and $PM_{2.5}$ represents particles of aerodynamic diameter 2.5 μm or less. Ground-level O_3 is formed through the photochemical reaction of nitrogen dioxide (NO_2) and volatile organic compounds (VOC) in the presence of sunlight, which are produced by petroleum-fueled vehicles. Methane (CH_4) is a species among VOC.

Carbon dioxide (CO_2) emissions are directly proportional to fuel consumption. Nitrous oxide (N_2O) and VOC emissions are affected by vehicle emission

control technologies for motorized vehicles on roads. The three pollutants (CO_2, CH_4, N_2O), not specifically regulated in the United States, are the principal "greenhouse gases" which, through increased concentrations in the atmosphere, can contribute to global warming and associated climate change on global and regional scales. NO_x and CO (predominantly vehicle emissions) also contribute to greenhouse warming (Bernow and Marron 1990). In principle, all molecules having two or more atoms can contribute to greenhouse warming due to their absorption of light in the infrared region. CO is a short-lived species in the atmosphere and therefore cannot contribute much. NO_x's role is not all bad. NO induces OH radical in the stratosphere, which, in turn, breaks down CH_4 – a GHG with a stronger warming force.

The overall uncertainty in CH_4 and N_2O emission estimates for the US inventory of mobile sources of GHG emissions is relatively minor due to the fact that these emissions are a small part of total highway vehicle GHG emissions. The significance of uncertainty in non-road vehicle modes (such as snowmobiles, off-road tractors and desert vehicles, lawn mowers, etc.) is low given the relatively small quantity of GHG released by these sources (Bernow and Marron 1990).

Urgent Need for Environmentally Sustainable Transportation Policies

The travel demand on the road infrastructure network in the United States has increased more than its capacity. Consequently, emissions from mobile sources grew 29 % between 1990 and 2004 (Davis and Hale 2007). Commuters waste millions of hours and gallons of fuel in traffic congestion. Each year, about 20 million barrels of diesel fuel are consumed by idling long-haul trucks in the United States, which produce about ten million tons of carbon emissions (Gaines et al. 2006). Additionally, residential emissions have increased 13 % in the last two decades. Both ground transportation and aviation emissions are adversely affecting the global atmosphere more than coal burning plants. They will have greater impacts in the coming years due to the expected exponential growth of vehicle and aviation transport worldwide and especially in the emerging economies. The emerging economies of China, India, and Brazil are all following the path of the United States and other industrialized nations in developing transportation infrastructure assets, increasing their transportation fleet, and accelerating carbon emissions. As reviewed in later sections, the rapid urban growth in developing countries and increase in the number of cities with five million inhabitants or more are expected to grow from 40 in 2001 to 58 in 2015. This growth in transport vehicles and urbanized areas will result in a higher energy demand and greater GHG emissions. A 50 % rise in energy use and carbon emissions is expected worldwide by the year 2030 (EIA 2007a). Therefore, mobile sources of CO_2 emissions will remain significant contributors to the release of greenhouse gases and its transport into the upper atmosphere. There is an urgent need to improve assessment of the contributing factors and find practical and cost-effective solutions. This will help to evaluate the benefits and economic costs of alternative abatement strategies before making major decisions on regional and global levels for an effective mitigation approach.

Related Research Sources

This chapter summarizes an up-to-date literature review of the Internet sources, published papers and reports, news articles, as well as research studies undertaken by the author. The resources referenced and used include:

Mobile Sources of GHG Emissions

Mobility Needs and Transportation-Related CO_2 Emissions

Transportation and Economic Prosperity

Having "efficient public mobility" and "safe and secure transportation infrastructure assets" is imperative for mobility needs, distribution of resources and goods through intermodal facilities, assistance to communities during disasters and emergencies, and other services to society. The economic prosperity of a country is strongly associated with the relative size and physical condition of its road network, which is the most important component of its transportation infrastructure according to the

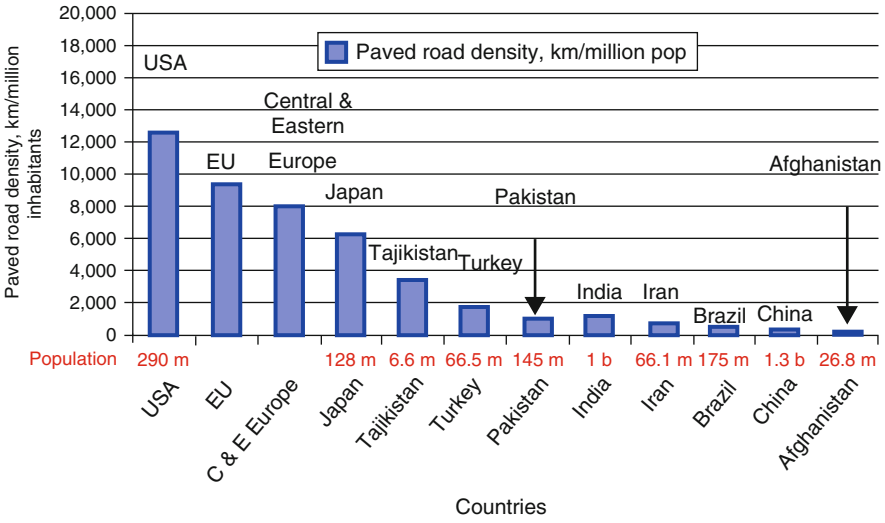

Fig. 4 Comparison of paved-road density of industrialized and developing countries, 2001

World Bank's study (Hudson et al. 1997). The study reports that the road infrastructure asset inventory shows high positive correlation with the gross national product (GNP) per capita of a country. The GNP per capita reflects a country's total market value of the goods and services produced annually divided by the population. High paved-road density values in km per million inhabitants (Uddin et al. 2005; Queiroz and Gautam 1992) are reported for industrialized countries (Fig. 4). Comparatively, low values of this important economic development indicator are observed in developing countries. However, China's expressways and highways will exceed most other developed countries within the next decade due to accelerated construction programs. India, Brazil, and several other countries are also expanding their road and highway networks to provide connectivity to a larger number of their populated areas and serve the mobility needs of the public, agriculture, and industries. The World Bank's use of only paved-road density for correlation with economic prosperity indicator is misleading because it ignores other transport infrastructure assets of a country such as rail and water transport. Rail infrastructure represents a significant modal share in Europe and most developing countries for serving passenger and freight travel demands.

Regardless of a region's characteristics such as culture, income, or geography, people on average spend a significant amount of time traveling on the road and/or wasting fuel on congested roadways. People in less developed regions spend a great deal of their time traveling to and from destinations due to lack of transportation facilities and/or urbanization, while people in more developed countries such as Japan, Western Europe, and the United States spend half of their time leisurely traveling and the other half in route (Schäfer et al. 2009). The US automobile ownership in terms of persons per motor vehicle is estimated at 1.27 persons per

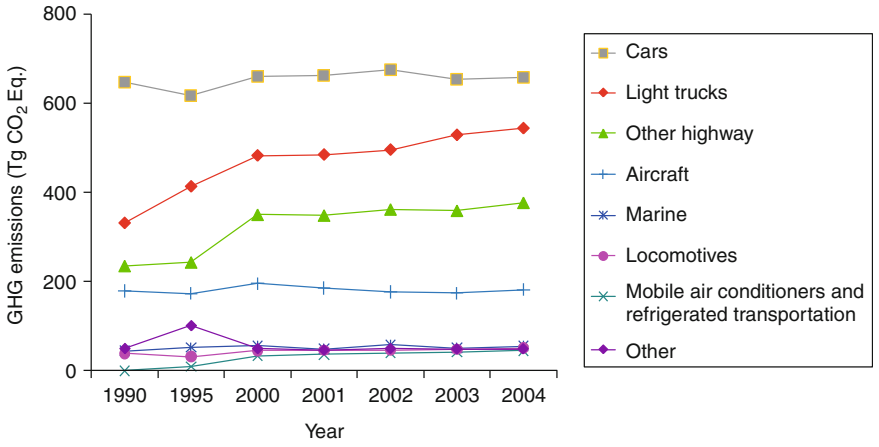

Fig. 5 US greenhouse gas emissions from all mobile sources, by travel mode and vehicle

car considering 235.9 million registered automobiles in 2007 which include cars, vans, pickup truck, and sport-utility vehicle (SUV). Brazil has 48 million vehicles as of 2006 and a population of 175 million that translates to 3.6 persons per vehicle. The 2008 automobile ownership rate (total number of motor vehicles per 1,000 population) of 842 in the United States is higher compared to other countries, such as Brazil's rate of 156 motor vehicles per 1,000 population as of 2009. Vehicle mix indicates the utilization of different modes on roads. Traffic demand can also largely impact air quality, public health, and public safety on society as well. Accurate and timely collections of traffic attributes are necessary for traffic management, performance evaluation of transportation systems, and measuring emission inventory.

Mobile Sources of GHG

Figure 5 shows the US greenhouse gas emissions from all mobile sources, by travel mode and vehicle type between 1990 and 2004 (EPA 2005a). Figure 6 shows the US transportation emissions by transport mode. Aviation produced about 9 % of transportation GHG emissions in 2003, the largest source of non-road transportation GHG emissions. In total, aircraft GHG emissions decreased about 3 % from 1990 to 2003. Following a substantial decline in travel after the terrorist attacks on September 11, 2001, in the United States, passenger travel rose more rapidly than the GHG emissions due to a higher number of seats occupied. Aircraft emissions have risen due to increased passenger travel and freight activities, but this has been offset by the improved fuel efficiency of aircraft and their operations. Between 1990 and 2003, passenger miles traveled on domestic services increased by 48 %, from 345.9 to 505.2 billion passenger miles. This is higher the than 31 % increase in light-duty vehicle passenger miles over the same period (EPA 2008a). The United States accounts for approximately 40 % of all commercial aviation and 50 % of all general aviation activity in the world (Uddin 2010c). The US airlines carried 20.4 % more

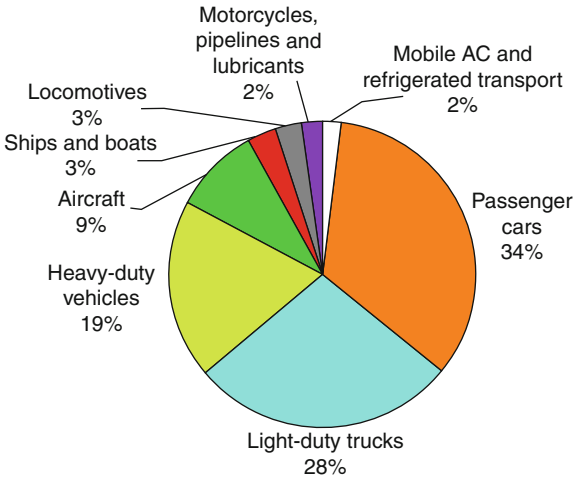

Fig. 6 US transportation-related GHG emissions, 2004

passengers and cargo traffic in 2007 compared to that in 2000, but they used 3 % less fuel in doing so. This resulted in a reduction of 5.1 million tons of CO_2 emissions in 2007 compared to that in 2000, and the FAA's satellite-based Next Generation Air Transportation System (NextGen) is expected to increase efficiency and further reduce the aviation GHG emission (McCarthy 2010). Therefore, the main concern of mobile GHG emission is from on-road vehicles which make up 81 % of the transportation-related emissions.

In the last three decades, the total number of vehicle miles driven rose to 2.9 trillion miles per year, four times faster than the rate of population growth of the United States. Per capita vehicle mile traveled (VMT) in 2003 was 9,941. This indicates that vehicle fuel efficiency and improvements in emission control may be offset by increased VMT in the United States (McCarthy 2010). The VMT distribution by vehicle on roads is plotted in Fig. 7 (ORNL 2004). The vehicle mile travel proportions of 58.1 % by automobiles and 36.5 % by trucks show a significant amount of freight by roads at 3.46 times less fuel efficiency.

Older model vehicles and absence of effective vehicle emission regulations and testing will yield higher amounts of emissions. Not all states in the United States have emission testing programs (such as Mississippi), but the manufacturers strictly follow federal emission and fuel efficiency regulations in all states. In many countries where there are no stringent emission regulations and/or no effective enforcement control, older model and relatively aged vehicles are used to make more trips and pollute roads more with both GHG and other pollutants. This was the case in China where, in the 1990s, most automobiles, including cars and trucks, were still using 10–20-year-old technologies and polluting urban areas with more than ten times emissions compared to the United States and Japan. In view of rapidly growing economy and vehicle fleet, China has already embarked upon a national program to implement lead-free fuel, fuel economy requirements, and emission standards to

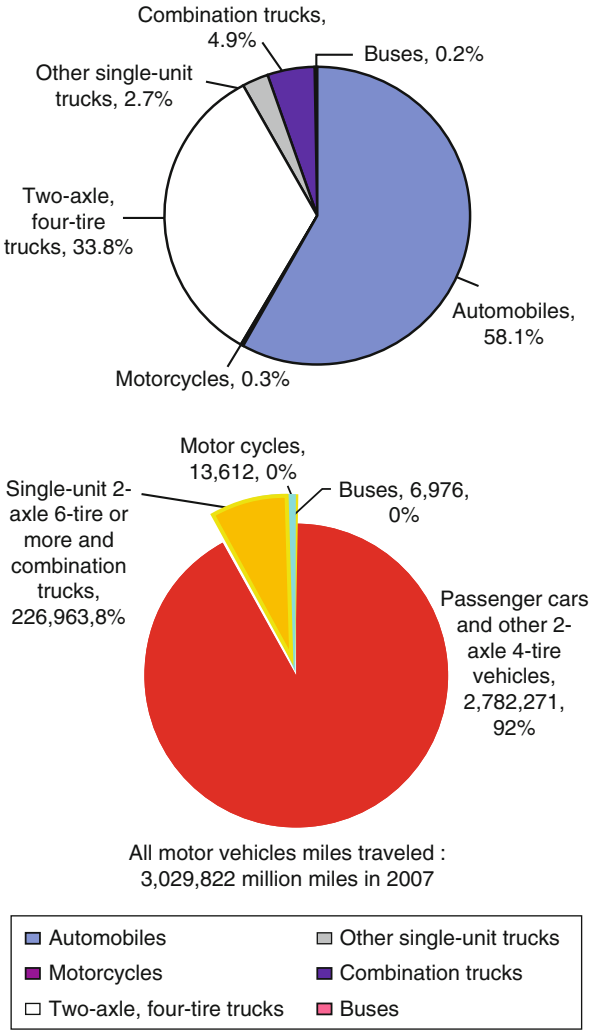

Fig. 7 Vehicle fleet mix distribution (*left*) and VMT distribution (*right*) in the United States

reduce vehicular emission. Old vehicle technology is still common in many other cities of developing countries. Reportedly, some 70 % of the 18 million people in Kolkata (formerly known as Calcutta) in India suffer from respiratory disorders caused by air pollution (BBC 2007).

Science Models of CO_2 Emissions from Traffic Volume Demand

Methodology for CO_2 Emissions from Vehicle Mile Traveled

The CO_2 emission problem inherent to the mobile transportation originates from the burning of petroleum-derived fuel (gasoline and diesel) for power. The burning of

petroleum and natural gas fuel primarily emits CO_2 which represents 82 % of the total US anthropogenic GHG emissions (EIA 2007a).

The GHG emission inventory data are reported in units of tons of carbon dioxide equivalent (CO_2e), which allows emissions of greenhouse gases of different heat trapping potential to be combined for a direct comparison of different GHG emission inventory. In the United States, 28 % of all GHG emissions are from the transportation sector as shown in Fig. 3 (EPA 2005a). Other criteria emissions contribute greatly to pollute ground-level air and cause smog, ozone, cancer, lung disease, and respiratory disease. The following methodology is used by the US EPA to estimate CO_2 emission from vehicle mile traveled data (EPA 2005b).

Assumptions:

- CO_2 emissions from a gallon of gasoline = 19.4 lbs (assuming 99 % of carbon is eventually oxidized)
- CO_2 emissions from a gallon of diesel fuel = 22.2 lbs (assuming 99 % of carbon is eventually oxidized)
- Average fuel efficiency for gasoline passenger car = 20.3 miles per gallon (mpg)
- Average fuel efficiency for diesel truck = 5.9 mpg
- Typical vehicle travel (cars, vans, light trucks combined) = 12,000 miles per year

CO_2 emissions:

$$\{(\text{number of miles driven per year})/\text{average vehicle fuel effiiciency}\} * \text{pounds of } CO_2 \text{ emitted pergallon} \quad (1)$$

Example:

$$\begin{aligned} CO_2 \text{ Emissions for passenger vehicle} &= \{12,000/20.3\} * 19.4 \\ &= 11,468 \text{ lbs} \\ &= 5.7 \text{ tons per year per passenger vehicle} \end{aligned}$$

$$\begin{aligned} CO_2 \text{ Emissions for diesel truck} &= \{12,000/5.9\} * 22.2 \\ &= 45,153 \text{ lbs} \\ &= 22.6 \text{ tons per year per truck} \end{aligned}$$

This example shows that due to very low fuel efficiency, diesel trucks produce four times more CO_2 in comparison to typical cars.

Natural gas is accounted for 28.5 % of fossil energy use in 2008, but only 21.4 % of the total energy-related CO_2 emissions in the United States (EIA 2009). Carbon intensity of natural gas is 55 % of the carbon intensity of coal and 75 % of the carbon intensity for petroleum. Therefore, a hybrid vehicle operating on mostly compressed natural gas (CNG) and liquid natural gas (LNG) may be assumed to emit 75 % of the CO_2 emission calculated for petroleum fuel using Eq. 1. These types of hybrid vehicles are common in several countries, including Brazil and Pakistan (Uddin 2007), but the CNG and LNG consumption is accounted for only 6.9 % transportation share of energy consumption in the United States in 2003 (ORNL 2004).

Energy- and Transportation-Related Global CO_2 Emissions

Recent Department of Energy (DOE) data of the 2008 US inventory of anthropogenic GHG emission shows seven billion metric tons of CO_2e. This includes 5.814 million metric tons of energy-related emissions of which 40.6 % is for electric power generation, 33.1 % transportation-related emission, and 26.3 % produced by residential buildings, commercial sources, and industries (EIA 2009). About 25 % of all world petroleum produced was consumed in the United States. About 66.5 % of this was used by the transportation sector in the United States, as shown in Fig. 8 (EIA 2007b). Consumption of fossil fuel produces CO_2 that is distributed by source in the United States as 42 % from petroleum, 37 % from coal, and 21 % from natural gas. The 1990 data from OECD countries shows that highways account for 94 % air pollution from all transportation modes. About 81 % of GHG emission comes from on-road vehicles, as shown in Fig. 6 for the 2004 emission inventory in the United States (EIA 2007b). The United States, in turn, was responsible for 20 % of energy-related CO_2 emissions worldwide in 2006, though the country accounts for only 5 % of the world's population. In comparison, China's share of global energy-related CO_2 emissions was 21 %, which is projected to grow to 29 % in 2030, and China accounts for 51 % of the projected increase worldwide during this period, followed by India with 7 % projected increase (EIA 2009).

Multimodal Transportation and Travel Demand Management

CO_2 Footprint Indicators of Multimodal Travel

It is useful to compare CO_2 emissions for vehicle distance traveled per person and freight distance traveled per ton to assess their impacts on the sustainability scale. Transportation accounts for 23 % of all global CO_2 emissions, and Fig. 9 shows the CO_2 footprint (grams per passenger per km) contributed by each travel mode for one

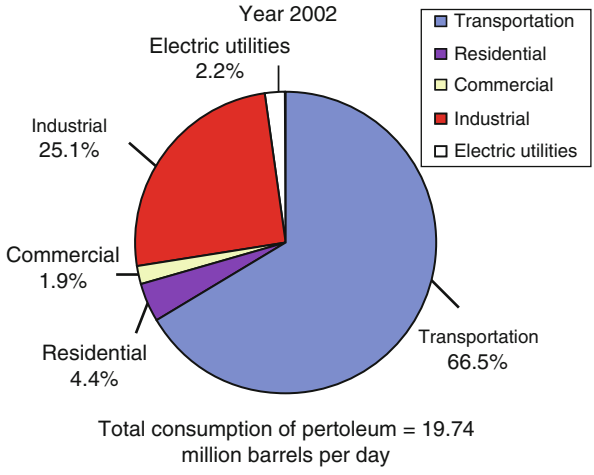

Fig. 8 Distribution of annual consumption of petroleum fuel by sectors

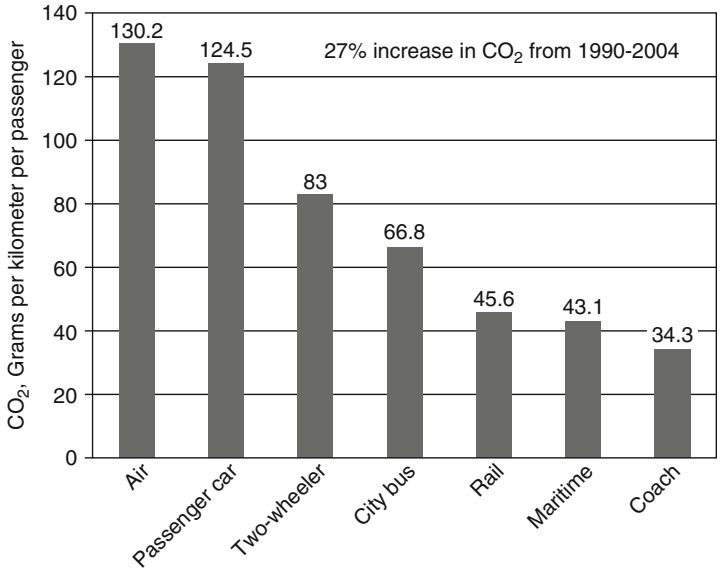

Fig. 9 Production of CO_2 emission by transport mode

person to travel 1 km (EEA 2008; Allianz 2010). Clearly, aviation and passenger car travelers are the most polluting modes of transportation, and rail/train is one of the lowest polluting at one-third CO_2 footprint emission. This shows that public bus and other mass transit modes will reduce emissions significantly in urban areas and cities. In 2005, public transportation (transit buses, mass transit rail) reduced carbon emission by 6.9 million metric tons and avoided 400,000 t of other GHG emissions in the United States (Davis and Hale 2007). The CO_2 footprint emission of freight truck travel per ton km will be several times larger than that by freight train considering that:

- A diesel truck's fuel efficiency is poor at 9.4 km (5.9 miles) per gallon, and on the average a truck travels approximately 40,000 km (25,000 miles) annually, about twice that of an average car travel.
- Truck CO_2 footprint emission is estimated at 25 g per ton km of freight travel by road assuming an average 20 metric tons of freight per truck per km at above fuel efficiency.
- Rail CO_2 footprint emission is estimated at 5–10 g per ton km of freight travel by rail/train. However, the actual emission by rail/train will be even less because trains are able to carry several times more freight than a truck and it would be more economic than a freight truck.

Traffic gridlock and delays on roads and highways further deteriorate air quality by producing excess vehicle emissions. Additionally, road user time is wasted at slower speeds in congested hours of travel. Unlike road vehicles, a dual-track rail

infrastructure keeps trains moving at designated speeds safely, efficiently, and free of "gridlock" eliminating unnecessary emissions. Figure 10 shows the growth trends in passenger and freight travel demands during 1970–2000 in the United States. An indication of the deficit between travel demand and capacity is the congestion, which is measured in terms of traffic density or travel time. The GAO stated that the US interstate highways have become more congested than other similar roads (GAO

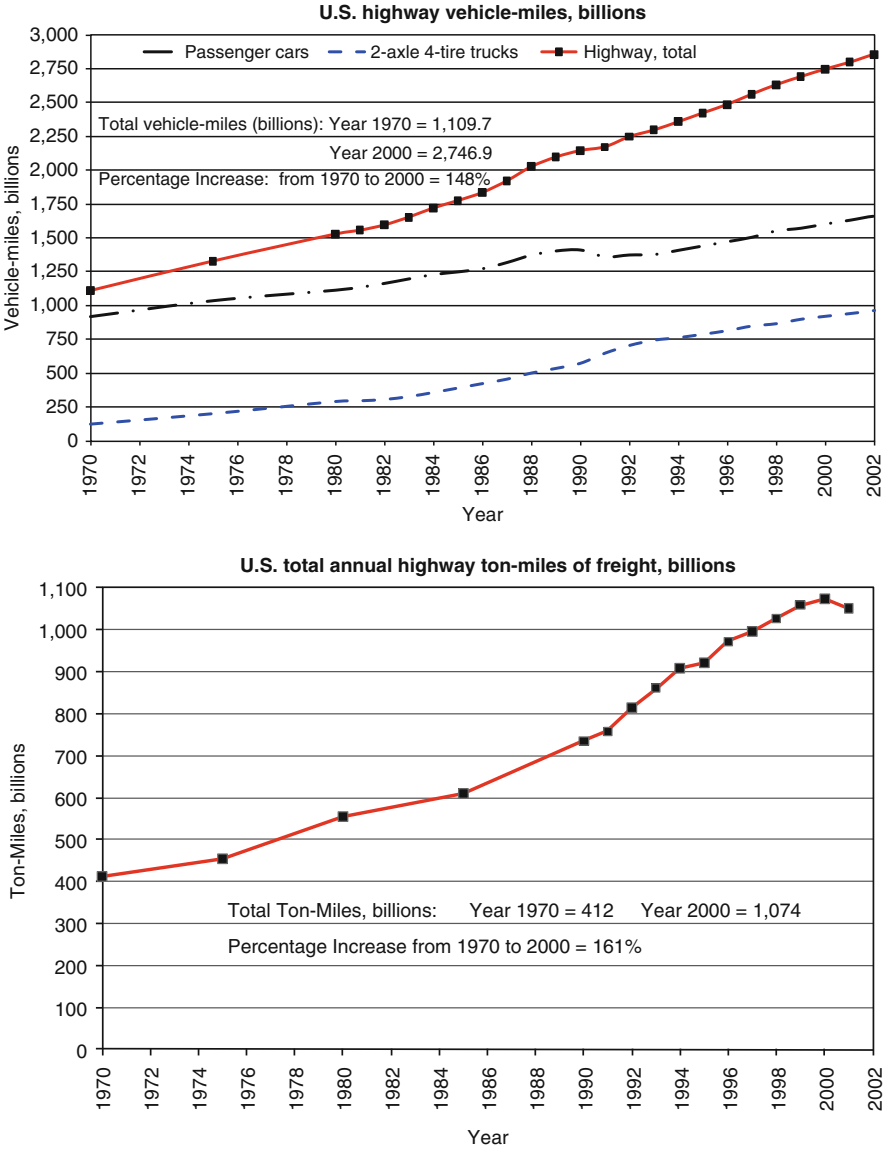

Fig. 10 US travel demand trends; (*left*) VMT, (*right*) freight ton miles

2002a) and that metropolitan areas are reportedly having problems with congestion and degraded air quality (GAO 2002b). The overall density of traffic on the interstate highway system has increased 31.7 % over the past decade. More recent US studies on changes in mobility patterns, driving in the built environment, federal guidelines, and states' efforts (Pisarski 2006; TRB 2009; NCHRP 2010a; Keck et al. 2010) indicate that CO_2 footprints and GHG emissions are being used as one of the key performance indicators of urban and regional traffic management and transportation infrastructure asset management.

Repercussions of Traffic Congestion on Air Pollution and Commuters' Woes

Urban Growth and Travel Demand, and Congestion

As of 2008, for the first time in history, more than half of the world's population lives in towns and cities, as reported by the United Nations (United Nations 1999). Urbanization is very high in industrialized and developed countries, where as of 2000, 75 % of the population lives in urban areas. The urban growth during the last five decades has increased travel demand more than the infrastructure supply, resulting in frequent traffic jams and long peak hours. As reported in TIMES, the term gridlock apparently originated in New York City during a transit workers' strike in 1980, when a surge of commuter autos paralyzed Manhattan's street grid (Koepp 1988). American workers are frequently caught in traffic because commuting patterns have changed drastically in recent decades. Figure 11 shows that road bottlenecks and traffic incidents contribute 65 % to congestion (Uddin and Uddin 2010).

It is estimated that commuters spend millions of hours annually stuck in traffic congestion and waste billion gallons of gas. In 2003, the US commuters suffered 43.8 million total person-hours delay in urbanized areas at an average 25-h delay per person and resulting in 15 gal of fuel wasted per person (ORNL 2004; Uddin and Uddin 2010; Schrank and Lomax 2008). This increment in congestion directly affects the increase in air pollution and greenhouse gases, mobility costs, user operating costs, public health costs, discomfort and stress, and other societal costs.

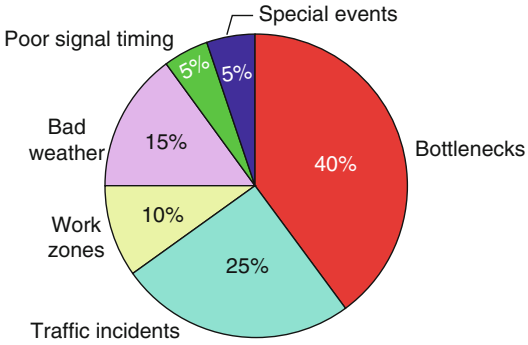

Fig. 11 Causes of traffic congestion (From US data)

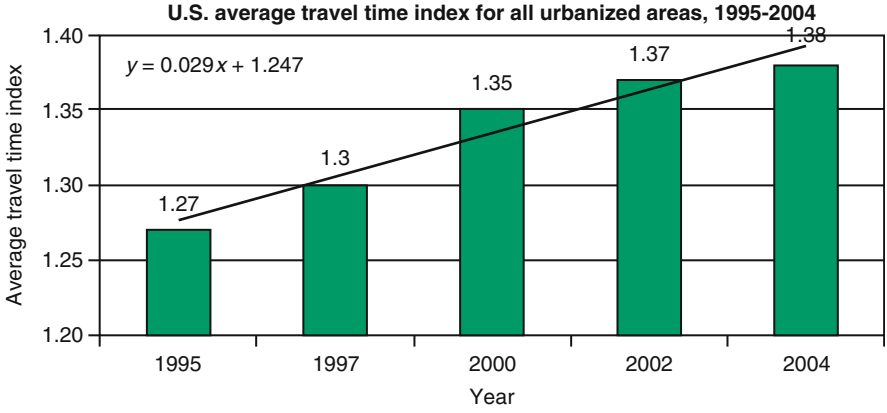

Fig. 12 Increased congestion trend in urban areas of the United States, indicated by average TTI

Travel Time Delay Comparisons

The Travel Time Index (TTI) is another indication of traffic congestion used in the United States to compare travel time delays in several urbanized areas (Schrank and Lomax 2008). It is the ratio of peak-period travel time during congested condition to free-flow travel time for a given road section. A TTI of 1.3, for example, indicates that a 20-min free-flow trip will take 26 min during the peak travel time periods, a 6-min (30 %) travel time penalty. Figure 12 illustrates the trend of average TTI for urbanized areas in the United States for the time period 1995–2004. While it depicts that the TTI is on a rise, for the period of data shown, it was below 1.40. The TTI has increased 12 % in the last decade in urbanized areas in the United States. This number is higher approaching 2.0 or more, for some cities such as Los Angeles and New York. The TTI value estimated in 2007 for Karachi, Pakistan, was of the order of 3.5–4.0 during several hours of peak travel. This high ratio indicated undesirable congestion and provided basis to study traffic congestion in Karachi. Strategies were recommended using geographical information system (GIS) and intelligent transportation system (ITS) technologies to enhance traffic management as discussed later in the section "Geospatial Analysis of Built Environment and Traffic Demand Impacts" (Uddin and Ali 2007).

Health Risks Associated with Transport Patterns, Travel Behavior, and Built Environment

Besides other environmental hazards, built environment and transport-related emissions pose serious health risks to cities in developed countries and the majority of cities in developing countries. In the United States (TRB 2005, 2009; Keck et al. 2010; NCHRP 2010b) and Europe (WHO 2004, 2009b), transport-related health and environment risks have been a major focus of research and transport policy formulation. However, in many developing countries, transport-related health

risks have not received attention and priority for investment and policy actions (ORNL 2004; WHO 2009b). Important health risks and public health hazards due to transport and travel patterns include the following (Uddin et al. 2005; Uddin 2006, 2007; Uddin and Uddin 2010; TRB 2005; WHO 2004, 2009b):

- *Public health hazards from urban air pollution*: Increased exposure to air pollution is associated with higher rates of cardiovascular and respiratory diseases, asthma, and other diseases, which are estimated to kill nearly one million people each year worldwide.
- *Traffic fatalities and injuries*: Road transport is responsible for another estimated 1.2 million deaths and 50 million injuries; pedestrians and cyclists are among the groups most at risk. A significant proportion of injuries in developing countries is related to the lack of safe space for bike/motorcycle and nonmotorized transport.
- *Health risks due to physical inactivity*: Motorization and built environment are the driving force in lifestyles which lack physical activity, especially in the United States and other car-culture countries where urban sprawl requires many more trips. Physical inactivity is a risk factor for cardiovascular diseases; cancers of the breast, colon, and rectum; and diabetes mellitus. Globally, the lack of or insufficient routine physical activity is reported to cause an estimated 3.2 million deaths annually.

Additionally, the urban sprawl type land use favors car owners and promotes poverty and social inequalities (Uddin et al. 2005; Uddin and Uddin 2010). Over the past two decades, even as many developed cities have been rediscovering the health and environmental benefits of walking and cycling, nonmotorized travel is in decline in many cities of developing countries (WHO 2009b).

Commuters' Woes

Commuters stuck in long traffic jams lose patience and drive under stress. The 2010 report on IBM Global Commuter Pain Study surveyed 8,192 motorists in 20 cities on six continents to better understand consumer thinking toward traffic congestion crisis and environmental concerns related to higher levels of auto emissions (IBM 2010). The study Index gauges physical, emotional, and economic toll that everyday traffic has on commuters based on the following ten issues: (1) commuting time, (2) time stuck in traffic, (3) price of gas already too high, (4) traffic gotten worse, (5) start–stop traffic problem, (6) driving causing stress, (7) driving causing anger, (8) traffic affecting work, (9) driving stopped due to bad traffic, and (10) decision not to make trip due to traffic. The study's Pain Index ranks each city on a scale of 1–100, with 100 being the most onerous, as shown in Fig. 13.

The following highlights of the study provide useful insight into traveler's perception and evaluation of the transport and traffic management in their respective cities:

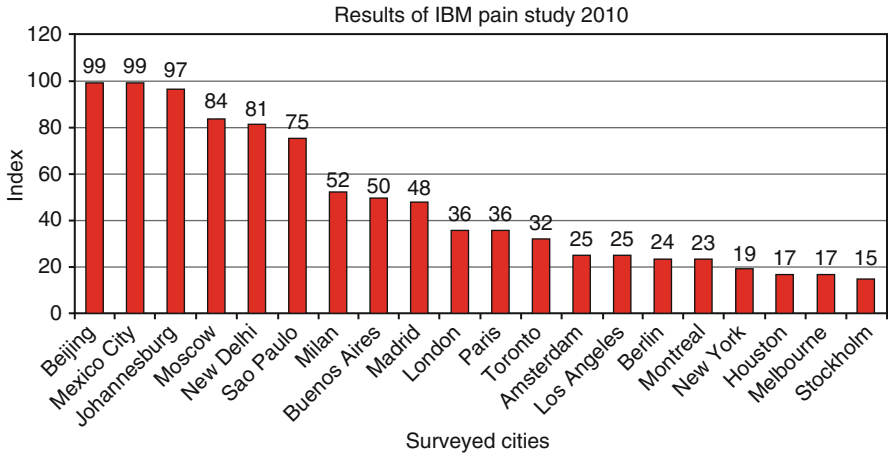

Fig. 13 Result of Pain Index summarized from 2010 IBM Global Commuter Pain study

- Overall traffic has gotten worse in the past 3 years according to the 67 % majority.
- Eight cities scoring 50 or more ranked as having horrible (worse) traffic, with Beijing and Mexico City topping the list of worst traffic and only Milan from Europe included in the list.
- Twelve other cities with bearable (better) traffic are in North America, Europe, and Australia with scores of less than 50, and the best two cities being Melbourne and Stockholm.
- While over 90 % of the respondents in New York and Los Angeles reported driving to work, only 32 % reported so in Paris, 34 % in Amsterdam and Buenos Aires, and 37 % in Milan.
- After driving, the most popular form of transportation was bus – at 12 %. The two cities with the most painful commutes, Beijing and Mexico City, have 44 % and 32 % commuters using bus, respectively. (Traffic in these cities would be more horrible if so many people did not travel by bus.)
- The perception of worsening traffic stemmed in large part from being stuck in traffic for significant lengths of time. This was indicated by 87 % of the respondents who were stuck in roadway traffic during the last 3 years.
- The average delay due to traffic congestion was 1 h for the surveyed cities worldwide – very similar to the figure for the United States alone in the previous two Commuter Pain surveys conducted by IBM. (Note: This number is not directly comparable to the delay hours stated in section "Repercussions of Traffic Congestion on Air Pollution and Commuters' Woes" for US urbanized areas.)
- Responding to the harmful effects of traffic on the health of commuters in any way, 57 % said yes. Among those respondents, increased stress (30 %) and anger (27 %) were the primary manifestations. Increased stress was most prominent in Mexico City (56 %), São Paulo (55 %), New Delhi (45 %), Buenos Aires (44 %), and Beijing (40 %), while anger prevailed in Beijing (53 %), Moscow (51 %),

New Delhi (48 %), and Mexico City (43 %). All of these cities were among those identified in the survey as having especially "painful" commutes.

The above insights from the commuter's survey in large cities are useful considering that cities are driving engines of a country and predicted to grow further and contribute more GHG emissions (Koch-Kraft 2008), as noted below:

- Seventy-eight percent of all CO_2 emissions originate in cities (including mobile sources and built-up areas).
- Eighty percent of economic growth is predicted in cities in emerging industrialized and developing countries.
- Sixty-six percent of the population will be in cities by 2030 with 350 million more urban dwellers in China and India.

Area- and Built Environment-Related GHG Sources

Open Area Sources and Built Environment Effects

GHG from Open Areas

Open area sources of GHG emissions include (predominantly CO_2 except where noted different):

- Petroleum fuel-related emissions during extraction, shipment, refining, storage, and distribution
- Industrial emissions (manufacturing, factories producing steel and other metals)
- Construction material production (cement, asphalt mix, plastics)
- Fires from industrial and commercial incidents (e.g., the oil well fire of 2010 in the Gulf of Mexico)
- Forest fires due to heat and dry spells which are increasingly caused by climatic changes but also blamed on clearing forest land for agriculture and development purposes
- Open burning of solid waste (commonly seen around most cities in developing countries whereas some industrialized countries use for energy production such as incinerators used in Denmark for heating homes in winter)
- Portable electric generators running on gasoline (again a common scene in many developing countries)
- Wastewater treatment areas and solid waste landfill (primarily emitting methane)
- Livestock (methane emissions) and manure management practices (methane and N_2O emissions)
- Agriculture land sources (N_2O emissions from agricultural soils and methane emissions from rice cultivation)
- Deforestation (carbon stock loss) and land-use management (soil carbon pool changes)

The IPCC report (IPCC 1996) provides further information on GHG inventory associated with wastewater and solid waste, manure management, agriculture, forest (including deforestation), and land-use changes. No further discussion is undertaken on the contribution of these open sources since the focus here is on mobile and built area sources of GHG emissions.

Heat Island Effects in the Built Environment

For the first time in history, more than half of the world's population live in towns, cities, and megacities. Towns are generally located in rural areas and smaller than a city in population. Cities are human settlements with a typical population of as small as a few thousands to several millions. On the other hand, a city is called a megacity if it is inhabited by ten million people or more. A major detrimental effect of urbanization is runoff from rapid urban growth and constructed impervious surfaces that continue to degrade coastal and inland waters. Buildings use 36 % of total energy, consume 65 % of electricity, and produce 30 % of greenhouse gas emissions in the United States (EIA 2000). These concerns must be addressed in the design and management of urban growth and cities. In most rural environments, people live amidst moderately abundant vegetation, but in most urban environments, trees are removed, and vegetation is relatively sparse. Vegetation cover has a profound influence on solar energy flux because vegetation absorbs radiation in the most energetic infrared part of the solar spectrum to use in photosynthesis (Landsberg 1981). The unused fraction of the incoming solar energy is either transpired with water or reflected at near-infrared wavelengths. Most materials used in the built-up areas absorb a significant fraction of this incoming solar energy and reradiate it as sensible heat (Landsberg 1981; Oke 1982). Man-made dark constructed surfaces, such as buildings, concrete, and asphalt, absorb more heat from sunlight in comparison to other natural surfaces (soils, grass, trees, and water bodies). This is due to the low solar reflectivity of dark surfaces or albedo (the ratio of the amount of light reflected from a material to the amount of light incident on the material). These low albedo surfaces can raise the local ambient air temperature in an area by as much as 8 °F (4 °C) over the surrounding areas (Pomerantz et al. 2003; Rosenfeld et al. 1998). This phenomenon is known as the "heat island" effect.

A growing percentage of the population lives in urban areas where this heat island effect is more pronounced and induces physical stress, loss of productivity, and even death during heat waves. The heat island effect has been observed even in smaller towns, and on hot summer days, the surface temperature of the constructed surfaces (asphalt, concrete, buildings) during the hottest hours can be significantly higher than the daily maximum air temperature depending on solar radiation, clouds, and wind speed. Using 1-m satellite imagery to classify surfaces and conducting thermal analysis (Uddin and Tang 1999), a surface temperature map of Oxford, Mississippi, in the United States was developed. Figure 14 shows the surface temperature plotted for a strip along the east–west cross section of the city layout plan (Uddin and Boriboonsomsin 2006). The surface temperature difference between the inner city and outskirts can be much higher for larger metropolitan urban areas. A similar analysis for Memphis, Tennessee, showed built-up area about 67.3 % of the total

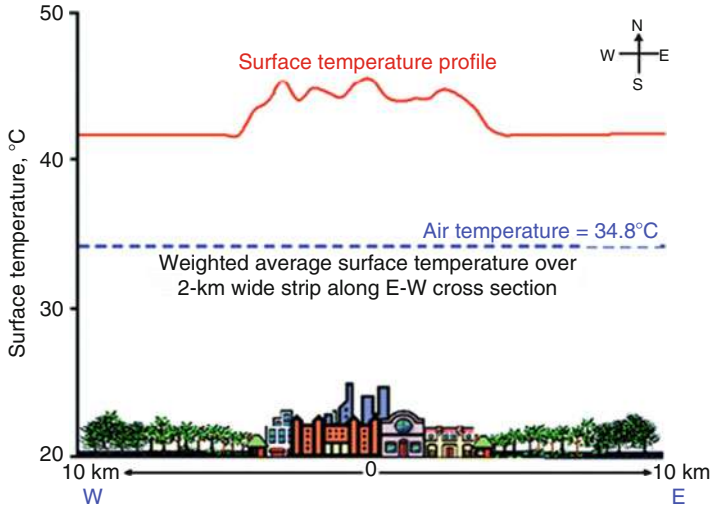

Fig. 14 Heat island effect in Oxford, Mississippi, United States

area of 1,211 km^2. Other non-built natural surfaces include 16.9 % trees, 12.5 % grass, 2.8 % water, and 0.5 % soil. The average surface temperature on the hottest hour of summer is 55.9 °C, which is 21.1 °C higher than the maximum air temperature of 34.8 °C that day due to about three times more built-up surfaces in Memphis than in Oxford, Mississippi. The heat island effect is compounded in most urbanized and populated areas by higher energy use in summer, vehicle traffic density, and emissions from congested conditions.

In many areas of the United States, a warming of 2.2 °C (4 °F) could increase ground-level O_3 concentrations by about 5 % (Akbari 2005). Air quality is also degraded due to the increase in O_3 and PM levels. Additionally, it requires extra electricity to cool down buildings in summer days, which results in increased energy demands, larger air-conditioning bills, and greater demand on power consumption. In the United States, about one-sixth of all electricity generated (about $40 billion per year) is used to air-condition buildings (Rosenfeld et al. 1998). This in turn increases air pollution.

Impacts of Urbanization and Megacities

Historical Overview of Urbanization and Current Trends in Growth of Megacities

The following discussions about historical development of cities, urbanization, and growth of megacities in modern times are based upon historical facts and extensive published research reviewed for this chapter (Wikipedia 2009; Abhat et al. 2005; DB Research 2008; Molina and Molina 2004; WRI 2007; MEGAPOLI 2009; City

Mayors Development 2007). A chronological account of birth of cities to modern era's megacities follows:

- *Pre-Christian era before Roman Empire*: Probably the birth of the world's first city took place on the plains of Mesopotamia near the banks of the Tigris and Euphrates Rivers in what is now Iraq in the Middle East. The development of the metropolis of *Athens* in ancient Greece was a milestone for all future mankind, where a disciplined civil society evolved with planned buildings, iconic architectural structures, institutions of learning, and sports stadium facilities.
- *Rome*: The first major populous city in the world became *Rome* when the Roman Empire spread to most parts of Europe and the Middle East. Rome was populated by more than one million people in 5 AD when the world's population was only 170 million. Romans were the first civil engineers and urban planners building roads and bridges for transportation, aqueducts for water supply, massive temples and sports structures, urban housing, and suburbs. It was the largest, wealthiest, and most politically important city in Europe for over a thousand years. Its population declined to about 20,000 during the Early Middle Ages, and it became a city of ruins. However, Roman roads and bridges served Europe until the times of Late Middle Ages and Industrial Revolution since the modern roads were not built until the 1800s.
- *Constantinople and Chang'an*: The city of *Istanbul* in modern-day Turkey was the Eastern Roman Byzantine Empire's seat and known as *Constantinople.* With its well-planned city streets, port, and commerce infrastructure, it remained a large prosperous metropolitan city for hundreds of years as well as during the Ottoman's Islamic Empire until the late 1800s. Istanbul has grown rapidly in the twentieth century, and with ten million population, it is now ranked 21 in the list of the top 25 megacities in the year 2006. The Chinese Imperial capital city of Chang'an was located northwest of today's Xi'an during the Han Dynasty. Around AD 750, Chang'an had an estimated one million people within city walls as recorded in Chinese history.
- *Cities in the modern era of 1800 to the mid-twentieth century*: In 1800, *Beijing* and *London* were the only major cities with populations of over one million. During the 1800s, only 3 % of the world's population lived in cities, which rose to 47 % by the end of the twentieth century. The invention of steam power and railways facilitated intercity traffic and commerce. But the discovery of petroleum and invention of the gasoline-powered car in the early 1900s revolutionized transportation, provided freedom of mobility, promoted manufacturing and businesses, and accelerated growth of cities and urban population through migration from countryside and abroad. In 1900, North America and Europe possessed nine out of the ten largest cities in the world.
- *Post-World War II era and emergence of megacities*: A city with a population of ten million or more has been generally described as a megacity. In 1950, New York, London, Tokyo, Paris, Chicago, and Moscow were inhabited by the world's largest metropolitan populations. New York City was the only megacity urban area with a population of over ten million. Since then, many megacities

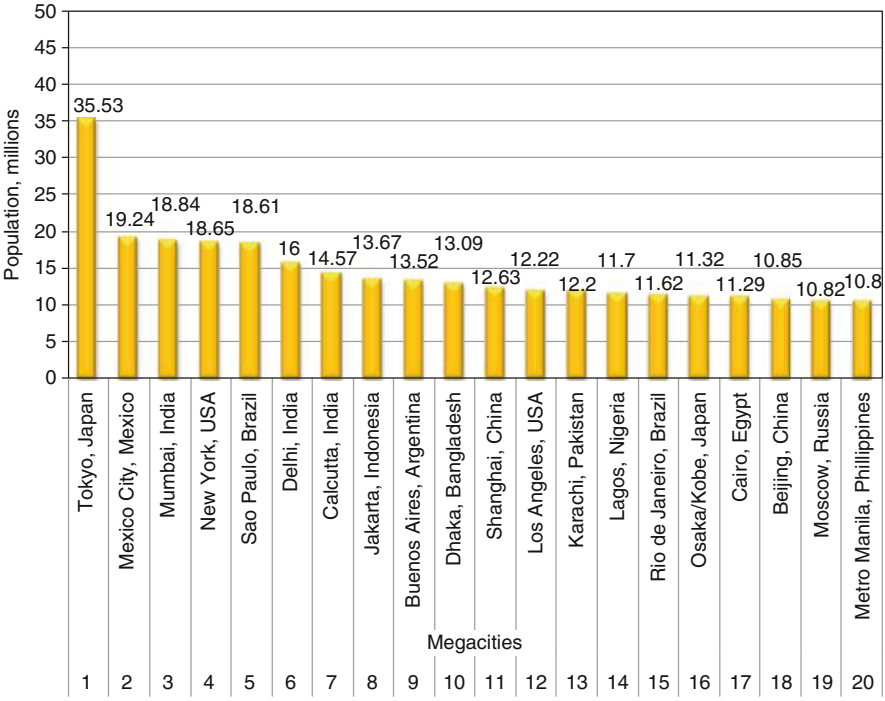

Fig. 15 Top 20 megacities in the world ranked by descending population, 2006

have evolved, and the majority of these are outside North America and Europe. This increase has happened as the rest of the world's population moves toward the high urbanization levels of North America and Western Europe, 75–85 %.

The largest megacity in the twenty-first century is the Greater Tokyo Area. Figure 15 shows the top 20 megacities in the world as of 2006, where New York is ranked number 4 and Los Angeles at 12 (DB Research 2008; City Mayors Development 2007). There is no other city from North America or Western Europe in the list. The increase in urban population is expected to be most dramatic in the developing countries of Asia and Africa. One study predicts that Asia alone will have at least ten megacities by 2025 (Wikipedia 2009). Additionally, the number of cities with five million inhabitants or more is expected to increase worldwide from 40 (year 2001) to 58 (year 2015).

Urban Population Density Impacts

The ratio of central city to metro population in the US urbanized areas decreased 30 % in 50 years from 0.57 in 1950 to 0.38 in 2000 (TRB 2009). Suburbs and outskirts of cities have typically low density, resulting in longer driving distances to work, more cars on roads, increased congestion, and higher GHG emissions. Dense population and demand on energy and mobility make the environment of a large city

and urbanized area different from the environment of smaller towns in rural and other uninhabited areas. Cities and urban areas are now major contributors of GHG emission, air pollution, and associated health risks (United Nations 1999; WHO/UNEP 1992, 2009; WBCSD 2004; EEA 2008; WHO 2009a; Uddin 2006, 2009; Uddin and Uddin 2010; Molina and Molina 2004; WRI 2007; MEGAPOLI 2009). Cities are sources of most of the anthropogenic GHG, other air pollutants, and aerosols that are known to alter the state of the global atmosphere and climate. Megacities produce 12 % of the anthropogenic CO_2 emissions and lesser fractions of the methane and nitrous oxide emissions. Even emission levels are maintained at that of the year 2005, simulation results show that megacities will be responsible for a 225-mK warming over the next 100 years with just under 90 % of this warming due to the CO_2 (MEGAPOLI 2009). Cities drive economic and societal development in all countries and offer better economic prosperity than rural areas, which is the primary cause of urban migration. At the same time, they are the largest consumers of natural resources and the biggest sources of pollution and greenhouse gas emissions. City inhabitants own more automobiles due to higher income levels and greater needs for mobility. This highlights the important role cities should play in mitigating climate change mechanisms.

Urbanization and Motorization Links

Uddin et al. (Uddin et al. 2005) discuss linkage between road transport and urbanization which affects physical inactivity, safety and traffic fatalities, air pollution and environmental degradation, public health, societal costs, quality of life, and social integration problems. Additionally, diminishing energy resources are equally important issues for environmentally sustainable transportation policy and decision-making.

Urban Growth and Travel Demand

Travel demand (number of vehicles and vehicle km traveled) is at its highest level both for automobile and truck traffic. Particularly, high traffic density and associated congestion is a constant reminder of the adverse impacts of urbanization as indicated by road users' woes in large cities (Fig. 13). As reported by City Mayors organization (City Mayors Development 2007) based on the key findings of a survey of 522 decision-makers from 25 megacities, "solving transportation issues has the highest priority in the cities surveyed, and air pollution is seen as the main environmental issue."

The link between urbanization and motorization has been strong in the United States and other industrialized countries due to greater mobility needs (Auch et al. 2004; Uddin and Uddin 2010; Pisarski 2006; Koepp 1988; Kozel 2007). This link is also displaying in emerging economies and developing countries. The change in travel pattern has significantly impacted travel demand on roads, which is typically indicated by Average Annual Daily Traffic (AADT) volume and vehicle mile traveled. These statistics have steadily increased over the years in the United

States (Uddin and Uddin 2010; Pisarski 2006), as shown by changes during 1970–2000: 58 % increase in vehicles registered, 148 % increase in total vehicle miles, and 161 % increase in total freight ton miles. Significant travel demand indicators (in 2007 except where noted otherwise) in the United States were (DOT 2007, 2008; Uddin and Uddin 2010):

- *Number of vehicles registered*: 254.4 million, 93.3 % (cars, 2-axle 4-tire vehicles) and 3.5 % (2-axle 6-tire or more trucks, combination)
- *Total vehicle miles*: 3.08 billion, 92 % (cars, 2-axle 4-tire vehicles) and 8 % trucks and less than 0.5 % (bus and motorcycles)
- *Total freight ton miles*: 1,293 billion (year 2005)
- *Average miles traveled per vehicle*: 11,720 miles (cars) and 25,141 miles (trucks)
- *Fuel economy (average miles traveled per gallon of fuel)*: 20.4 miles (cars), 5.9 miles (trucks), 6.1 miles (buses), and 56.2 miles per gallon (motorcycles)

Figure 16 shows the 2008 vehicle miles traveled and GHG emissions (DOT 2008), which indicate that though all trucks combined accounted for only 7.6 % VMT, they emitted 60 % CO_2 of all on-road vehicles. In comparison, cars contributed 54.3 % VMT but only emitted 39 % CO_2, implying that mobile GHG emissions are undesirably high even outside cities where most trucks operate. The results of a comparative study of national transportation policies over the last 25 years in the United States and France by Gires (Gires 2005) show that in the early 2000s:

- The US consumption of fuel and emission levels has not changed much due to the increase in car ownership, more travel mileage, and larger market share of fuel gulping SUVs and pickup trucks that has risen to 50 %.
- The average gasoline consumption has remarkably decreased by more than 20 % in France, but diesel market share rose by 70 %.

Figure 17 shows that car ownership per 1,000 population in large cities of industrialized countries was 2–30 times that of the major cities of developing countries based on the data from the 1990s (Imran 2010). This implies that the cities in developed and industrialized countries will have significantly higher GHG emissions due to higher AADT, larger number of car trips, and low fuel economy of on-road vehicles.

A reasonably quantifiable sustainability scale is CO_2 emission per capita that can be used by government agencies and cities for evaluating the performance of sustainable transportation policies. Using the 2007 daily vehicle demand volume (DOT 2007; Uddin 2010a; Molina and Molina 2004; WRI 2007; Imran 2010), vehicle fleet composition, typical vehicle miles driven per day, and CO_2 calculations (Eq. 1), transportation-related on-road vehicle emissions were estimated for many US cities including two megacities (New York and Los Angeles) and compared with three megacities in developing countries (São Paulo, Brazil; Mexico City, Mexico; and Karachi, Pakistan) as a part of research by Headrick (Headrick 2010; Uddin and Uddin 2010). The CO_2 calculations assumed that bus and trucks are operated on

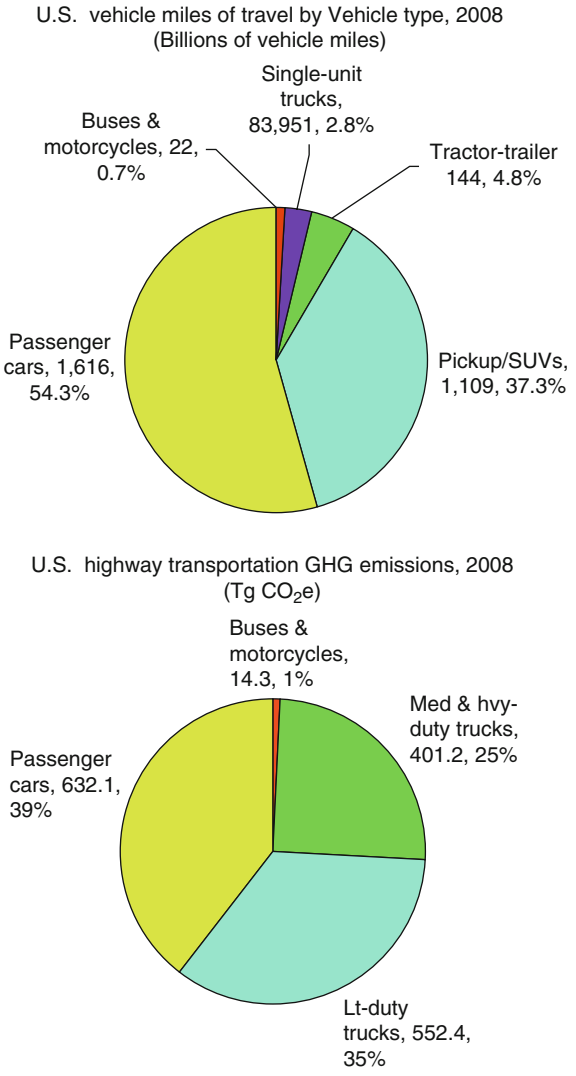

Fig. 16 Vehicle miles traveled and GHG emissions in the United States, 2008

diesel and cars and other passenger vehicles run on gasoline. The results of annual CO_2 emission per capita sustainability index, plotted in Fig. 18 (Headrick 2010; Uddin and Uddin 2010), and population data show that:

- In comparison to US cities, the CO_2 per capita for the three megacities of the developing world is substantially less (1.4 for São Paulo, 0.4 for Mexico City, and 0.4 for Karachi).
- The CO_2 per capita is the highest for Montgomery, Alabama (8.9 t), which is one of the eight US cities at 5.6 t or higher CO_2 per capita, followed by five more

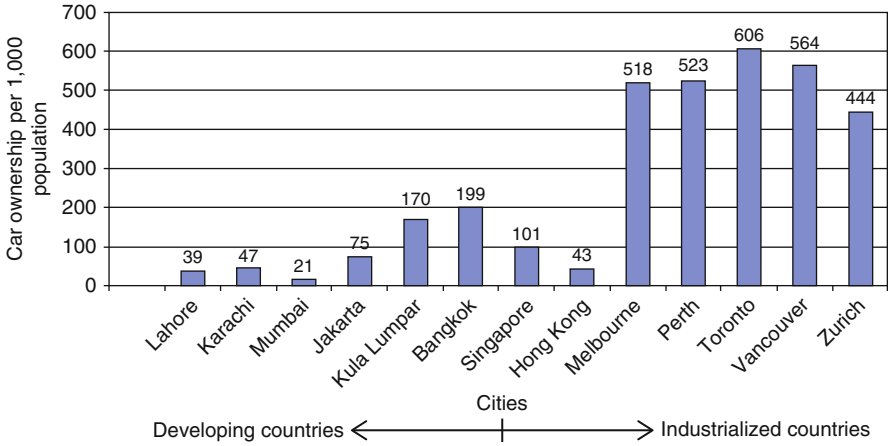

Fig. 17 Comparison of car ownership per 1,000 people in selected cities, 1990s

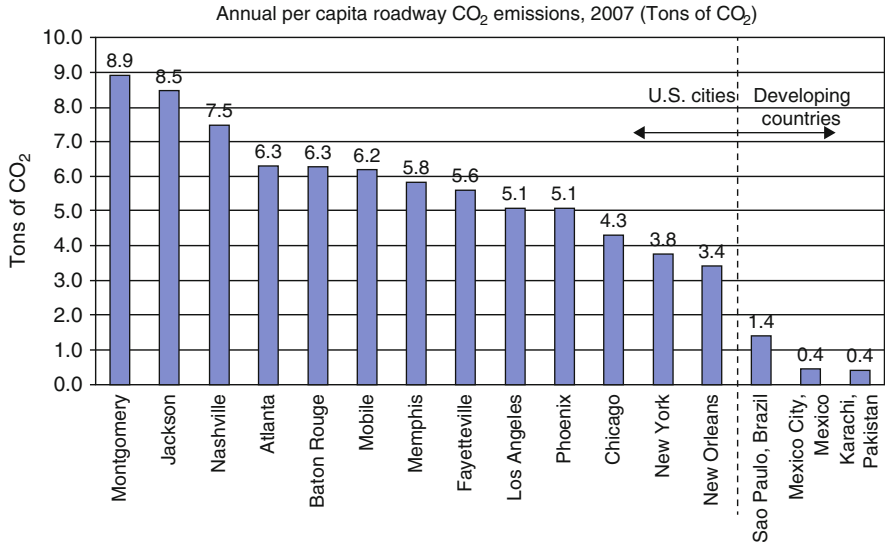

Fig. 18 Comparison of selected US cities and three megacities abroad on sustainability scale

populous cities at 5.1–3.4 t (Los Angeles, Phoenix, Chicago, New York, and New Orleans).

- New York and Los Angeles top the list at 68.4 and 62.7 million tons of CO_2 emissions annually for the two highest CO_2 emissions, followed by Chicago (38.7), Atlanta (28.3), São Paulo (25.0), Phoenix (17.6), Mexico City (7.6), Nashville (7.4), and lesser emissions for all other cities.

- Except for New York (18.2 million), Los Angeles (12.3 million), and Chicago (nine million), populations of other US cities range from 0.2 to 4.5 million in 2007. Populations of megacities abroad range high, from 17.7 million (São Paulo), 17.4 (Mexico City), and 14.0 (Karachi).
- However, population density (1,000 persons per sq. mile) of the three megacities abroad is 3.5–5 times higher than Los Angeles, the highest population density city in the United States (6.3 for Los Angeles and 4.1 for New York).

The above CO_2 per capita analysis assumes all vehicular traffic is operated by gasoline for cars and other automobiles and diesel for trucks. The CO_2 per capita will be less for São Paulo, where up to 25 % of cars operate on ethanol and biofuel, and Karachi, where up to 70 % of cars and an increasing number of auto-rickshaws operate as hybrid vehicles mainly on CNG. Furthermore, this analysis shows that the three megacities of developing countries have less car traffic volume on roads and more people traveling by mass transit and other modes of public transportation in comparison to most US cities.

The impact of utilizing efficient multimodal mass transit systems on reducing CO_2 emitted by on-road vehicles is evident in large cities and urbanized areas both in the United States (such as New York City) and developing countries (e.g., São Paulo and Singapore). New York City Mayor's office of planning and sustainability compiled 2005 GHG emission inventory results considering all mobile, buildings, and other area sources (New York City 2007). The results showed that (1) contributions of 20 % were from on-road vehicles and 3 % from transit and (2) on the sustainability scale New York City, at 7.1 metric tons CO_2e emission per capita, ranked next higher to London, while the average US emission per capita was 3.5 times that of New York City (Fig. 19). The above comparison of citywide GHG emission per capita and preceding analysis of on-road GHG emission per capita for several US cities and megacities in emerging economies and developing countries

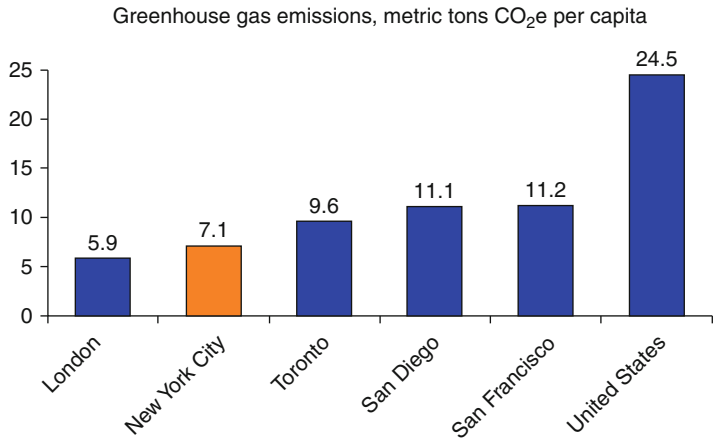

Fig. 19 New York City on sustainability scale based on 2005 GHG emission inventory

clearly demonstrate the strong link between urbanization and motorization in producing GHG emissions.

Geospatial Analysis of Built Environment and Traffic Demand Impacts

Modern geospatial analysis and GIS software tools and availability of aerial and spaceborne remote sensing data provide new opportunities for mapping and spatial analysis of the built environment including land use, urban growth, transportation network, and traffic demand volume and temporal characteristics.

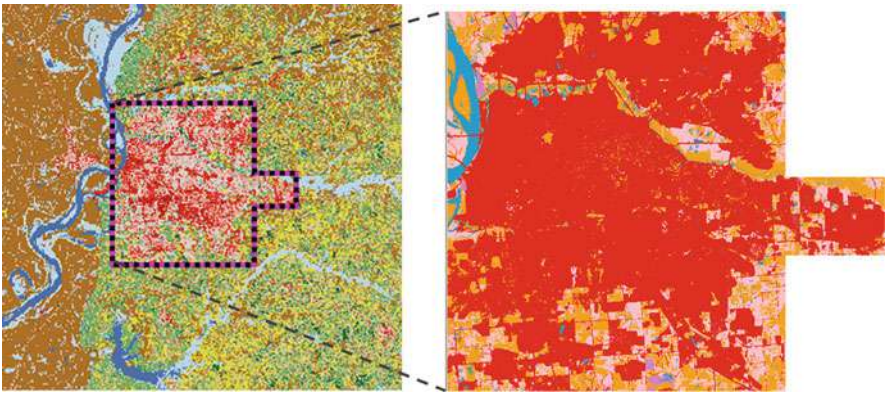
GIS Maps of Urbanized Areas, Urban Growth, and Built-Up Areas in the United States

The USGS has used Landsat satellite imagery data for mapping of the continental United States into the National Land Cover Dataset (NLCD) of 1992. This dataset has been updated by the NLCD 2001 project which uses both Landsat5 and Landsat7 data from 1999 to 2003. The purpose of using both satellites was to prevent clouds from adversely affecting data availability. The spatial resolution of both NLCDs is 30 m. During the period from 1973 to 1992, the urban area of Las Vegas, Nevada, grew dramatically throughout the level basin (Auch et al. 2004).

Built-up areas from imagery and geospatial analysis of NLCD 2001 land cover class maps were estimated for the city of Memphis, Tennessee, and used to create a surface temperature map (Fig. 20) for a hot summer day. The weighted surface temperature for the study area of Memphis in Tennessee was 55.9 °C as discussed in detail by Uddin et al. (2009a). This was 21.1 °C higher than the maximum air temperature of 34.8 °C that day. The availability of high-resolution commercial satellite imageries provides new opportunities to develop computationally efficient geospatial analysis tools for estimating built-up and natural surface areas. For example, the NLCD 2001 map of Oxford, Mississippi, overestimated the built-up area by 43 % in comparison to geospatial analysis of 1-m multispectral satellite imagery.

Imagery-Based Geospatial Analysis for Karachi Metropolitan Road Network GIS and Traffic Demand Volume

A recent traffic management study for the megacity of Karachi, Pakistan, was sponsored by the United States Agency for International Development (USAID) under its "US-Pakistan Science and Technology Cooperative Program" and implemented by the National Academy of Sciences (NAS) during 2007–2010 (Uddin 2009). The project is primarily focused on improving urban traffic flow management and air quality using GIS and spaceborne remote sensing technologies. Karachi is inhabited by more than 14 million people in 2007, and its population is growing at an annual 5 % due to migration from the countryside. Karachi's existing roadways are over-congested and inadequate considering its rapidly growing daily traffic volume demand. More than 40 % road fatalities involve pedestrians. No



CAIT surface classes	Percentage area from NLCD2001	Predicted surface temperature, °C
1. Built-up area	67.4	61.1
2. Grass	12.5	46.8
3. Tree	16.9	45.3
4. Soil	0.5	54.1
5. Water	2.8	34.4
Weighted average surface temperature		55.9

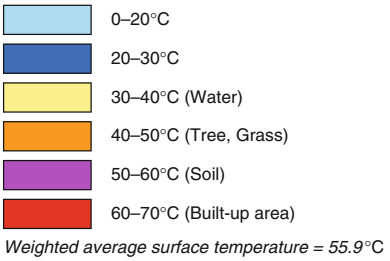


Fig. 20 (*Top left*) Memphis boundary shown on NLCD map, (*top right*) surface temperature map of Memphis, (*bottom left*) summary of built and non-built areas for Memphis, (*bottom right*) legend used for surface temperature scale

improvement in public transport, transit fleet, and operation is evident by overcrowded transit buses and vans (Uddin and Ali 2007). However, the City's Command and Control Centre (CCC), essentially an ITS-based traffic video surveillance system implemented during 2008–2010, is a significant addition to its infrastructure for incident management and crime prevention. The ITS video surveillance system is further helping to reduce emergency response time and promote timely utilization of traffic police for traffic flow management during peak hours and crash incidents. There is no comprehensive road network and land-use GIS, infrastructure database, and traffic volume demand data. The 0.6-m multispectral satellite imagery (Karachi-1) was used to extract vector maps of transportation network, buildings, and other land-use footprint planimetrics (Uddin et al. 2009b; Uddin 2010a).

An innovative geospatial methodology for extracting traffic count data from high-resolution imagery was developed and validated using selected road sections of Gulfport and Oxford, Mississippi, USA (Osborne 2009; Uddin 2010a). This methodology extracts traffic counts from the imagery to calculate average measured density per lane. Posted traffic speed, jamming density, and measured density and flow relationships are used to calculate expected speed. Speed multiplied by density gives volume per hour for the hour of the imagery. Furthermore, daily traffic volume can be estimated if the fraction of traffic volume in that hour based on hourly volume distribution for the entire day is known. The geospatial methodology for traffic data

extraction was then implemented for the Karachi road network. The hourly volume factor was estimated from on-road video data analysis of an arterial in Karachi. Average daily traffic volumes were calculated for 40 road sample sections selected from a factorial design, and a traffic volume map was created using GeoMedia Pro and 0.6-m Karachi-1 imagery as well as Google Earth Imagery for areas outside Karachi-1 imagery scene. The results for all sampled road sections of Karachi yielded an average AADT of 49,564 vehicles per day (Osborne 2009). Most major and multilane roads experienced high hourly traffic volume and poor level of service (Headrick 2010; Uddin 2010a). The results indicated that the average daily traffic volume was affected significantly by road classification and area of the city (71 % inner city vs. 29 % outskirts). These data were used to calculate CO_2 emissions as discussed later.

GHG Abatement Strategies

The worldwide reduction of greenhouse gases and the efficient use of energy in urban, transportation, and industrial applications are important issues for all countries. Recognizing the continuing global increase in mobile travel, the application of traffic congestion-reducing strategies must be implemented in order to meet the target GHG levels and infrastructure needs. In the United States, several traffic management strategies have been widely implemented in recent years in order to improve traffic flow and reduce traffic congestion. These strategies include Travel/Transportation Demand Management (TDM) in urban areas, mass transit deployment, use of ITS technologies, and signal-free corridors and road junction design alternatives. In 2005, public mass transportation in the United States reduced carbon emission by 6.9 million metric tons and avoided 400,000 t of other GHG emissions (Davis and Hale 2007). Simulation studies have shown the promise of reduction in CO_2 and improved air quality as a result of increased vegetation in urban areas.

Sustainable Transport and Traffic Management Solutions

Transport Demand Management and Sustainable Strategies to Reduce CO_2 Emissions

The transportation sector's CO_2 emissions are a function of vehicle fuel efficiency, fuel carbon content, and VMT. Energy and climate policy initiatives at the federal and state levels have focused almost exclusively on technological advances in vehicles and fuels. The evolving gridlock problems and their societal and environmental impacts require innovative solutions to manage urban growth, VMT, and vehicle use. Therefore, any "solution" to the global warming and climate change crisis must involve slowing the growth of CO_2 emissions from mobile sources in the United States. The same is applicable to all other industrialized and rapidly developing countries where car ownership and single-occupancy vehicle (SOV) use are increasing at alarming rates, such as China, Brazil, and India. The worldwide per

capita passenger kilometer traveled per year is expected to increase 48 % between 2000 and 2050 with the highest increase (279 %) projected for China (WBCSD 2004; EEA 2008). An important factor in energy consumption increase is population and urban growth rate, which is high in almost all emerging cities in developing countries. It is imperative to consider the following abatement strategies to reduce mobile GHG sources (Uddin 2009; Molina and Molina 2004; Foletta and Heyen-Perschon 2009):

- *Motorized travel demand reduction*: Reduce the amount of passenger kilometers traveled and freight ton kilometers traveled, discourage SOV trips to ease congestion, and decrease motorcycle traffic to improve road user safety.
- *Idling long-haul trucks on highway rest stops and truck parks*: Eliminate the practice of idling long-haul trucks for long hours (a common scene on US highways). States should use highway patrol to enforce, encourage trucker employers to pay for motel/hotel accommodation for the night, and consider penalty charges for "polluting" trucks who follow this practice.
- *Sustainable multimodal transport implementation*: Implement less polluting mass transit transport strategies for urban mobility with less or fewer emissions per km travel, and increase freight modal share of efficient freight rail.
- *Nonmotorized travel promotion*: Make policy and facilities to promote nonmotorized trips in congested inner city areas.
- *Vehicle inspection and emission testing program*: Develop and enforce regulations for annual vehicle inspection and emission testing programs by developing testing and maintenance facilities and workforce.
- *Transport technology improvements*: Improve performance of transport mode engines and vehicles (lightweight vehicles, smart/intelligent cars) for more safe and efficient use of petroleum fuel and design hybrids to use alternative energy sources with reduced or zero carbon emissions.
- *Regulatory measures based on technology*: Enforce regulations on fuel efficiency, emission levels, and market share of hybrid and battery-driven vehicles.
- *Market-based economic instruments (congestion pricing and emission trading)*: Consider densely trafficked downtown areas, urban roads, and other surrounding corridors as good candidates for congestion pricing to reduce congestion and emissions. Emission trading has been most widely applied in the United States to reduce power plant emissions and is a candidate for global CO_2 trading.
- *Public awareness campaigns*: Develop and conduct public education and awareness campaigns (to implement any of the above strategies successfully) in cooperation with civil society groups.

Technology improvement programs initiated in California have resulted in a slow but consistent reduction in air pollution over the last four decades (Molina and Molina 2004). This is a testimony of regulatory enforcements and public awareness considering there has been consistent urban growth and increase in vehicle kilometers traveled. Congestion pricing schemes need public awareness and support (as implemented successfully in London and Singapore).

Metropolitan Transportation Demand Management

Examples of travel demand and transportation system management actions and TDM marketing to improve traffic operations in large cities and urban areas include (Uddin and Uddin 2010; NCHRP 2010a):

- *Improved traffic flow*: Replacement of stop-controlled intersections by modern roundabout, reversible lanes, transit-stop relocation, removal of encroachments, and ITS traveler's information and congestion warning system.
- *Priority treatment of high-occupancy vehicles*: Dedicated high-occupancy vehicle (HOV) lanes, bus preemption of traffic signals, ITS surveillance and traveler's information technologies, toll policies, and all electronic toll charge system.
- *High-occupancy automobile use*: Car pooling, van pooling, ridesharing, and discouraging use of single-occupancy vehicles.
- *Non-automobile, biking, or pedestrian trips*: Nonmotorized travel modes and auto-restricted zones.
- *Reduced peak-period travel and delays*: Flexible hours, congestion pricing, and peak-period truck restrictions. These strategies are also applicable for nonrecurring events such as adverse weather conditions (hurricane, snow, ice, or rain), work zones, special events, and major incidents and emergencies.
- *Parking management*: Enforcement of parking regulations, video surveillance, park-and-ride facilities, and parking disincentives (e.g., very high parking fee and charges for parking tickets).
- *Transit and paratransit service improvements*: Transit incentives and marketing, transit shelters, terminals, transit-fare-collection techniques, connectivity with other transportation services, and ITS technologies for improved deployment and scheduling.
- *Transit management of efficiency measures*: Routing and surveillance, on time and reliable service, vehicle communications, and maintenance policies to provide state of good repair.
- *Large capacity change alternative on existing roadways*: Travel time reduction for a large capacity alternative is 30 % for one-way operation, 30 % for reversible flow, and 50 % for left-turn prohibition. Additionally, crashes and incidents tend to reduce, while capacity is increased for a large capacity change alternative.
- *Innovative shared transport infrastructure alternative*: Transportation and urban planning approach should be changed toward the green and cool approach by reducing the number of autos on the road and increasing innovative shared transportation and transit alternatives.

Clearly, there is a need to design innovative transport infrastructure to operate at low speeds for shared use of commuters for many congested cities with thriving downtowns and existing ground-level mass transit systems and underground subway/metro tracks. Mass transit systems include bus transit, bus rapid transit (BRT), and light rail transit (LRT). Examples of such metropolitan cities are Chicago, New York, Los Angeles, and many European cities where simply there is no space to increase capacity by building more traditional transport facilities. Costs are also

very high for adding more bus lanes to expand BRT operations. The answers to the urban commuter problem in such developed and congested cities are dedicated elevated transportation pathways maximizing the use of existing right-of-ways of public roads. The key to the success of this innovative approach is in selecting the "right" vehicle technology that can be lightweight and energy efficient. Powered by electricity or magnetic levitation (Maglev) technology and operated at city speed range, a personal rapid transit system is a sustainable pollution free solution for urban areas and cities (Uddin and Uddin 2010). This innovative "green" transport alternative can be economically justifiable based on life cycle costs and benefits.

Smart Growth, Space Planning, and Sustainable Infrastructure

Mixed Land Use and Compact Development to Reduce Cars on Roads in Cities

Encouraging mixed land use and compact development will mitigate and avoid the many flaws of traditional urban development. Urban sprawl and suburban development are characterized by low densities, automobile intensive strip development, poorly connected streets, automobile-oriented transportation planning and traffic management, and detached single family homes and similar land use. Dense or compact development typically involves medium to high densities, more vibrant-centered development, interconnected streets, pedestrian-friendly and transit-friendly road design, and mixed uses of land and roads. Cities should increase the deployment and use of public transport and cool commuting alternatives. Urban growth is inevitable worldwide as metropolitan cities offer more job opportunities, excellent community facilities, and a better quality of life to people migrating from rural areas or smaller cities. Realizing that a single solution is not the answer, a combination of the following abatement strategies should be evaluated to explore practical solutions for reducing transportation-related emissions:

- *Promote smart growth*: Examples include high urban density, less travel distance for commuting to work and shopping, green spaces, and energy conservation.
- *Implement space planning applications*: Space planning approach will be helpful to achieve sustainable growth on ground, below ground, and elevated structures.
- *Establish green and cool cityscapes and communities in and around cities*: Some examples include light-colored, eco-friendly block pavements for sidewalks and parking lots. Residents and homeowners should be given tax-break incentives for the use of white- and light-colored roofs to reduce heat island effects. Similarly, use of solar panel and green roof should be supported to promote energy conservation and renewable energy.
- *Develop sustainable multimodal infrastructure*: Sustainable multimodal transport facilities and operations are possible by providing less polluting mass transit, discouraging SOV use, and introducing safe pathways for walking trips and dedicated bike lanes for nonmotorized travelers.

- *Reduce congestion in cities and metropolitan areas*: Congestion can be reduced by deploying efficient public transportation, ITS technologies to improve operational efficiency, and reducing number of vehicles on roads to ease congestion.
- *Use GIS- and ITS-based speed data to visualize congestion and air pollution trends*: Introduction of geospatial analysis and online GIS visualization products to show public near real-time status of congestion reduction, improvement in air quality from reduced pollution, and reduction in GHG emissions. This education and media campaign will promote wider voluntary use of fuel-efficient cars, public transport, and energy conservation.
- *Consider sustainability related to natural resources and energy demand*: Life cycle analysis of sustainable transport infrastructure assets and mitigation strategies should look into all opportunities related to conservation of materials and energy sources, space-use and land-use planning, and multimodal transportation policies (Uddin 2010b). Two major areas for sustainable road infrastructure assets are (1) pavement construction and maintenance and (2) non-pavement assets (such as bridges, sidewalks, drainage).

Multimodal Alternatives for Travel in Cities, Intercity Connectivity, and Regional Transport

A multimodal transport system makes efficient use of the space and existing transport infrastructure in cities and urban areas having limited funding resources. Historically, an underground mass transit rail subway system provided good use of the space, but its construction and expansion are very expensive. Such rail subway systems may not be the best cost-effective solution in megacities of emerging economies and developing countries. In comparison, the construction of a designated bus lane costs only a fraction of a comparable subway rail line. The bus transit and BRT systems can be implemented in any megacity, adapted quickly, and provide good connectivity to rail network.

Regional and intercity rail network should play an important role in a multimodal approach to reduce GHG emissions. Rail engines are becoming less polluting in compliance with the EPA's clean air non-road diesel rules of 2004 and 2008 (EPA 2008b) with reductions of 99 % in sulfur, up to 90 % in PM, and 80 % in NO_x emissions. Rail locomotives are four times more fuel efficient than trucking, and a train can carry the freight of 280 or more trucks reducing highway congestion and significant reduction in GHG and other emissions (AAR 2010a, b). Electric-powered high-speed rail technology for efficient intercity and regional passenger transport can alleviate plaguing problems of urban and highway traffic congestion, wastage of gasoline fuel, vehicle emissions of criteria air pollutants, and GHG emissions. In the recent years, the US government has committed billions of dollars to several states for constructing high-speed rail corridors (Uddin and Uddin 2010).

Consumption and Hidden Cost of Petroleum

The hunger for petroleum fuel by transportation is enormous in every country. Most countries and especially developing countries spend a sizable amount of their national budgets on crude oil. In 2002, about 11 million barrels of crude oil

equivalent per day was burnt by highway vehicles in the United States (ORNL 2004). The share of light automobiles was 8.5 million barrels, and medium/heavy freight trucks consumed about 2.4 million barrels. In comparison, total rail traffic consumed only 260,000 barrels per day with a major portion (245,000 barrels) by freight train and only 15,200 barrels by passenger rail. The US share of petroleum consumption was 25.3 % of the total world consumption of 79.08 million barrels of petroleum per day in 2003 (ORNL 2004). The accelerated industrialization and economic prosperity of China has made it the second largest petroleum consumer after the United States. The known worldwide petroleum reserves are being diminished every year. The protection of this commodity and its supply has been a major reason of US military expenditures in the Middle East. One such estimate of 1996 is 20–40 billion dollar annual cost to defend all US interests in the Persian Gulf (Delucchi and Murphy 1996). The 2000s Iraq war cost is even substantially higher. (The gasoline cost at fill station may exceed $7 per gallon if the "petroleum protection war cost" is accounted for.) This hidden cost of petroleum is generally ignored in economic evaluation.

Alternative Energy and Fuel, Vehicle Innovations, and Nonmotorized Transport

Cities face challenges of inadequate parking space and polluting transport services. Recent transportation policies and strategies, such as congestion pricing and the use of BRT and LRT systems, have shown some benefits by reducing the number of cars on roads. The key to success for achieving sustainability in the transportation system is to reduce the number of vehicles and number of trips on roads. Increased shares of nonmotorized trips by mixed land use and pedestrian-friendly road design are complimentary strategies to reduce vehicle volume on roads. Sustainable solutions to mobility require a combination of multimodal strategies with reduction of cars on congested roads, reduction in gasoline vehicles, increased share of biofuel vehicles, and zero carbon battery-powered vehicles. Sustainable mass transit strategies include vehicles running on natural gas (CNG and LNG), liquid petroleum gas (LPG), biodiesel, and hybrid and other energy-efficient technologies.

Vehicle efficiency policies and government regulations can be effective if supported by the public. For example, California required that 2 % of vehicle sales had to be zero-emission vehicles by 1998, considering that battery-powered vehicles would meet this need. Initially this was not achieved, but research in hybrid gasoline-electric vehicles is paid off by creating small batteries that could be continuously recharged by a small gasoline-powered generator (Molina and Molina 2004). These near zero-emission hybrid vehicles are now popular and fuel efficient by almost doubling the mileage of a traditional small car.

Some countries with CNG vehicles in use as of 2007 (Uddin 2007) rank in the following order (total number of CNG vehicles in parenthesis): Argentina (1.454 million), Brazil (1.303 million), Pakistan (1.300 million), Italy (0.410 million), India (334,000), the United States (142,000), and China (125,000). The number of

CNG vehicles in the United States is approximately 10 % of the three highest ranking users of CNG vehicles (Argentina, Brazil, and Pakistan). The US consumption of CNG was only 6.4 % followed by 0.4 % LNG consumption in 2004. The United States should consider taking advantage of its large domestic reserves of natural gas for consumption in hybrid cars and other light vehicles. Federal government can take the lead by converting all government-owned cars to gasoline/natural gas hybrid vehicles. Federal and state government agencies can require car manufacturers to produce certain percentage of new cars each year with CNG/gasoline hybrid technology. It will not take a new infrastructure to supply gas because a comprehensive gas pipeline network already exists throughout the United States.

GIS-Based Decision Support System and Value Engineering

Geospatial Mapping and GIS Decision Support System Examples

Spaceborne and airborne remote sensing technologies, GIS and geospatial visualization tools, and air pollution models can be used to prevent and mitigate the adverse effects of transportation systems. GIS-based decision support systems should be developed for identifying the problem areas, vulnerability assessment of transportation infrastructure, and life cycle benefit–cost analysis. A geospatial analysis of CO_2 inventory by states for 1990 and 2003 in the United States, reported by EPA (2008a), indicates:

- Carbon dioxide emissions in 2003 are 15 % above 1990 levels.
- The five states that produce the least amount of transportation emissions are Vermont, Rhode Island, Delaware, South Dakota, and the District of Columbia. These are smaller and less populated areas.
- California, Texas, Florida, New York, and Pennsylvania remain the five states with the highest emissions in 2003 as in 1990.
- This shows that these five states, containing large populated urban metropolitan cities, produce more emissions than other smaller and rural states.

The GIS maps are not shown here for brevity, but this analysis shows an example of GIS-based decision support system on the regional and national level. These results can be used by federal and state agencies to make a decision related to the allocation of funds among states and cities for planning and implementing GHG abatement strategies. Another example of GIS-based decision support system is quantification of built and non-built surface areas in a city. An increase in the percentage area of these built-up surfaces will definitely increase the weighted average surface temperature (by surface area). The increased urban area temperature and increased traffic emission result in air quality degradation which adversely impacts lung disease sufferers. The associated public health cost is about 19 % of the total societal costs, as shown in a previous study in Oxford, Mississippi (Uddin and Boriboonsomsin 2006).

Value Engineering and Life Cycle Analysis

Value engineering (VE) enables to evaluate a cost-effective solution by selecting alternative technologies and methods to achieve reduction in overall life cycle costs without compromise to safety and efficiency. The traditional life cycle analysis (LCA) considers agency costs and user costs associated with pavement life cycle (Uddin et al. 2005). Agency costs for building and maintaining roads require lots of natural resources, such as asphalt, aggregate, cement, concrete, and steel. User costs include vehicle operating cost (voc). For example, the pavement roughness condition deteriorates with time and traffic repetitions that can influence fuel and oil consumption, tire deterioration, and vehicle maintenance. These voc components have been well established in the World Bank's and the US FHWA studies (Uddin et al. 2005). The present worth of life cycle vehicle operating cost is in the range of 18–29 cents per vehicle mile for two-lane rural roads in good to poor condition. The PSI scale (0 for the worst and 5 for the best) is used to define surface condition of pavements. Figure 21 shows the relative weights of these voc components and the influence of Pavement Serviceability Index (PSI) on voc (Uddin et al. 2005).

As pavement surface deteriorates, PSI reduces and voc increases. Reduction in voc due to improved pavement condition and travel time saved due to increased capacity and reduced congestion has been traditionally used to calculate life cycle benefits. However, vehicle emission-related and air pollution-related environmental and societal costs have been lacking from the traditional LCA practice of highway project evaluation. The effects of transportation-related emissions and air pollution on public health and associated medical costs are reviewed and summarized by Uddin (2006). These cost models, congestion pricing, and carbon emission taxes can be used for a comprehensive life cycle analysis to evaluate sustainable alternative transportation and development strategies as a part of value engineering analysis. The life cycle analysis strategies for sustainable transportation system and development should consider:

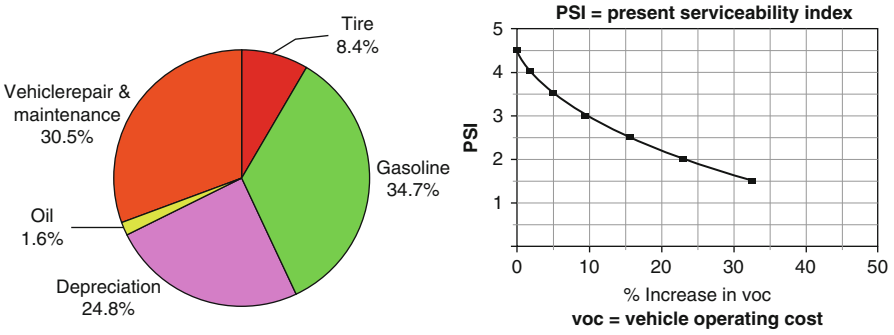

Fig. 21 Road vehicle operating cost components (*left*) and voc increase due to pavement deterioration indicated by lower present serviceability index of road pavements (*right*)

- Providing sufficient and safe mobility to commuters to be productive in the workplace.
- Supporting commercial businesses to flourish without losing potential customers.
- Improving mobility using multimodal approach as a part of the space planning concept.
- Increasing mass transit mode share by increasing car parking prices and using transit modes operating on alternative less polluting energy.
- Improving traffic flow management through video surveillance and other ITS technologies to reduce congestion and gridlocks, user delays, wastage of fuel in queues, and emissions.
- Evaluating and implementing less polluting and more efficient rail and pipeline solutions for freight transport in place of current dependence on highway trucks. The diesel-gulping trucks are highly polluting and emit several times more GHG emissions than alternative freight rail mode. This strategy will also require the construction and management of intermodal facilities.
- Creating new financing opportunities by collecting transportation-related carbon emission tax from trip makers and giving incentives of no such tax for commuters who predominantly use transit.
- Constructing more green spaces and promoting nonmotorized cycling and walking.
- Monitoring air quality and striving for less air pollution and clear skies.
- Reducing backlog of infrastructure and preserving state of good repair using increased revenues by collecting higher fuel taxes on gasoline and diesel.
- Serving more people and creating/preserving jobs.

Life Cycle Analysis of Sustainable Transport Solutions and Value Engineering Case Study

Agency costs for building and maintaining roads require lots of natural resources, such as asphalt, aggregate, cement, concrete, and steel. The process of constructing, pavement material processing, and compacting operations consumes significant amount of fuel and energy. The service life of a typical asphalt highway pavement is 10–15 years, whereas the life of a typical concrete highway pavement is 15–30 years. Functional life of road vehicles is also limited to 10–15 years. In comparison, alternative mass transit of a regional/national high-speed rail (HSR) network and personal rapid transit (PRT) in urbanized areas can last several times longer with less maintenance cost. These alternatives are also safer due to operation on dedicated pathways with no vehicle conflict or congestion. Life cycle analysis of costs and benefits should be evaluated for a longer analysis period of 60–70 years as a part of value engineering evaluation. Over this analysis period, the track-based mass transport system lasts without major rehabilitation or reconstruction, operated typically on electricity. During this period, road infrastructure and vehicle fleets need to be replaced one to three times. Road vehicle operating cost (Fig. 21) is a large component of road user cost (Uddin et al. 2005), which is substantially reduced by the proportion of the road users who switch to the new transit technology. Other benefits include reduction in fuel and low pollution cost. The benefits from each

alternative should include user benefits as well as societal benefits per passenger km or freight ton kilometer which include savings from reduced fuel consumption, time saved due to less delay, public health benefits from reduced air pollution, fewer crash-/accident-related costs, and lesser societal costs due to reduction in CO_2 emissions.

In metropolitan cities and urban areas, dedicated elevated PRT pathways provide a sustainable solution to the urban commute and congestion by maximizing the use of existing right-of-ways of public roads. This will require the selection of the "right" PRT vehicle technology that can be lightweight and energy efficient. The PRT infrastructure requires the use of elevated structures and efficient cleaner energy sources of electricity and Maglev for PRT operations designed to reduce congestion and impacts on the environment. Examples are Swedish SkyCab (electricity driven) and Brazilian Cobra Maglev vehicle/track systems (Uddin and Uddin 2010). The approach to determine economic cost is derived from a study of the traffic volume data, where there are new lines built, users' time savings, number of users willing to pay for such a transport, release of capacity in congested roads, and broader economic benefits including development of less developed regions and creation of jobs. The life cycle economic evaluation includes several financial considerations such as present worth analysis of benefits and costs over a reasonable analysis period considering an appropriate discount rate and calculating the net present value (NPV) of minimum two alternatives. The base alternative is "do nothing," and the reduction in user delay hours and emissions is considered an indirect benefit from the new alternative transit strategy.

To illustrate life cycle benefit and cost analysis of a PRT system, it is assumed that the agency cost for building a 30–40 miles/h speed PRT system on elevated alignment may cost around four million US$ per km, much lower than an HSR system. The PRT's annual operating cost will also be significantly lower than an HSR alternative due to energy-efficient and lightweight vehicle technology. The PRT construction cost of a 10-km stretch is about 40 million dollars with annual 0.5 million dollar operating cost. Assume that each person using the PRT system saves annually 25 h of delay at $16 per hour and avoids wastage of 15 gal of fuel and oil at $3 per gallon. Therefore, for 20,000 commuters (or 20 % car owners in the daily traffic volume) using PRT instead of driving single-occupancy cars, the total user saving is about nine million dollars annually. This example implies that the PRT's initial construction cost is covered within 5 years (at 0 % discount rate) just by considering annual user saving. This analysis simply ignores the passenger fare revenue that will be an agency benefit. Additionally, the societal benefit will be enormous in terms of reduction in CO_2 at 2,765 t daily or about one million tons annually (Uddin and Uddin 2010). Other indirect benefits include less air pollution, reduction in associated public health cost, less risk of on-road crashes, and increased productivity. Showing this type of evidence to the traveling public and other stakeholders, they can be persuaded to approve the PRT system implementation. Building and operating these innovative energy-efficient and cleaner mass transit solutions in metropolitan areas and other large cities can be successful if disincentives are in place to discourage commuters from driving their cars.

Monitoring, Targets, and Applicable Laws

The US EPA uses standard models for measuring and preparing inventory of GHG from all possible sources (EPA 2008a). It is also important to make real-time measurements to assess impacts of mobile and area sources of air pollution and greenhouse gases on air quality and global warming. The methods reviewed will benefit practitioners and decision-makers involved in federal, statewide, tribal, metropolitan, or small community transportation planning agencies.

Terrestrial Remote Sensing and Space-Based Monitoring

The annual emission inventories from transportation and industrial sources need to be verified by measuring CO_2 and other air pollutants. Monitoring of air quality involves analysis of air samples for criteria air pollutants (short lived, requiring frequent measurements) and CO_2 (long lived) emissions (Molina and Molina 2004). Monitoring methods range from simple passive sampling and measuring techniques to continuous gas analyzers and remote sensors. The measurement quantifies the amount of CO_2 higher than the background level in which traffic or other anthropogenic emissions are absent.

Remote Sensing Monitoring of CO_2 and Other Air Pollutants

Remote sensing LIght Detection and Ranging (LIDAR) active sensor in infrared band is used for CO_2, measurements. Tunable differential absorption LIDAR was used for real-time in situ measurements of air pollutants in a previous study for air quality modeling (Uddin 2002). The remote sensing instrument can be set up near any highway or industrial area and measure CO_2 and other emissions in different spectral bands using a target 1 km away (Velasco and Roth 2009). An eddy covariance (EC) flux remote sensing equipment has been used in several studies for measuring CO_2 levels, usually mounted at the top of towers or masts at least twice the mean height of the surrounding buildings. The EC system consists of an ultrasonic anemometer to measure wind fluctuations coupled with an infrared gas analyzer to measure water vapor and CO_2 measuring from 2 to 20 times per second. The results of CO_2 measurements from several cities in the United States, Europe, South America, and Asia showed that built-up areas provide a constant source of CO_2 (Velasco and Roth 2009; Andrade 2007; CO_2 Science 2006). The level of emissions is higher for densely populated larger cities with high traffic volume such as that shown for São Paulo, Brazil, by measuring CO_2 and other pollutants inside and outside road tunnels (Andrade 2007); Mexico City and Singapore (Velasco and Roth 2009); Paris, France; and Phoenix, United States (CO_2 Science 2006). The Paris study results revealed that atmospheric CO_2 concentrations near surface throughout the country outside Paris averaged 415 ppm, which was significantly lower than 950 ppm observed in the city. Furthermore, considering other air pollutants and aerosols in addition to GHG, cities are the source of most of the pollutants

that are known to alter the state of the global atmosphere and the climate. Therefore, cities play an important role in mitigating the GHG emissions (Velasco and Roth 2009).

Spaceborne Remote Sensing for Pollution Monitoring

Recent National Aeronautics and Space Administration (NASA) satellites and European Organisation for the Exploitation of Meteorological Satellites (EUMETSAT) use both active and passive remote sensing instruments to probe throughout the troposphere (McMillan et al. 2009). These instruments measure atmospheric aerosols, clouds, and trace gases across the spectrum from the ultraviolet to the microwave bands. The Atmospheric InfraRed Sounder (AIRS) and Advanced Microwave Sounding Unit (AMSU) are deployed onboard the NASA's Aqua satellite. These spaceborne sensors see 70 % of the Earth both day and night and provide detailed vertical retrievals of temperature and water vapor and weighted free tropospheric concentrations of CO, CH_4, CO_2, and O_3 (McMillan et al. 2009).

In addition to spaceborne remote sensing measurements of emissions, geospatial analysis of spaceborne satellite imagery provides a remote sensing alternative to estimate built-up area estimates and traffic volume for any city or urban area in the world, as discussed previously for Karachi (Osborne 2009; Headrick 2010; Uddin 2009, 2010a). This approach is especially useful where these citywide data are not measured on routine basis. Karachi port area extracted from 0.6-m satellite imagery showed 58.7 % built-up area and 41.3 % non-built area (ocean, river, soil, grass, trees). Accurate and timely collections of traffic attributes are necessary for traffic management and calculation of mobile GHG emissions for sustainability performance evaluation of transportation systems. Furthermore, the imagery-based traffic volume method can be used to fill up missing daily traffic volume and identify candidate locations for ITS traffic video surveillance installation. The 2007 estimated daily traffic volume for the entire megacity was 9.3 million vehicles. Daily traffic volume per sq km in the inner city buffer is about ten times more than the traffic volume in the outskirt area. This also implies that vehicle emission of air pollutants is also higher in the inner city area, which is adversely affecting the public health of residents and commuters alike. The traffic congestion on most major roads and vehicle emissions are adversely affecting travel time productivity and air quality. Based on the US EPA procedures (Eq. 1), citywide CO_2 emission from the imagery-based road traffic volume is estimated 5.5 million tons as of 2007 for Karachi (Headrick 2010; Uddin 2010a).

The United States and European Initiatives

Sustainable Transport Policies

Although CO_2 emissions from road transport and road passenger kilometers continue to grow, fuel efficiency per passenger kilometer is improving. Road ton kilometers are increasing but truck fuel efficiency is not. It is important to recognize that improvements in energy efficiency of vehicles, less polluting fuel like CNG, and

nonfossil fuels are still not enough to counteract the growth in transport demand. Therefore, measures focused on reducing transport demand or shifting demand to more sustainable modes of transportation are extremely important to provide significant emission reduction results. A sustainable solution requires a shift to multimodal transportation systems with emphasis on reducing travel time to commute and better facilities for bikes and nonmotorized modes. It has been argued that improvements in energy efficiency of vehicles and nonfossil fuels are not enough to counteract the increasing road travel demand and transportation-related GHG emission (McCarthy 2010). Therefore, measures focused on reducing transport demand or shifting demand to more sustainable modes of transportation are extremely important to provide significant emission reductions. A sustainable transportation and development policy should encourage building parks, preserving wooded areas, and providing additional water bodies as an integral part of the built environment and residential neighborhood "green" communities. Reduction of energy consumption and emissions requires ecological-friendly pavement materials and related technologies with minimum use of traditional hot mix asphalt (Uddin 2010b).

Recent Transport- and GHG-Related Regulations, Policies, and Initiatives in the United States

The EPA and USDOT federal agencies are drawing on current laws to mandate fuel efficiency standards and reduced GHG emissions per mile traveled by passenger vehicles. Several legislative and regulatory actions, being undertaken in the United States to reduce transportation-related GHG emissions as reviewed in EIA (2009) and based upon the recent news, include:

- The EPA as required by public law 110–161 (December 26, 2007) developed a mandatory reporting rule for GHG on September 22, 2009. The rule requires emitters of GHGs from 31 different source categories to report their emissions to the EPA. Approximately 80–85 % of total US GHG emissions from 10,000 facilities are expected to be covered by the rule. Reporters must begin to monitor their emissions on January 1, 2010; the first annual emission reports will be due in 2011.
- On April 2, 2007, the US Supreme Court authorized the EPA under Section 202 (a)(1) of the Clean Air Act (CAA) to announce that the six key GHGs pose a threat to public health and welfare for current and future generations and that GHG emissions from new motor vehicles and motor vehicle engines contribute to climate change.
- The draft rule of EPA, published in the Federal Register on October 27, 2009, limits the applicability of CO_2 emission standards under the CAA to new and modified stationary sources that emit more than 25,000 million tons CO_2e annually. The EPA expects that 14,000 large industrial sources, which are responsible for nearly 70 % of US GHG emissions, will be required to obtain Title V operating permits. This threshold rule would cover power plants, refineries, and other large industrial operations but except small farms, restaurants, schools, and other small facilities.

- EPA recently released the RFS2 volumetric requirements for 2010, calling for approximately 8 % of the total gasoline and diesel pool to consist of renewable content, mostly from corn-based ethanol.
- According to the EPA requirements, a larger percentage of renewable fuels will consist of these second- and third-generation biofuels, such as algal diesel and cellulosic ethanol. By 2022, advanced biofuels will comprise almost 60 % of the renewable fuel mandate. In this way, the move to renewable fuels will contribute a greater share of the drop in transportation's GHG emissions.
- The American Recovery and Reinvestment Act of 2009 ("The Stimulus Bill") was signed into law by President Obama on February 17, 2009. Under the Act, the DOE received $36.7 billion to fund renewable energy, carbon capture and storage, energy efficiency, and smart grid projects, among others. The projects are expected to provide reductions in both energy use and GHG emissions.
- The Energy Independence and Security Act of 2007 (EISA) mandated national GHG emission standards for mobile sources, authorized by the CAA, and updated Corporate Average Fuel Economy (CAFE) standards, required by EISA.
- On September 15, 2009, EPA and USDOT formalized an agreement announced in May 2009 between the Administration and automobile industry stakeholders to accelerate the existing CAFE mandate and impose nationwide the tailpipe GHG standards sought by California.
- On September 25, 2009, the State of California imposed a fee on carbon emissions, the second government body in the United States (after Boulder, Colorado). The fee will be used to fund implementation of the State's GHG cap-and-trade program. The fee is expected to raise $63 million per year from approximately 350 large emitting entities in the State. The state law will go into effect in fiscal year 2010–2011 and will be apportioned among entities on the basis of their annual GHG emissions, at a cost of approximately 15.5 cents per million ton CO_2e.
- In March 2010, EPA and DOT released emissions and CAFE standard that will go into effect by 2012 and increase the fuel economy of passenger vehicles by 2016. By model year 2016, the combined car and truck standard will be 250 g of CO_2 emissions per mile. Additional GHG standards to improve air-conditioning systems in vehicles will achieve the fuel economy equivalent of 35.5 miles per gallon.
- In May 2010, President Obama's memorandum directed EPA and US DOT to begin the rule-making process for further reductions for model year 2017 through 2025. The memorandum also directed both EPA and National Highway Traffic Safety Administration (NHTSA) to establish fuel efficiency and GHG standards for commercial medium and heavy-duty trucks, starting with model year 2014, in accordance with the CAA and EISA.
- On September 15, 2009, the United States, Canada, and Mexico expressed their support for a proposal to include chlorofluorocarbons (HFCs) under the Montreal Protocol. These gases are used primarily in refrigeration and air-conditioning applications. The proposal calls for reductions in the consumption and production of HFCs around the world, with developed nations taking the lead.

Global Accords and Developing World Efforts

International Climate Change Mitigation Accords

The United Nations Framework Convention on Climate Change (UNFCC) has been the primary organization for international accords (http://unfccc.int/essential_background/items/2877.php). *The Kyoto Protocol* was initially adopted on December 11, 1997, in Kyoto, Japan. Under the Protocol, 37 countries committed themselves to a reduction of greenhouse gases, and all member countries gave general commitments. The benchmark 1990 emission levels were accepted by the Conference of the Parties of the Convention, which were the values of "global warming potential" calculated for the IPCC Second Assessment Report. These figures are used for converting the various greenhouse gas emissions into comparable CO_2e when computing overall sources and sinks.

In December 2008, the fourteenth *Conference of the Parties to the United Nations Framework Convention on Climate Change* and the fourth *Meeting of the Parties to the Kyoto Protocol* were held in Poznan, Poland. Key areas of discussion included the following:

- Governments shifted into "full negotiating mode" in hopes of delivering a comprehensive new climate change agreement in December 2009 in Copenhagen, Denmark.
- The European Union called on developed countries as a group to reduce their emissions to 30 % below 1990 levels by 2020 and on developing countries to reduce their emissions by 15–30 % below business-as-usual levels.
- Ministers encouraged the parties to view the global economic crisis as an opportunity to address climate change and, simultaneously, contribute to economic recovery, rather than as a hindrance to progress on climate change.

On March 28, 2009, US President Obama launched the *Major Economies Forum on Energy and Climate*. The Forum facilitated dialog among the major economies, leading up to an agreement at the fifteenth *Conference of the Parties to the UNFCC* in Copenhagen. Further, the Forum seeks to advance joint ventures to develop clean energy resources. Discussions have centered on adaptation, mitigation, measuring, reporting and verification, and technological cooperation. At least 29 countries indicated that they will join the accord representing more than 70 % of global greenhouse gas emissions. Major countries committed to cut emissions below 1990 levels by 2020 are as follows: the United States by 17 %, China by 40 %, India at least 20 %, Brazil at least 36 %, South Africa by 34 % in emissions from coal, and the European Union by at least 20 % in its overall emissions.

The United Nations Conference on Climate Change in Cancun, Mexico, concluded on December 10, 2010. Over 190 countries of the UNFCC agreed on a new international deal "The Cancun Agreement" to mitigate global warming impacts. This is the latest climate change agreement after the Kyoto Protocol. The Cancun Agreement adopted 33 pages of text outlining a framework for further progress of

negotiating emission reductions, monitoring and verifying emissions, funding adaptation, and forest protection. The key points of the agreement included:

- Carbon dioxide capture and storage in geological formations will be included as an eligible project activity.
- The 37 countries are allowed to fulfill their greenhouse gas emission obligations by investing in projects that reduce emissions in developing countries.
- Action is included to protect the world's forests because deforestation accounts for nearly one-fifth of all global carbon dioxide emissions.
- Technology transfer will be facilitated to reduce GHG emissions through innovation in transport infrastructures.
- A Green Climate Fund of US$30 billion of new contributions for the period 2010–2012 is established to help the most vulnerable developing countries adapt to the unavoidable impacts of climate change and reduce their carbon footprints.
- In the longer term, developed countries committed to a goal of mobilizing jointly US$100 billion per year by 2020 to address the needs of poorer countries. A "significant share" of new multilateral funding for adaptation should flow through the Green Climate Fund, which will be managed by the World Bank for the first 3 years, delegates agreed.

The United Nations Collaborative Programme on Reducing Emissions from Deforestation and Forest Degradation in Developing Countries (REDD) has lead REDD efforts in some countries in 2010, such as Bolivia, Congo, Indonesia, Panama, Tanzania, Vietnam, and Zambia. More info is available from http://www.un-redd.org. Inventory and monitoring of forest is an essential step for such efforts, including the use of airborne and spaceborne remote sensing technologies. After the Cancun agreement, many developing countries are initiating REDD plans to preserve national forests, such as announced by the Environment Minister of Pakistan during the international biodiversity conference on December 31, 2010 (International conference on biodiversity is our life).

Lack of Multimodal Transport Strategy Consideration by International Lending Institutions

As a part of the infrastructure loan evaluation, the World Bank and other international lending institutions historically did not encourage multimodal strategy evaluation for transportation infrastructure loan projects in urban areas or at regional levels, as evidenced by the following discussion. Since the World Bank's first loans during the late 1940s to finance the reconstruction of the postwar economies of Western Europe, the World Bank has loaned more than $330 billion to developing countries (Driscoll 1996). The latest data shows that the World Bank's worldwide lending accounts for 20 % in the transport sector (World 2010). Total loan amount of about $33 billion in the last decade was dispersed to transport infrastructure and services. Of that, a significant 73 % was spent on roads, with the remaining only 27 % on rail, ports, aviation, and transport services (Martin 2007). Highway project analysis traditionally lacked considerations for congestion, vehicle emissions, and

public health impacts in comparison of life cycle costs and benefits of roads versus rail transportation strategies. Additionally, the World Bank financing of the transport vehicle fleet has been decreasing, and effort has been made to transition from public to private enterprises, especially for freight haul trucks. This in turn became impetus for building more roads with higher emitting vehicular traffic and increasing the decay of (lower emission per passenger) rail infrastructure in many countries.

The World Bank increased its efforts in recent years to provide developing countries greater access to finance and technology for climate change mitigation efforts. However, climate change mitigation was considered in less than 20 % of the World Bank's energy sector lending in 2005 (Sohn et al. 2005). Additional funding sources in recent years include the Clean Technology Fund (CTF) in 2008 (Weiss and Logan 2008), Climate Investment Funds (CIF) fund, and Global Environment Facility (GEF) funds, established in 1991 (Rooke et al. 2009). However, some groups of civil society (Martin 2007; Sohn et al. 2005; Rooke et al. 2009) are skeptical of the World Bank's CTF and other environment-related financing programs because of the evidence of unsustainable growth outcomes of loan projects, including more spending on oil, coal, and gas (94 % in 2007–2008 alone), privatization and export-driven production which do not emphasize on environmental sustainability, lack of gender justice by ignoring women from loan negotiations, and priority for highway funding, resulting in decay of rail infrastructure. These concerns and future use of Green Climate Fund created by the UNFCC's 2010 Cancun Agreement warrant that the World Bank and other international lending institutions should change their outlook of transport and energy loan evaluation policies, considering the adverse impacts of GHG emission, air pollution, and social and economic deterioration of the poor and women.

Best Practices

Annually 33 billion tons of anthropogenic CO_2 emission is produced worldwide (Andrade 2007; The Realignment 2009). A significant part of the anthropogenic CO_2 emission is produced by on-road vehicles, especially in cities. These emissions can be reduced by implementing more efficient and low fuel mass transit systems and other sustainable multimodal transport strategies. A successful sustainable transportation policy requires all stakeholders (car manufacturers and dealers, general public, and government agencies) and policy makers to set goals to reduce emissions on national levels. Examples of the best practices of abatement strategies for transport alternative and their effectiveness evaluation methods are discussed in this section. These best practices will be viable options for adaptation and implementation by other urbanized areas and megacities in the rest of the world.

United States Examples

Reductions in transport-related emissions and subsequent improvements in air quality have been made through government enforcements of regulations and voluntary participation by the industry and the public in the United States. The

current economic recession has shown an inherent vulnerability in the automotive industry due to the slump in demand of new cars. The "Cash For Clunkers" program, initiated by Obama Administration in the United States, was extremely successful to remove older fuel drinking cars from the roads. Additionally, according to the US Treasury (The Realignment 2009), the $3 billion spent on the program produced 42,000 jobs, sold 700,000 cars, and created 0.3–4 % worth of gross domestic product (GDP).

Statewide efforts (California and Maryland): With 36 million inhabitants, California is the most populated state. California Department of Transportation (Caltrans) operates and maintains 15,269 highway miles which is less than 9 % of total 170,000 miles of public roads. California's highway network supports the sixth largest economy in the world due to its rich agriculture and timber production, diverse industries, computer technology firms, and movie industry (NCHRP 2010a). Caltrans evaluates transportation project delivery using several key indicators of performance measures/outcomes: travel time and delay (mobility), travel modal choice (accessibility), person- and vehicle-traveled distance (productivity), condition index (system preservation), crashes/fatalities (traveler safety and security), and indictors of air quality, noise, and energy consumption (environmental quality). California's Climate Action Team expects "smart land use and intelligent transportation" to make the second largest contribution toward meeting the state's ambitious GHG reduction goals (EIA 2009).

Maryland is relatively a small state, ranked 42nd in area, but it is the fifth densest state in the United States with an estimated population of 5.6 million. Per capita VMT is nearly the same as the US average, with nearly 75 % VMT occurring in urbanized areas (Keck et al. 2010). Maryland State Highway Administration (SHA) operates and maintains 5,263 highway/road centerline miles, which represents less than 20 % of the total 29,265 roadway centerline miles in the state. However, the highway network carries 70 % of the total VMT in the state. Mass transit infrastructure consists of subway, light rail, and bus service. Currently, 82 % of freight moves by roads with half of the freight simply passing through the state. Maryland publishes the annual attainment report on transportation system performance in five categories against target values (NCHRP 2010a). These performance measures include driver satisfaction, percent of highway network in preferred condition, acres of wetland or wildlife habitats restored, fuel usage of light vehicle fleet, user cost saving due to incident management, transport-related emission by region, transport-related GHG emissions, vehicle emission reduction, travel demand management performance, reduction in VMT through park and ride, bicycle and pedestrian fatalities and injuries, percentage of highway centerline miles with a bicycle level of comfort target and miles of highways with marked bicycle lanes, and percentage of SHA road centerline miles in urban areas with sidewalks and percentage of sidewalks compliant with the Americans with Disabilities Act (ADA). A success story for a multimodal highway project was the Intercounty Connector (ICC) designed to relieve congestion between two major corridors (Interstate Highway I-270 and I-95) in Montgomery and Prince George's counties (NCHRP 2010a).

Sustainable energy and transport strategies in major cities (Atlanta, Georgia, and Austin, Texas): Atlanta, Georgia, has been a nonattainment urban area for many years due to higher level of air pollution. One of the factors for its program success is TDM marketing by the Georgia Department of Transportation (GDOT) to reduce congestion and GHG emissions, using reliable performance metrics to pitch its messages to the public (Keck et al. 2010). For example, the Clean Air Campaign (CAC), a not-for-profit corporation, was formed in 1996 by collaboration between government, business, and civic organizations (Keck et al. 2010). Originally funded by the GDOT as a public awareness campaign for air quality degradation associated with vehicle emissions, the CAC began to conduct employer outreach in 2000. For the most part, this role focuses on changing travel behaviors through informed decision-making and public education campaign. The most effective TDM marketing programs involve a variety of partners within a community, including public officials, community organizations, and individual support transportation alternatives. These partner organizations include Transportation Management Association (TMA), Employer Service Organizations (ESOs), Rideshare matching and guaranteed ride home (GRH) service, and Vanpool services. Through these TDM efforts commuting alternatives in the Atlanta metro area boasts an annual reduction in pollution and the following benefits each year (Keck et al. 2010):

- Sixteen million car trips eliminated from metro Atlanta roadways
- More than 200,000 t of pollution not released into the air
- More than $156 million estimated in reduced commute costs
- Thirty million dollars estimated in health-related cost savings due to improved air quality

Austin, Texas: The city of Austin, Texas, initiated its energy conservation and GHG reduction program in 2007. By winning the 2010 national climate protection award on September 29, 2010, Austin has been recognized nationally for reaching the 5th milestone of monitoring and verifying results of the city's carbon reduction plans (City of Austin 2010). This was announced by the Local Governments for Sustainability, USA, which is associated with the International Council for Local Environmental Initiatives (ICLEI). The city of Austin has implemented an innovative transportation user fee (TUF) which averages $30–40 annually for a typical household in their utility bills. This charge is based on the average number of daily motor vehicle trips made per property, reflecting its size and use. This regulation rewards households that reduce their vehicle ownership. The city provides exemptions to residential properties with occupants that do not own or regularly use a private motor vehicle for transportation or if they are 65 years of age or older. The Austin Climate Protection Plan, developed by the city to reduce GHG emissions, includes many elements (City of Austin 2010) such as:

- Making all city facilities and operations carbon neutral by 2020
- Reducing Austin Energy's carbon footprint and making any new electricity generation carbon neutral

- Enhancing Austin Energy's Green Building program for achieving energy efficiency in buildings
- Engaging businesses and citizens to reduce their carbon footprints

London, United Kingdom

London implemented a congestion pricing program effective February 2003 that charges drivers £5 each time they enter the central city (22 km^2 area, 1.2 % of greater London), similar to the toll charged at major bridge crossings (Molina and Molina 2004; Limanond 2010). This congestion-designated zone is surrounded by perimeter roads that serve as its boundaries. The charge is enforced by fixed and mobile surveillance cameras that are linked to automatic licensed plate number recognition technology. Heavy penalty of £80 is assessed against the vehicle owner if the charge is not paid by midnight. There is also a 90 % discount for residents of the congestion zone. There is a concern about negative financial impact on the local retail sector and on wider economy (Molina and Molina 2004). The program showed the following benefits to Central London: a 30 % reduction of car travel, average travel speed increased from 13 to 17 km/h, and congestion delay reduced by 30 % (Limanond 2010). The reduction in vehicular traffic volume also improved air quality. The levels of NO_x, PM_{10}, and CO_2 concentrations in London decreased by 16–19 % after the congestion pricing program was implemented (Limanond 2010).

Mexico City

Metropolitan Mexico City ranks second in the 2006 list of megacities at 19.24 million population (Fig. 15). The city expanded in the late 1930s when a combination of rapid economic growth, population growth, and a considerable rural migration filled the city with people. Mexico City houses 80 % of all the firms in the country, and 2.6 million cars and buses bring people to work and shop in them. Street vendors make up an enormous part of Mexico's job force (Abhat et al. 2005). The extensive industrial and commercial activities within the city are primarily responsible for its prosperity as well as many of the environmental problems. High levels of emissions are responsible for permanent respiratory problems suffered by more than one million people. Air quality degradation worsens by the fact that Mexico City is situated in a basin (Abhat et al. 2005). The geography prevents winds from blowing away the pollution, trapping it above the city. More than 30 % of the city's vehicles are more than 20 years old. The city has been striving to implement solutions which include (Abhat et al. 2005; DB Research 2008):

- Bicycles and motorcycles are popular. Numbers of cars are reduced on roads by enforcing the law of banning cars on roads on certain weekdays.
- A thriving LRT system is in operation for years, with nine lines and 75 miles of tracks and more under construction.
- The metrobus public transport system has significantly contributed in improving both air quality and easing transport problems. Bus journey times have been halved, and CO_2 emissions have been reduced by 80,000 t a year.

São Paulo, Brazil

The megacity of São Paulo has a population of 18.61 million and ranks 5th in the 2006 list of top megacities (Fig. 15). Although it is home to only 15 % of the country's inhabitants, this megacity consumes 60 % of Brazil's energy. The city emitted 83 million tons of CO_2 in 2003. In metropolitan São Paulo, there were 2,000 major industrial facilities and 7.2 million passenger and commercial vehicles as of 2006, which include 93.5 % light-duty and 6.5 % heavy-duty diesel vehicles (Andrade 2007). Approximately 76.3 % of the light-duty vehicles burn a mixture of 78–80 % gasoline, 22 % consume ethanol (referred to as gasohol), and 17.2 % use hydrated ethanol (95 % ethanol + 5 % water). In comparison, up to 10 % ethanol is used in gasoline in the United States for cars and light vehicles. On a daily basis, public transportation plays a key role in meeting the transportation needs of people living in and commuting from 39 municipalities in São Paulo. São Paulo's complex but successful public bus transit system operates over 26,000 buses on nearly 2,000 routes carrying up to 11 million people daily. The bus system uses especially constructed bus lanes, which enable bus commuters to avoid traffic jams on the streets and buses to travel faster than cars (Molina and Molina 2004; Andrade 2007). There are also several rail transit systems and connecting train lines. A noncontact smart card allows riders discounted prices for multiple rides and makes for easier transitions between bus, train, and subway transit systems.

Bangkok, Thailand

Bangkok has long been considered a city plagued by congestion and poor air quality. The country and metropolitan city governments adapted several environmental strategies in the 1990s and included the formation of environmental law enforcement bodies. The key steps for automobile emission reductions were phasing out lead from fuel by the mid-1990s by making unleaded gas cheaper, introducing vehicle inspection and maintenance programs, and reducing the number of cars on roads by providing better public mass transport options. Bangkok Mass Transit Authority operates air-conditioned and ordinary buses. Articulated buses used in the BRT system are for 90, and other buses are for 40–50 passengers. However, the ordinary buses are being phased out (DB Research 2008; MEGAPOLI 2009). Most of the buses run on diesel, but they are being converted to a cleaner and cheaper natural gas vehicle (NGV) engine. Recently, it operates new routes of NGV-powered air-conditioned vans, shuttling people between the city center and suburban communities.

Future Directions

There is a strong link between mobile sources of GHG, air quality, and the transportation sector. First, transportation emissions are the main cause of air quality problems in many megacities and large urban centers. This seems to be the trend in the megacities of the developing world, where these emissions will soon become the

dominant source of air pollutants. Second, economic growth is closely linked to personal and freight transportation and efficient mobility; thus, restrictions of transportation activities for improving air quality could hinder economic growth. The challenge is thus to improve air quality and reduce GHG emissions while ensuring personal and freight mobility.

Livable Cities and Eco-friendly Lifestyles

A 2004 report by the US National Academies examined the influence of the built environment on physical inactivity in the United States and recommends that opportunities be provided to increase physical activity and study social marketing when changes are made to the built environment – whether retrofitting the existing facilities or constructing new developments and communities (TRB 2005). The lack of physical mobility and walking as a means of traveling about has attributed to obesity and related health problems in US cities. Similar concerns about transport equity are discussed in a 2009 WHO report (WHO 2009b). Modern cities have typically been designed for cars and vehicular traffic. Unlike residents in urban areas, residents in rural places are less likely to walk to work or commercial establishments. This is the case in Mississippi, a rural state which has been ranked one of the top three states for obesity problems for the past several years.

Transport infrastructure and traffic operation management also influence livability of a city and eco-friendliness of its people. Zurich, Switzerland, topped the 2007 list of the most livable cities in Western Europe. Zurich' shares of commuter trips include 24 % walking trips, 40 % public transport, and 36 % private automobiles (Gires 2005). The proportion of private automobiles is almost less than half of the automodal share in other major cities of the western world and Australia. Additionally, bikeways, well-managed intercity rail services, and about 2,000 trains traveling daily to different destinations reflect the eco-friendly lifestyles of Zurich's inhabitants. The long-term sustainability vision adopted by New York City also includes better transit mobility, less congestion, and nonmotorized transport facilities (New York City 2007). Many cities in Western countries have been recognizing the health and environmental benefits of walking and cycling and are trying to provide safe eco-friendly facilities for these activities. However, during the same period, nonmotorized trips in many cities of the developing world have been declining due to a focus on improving motorized vehicle flow on roads and ignoring the needs of pedestrians and other people who depend on mass transit vehicles to commute.

Sustainable Accessibility, Mobility, Commuting, and Economic Prosperity

Mobility and access to affordable and clean transportation to all people in a city is the key to economic growth, social welfare, and quality of life. In emerging economies

and developing countries, economic growth drives development and prosperity. Inadequate mobility places limitations on the poor and other disadvantaged groups to job access, educational institutions, medical care and hospitals, safe recreational facilities, as well as making them more susceptible to fire, rain, and other natural hazards. However, in many large cities of the developing world, adequate mass transit and public transportation modes are not sufficiently provided and managed. Millions of other inhabitants without cars waste long hours in congestion and unsafe travel. Traffic safety data from Karachi shows that in 2007 more than 40 % road fatalities involved pedestrians (Jumma 2008). People in many megacities suffer from stress, air pollution-related health problems, and deterioration of quality of life.

Sustainable mobility is defined as the ability to meet people's mobility needs without adversely impacting societal or ecological values for present and future generations. Due to the important role of nonmotorized modes of travel in promoting better livable cities, a more suitable term is *sustainable accessibility*. Transport strategies for sustainable accessibility and mobility should be environmentally sustainable, socially sustainable to ensure equity among all sectors of the society, and economically and financially sustainable (WRI 2007). Sustainable accessibility is imperative when planning and implementing nonmotorized and multimodal transportation strategies to support sustainable growth of cities while responding to mobility and accessibility needs of all sectors of the society.

Equity and Shared Responsibility

Emissions from fuel combustion are growing faster for the transport sector than for other sectors; this growth is more pronounced in the developing world than in the industrialized and developed countries. Increases in CO_2 emissions have been seen in all transport modes, but particularly in road transport.

Passenger and Freight Rail Modal Share

Emissions from mobile sources in the United States grew 29 % between 1990 and 2004 (Davis and Hale 2007). Residential emissions have increased 13 % in the last two decades. Commuters waste millions of hours and gallons of fuel in traffic congestion in and around cities. Lots of emphasis for reducing congestion and GHG emissions have been on increasing the modal share of mass transit, increasing car fuel efficiency and reducing volume of cars and other two-axle automobiles by travel demand management strategies (car pooling, HOV lanes, and increasing parking prices downtown). The executive branch of the US government and Congress has put forth little known effort to reduce truck travel and associated GHG emissions. Publicly, no pressure has been put on truck travel which produces three to four times more GHG emissions for every gallon of fuel in comparison to cars. Fuel efficiency drive has not been geared to trucks. Considering freight truck business employs millions of heavy truck drivers, both technologically and politically, and there is little pressure on the trucking industry to reduce GHG emissions.

The EPA data (EPA 2005a) also shows that in the United States (a) medium and heavy trucks used for freight travel produced 410.8 million tons of CO_2e emissions in 2007, amounting to 79.5 % increase from 1990, and (b) the truck share of total transportation-related GHG emission was 20.5 % in 2007. But what is the real cost of truck-related GHG emissions and physical damage to road and highways? Here are some underlying facts:

- Trucks occupy more lane space on publicly owned and financed urban roads, intercity roads, and all types of public highways.
- Trucks worsen congestion on urban and suburban highways and cause safety problems and crashes.
- Trucks pay a small share of their use of roads and highways and none for construction or maintenance costs.
- Trucks cause most of the physical damage to pavement structures and bridges, which are structurally designed for truck weight and cumulative applications over the highway design life. Car traffic has virtually no deterioration effect on pavements.
- The road and highway infrastructure is totally built and maintained by taxpayer's money, and trucking companies do not have to factor these costs in their business decisions.
- In other words, freight trucks are being subsidized heavily by taxpayer money for providing and maintaining the road and bridge infrastructure.

A national transport policy decision is needed to apply additional charge or fee on trucks for (1) road-use charge on lump-sum annual basis or truck-travel distance basis, (2) pavement damage cost attributed by annual distance driven, and (3) carbon emission charges per ton mile or ton km because of their significant carbon footprint. The revenue should be used to improve road infrastructure condition, build more intermodal facilities at primary distribution centers throughout the United States, and encourage businesses to use rail mode more often and for longer regional destinations. For example, Norway and Germany have implemented road-use pricing and road tolls on freight trucks; however, several civil society groups argue that this toll revenue should not be simply used on road maintenance and reducing congestion on roads, but to invest in other alternatives, for example, fuel-efficient and mass transit transport.

Compliance with EPA rules for emission reductions of locomotives (EPA 2008b) and more use of fuel-efficient rail transportation of freight throughout the United States and passenger travel on heavily trafficked road corridors will reduce the mobile GHG emissions significantly and improve air quality. Moreover, freight rail mode is privately owned in the United States, and, unlike freight trucks, no taxpayer money is used to subsidize freight rail and bridge infrastructure costs. Here are some numbers reported by the US rail industry (AAR 2010a, b):

- Rail locomotives are four times more fuel efficient than trucking; therefore, moving freight by train instead of truck reduces GHG emissions by 75 %.

- Replacing just 10 % long-haul freight trucks by rail can reduce GHG emissions annually by 12 million tons. This reduction is equivalent to taking off two million cars from roads or planting 280 million trees.
- A train can carry the freight of 280 or more trucks reducing highway congestion and creating space for 1,100 or more cars.
- Rail track costs about 2–4 million dollars per mile in relatively short time in comparison to about 10–15 million dollars per mile for highway construction and 5–10 years to build and for higher life cycle costs due to pavement maintenance needs.

Unlike road vehicles, a dual-track rail infrastructure keeps trains moving at designated speeds safely and efficiently with no "congestion" and no extra emission. The purpose of this discussion is that equal opportunity should be provided by the authorities to rail/train operators on selected long-distance corridors to compete with freight truck operators and expressways for regional commuters. This approach should be considered as a national policy and priority matter. The freight trucks in the United States are subsidized by operating on public highways, whereas the rail/train operators do not have similar assistance of public funds for constructing and maintaining rail infrastructure. Unfortunately, similar disparity is happening in most developing countries where rail generally is operated by public agencies like highways, but rail gets little or no funding to modernize its train stocks and rail infrastructure. National transportation policies have been derived from the lack of understanding of the mobile sources of GHG emissions and effects of other road transportation-related pollutants on public health and quality of life. This led to a gradual decline in rail service quality over the last three decades because passenger rail transport has been predominantly used by the poor people.

Traditionally European countries have been building and using a passenger rail infrastructure. Lately, China has been striving to build rail infrastructure and promoting passenger rail service. Passenger rail mode has been popular in these countries for providing connectivity to airports, as well as for serving commuters in urban areas and intercity corridors. The megacity of São Paulo has been a leader in Brazil in multimodal passenger transport of electric powered commuter rail that serves millions of commuters every day in harmony with BRT and several transit bus routes. By intermodal integration through one electronic ticket accepted by all these services, congestion and travel time were reduced significantly, which led to lower CO_2 emissions (InfrastructureGlobal 2012). Brazil invested in elevated monorail lines in São Paulo and other cities that opened for service just before the 2014 Soccer World Cup.

Recently, an economic viability study was conducted that recommended a commuter rail combined with intercity rail service in the rural area of the Mississippi Gulf Coast (CAIT 2014). Major highways on the Gulf Coast suffer from severe traffic congestion with an average travel speed on I-10 near Gulfport reducing by over 20 % to or below 55 mph (88 kmph). The study revealed that trams and street rail cars, BRT, and high-cost tram or light rail transit are not feasible for the rural area due to degradation of highway traffic capacity from lane occupancy and rail track

intrusion. These also add safety risks of mixed multimodal traffic. Consequently, these modes are not technically feasible from value engineering perspectives of functional and safety requirements. The monorail line is not recommended due to very high initial capita cost. The final recommended strategies include commuter rail passenger service on existing freight rail tracks: (1) "Casino Train" in E-W corridor and (2) commuter rail line "Beach Train" in N-S corridor. Considering direct revenues only (fare, advertising on train and stations, annual fee charges to concessions on stations and shuttle service operators), the breakeven period is 6–7 years until the rail service will become financially self-sustaining (CAIT 2014). Other benefits include an increase in income from casino patrons and tourists/visitors, additional gaming and sales tax revenues, reduction in emissions, and fuel cost savings as a result of moving a significant number of auto commuters to rail lines. Economic development impacts will create a total of 500 jobs and boost regional economy.

Involving Stakeholders and Public for Sustainable Transport and Mitigation Strategies

Successful implementation of socially equitable and environmentally sustainable development requires area monitoring of air pollutants including CO_2, life cycle cost analysis, marketing plans, involvement of all stakeholders (oil and motor vehicle industries, retail businesses, and transport services), and public awareness campaigns for shared responsibility within a region and globally. It is estimated that 30 % of fuel is wasted in congested cities in finding parking places. Many car manufacturers are working on future concept cars for megacity markets to serve the city center area without traditional carbon footprint (Moves 2010). These small lightweight lithium battery-powered green cars are designed for lower speeds and very small or zero CO_2 emission per mile. By reducing vehicular emissions, air quality will be protected, greenhouse gases will be reduced, and the effect on global warming will diminish. In order to develop and implement green transport technologies to reduce GHG emissions, it is recommended for governments at national, state/provincial, and local levels to institute policies and provide initiatives for green technology growth. At the same time, a push for public support is crucial for the future success of green technology implementation so that it may be firmly established in the long term.

Stakeholders' cooperation and involvement are required for the following: (1) sustainable development of the built environment, (2) identification of less polluting transportation technologies, and (3) implementation of abatement strategies to mitigate congestion and its adverse impacts on traffic safety, global warming, and air quality. Stakeholders should be identified at community, regional, and national levels. An integrated approach involving all stakeholders can help manage and reverse many blighted parts of our cities, urban and suburban communities, and rural and industrial areas to livable conditions. Governments must take initiatives to increase public awareness of mobile GHG problems, mitigate adverse transportation impacts and sprawl, and improve air quality and quality of life of millions of people each year. The use of nongovernmental organizations (NGOs) (WRI 2007; Foletta

and Heyen-Perschon 2009; Jumma 2008) and public–private partnerships should be promoted to create environmentally and financially sustainable transport management strategies.

During the last few years, social media has been extensively used by interested people, news media, and the general public to convey news and campaign messages. Blogging and Twitter have empowered all people in a region or globally to interact and communicate with others (InfrastructureGlobal 2011; Twitter 2014). Environmental awareness, energy, CO_2 emissions, and climate change impacts are popular topics on social media, which have been powerful to educate, disseminate information, and raise global concerns to reduce carbon emissions.

Global Responsibility for CO_2 Reductions

During 2013 and 2014 major initiatives have emerged on international levels to reduce CO_2 and other harmful emissions from energy and transport sectors. Climate change impacts are triggering major natural disasters in some Asian countries who are not major contributors to global GHG emissions, displacing millions of people and destructing their economies (Twitter 2014). The White House launched its Climate Action Plan (CAP) in 2013 to prepare US citizens and communities for climate change adaptation in response to an increase in frequency of weather-related floods and coastal hurricane disasters (White 2014). The most recently concluded climate change talks in Peru's capital Lima in December 2014 reached agreement on carbon targets for all countries (The Guardian 2014). And with 2014 on course to be the hottest year on record, activists and campaigners warned that the plan was far too weak. Countries are expected to declare their proposed emission reduction targets by March 2015. China, with 8,548 million tons of CO_2 emissions from energy in 2012 overtaking the United States by 38 %, will formally pledge to cut its greenhouse gas emissions, joined by similar pledges from India, Brazil, and other developing countries.

Concluding Remarks

The vehicle emission and demand on energy (due to the increased built areas and population migration from rural areas) have adverse impacts on the environment, both in air quality degradation and increases in greenhouse gas emission. Governments throughout the world must consider reduction in greenhouse gas emissions and other air pollution a national priority. Further, they should involve all stakeholders in finding multimodal solutions including nonmotorized trips for the mobility and accessibility in growing cities and long-haul transport needs to support development and economy. A reasonably quantifiable sustainability scale is CO_2e emission per capita that can be used worldwide for evaluating performance of sustainable transportation and development policies by government agencies and cities.

The worldwide reduction of greenhouse gases from transportation sources and the efficient use of energy in urban and industrial applications should be important for

sustaining the quality of life of current and future generations. Although awareness has increased in the public related to the global damaging effect of greenhouse gas emission and public health hazards from other air pollution, when it is directly tied to economic prosperity, survival, and individual freedom to travel by car, vehicle emissions and air pollution becomes secondary. By providing knowledge to decision-making authorities in both industrialized and developing countries, it is expected that they will be able to adapt and implement many available high payoff research products in response to sustainable national transportation planning priorities.

Acknowledgments The author's research was primarily conducted at the Center for Advanced Infrastructure Technology (CAIT) of the University of Mississippi. Thanks are due to the author's former graduate students Katherine Osborne, Jessica Headrick, Bikila Wodajo, Carla Brown, and Kanok Boriboonsoms for their contributions. Thanks are also due to CAIT research assistants Eric Shackelford for the CO_2 calculations associated with road vehicle emissions in selected cities, Seth Cobb for assistance in the Gulf Coast passenger rail study and Cherrelle Williams for editorial assistance.

Abstract

The world has a wide variety of biofeedstocks. Biomass is a term used to describe any material of recent biological origin, including plant materials such as trees, grasses, agricultural crops, or animal manure. In this chapter, the formation of biomass by photosynthesis and the different mechanisms of photosynthesis giving rise to biomass classification are discussed. Then, these classifications and composition of biomass are explained. The various methods used to make biomass amenable for energy, fuel, and chemical production are discussed next. These methods include pretreatment of biomass, biochemical routes of conversion like fermentation, anaerobic digestion, transesterification, and thermochemical routes like gasification and pyrolysis. An overview of current and future biomass feedstock materials, for example, algae, perennial grass, and other forms of genetically modified plants, is described including the current feedstock availability in the United States.

Introduction

The world is dependent heavily on coal, petroleum, and natural gas for energy and fuel and as feedstock for chemicals. These sources are commonly termed as fossil or nonrenewable resources. Geological processes formed fossil resources over a period of millions of years by the loss of volatile constituents from plant or animal matter. The human civilization has seen a major change in obtaining its material needs through abiotic environment only recently. Plant-based resources were the predominant source of energy, organic chemicals, and fibers in the western world as recently as 200 years ago, and the biotic environment continues to play a role in many developing countries. The discovery of coal and its usage has been traced back to fourth century B.C. Comparatively, petroleum was a newer discovery in the nineteenth century, and its main use was to obtain kerosene for burning oil lamps. Natural gas, a mixture containing primarily methane, is found associated with the other fossil resources, for example, in coal beds. The historical, current, and projected use of fossil resources for energy consumption is given in Fig. 1. Petroleum, coal, and natural gas constitute about 86 % of resource consumption in the United States. The remaining 8 % comes from nuclear, and 6 % comes from renewable energy. Approximately 3 % of total crude petroleum is currently used for the production of chemicals, the rest being used for energy and fuels.

The fossil resources are extracted from the earth's crust, processed, and burnt or converted to chemicals. The proven reserves, in North America, for coal were 276,285 million tons (equivalent to 5,382 EJ [exajoule $= 10^{18}$ J]) in 1990, for oil were 81 billion barrels (equivalent to 476 EJ) in 1993, and for natural gas were 329×10^3 billon ft^3 (equivalent to 347 EJ) in 1993 (Klass 1998). The United States has considerable reserves of crude oil, but the country is also dependent on oil imports from other countries for meeting the energy requirements. The crude oil price has fluctuated over the past 40 years, the most recent price increase over $130

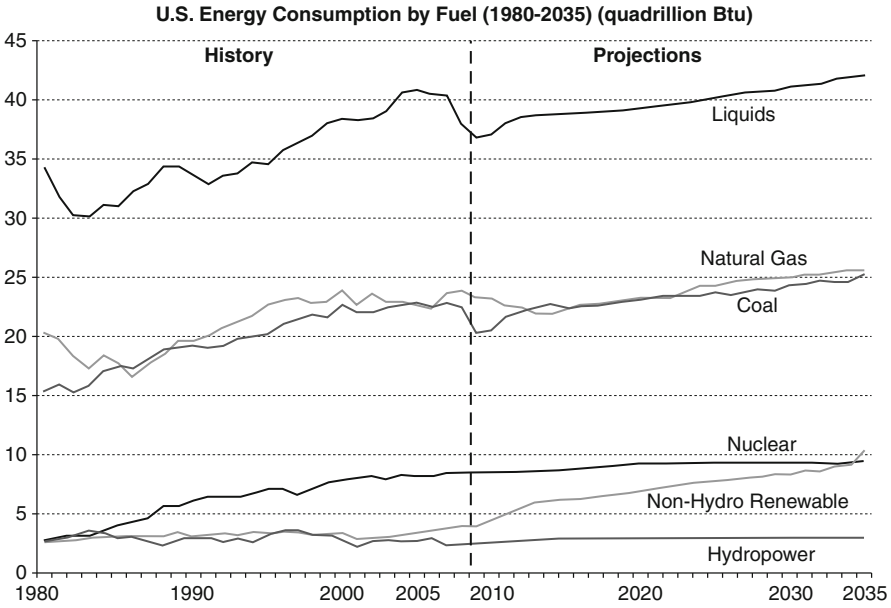

Fig. 1 Energy consumption in the United States, 1980–2035 (EIA 2010)

per barrel being in 2008. The EIA published a projection of the price of crude oil over the next 25 years, where high and a low projections were given in addition to the usual projection of crude oil price, as shown in Fig. 2 (EIA 2010). The projection shows a steady increase in price of crude to above $140 per barrel in 2035. With a high price trend, the crude can cost over $200 per barrel.

The fossil resources are burnt or utilized for energy, fuels, and chemicals. The process for combustion of fossil resources involves the oxidation of carbon and hydrogen atoms to produce carbon dioxide and water vapor and releasing heat from the reactions. Impurities in the resource, such as sulfur, produce sulfur oxides, and incomplete combustion of the resource produces methane. The Intergovernmental Panel on Climate Change identified that changes in atmospheric concentration of greenhouse gases (GHG), aerosols, land cover, and solar radiation alter the energy balance of the climate system (IPCC 2007). These changes are also termed as climate change. The green house gases include carbon dioxide, methane, nitrous oxide, and fluorinated gases. Atmospheric concentrations of carbon dioxide (379 ppm) and methane (1,774 ppb) in 2005 were the highest amounts recorded on the earth (historical values computed from ice cores spanning many thousands of years) till date. The IPCC report states that global increases in CO_2 concentrations are attributed primarily to fossil resource use. In the United States, there was approximately 5,814 million metric tons of carbon dioxide released into the atmosphere in 2008, and this amount is projected to increase to 6,320 million metric tons in 2035 (EIA 2010) as shown in Fig. 3.

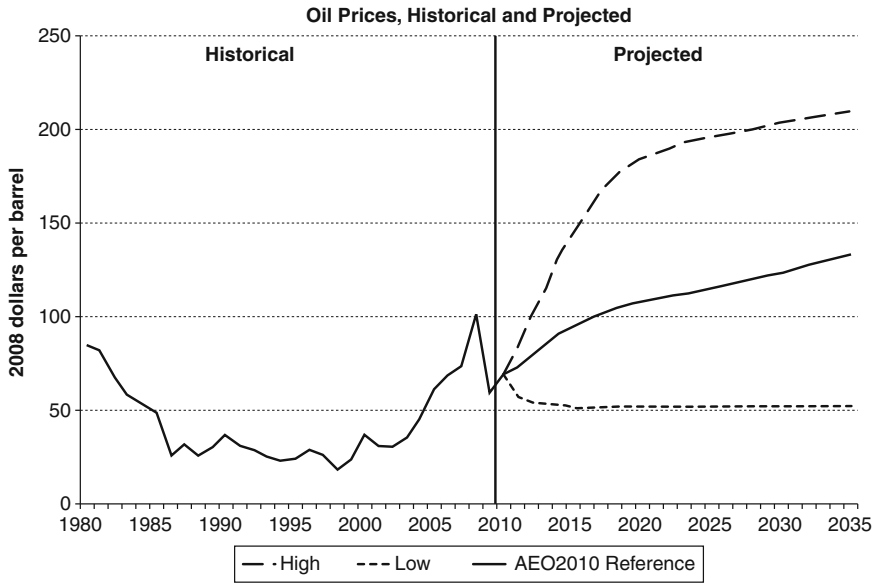

Fig. 2 Oil prices (in 2008 dollars per barrel), historical data, and projected data (Adapted from EIA (2010))

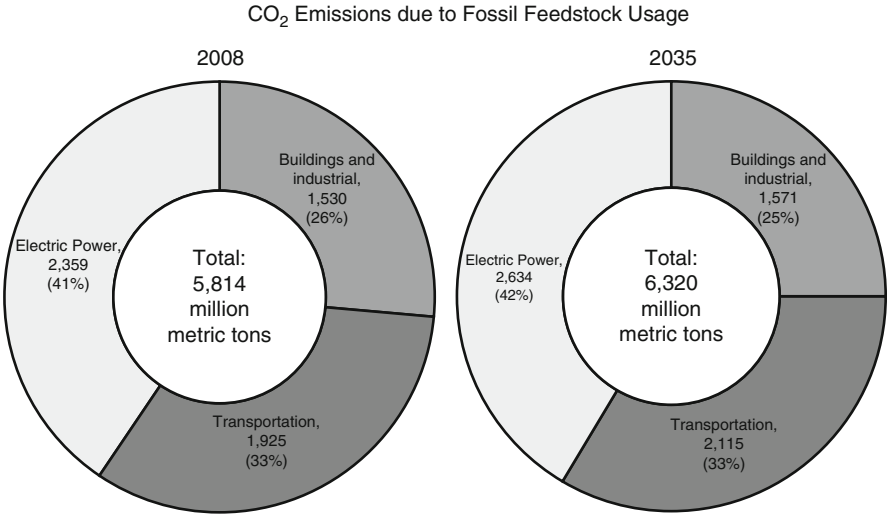

Fig. 3 Carbon dioxide emissions in 2008 (current) and 2035 (projected) due to fossil feedstock usage (Adapted from EIA (2010))

The increasing trends in resource consumption, resource material cost, and consequent increase carbon dioxide emissions from anthropogenic sources indicate that a reduction of fossil feedstock usage is necessary to address climate change.

This has prompted world leaders, organizations, and companies to look for alternative ways to obtain energy, fuels, and chemicals.

Thus, carbon fixed naturally in fossil and nonrenewable resources over millions of years is released to the atmosphere by anthropogenic sources. A relatively faster way to convert the atmospheric carbon dioxide into useful resources is by photosynthetic fixation into biomass. The life cycle of the fossil resources showed that the coal, petroleum, and natural gas all are derivatives of decomposed biomass on the earth's surface trapped in geological formations. Thus, biomass, being a precursor to the conventional nonrenewable resources, can be used as fuel, generate energy, and produce chemicals with some modifications to existing processes.

Biomass can be classified broadly as all the matter on earth's surface of recent biological origin. Biomass includes plant materials such as trees, grasses, agricultural crops, and animal manure. Aquatic plants, such as algae, also undergo photosynthesis and provide good sources for carbohydrates and lipids. Just as petroleum and coal require processing before the use as feedstock for the production of fuels, chemicals, and energy, biomass also requires processing such that the resource potential can be utilized fully. As explained earlier, biomass is a precursor to fossil feedstock, and a comparison between the biomass energy content and fossil feedstock energy content is required. The heating value of fuel is the measure of heat released during the complete combustion of fuel at a given reference temperature and pressure. The higher or gross heating value is the amount of heat released per unit weight of fuel at the reference temperature and pressure, taking into account the latent heat of vaporization of water. The lower or net heating value is the heat released by fuel excluding the latent heat of vaporization of water. The higher heating values of some bioenergy feedstocks, liquid biofuels, and conventional fossil fuels are given in Table 1. It can be seen from the table that the energy content of the raw biomass species is less than bioethanol, and biodiesel compares almost equally to the traditional fossil fuels.

This chapter gives an outline for the use of biomass as feedstock. The following sections will discuss various methods for biomass formation, biomass composition, conversion technologies, and feedstock availability.

Biomass Formation

Biomass is the photosynthetic sink by which atmospheric carbon dioxide and solar energy are fixed into plants (Klass 1998). These plants can be used to convert the stored energy in the form of fuels and chemicals. The primary equation of photosynthesis is given by Eq. 1:

$$6CO_2 + 6H_2O + \text{Light} \rightarrow C_6H_{12}O_6 + 6O_2 \quad (1)$$

The photosynthesis process utilizes inorganic material (carbon dioxide and water) to form organic compounds (hexose) and releases oxygen. The Gibbs free energy change for the process is +470 KJ per mole of CO_2 assimilated, and the

Table 1 Heating value of biomass components (Klass 1998; McGowan 2009)

Component	Heating value (gross) (GJ/MT unless otherwise mentioned)
Bioenergy feedstocks	
Corn stover	17.6
Sweet sorghum	15.4
Sugarcane bagasse	18.1
Sugarcane leaves	17.4
Hardwood	20.5
Softwood	19.6
Hybrid poplar	19.0
Bamboo	18.5–19.4
Switchgrass	18.3
Miscanthus	17.1–19.4
Arundo donax	17.1
Giant brown kelp	10.0 MJ/dry kg
Cattle feedlot manure	13.4 MJ/dry kg
Water hyacinth	16.0 MJ/dry kg
Pure cellulose	17.5 MJ/dry kg
Primary biosolids	19.9 MJ/dry kg
Liquid biofuels	
Bioethanol	28
Biodiesel	40
Fossil fuels	
Coal (low rank; lignite/sub-bituminous)	15–19
Coal (high rank; bituminous/anthracite)	27–30
Oil (typical distillate)	42–45

corresponding enthalpy change is +470 KJ. The positive sign on the energy denotes that energy is absorbed in the process. The initial product for biochemical reactions for photosynthetic assimilation is sugars. Secondary products are derived from key intermediates of the biochemical reactions and include polysaccharides, lipids, and proteins. A wide range of other organic compounds may also be produced in certain biomass species, such as simple low molecular weight organic chemicals (e.g., acids, alcohols, aldehydes, and ethers), complex alkaloids, nucleic acids, pyrroles, steroids, terpenes, waxes, and high molecular weight polymers such as polyisoprenes. A detailed description of how these components are formed from the intermediates is beyond the scope of this chapter. The basic reactions for photosynthesis will be discussed in this section, and the key products will be explained.

Photosynthesis is a two-phase process comprising of the "light reactions" (in the presence of light) and "dark reactions" (in the absence of light). The light reactions capture light energy and convert it to chemical energy and reducing power. In the

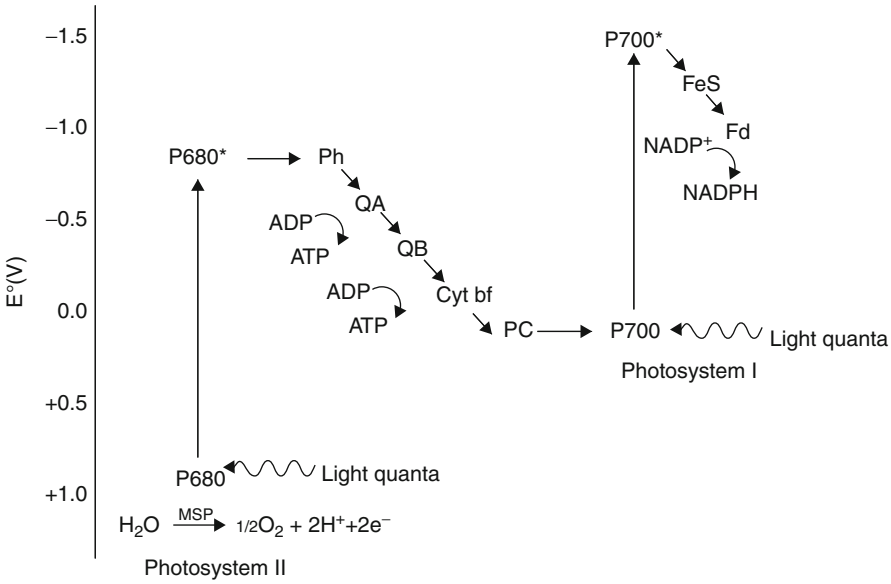

Fig. 4 Z-scheme of biomass photosynthesis P680 and P700 is the chlorophylls of the photosystem II and I, respectively. (*MSP* manganese stabilizing protein, *Ph* pheophytin, *Q* quinone, *Cyt* cytochrome, *PC* plastocyanin, *FeS* nonheme iron-sulfur protein, *Fd* ferredoxin) (Adapted from Drapcho et al. (2008))

dark reactions, chemical energy and the reducing power from light reactions are used to fix atmospheric carbon dioxide.

The light reaction in photosynthesis is explained using the "Z-scheme" diagram as shown in Fig. 4 (Drapcho et al. 2008). Solar energy in the wavelength range of 400–700 nm is captured by chlorophylls within the cells of plants and microorganisms like green algae or cyanobacteria. The flow of electrons is shown in Fig. 4. Two photosystems, photosystem I and photosystem II, are used in the light reactions. All the terms in Fig. 4 are not explained in this text, but the most important intermediates are listed below the figure. In photosystem II (PSII), light energy at 680 nm wavelength is used to split water molecules as shown in Eq. 2:

$$2H_2O \overset{\text{light energy}}{\rightarrow} O_2 + 4H^+4e^- \tag{2}$$

The electrons are accepted by the chlorophyll in PSII and reduce it from a reduction potential of +1 V to approximately −0.8 V. The electrons are then transferred to photosystem I (PSI) through a series of membrane-bound electron carrier molecules. ATP (adenosine triphosphate) is produced as the electrons are transferred due to a proton-motive force that develops as protons are pumped across the thylakoid membrane. Acceptance of the electron reduces the potential of PSI to approximately −1.4 V. The reduction potential of PSI is then sufficient to reduce ferrodoxin, which

in turn reduces NADP+ to NADPH. This NADPH is used to reduce inorganic carbon for new cell synthesis.

Thus, the light reactions are common to all plant types, where eight photons per molecule of carbon dioxide excite chlorophyll to generate ATP (adenosine triphosphate) and NADPH (reduced nicotinamide adenosine dinucleotide phosphate) along with oxygen (Klass 1998). The "Z-scheme" transfers electrons from a low chemical potential in water to a higher chemical potential in NADPH, which is necessary to reduce CO_2.

The ATP and NADPH produced in the light reactions react in the dark to reduce CO_2 and form the organic components in biomass via the dark reactions and regenerate ADP (adenosine diphosphate) and $NADP^+$ (nicotinamide adenosine dinucleotide phosphate) for the light reactions. The biochemical pathways and organic intermediates involved in the reduction of CO_2 to sugars determine the molecular events of biomass growth and differentiate between various kinds of biomass.

In photosynthesis, CO_2 enters the leaves or stems of biomass through stoma, the small intercellular openings in the epidermis. These openings provide main route for photosynthetic gas exchange and water vapor loss in transpiration. The dark reactions can proceed in accordance with at least three different pathways, the Calvin-Benson cycle, the C4 cycle, and the CAM cycle, as discussed in the following sections.

The Calvin-Benson Cycle

The Calvin-Benson cycle is shown in Fig. 5. The overall reaction for the Calvin cycle is given in Eq. 3. Plant biomass species, which use the Calvin-Benson cycle to form products, are called the C3 plants (Klass 1998).

$$6CO_2 + 12\ \ NADPH + 18\ \ ATP \rightarrow C_6H_{12}O_6 + 12NADP^+ + 18\ \ ADP \quad (3)$$

This cycle produces the 3-carbon intermediate 3-phosphoglyceric acid (3-phosphoglycerate) and is common to fruits, legumes, grains, and vegetables. C3 plants usually exhibit low rates of photosynthesis at light saturation, low light saturation points, sensitivity to oxygen concentration, rapid photorespiration, and high CO_2 compensation points. The light saturation point is the light intensity beyond which it is not a limiting factor for photosynthesis. The CO_2 compensation point is the CO_2 concentration in the surrounding environment below which more CO_2 is respired by the plant than is photosynthetically fixed. Typical C3 biomass species are alfalfa, barley, chlorella, cotton, *Eucalyptus*, *Euphorbia lathyris*, oats, peas, potato, rice, soybean, spinach, sugar beet, sunflower, tall fescue, tobacco, and wheat. These plants grow favorably in cooler climates.

The C4 Cycle

The C4 cycle is shown in Fig. 6. In this cycle, CO_2 is initially converted to 4-carbon dicarboxylic acids (malic or aspartic acids) (Klass 1998). Phosphoenolpyruvic acid

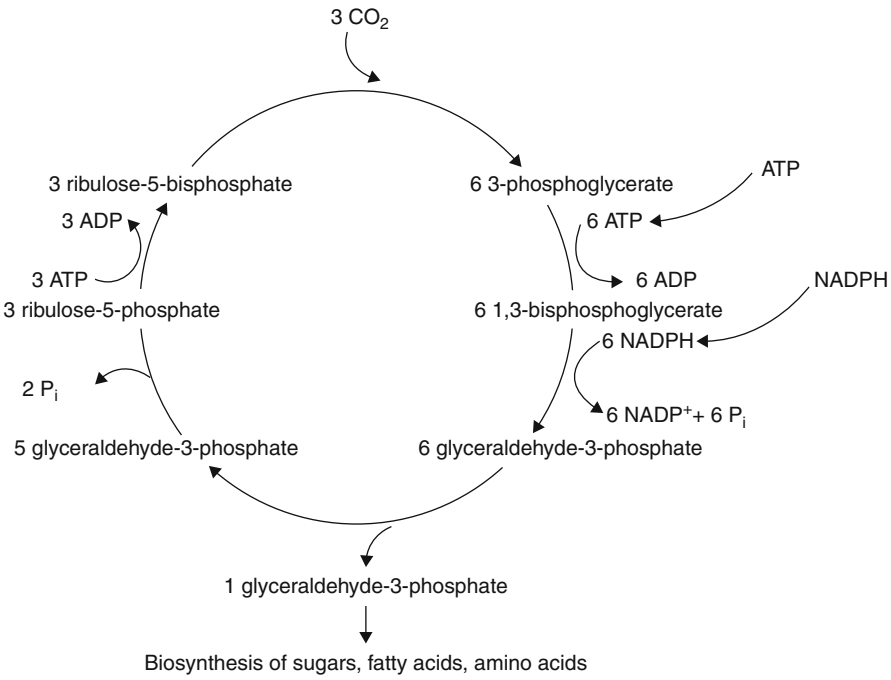

Fig. 5 Calvin-Benson cycle for photosynthesis (Adapted from Drapcho et al. (2008))

reacts with carbon dioxide to form oxaloacetic acid. Malic or aspartic acid is formed from the oxaloacetic acid. The C4 acid is transported to bundle sheath cells where decarboxylation occurs to regenerate pyruvic acid, which is returned to the mesophyll cells to initiate another cycle. The CO_2 liberated in the bundle sheath cells enter the C3 cycle described above, and it is in this C3 cycle where the CO_2 fixation occurs. The subtle difference between the C3 and C4 cycles is believed to be responsible for the wide variations in biomass properties. Compared to C3 biomass, C4 biomass is produced in higher yields with higher rates of photosynthesis, high light saturation points, and low levels of respiration, low carbon dioxide compensation points, and greater efficiency of water usage. Typical C4 biomass includes crops such as sugarcane, corn, and sorghum and tropical grasses like Bermuda grass.

The CAM Cycle

The CAM cycle is the crassulacean acid metabolism cycle, which refers to the capacity of chloroplast containing biomass tissues to fix CO_2 in dark reactions leading to synthesis of free malic acid (Klass 1998). The mechanism involves β-carboxylation of phosphoenolpyruvic acid by phosphoenolpyruvate carboxylase enzyme and the subsequent reduction of oxaloacetic acid by maleate dehydrogenase.

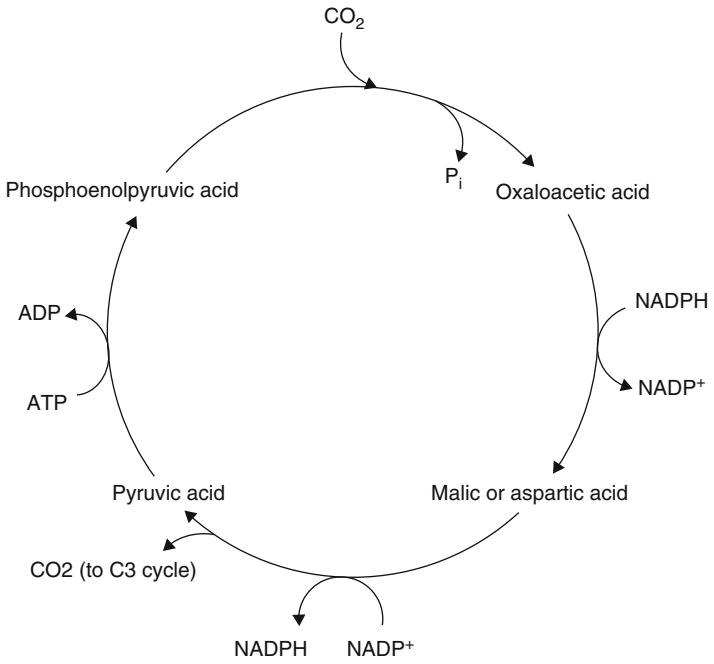

Fig. 6 Biochemical pathway from carbon dioxide to glucose for C4 biomass (Adapted from Klass (1998))

Biomass species in the CAM category are typically adapted to arid environments and have low photosynthesis rates and higher water usage efficiencies. Plants in this category include cactus and succulents like pineapple. The CAM has evolved so that the initial CO_2 fixation can take place in the dark with much less water loss than C3 or C4 pathways. CAM biomass also conserves carbon by recycling endogenously formed CO_2. CAM biomass species have not been exploited commercially for use as biomass feedstock.

Thus, different photosynthetic pathways produce different intermediates leading to different kinds of biomass. The following section discusses the different components in biomass.

Biomass Classification and Composition

The previous section gave the mechanisms for the formation of biomass by photosynthesis. The classification and composition of biomass will be discussed in this section. Biomass can be classified into two major subdivisions, crop biomass and wood (forest) biomass. There are other sources of biomass, like waste from municipal areas and animal wastes, but these can be traced back to the two major sources. Crop biomass primarily includes corn, sugarcane, sorghum, soybeans, wheat, barley,

rice, etc. These contain carbohydrates, glucose, starch, or oils as its primary constituents. Wood biomass is composed of cellulose, hemicellulose, and lignin. Examples of woody biomass include grasses, stalks, stover, etc. Starch and cellulose are both polymeric forms of glucose, a 6-carbon sugar. Hemicellulose is a polymer of xylose. Lignin is composed of phenolic polymers. Oils are composed of triglycerides. Other biomass components, which are generally present in minor amounts, include proteins, sterols, alkaloids, resins, terpenes, terpenoids, and waxes.

Apart from crop and woody biomass, a class of microorganisms exist which are capable of producing biomass. These are single-celled organisms like algae or cyanobacteria and have the capability of photosynthesis to produce oils, carbohydrates, proteins, etc. These are discussed in details in a later section.

The components of biomass are discussed in details below.

Saccharides and Polysaccharides

Saccharides and polysaccharides are hydrocarbons with the basic chemical structure of CH_2O. The hydrocarbons occur in nature as 5-carbon or 6-carbon ring structure. The ring structures may contain only one or two connected rings, which are known as monosaccharides, disaccharides, or simply as sugars, or they may be very long polymer chains of the sugar building blocks.

The simplest six-sided saccharide (hexose) is glucose. Long-chained polymers of glucose or other hexoses are categorized either as starch or cellulose. The characterization is discussed in the following sections. The simplest five-sided sugar (pentose) is xylose. Pentoses form long-chain polymers categorized as hemicellulose. Some of the common 6-carbon and 5-carbon monosaccharides are listed in Table 2.

Starch is a polymer of glucose as the monomeric unit (Paster et al. 2003). It is a mixture of α- amylose and amylopectin as shown in Fig. 7. α-Amylose is a straight chain of glucose molecules joined by α-1,4-glucosidic linkages as shown in Fig. 7a. Amylopectin and amylase are similar except that short chains of glucose molecules branch off from the main chain (backbone) as shown in Fig. 7b. Starches found in nature contain 10–30 % α-amylose and 70–90 % amylopectin. The α-1,4-glycosidic linkages are bent and prevent the formation of sheets and subsequent layering of polymer chains. As a result, starch is soluble in water and relatively easy to break down into utilizable sugar units.

Lignocellulosic Biomass

The non-grain portion of biomass (e.g., cobs, stalks), often referred to as agricultural stover or residues, and energy crops such as switchgrass are known as lignocellulosic biomass resources (also called cellulosic). These are comprised of cellulose, hemicellulose, and lignin (Paster et al. 2003). Generally, lignocellulosic material contains 30–50 % cellulose, 20–30 % hemicellulose, and 20–30 % lignin. Figure 8a illustrates

Table 2 Common 6-carbon and 5-carbon monosaccharides

6-Carbon sugars	Structure	5-Carbon sugars	Structure
D-Fructose		D-Xylose	D-Glucose		D-Ribulose	D-Gulose		D-Ribose	D-Mannose		D-Arabinose	D-Galactose			

how cellulose, hemicellulose, and lignin are physically mixed in lignocellulosic biomass. Figure 8b illustrates how pretreatment is necessary to break the polymeric chains before cellulose and hemicellulose can be used for chemical conversions. Some exceptions to this are cotton (98 % cellulose) and flax (80 % cellulose). Lignocellulosic biomass is considered to be an abundant resource for the future bio-industry. Recovering the components in a cost-effective way requires pretreatment processes discussed in a later section.

Cellulose

Cellulosic biomass comprises 35–50 % of most plant material. Cellulose is a polymer of glucose with degree of polymerization of 1,000–10,000 (Paster et al. 2003). Cellulose is a linear unbranched polymer of glucose joined together by $\beta - 1,4$-glycosidic linkages as shown in Fig. 9. Cellulose can either be crystalline or amorphous. Hydrogen bonding between chains leads to chemical stability and insolubility and serves as a structural component in plant walls. The high degree of crystallinity of cellulose makes lignocellulosic materials much more resistant than

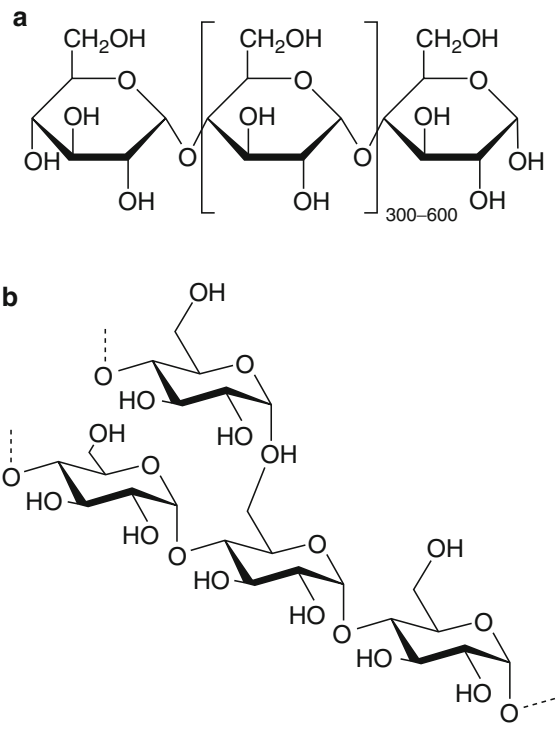

Fig. 7 Structure of starch; (**a**) α-amylose; (**b**) amylopectin

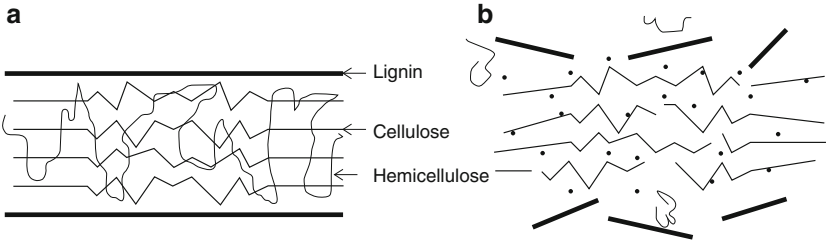

Fig. 8 (**a**) Physical arrangement of lignocellulosic biomass; (**b**) lignocellulosic biomass after pretreatment

starch to acid and enzymatic hydrolysis. As the core structural component of biomass, cellulose is also protected from environmental exposure by a sheath of lignin and hemicellulose. Extracting the sugars of lignocellulosics therefore involves a pretreatment stage to reduce the recalcitrance (resistance) of the biomass to cellulose hydrolysis.

Hemicellulose

Hemicellulose is a polymer containing primarily 5-carbon sugars such as xylose and arabinose with some glucose and mannose dispersed throughout (Paster et al. 2003).

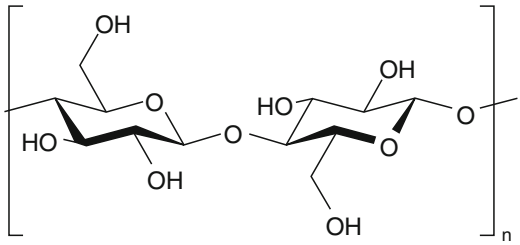

Fig. 9 Structure of cellulose

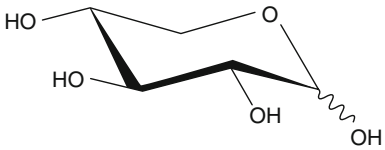

Fig. 10 Structure of xylose, building block of hemicellulose

The structure of xylose is shown in Fig. 10. It forms a short-chain polymer that interacts with cellulose and lignin to form a matrix in the plant wall, thereby strengthening it. Hemicellulose is more easily hydrolyzed than cellulose. Much of the hemicellulose in lignocellulosic materials is solubilized and hydrolyzed to pentose and hexose sugars during the pretreatment stage. Some of the hemicellulose is too intertwined with the lignin to be recoverable.

Lignin

Lignin helps to bind the cellulose/hemicelluloses matrix while adding flexibility to the mixture. The molecular structure of lignin polymers is very random and disorganized and consists primarily of carbon ring structures (benzene rings with methoxyl, hydroxyl, and propyl groups) interconnected by polysaccharides (sugar polymers) as shown in Fig. 11. The ring structures of lignin have great potential as valuable chemical intermediates, mainly aromatic compounds. However, separation and recovery of the lignin is difficult. It is possible to break the lignin-cellulose-hemicellulose matrix and recover the lignin through treatment of the lignocellulosic material with strong sulfuric acid. Lignin is insoluble in sulfuric acid, while cellulose and hemicellulose are solubilized and hydrolyzed by the acid. However, the high acid concentration promotes the formation of degradation products that hinder the downstream utilization of the sugars. Pyrolysis can be used to convert the lignin polymers to valuable products, but separation techniques to recover the individual chemicals are lacking. Instead, the pyrolyzed lignin is fractionated into a bio-oil for fuels and high phenolic content oil which is used as a partial replacement for phenol in phenol-formaldehyde resins.

Lipids, Fats, and Oils

Oils can be obtained from oilseeds like soybean, canola, etc. Vegetable oils are composed primarily of triglycerides, also referred to as triacylglycerols.

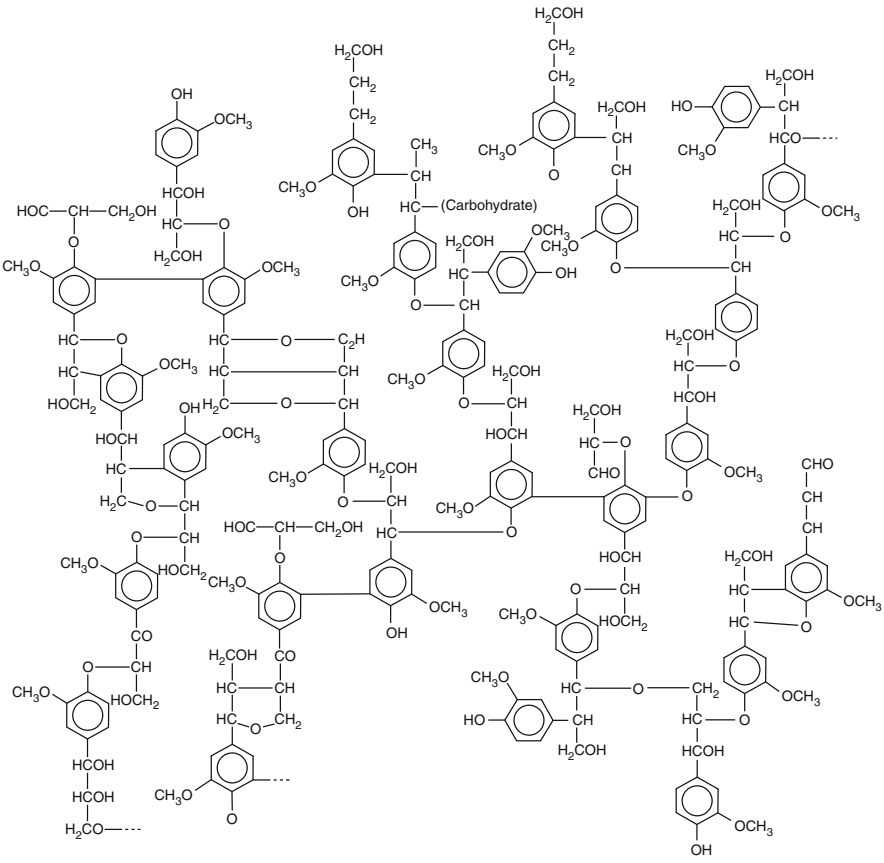

Fig. 11 Structure of lignin (Glazer and Nikaido 1995)

Triglycerides contain a glycerol molecule as the backbone with three fatty acids attached to glycerol's hydroxyl groups. The structure of a triglyceride is shown in Fig. 12 with linoleic acid as the fatty acid chain. In this example, the three fatty acids are all linoleic acid, but triglycerides could be a mixture of two or more fatty acids. Fatty acids differ in chain length and degree of condensation. The fatty acid profile and the double bonds present determine the property of the oil. These can be manipulated to obtain certain performance characteristics. In general, the greater the number of double bonds, the lower the melting point of the oil.

Proteins

Proteins are polymers composed of natural amino acids, bonded together through peptide linkages (Klass 1998). They are formed via condensation of the acids through the amino and carboxyl groups by removal of water to form polyamides.

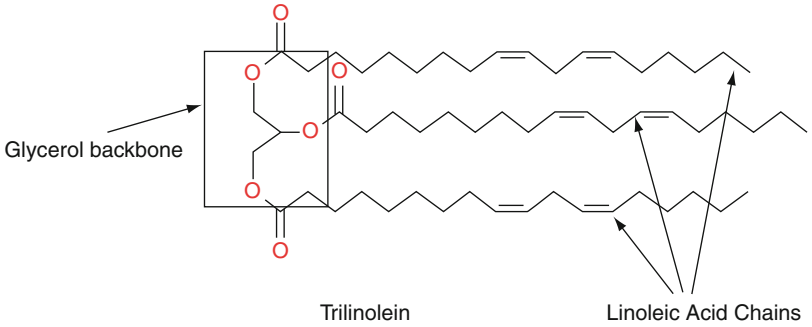

Fig. 12 Formation of triglycerides (linoleic acid as representative fatty acid chain)

Table 3 Amino acid groups present in proteins

Family	Amino acids
Glutamate	Glutamine, arginine, proline
Aspartate	Asparagine, methionine, threonine, isoleucine, lysine
Aromatic	Tryptophan, phenylalanine, tyrosine
Serine	Glycine, cysteine
Pyruvate	Alanine, valine, leucine

Proteins are present in various kinds of biomass as well as animals. The concentration of proteins may approach zero in different biomass systems, but the importance of proteins arises while considering enzyme catalysis that promotes the various biochemical reactions. The apparent precursors of the proteins are amino acids in which an amino group, or imino group in a few cases, is bonded to the carbon atom adjacent to the carboxyl group. Many amino acids have been isolated from natural sources, but only about 20 of them are used for protein biosynthesis. These amino acids are divided into five families: glutamate, aspartate, aromatic, serine, and pyruvate. The various amino acids under these groups are shown in Table 3.

Table 4 gives the composition of some biomass species based on the above components. The biomass types are marine, fresh water, herbaceous, woody, and waste biomass, and a representative composition is given in the table. Other components not included in the composition are ash and crude protein.

Biomass Conversion Technologies

The conversion of biomass involves the treatment of biomass so that the solar energy stored in the form of chemical energy in the biomass molecules can be utilized. Common biomass conversion routes begin with pretreatment in case of cellulosic and grain biomass and extraction of oil in case of oilseeds. Then the cellulosic or starch containing biomass undergoes fermentation (anaerobic or aerobic),

Table 4 Component composition of biomass feedstocks (Klass 1998; McGowan 2009)

Name	Celluloses (dry wt %)	Hemicelluloses (dry wt %)	Lignins (dry wt %)
Corn stover	35	28	16–21
Sweet sorghum	27	25	11
Sugarcane bagasse	32–48	19–24	23–32
Hardwood	45	30	20
Softwood	42	21	26

Arundo donax	31	30	21
RDF (refuse-derived fuel)	65.6	11.2	3.1
Water hyacinth	16.2	55.5	6.1
Bermuda grass	31.7	40.2	25.6
Pine	40.4	24.9	34.5

gasification, or pyrolysis. The oil in oilseeds is transesterified to get desired product. There are other process technologies including hydroformylation, metathesis, and epoxidation, related with direct conversion of oils to fuels and chemicals, the details of which are not included in this chapter.

Biomass Pretreatment

Biomass is composed of components such as starch, sugars, cellulose, hemicellulose, lignin, fats, oils, etc., as described in the previous section. Often two or more of these components are physically mixed with each other, and a pretreatment is necessary before the chemical energy in biomass molecules can be utilized in a useful way. For example, lignocellulosic biomass is composed of cellulose, hemicelluloses, and lignin. The cellulose and hemicelluloses are polysaccharides of hexose and pentose. Any process that uses biomass needs to be pretreated so that the cellulose and hemicellulose in the biomass are broken down to their monomeric form. Pretreatment processes produce a solid pretreated biomass residue that is more amenable to enzymatic hydrolysis by cellulases and related enzymes than native biomass. Biocatalysts like yeasts and bacteria can act only on the monomers and ferment them to alcohols, lactic acid, etc. The pretreatment process also removes the lignin in biomass which is not acted upon by enzymes or fermented further.

Pretreatment usually begins with a physical reduction in the size of plant material by milling, crushing, and chopping (Teter et al. 2006). Some of the equipment used in the industry for size reduction include rotary breaker, roll crusher, hammer mill,

impactor, tumbling mill, and roller mill. The size of biomass particles needs to be reduced to nominal size of 1–6 mm (Womac et al. 2007). For example, in the processing of sugarcane, the cane is first cut into segments and then fed into consecutive rollers to extract cane juice rich in sucrose and physically crush the cane, producing a fibrous bagasse having the consistency of sawdust. In the case of corn stover processing, the stover is chopped with knives or ball milled to increase the exposed surface area and improve wettability. Corn is hammer milled to flour before it is transferred to cook tanks.

The physical reduction in size enables a wider surface area to come in contact for further chemical conversions. However, physical size reduction is an energy-intensive process, and an optimum size reduction is required to balance energy consumption and conversion efficiency. For example, recent research in corn fermentation using finer ground corn enables the liquefaction to be conducted at lower temperatures, and this process is known as cold starch hydrolysis.

After the physical disruption process, the biomass may be chemically treated to remove lignin. This is shown in Fig. 8b. Lignin forms a coating on the cellulose microfibrils in untreated biomass, thus making the cellulose unavailable for enzyme or acid hydrolysis. Lignin also absorbs some of the expensive cellulose-active enzymes.

The following chemical pretreatment processes are employed for biomass conversion.

Hot wash pretreatment: This pretreatment concept was developed at the National Renewable Energy Laboratory and uses hot water or hot dilute acids at temperatures above 135 °C to wash out the solubilized lignin and hemicellulosic sugars (Tucker et al. 2011). The hot wash pretreatment process involves the passage of hot water through heated stationary biomass and is responsible for solubilization of the hemicellulose fraction (Teter et al. 2006). The hemicellulose is converted to pentose oligomers by this process which needs to be further converted to respective monosaccharides before fermentation. The performance of this pretreatment process depends on temperature and flow rate, requiring about 8–16 min. About 46 % of lignin is removed at high rates and temperatures. The hydrothermal process does not require acid resistant material for the reactors, but water use and recovery costs are disadvantages to the process.

Acid hydrolysis: Hydrolysis is a chemical reaction or process where a chemical compound reacts with water. The process is used to break complex polymer structures into its component monomers. The process can be used for the hydrolysis of polysaccharides like cellulose and hemicelluloses (Katzen and Schell 2006). When hydrolysis is catalyzed by the presence of acids like sulfuric, hydrochloric, nitric, or hydrofluoric acids, the process is called acid hydrolysis. The reactions for hydrolysis can be expressed as in reaction given by Eqs. 4 and 5:

$$\text{Cellulose (Glucan)} \rightarrow \text{Glucose} \rightarrow 5-\text{Hydroxymethylfurfural} \rightarrow \text{Tars} \quad (4)$$

$$\text{Hemicellulose (Xylan)} \rightarrow \text{Xylose} \rightarrow \text{Furfural} \rightarrow \text{Tars} \quad (5)$$

The desired products of hydrolysis are the glucose and xylose. Under severe conditions of high temperature and acid concentrations, the product tends to form hydroxymethylfurfural, furfural, and the tars.

Dilute sulfuric acid is inexpensive in comparison to the other acids. It has also been studied and the chemistry well known for acid conversion processes (Katzen and Schell 2006). Biomass is mixed with a dilute sulfuric acid solution and treated with steam at temperatures ranging from 140 °C to 260 °C. Xylan is rapidly hydrolyzed in the process to xylose at low temperatures of 140–180 °C. At higher temperatures, cellulose is depolymerized to glucose, but the xylan is converted to furfural and tars. The pretreatment conditions used in lignocellulosic biomass (corn stover) feedstock-based ethanol process by (Aden et al. 2002) were acid concentration of 1.1 %, residence time of 2 min, temperature maintained at 190 °C, and a pressure of 12.1 atm.

Concentrated acids at low temperatures (100–120 °C) are used to hydrolyze cellulose and hemicelluloses to sugars (Katzen and Schell 2006). Higher yields of sugars are obtained in this case with lower conversion to tars. The viability of this process depends on low-cost recovery of expensive acid catalysts.

Enzymatic hydrolysis: Acid hydrolysis explained in the previous section has a major disadvantage where the sugars are converted to degradation products like tars. This degradation can be prevented by using enzymes favoring 100 % selective conversion of cellulose to glucose. When hydrolysis is catalyzed by such enzymes, the process is known as enzymatic hydrolysis (Katzen and Schell 2006). The temperature and pressure for enzymatic hydrolysis depend on the particular enzyme and its tolerance to a particular temperature. A detailed discussion of the particular temperatures for enzymes is beyond the scope of this chapter.

Enzymatic hydrolysis is carried out by microorganisms like bacteria, fungi, protozoa, insects, etc. (Teter et al. 2006). Advancement of gene sequencing in microorganisms has made it possible to identify the enzymes present in them which are responsible for the biomass degradation. Bacteria like *Clostridium thermocellum*, *Cytophaga hutchinsonii*, *Rubrobacter xylanophilus*, etc., and fungi like *Trichoderma reesei* and *Phanerochaete chrysosporium* have revealed enzymes responsible for carbohydrate degradation.

Based on their target material, enzymes are grouped into the following classifications (Teter et al. 2006). Glucanases or cellulases are the enzymes that participate in the hydrolysis of cellulose to glucose. Hemicellulases are responsible for the degradation of hemicelluloses. Some cellulases have significant xylanase or xyloglucanase side activity which makes it possible for use in degrading both cellulose and hemicelluloses.

Ammonia fiber explosion: This process uses ammonia mixed with biomass in a 1:1 ratio under high pressure (21 atm) at temperatures of 60–110 °C for 5–15 min, and then there is explosive pressure release. This process, also referred to as the AFEX process, improves saccharification rates of various herbaceous crops and grasses. The pretreatment does not significantly solubilize hemicellulose compared to acid pretreatment. The conversions achieved depend on the composition of

feedstock, e.g., over 90 % hydrolysis of cellulose and hemicellulose was obtained after AFEX pretreatment of Bermuda grass (Sun and Cheng 2002). The volatility of ammonia makes it easy to recycle the gas (Teter et al. 2006).

Fermentation

The pretreatment of biomass is followed by the fermentation process where pretreated biomass containing 5-carbon and 6-carbon sugars is catalyzed with biocatalysts to produce desired products. Fermentation refers to enzyme catalyzed, energy yielding chemical reactions that occur during the breakdown of complex organic substrates in presence of microorganisms (Klass 1998). The microorganisms used for fermentation can be yeast or bacteria. The microorganisms feed on the sucrose or glucose released after pretreatment and converts them to alcohol and carbon dioxide. The simplest reaction for the conversion of glucose by fermentation is given in Eq. 6:

$$C_6H_{12}O_6 \rightarrow 2C_2H_5OH + 2CO_2 \tag{6}$$

An enzyme catalyst is highly specific, catalyzes only one or a small number of reactions, and a small amount of enzyme is required. Enzymes are usually proteins of high molecular weight (15,000 < MW < several million Daltons) produced by living cells. The catalytic ability is due to the particular protein structure, and a specific chemical reaction is catalyzed at a small portion of the surface of an enzyme, called an active site (Klass 1998). Enzymes have been used since early human history without knowing how they worked. Enzymes have been used commercially since the 1890s when fungal cell extracts were used to convert starch to sugar in brewing vats.

Microbial enzymes include cellulase, hemicellulase, catalase, streptokinase, amylase, protease, clipase, pectinase, glucose isomerase, lactase, etc. The type of enzyme selection determines the end product of fermentation.

The growth of the microbes requires a carbon source (glucose, xylose, glycerol, starch, lactose, hydrocarbons, etc.) and a nitrogen source (protein, ammonia, corn steep liquor, diammonium phosphate, etc.). Many organic chemicals like ethanol, succinic acid, itaconic acid, lactic acid, etc., can be manufactured using live organisms which have the required enzymes for converting the biomass. Ethanol is produced by the bacteria *Zymomonas mobilis* or yeast *Saccharomyces cerevisiae*. Succinic acid is produced in high concentrations by *Actinobacillus succinogenes* obtained from rumen ecosystem (Lucia et al. 2007). Other microorganisms capable of producing succinic acid include propionate producing bacteria of the *Propionibacterium* genus, gastrointestinal bacteria such as *Escherichia coli*, and rumen bacteria such as *Ruminococcus flavefaciens*. Lactic acid is produced by a class of bacteria known as lactic acid bacteria (LAB) including the genera *Lactobacillus*, *Lactococcus*, *Leuconostoc*, *Enterococcus*, etc. (Axelsson 2004).

Commercial processes for corn wet milling and dry milling operations and the fermentation process for lignocellulosic biomass through acid hydrolysis and enzymatic hydrolysis are discussed in details in chapter "► Chemicals from Biomass."

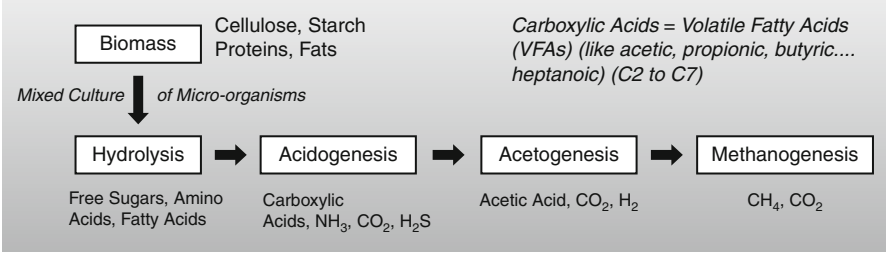

Fig. 13 Anaerobic digestion process

Anaerobic Digestion

Anaerobic digestion of biomass is the treatment of biomass with a mixed culture of bacteria to produce methane (biogas) as a primary product. The four stages of anaerobic digestion are hydrolysis, acidogenesis, acetogenesis, and methanogenesis as shown in Fig. 13.

In the first stage, hydrolysis, complex organic molecules are broken down into simple sugars, amino acids, and fatty acids with the addition of hydroxyl groups. In the second stage, acidogenesis, volatile fatty acids (e.g., acetic, propionic, butyric, valeric) are formed along with ammonia, carbon dioxide, and hydrogen sulfide. In the third stage, acetogenesis, simple molecules from acidogenesis are further digested to produce carbon dioxide, hydrogen, and organic acids, mainly acetic acid. Then in the fourth stage, methanogenesis, the organic acids are converted to methane, carbon dioxide, and water.

Anaerobic digestion can be conducted either wet or dry where dry digestion has a solid content of 30 % or greater, and wet digestion has a solid content of 15 % or less. Either batch or continuous digester operations can be used. In continuous operations, there is a constant production of biogas; while batch operations can be considered simpler, the production of biogas varies.

The standard process for anaerobic digestion of cellulose waste to biogas (65 % methane-35 % carbon dioxide) uses a mixed culture of mesophilic or thermophilic bacteria (Kebanli 1981). Mixed cultures of mesophilic bacteria function best at 37–41 °C, and thermophilic cultures function best at 50–52 °C for the production of biogas. Biogas also contains small amount hydrogen and a trace of hydrogen sulfide, and it is usually used to produce electricity. There are two by-products of anaerobic digestion: acidogenic digestate and methanogenic digestate. Acidogenic digestate is a stable organic material comprised largely of lignin and chitin resembling domestic compost, and it can be used as compost or to make low-grade building products such as fiberboard. Methanogenic digestate is a nutrient-rich liquid, and it can be used as a fertilizer but may include low levels of toxic heavy metals or synthetic organic materials such as pesticides or PCBs depending on the source of the biofeedstock undergoing anaerobic digestion.

Kebanli et al. (1981) give a detailed process design along with pilot unit data for converting animal waste to fuel gas which is used for power generation. A first-order

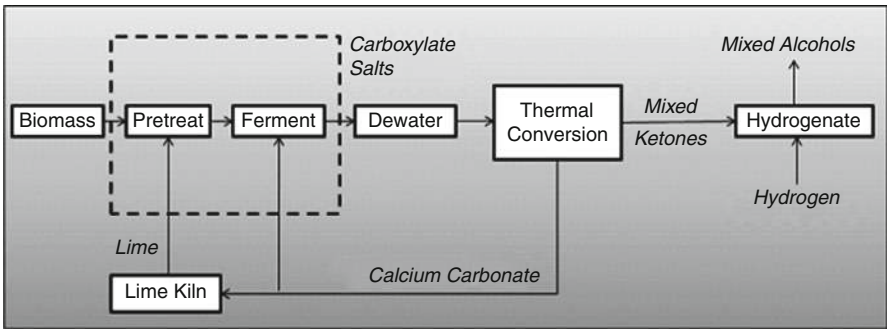

Fig. 14 Flow diagram for the MixAlco process using anaerobic digestion (Granda 2007)

rate constant, 0.011 ± 0.003 per day, was measured for the conversion of volatile solids to biogas from dairy farm waste. In a biofeedstock, the total solids are the sum of the suspended and dissolved solids, and the total solids are composed of volatile and fixed solids. In general, the residence time for an anaerobic digester varies with the amount of feed material, type of material, and the temperature. Resident time of 15–30 days is typical for mesophilic digestion, and residence time for thermophilic digestion is about one-half of that for mesophilic digestion. The digestion of the organic material involves mixed culture of naturally occurring bacteria, each performs a different function. Maintaining anaerobic conditions and a constant temperature is essential for the viability of the bacterial culture.

Holtzapple et al. (1999) describe a modification of the anaerobic digestion process, the MixAlco process, where a wide array of biodegradable material is converted to mixed alcohols. Thanakoses et al. (2003) describe the process of converting corn stover and pig manure to the third stage of carboxylic acid formation. In the MixAlco process, the fourth stage in anaerobic digestion of the conversion of the organic acids to methane, carbon dioxide, and water is inhibited using iodoform (CHI_3) and bromoform ($CHBr_3$). Biofeedstocks to this process can include urban wastes, such as municipal solid waste and sewage sludge, and agricultural residues, such as corn stover and bagasse. Products include carboxylic acids (e.g., acetic, propionic, butyric acid), ketones (e.g., acetone, methyl ethyl ketone, diethyl ketone), and biofuels (e.g., ethanol, propanol, butanol). The process uses a mixed culture of naturally occurring microorganisms found in natural habitats such as the rumen of cattle to anaerobically digest biomass into a mixture of carboxylic acids produced during the acidogenic and acetogenic stages of anaerobic digestion. The fermentation conditions of the MixAlco Process make it a viable process, since the fermentation involves mixed culture of bacteria obtained from animal rumen, which is available at lower cost compared to genetically modified organisms and sterile conditions required by other fermentation processes.

The MixAlco process is outlined in Fig. 14 where biomass is pretreated with lime to remove lignin. Calcium carbonate is also added to the pretreatment process. The resultant mixture containing hemicellulose and cellulose is fermented using a mixed

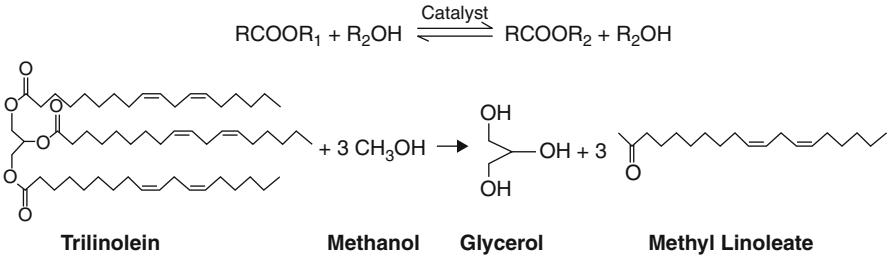

Fig. 15 General transesterification reaction with an example for $RCOOR_1$ as trilinolein and R_2OH as methanol

Table 5 Carboxylic acid products at different culture temperatures (Granda 2007)

Acid	40 °C	55 °C
C2 – Acetic	41 wt%	80 wt%
C3 – Propionic	15 wt%	4 wt%
C4 – Butyric	21 wt%	15 wt%
C5 – Valeric	8 wt%	<1 wt%
C6 – Caproic	12 wt%	<1 wt%
C7 – Heptanoic	3 wt%	<1 wt%
	100 wt%	100 wt%

culture of bacteria obtained from cattle rumen. This process produces a mixture of carboxylate salts which is then fermented. Carboxylic acids are naturally formed in the following places: animal rumen, anaerobic sewage digesters, swamps, termite guts, etc. The same microorganisms are used for the anaerobic digestion process, and the acid products at different culture temperatures are given in Table 5.

The MixAlco process proceeds to form carboxylate salts with the calcium carbonate. Dewatering process removes water. Then the carboxylate salts are thermally decomposed to mixed ketones like acetone, diethyl ketone, and dipropyl ketones. The mixed ketones can then be converted to ethanol by hydrogenation using Raney nickel catalyst at a temperature of 130 °C and pressure of 12 atm in a stirred tank reactor for 35 min.

Transesterification

In biomass conversion processes, transesterification refers to the reaction of an alcohol with natural oil containing triglycerides to produce monoalkyl esters and glycerol (Meher et al. 2006). The glycerol layer settles down at the bottom of the reaction vessel. Diglycerides and monoglycerides are the intermediates in this process. Figure 15 shows the general reaction for transesterification with an example for trilinolein as the representative triglyceride and methanol as the representative alcohol.

A wide variety of vegetable oils and natural oils can be used for transesterification. Table 6 gives a list of oils that can be used with their respective constituent fatty acid content. Linoleic acid and oleic acid are the main constituents for soybean oil. Algae oil composition varies according to the species of algae chosen and is discussed in a later section on algae. The alcohols that can be used for transesterification depend on the type of esters desired. Methanol (CH_3OH) gives methyl esters, and ethanol (C_2H_5OH) produces ethyl esters.

The catalyst used for transesterification may be an acid, a base, or a lipase. The commonly used catalysts are given in Table 7 along with their advantages and disadvantages (Meher et al. 2006; Fukuda et al. 2001; Ma and Hanna 1999).

The mechanism of alkali-catalyzed transesterification is described in Fig. 16. The first step involves the attack of the alkoxide ion to the carbonyl carbon of the triglyceride molecule, which results in the formation of a tetrahedral intermediate. The reaction of this intermediate with an alcohol produces the alkoxide ion in the second step. In the last step the rearrangement of the tetrahedral intermediate gives rise to an ester and a diglyceride.

The mechanism of acid-catalyzed transesterification of vegetable oil (for a monoglyceride) is shown in Fig. 17. It can be extended to di- and triglycerides. The protonation of carbonyl group of the ester leads to the carbocation, which after a nucleophilic attack of the alcohol produces a tetrahedral intermediate. This intermediate eliminates glycerol to form a new ester and to regenerate the catalyst.

Both the triglycerides in vegetable oil and methyl esters from the transesterification of vegetable oils can be used as monomers to form resins, foams, thermoplastics, and oleic methyl ester (Wool and Sun 2005). A thermosetting polymer is formed by the polymerization of triglycerides with styrene using a free radical initiator, and curing for 4 h at 100 °C that has very good tensile strength, rigidity, and toughness properties. Lignin can enhance toughness, and it can be molded to a material with an excellent ballistic impact resistance. Triglycerides can be functionalized to acrylated, epoxidized soybean oil that can be used for structural foam that has biocompatibility properties. Methyl esters can be functionalized to epoxidized oleic methyl ester and acrylated oleic methyl ester which can be polymerized with comonomers methyl methacrylate and butyl acrylate to form oleic methyl ester. A monolithic hurricane-resistant roof has been designed using these materials.

The methyl esters formed from transesterification from vegetable oil can be used as diesel in diesel engines, and this is referred to as biodiesel. Haas et al. (2006) describe an industrial-scale transesterification process for the production of biodiesel from the transesterification of soybean oil. Figure 18 gives a schematic overview of the process model. A two-reactor model was designed with crude degummed soybean oil as feedstock with phospholipid content of less than 50 ppm and negligible fatty acids, sodium methoxide catalyst, and methanol as the alcohol. The design contained three sections, a transesterification section, a purification section, and a glycerol recovery section. The transesterification section consisted of two sequential reactors. The purification section had a centrifugation column which separated esters from the aqueous phase. The glycerol recovery and purification section also consisted of a centrifugal reactor and subsequent distillation and

Table 6 Fatty acid compositions of common oils (percentages)

Fatty acid	Soybean (Meher et al. 2006)	Cottonseed (Meher et al. 2006)	Palm (Meher et al. 2006)	Lard (Meher et al. 2006)	Tallow (Meher et al. 2006)	Coconut (Meher et al. 2006)	Sunflower (Zamora 2005)

Table 7 Commonly used catalysts in transesterification and their advantages and disadvantages (Meher et al. 2006; Fukuda et al. 2001; Ma and Hanna 1999)

Type	Commonly used compounds/ enzymes	Advantages	Disadvantages
Alkali catalysts	NaOH, KOH, $NaOCH_3$,$KOCH_3$ (other alkoxides are also used)	1. Faster than acid-catalyzed transesterification	1. Ineffective for high free fatty acid content and for high water content (problems of saponification) 2. Energy intensive 3. Recovery of glycerol difficult 4. Alkaline wastewater requires treatment
Acid catalysts	HCl, H_2SO_4, H_3PO_4, sulfonic acid	1. Good for processes with high water content and free fatty acids	1. Slow process compared to alkali (alkoxides) 2. Required after treatment of triglycerides with alkoxides formed for purification purposes
Enzyme/ lipase/ heterogeneous catalysts	*M. miehi*, *C. antarctica*, *P. cepacia*, *C. rugosa*, *P. fluorescens*	1. Possibility of regeneration and reuse of the immobilized residue 2. Free fatty acids can be completely converted to alkyl esters 3. Higher thermal stability of the enzyme due to the native state 4. Immobilization of lipase allows dispersed catalyst, reducing catalyst agglomeration 5. Separation of product and glycerol is easier using this catalyst	1. Some initial activity can be lost due to volume of the oil molecules 2. Number of support enzyme is not uniform 3. Biocatalyst is more expensive that the natural enzyme

evaporation columns for 80 % (w/w) glycerol as a by-product. The cost analysis of the overall process was done with a depreciable life of 10 years and an escalation rate of 1 %. Annual production capacity for the methyl ester plant was set at 10×10^6 gal. With a feedstock cost of $0.236/lb of soybean oil, a production cost of $2.00/gal of methyl ester was achieved.

Gasification/Pyrolysis

Thermal conversion processes such as gasification can be used to convert biomass to synthesis gas, a mixture of carbon monoxide and hydrogen. The products and yields

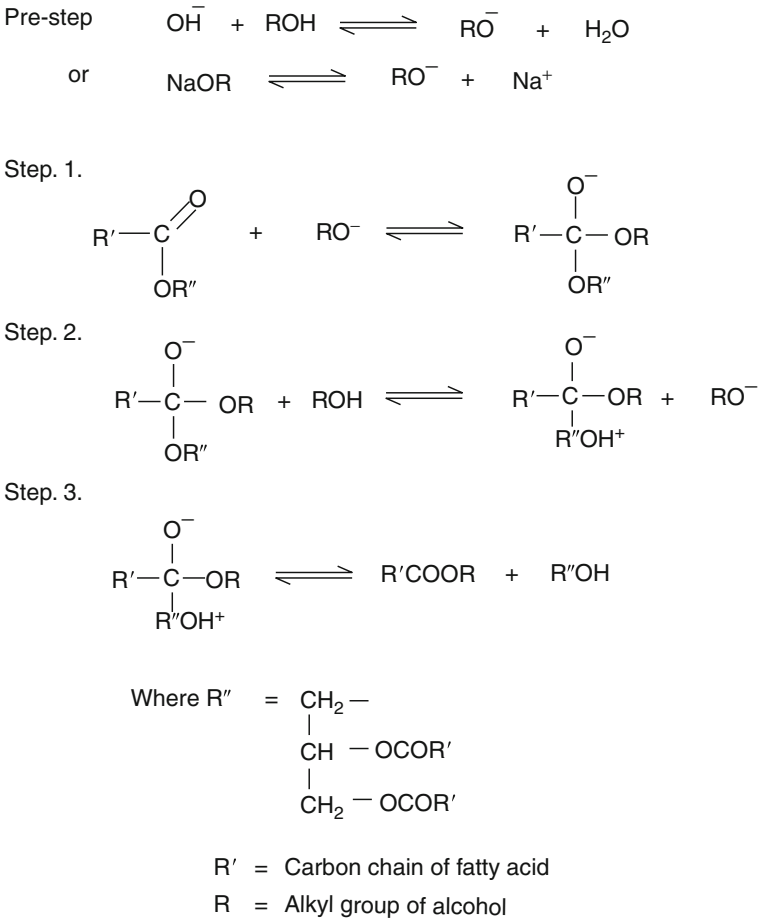

Fig. 16 Mechanism of alkali-catalyzed transesterification (Adapted from Meher et al. (2006))

depend on feed composition, dimension of feed particles, heating rate, temperature, and reaction time (Klass 1998). A detailed discussion for gasification is included in a later chapter.

In biomass gasification, steam and oxygen are used to produce synthesis gas where the amount of steam and oxygen are controlled to produce carbon monoxide and hydrogen with a minimum amount of carbon dioxide and other products. Synthesis gas is a 1:1 mixture of carbon monoxide and hydrogen. In the 1800s coal gasification was used to provide syngas used for lighting and heating. At the beginning of the twentieth century, syngas was used to produce fuels and chemicals. Many of the syngas conversion processes were developed in Germany during the First and Second World Wars at a time when natural resources were becoming scarce for the country and alternative routes for hydrogen production, ammonia synthesis,

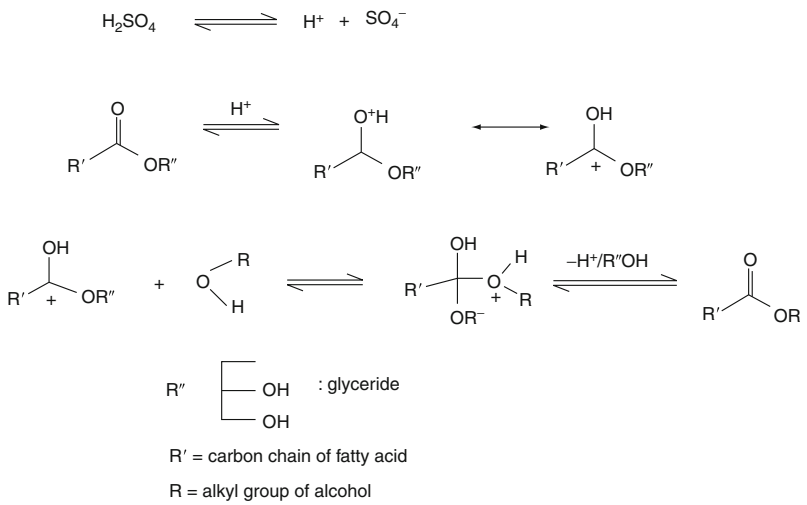

Fig. 17 Mechanism of acid-catalyzed transesterification (Adapted from Meher et al. (2006))

and transportation fuels were a necessity. With the development of the petroleum industry in the 1940s and beyond, the economics of many of these syngas routes became unfavorable and was replaced by petroleum-based processes. The Fischer-Tropsch synthesis reactions for the catalytic conversion of a mixture of carbon monoxide and hydrogen into liquid alcohol fuels was one such process developed in Germany.

The United States has the highest proven reserves of coal among all its natural resources. Coal co-fired with biomass and complete biomass gasification processes are alternatives that are being considered for the production of syngas for fuels and chemicals. The US DOE multiyear program plan for 2010 outlines the fuels, energy, and chemicals that can be produced from the thermochemical routes for biomass processing (DOE 2010b; Spath and Dayton 2003). Biomass gasification technologies are similar to coal gasification and both produce similar product gases. However, biomass contains more volatile matter, gasification occurs at lower temperatures and pressures than coal, and pyrolytic chars are more reactive than coal products. The increase in pressure lowers equilibrium concentrations for hydrogen and carbon monoxide and increases the carbon dioxide and methane concentrations. Biomass contains oxygen in cellulose and hemicellulose which makes them more reactive than oxygen deficient coal. Volatile matter in biomass is about 70–90 % in wood as compared to 30–45 % in coal.

There are three types of biomass gasification processes – pyrolysis, partial oxidation, and reforming. Pyrolysis, as explained before, is the combustion of biomass in absence of oxygen. Partial oxidation is the process where less than stoichiometric quantity required for complete combustion is used, and partially oxidized products are formed. Steam reforming process involves the reaction of biomass with steam.

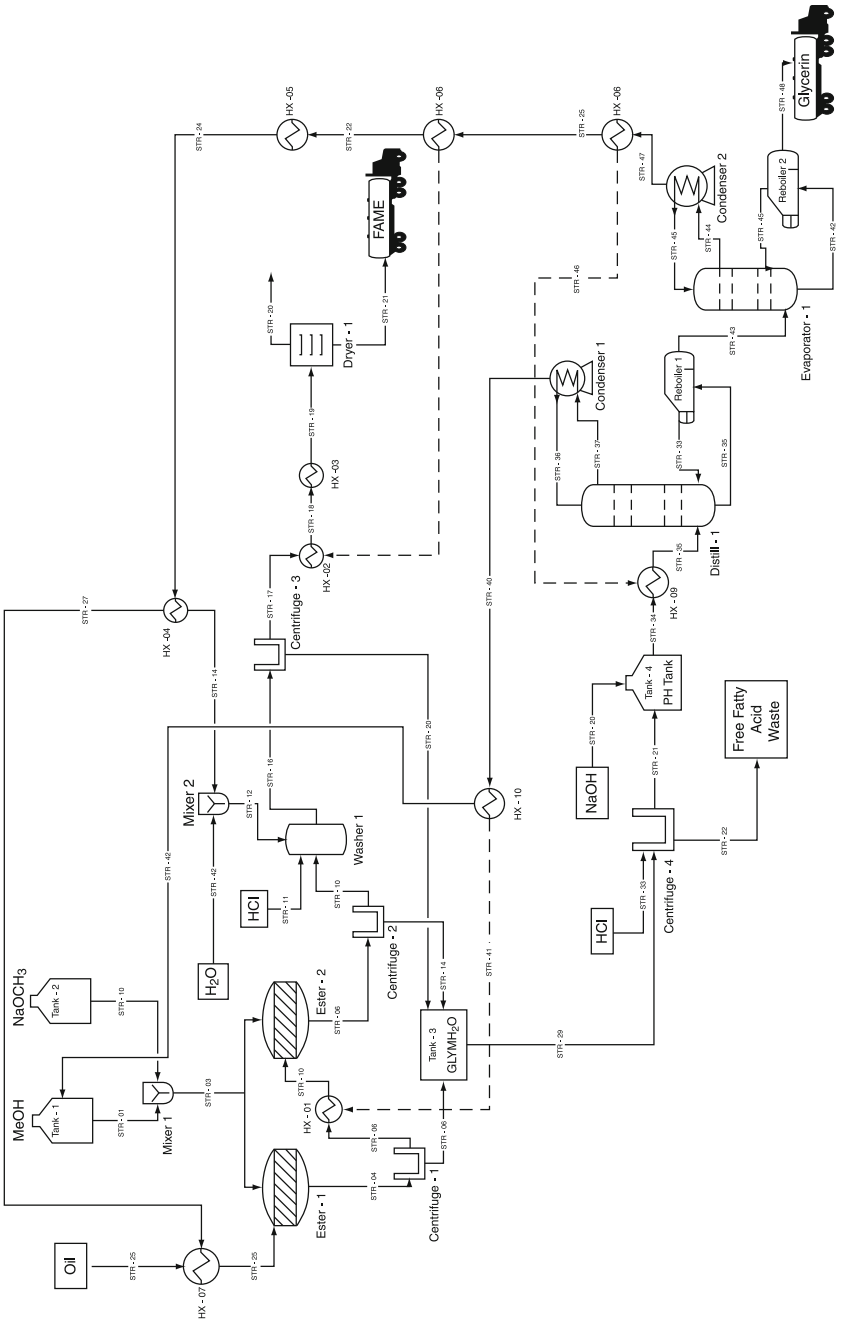

Fig. 18 A process model for the production of biodiesel and glycerol (Adapted from Haas et al. (2006))

The energy content of product gases from biomass gasification can be varied. Low-energy content gases (100–300 BTU/scf) are formed when there is direct contact of biomass feedstock with air (Klass 1998). Dilution of product gases with nitrogen occurs during the gasification process. Medium-energy gases (300–700 BTU/scf) are obtained from directly heated biomass gasifiers when oxygen is used and from indirectly heated biomass gasifiers when air is used, and heat transfer occurs via inert solid medium. High-energy product gases (700–1,000 BTU/scf) are obtained when gasification conditions promote the formation of methane and other light hydrocarbons.

Commercial biomass gasification facilities started worldwide in the 1970s and 1980s. Typically, gasification reactors comprise of a vertical reactor that has drying, pyrolysis, and combustion zones. Synthesis gas leaves the top of the reactor, and molten slag leaves the bottom of the reactor. The reactions that take place in the reactor are given in Eqs. 7, 8, and 9 using cellulose as representative of biomass (Klass 1998).

Pyrolysis:

$$C_6H_{10}O_5 \rightarrow 5CO + 5H_2 + C \tag{7}$$

Partial oxidation:

$$C_6H_{10}O_5 + O_2 \rightarrow 5CO + 5H_2 + CO_2 \tag{8}$$

Steam reforming:

$$C_6H_{10}O_5 + H_2O \rightarrow 6CO + 6H_2 \tag{9}$$

Synthesis gas is used in the chemical production complex of the lower Mississippi river corridor to produce ammonia and methanol. Currently, ammonia and methanol are produced using synthesis gas from natural gas, naphtha, or refinery light gas. Nearly 12.2 billion pounds of methanol are produced annually in the USA, and most of the methanol is converted to higher-value chemicals such as formaldehyde (37 %), methyl tertiary butyl ether (28 %), and acetic acid (8 %) (Paster et al. 2003). Ethanol can be produced from the synthesis gas, and Fischer-Tropsch chemistry is another approach to convert synthesis gas to chemicals and fuels. The chemicals that can be produced include paraffins, monoolefins, aromatics, aldehydes, ketones, and fatty acids.

Pyrolysis is the direct thermal decomposition of the organic components in biomass in the absence of oxygen to yield an array of useful products like liquid and solid derivatives and fuel gases (Klass 1998). Conventional pyrolysis is the slow, irreversible, thermal degradation of the organic components in biomass in absence of oxygen and includes processes like carbonization, destructive distillation, dry distillation, and retorting. The products of pyrolysis under high pressure and

temperature include mainly liquids with some gases and solids (water, carbon oxides, hydrogen, charcoal, organic compounds, tars, and polymers). The pyroligneous oil is the liquid product formed and mainly composed of water, settled tar, soluble tar, volatile acids, alcohols, aldehydes, esters, and ketones. The solid derivative from pyrolysis is referred to as biochar. Biochar can be used as a soil amendment and as a carbon sequestration medium. Depending on pyrolysis conditions and feedstock, the liquid product contains valuable chemicals and intermediates. The separation of these intermediates in a cost-effective manner is required. Pyrolysis can be slow, or fast, depending on the residence time and temperature. Slow pyrolysis occurs between 500 °C and 900 °C and produces low-energy gas, pyrolytic oil, and charcoal. Fast pyrolysis is operated in the range of 400 − 650 °C and residence times of a few seconds to a fraction of a second.

ConocoPhillips has funded a $22.5 million and 8-year research program at Iowa State University to develop new technologies for processing lignocellulosic biomass to biofuels (C & E News 2007). The company wants to investigate routes using fast pyrolysis to decompose biomass to liquid fuels.

Faustina Hydrogen Products LLC announced a $1.6 billion gasification plant in Donaldsonville, Louisiana. The plant will use petroleum coke and high sulfur coal as feedstocks instead of natural gas to produce anhydrous ammonia for agriculture, methanol, sulfur, and industrial-grade carbon dioxide. The hydrogen is produced for ammonia production from the water gas shift reaction of synthesis gas. Synthesis gas will be produced from gasification of coal and petroleum coke instead of natural gas. Capacities of the plant include 4,000 t per day of ammonia, 1,600 t per day of methanol, 450 t per day sulfur, and 16,000 t per day of carbon dioxide. Mosaic Fertilizer and Agrium Inc. have agreements to purchase the anhydrous ammonia from the plant. The carbon dioxide will be sold to Denbury Resources Inc. for the use in enhanced oil recovery of oil left after conventional rig drilling processes in old oil fields in Southern Louisiana and the Gulf Coast. The rest of the carbon dioxide would be sequestered and sold as an industrial feedstock. The facility claims to have the technology to capture all the carbon dioxide during manufacturing process.

Eastman Chemical Company, a Fortune 500 company, will provide the Faustina gasification plant with necessary maintenance and services and plans to have a 25 % equity position along with a purchase contract to buy the methanol produced in the plant. Eastman Chemicals will use methanol to make raw materials like propylene and ethylene oxide. Faustina is also backed by D. E. Shaw Group and Goldman Sachs.

Eastman Chemicals also plans to have 50 % stake in a $1.6 billion plant to be built in Beaumont, Texas, in 2011 (Tullo 2007). The plant will use gasification to produce syngas. Eastman will use the syngas to produce 225 million gallons of methanol and 225,000 metric tons of ammonia per year at Terra Industries in Beaumont. Air Products & Chemicals will supply 2.6 million metric tons per year of oxygen to the gasifiers and market the hydrogen produced in the complex.

Biomass Feedstock Availability

The challenge with biomass feedstock usage is the availability of biomass on an uninterrupted basis. Biomass, as a feedstock, has a wide variation due to a number of causes. These include climate and environmental factors like insolation, precipitation, temperature, ambient carbon dioxide concentration, nutrients, etc.

The availability of land and water areas for biomass production is important for the sustainable growth of biomass. The land capability in the United States is classified according to eight classes by the USDA and is given in Table 8. There have been numerous studies on the availability of biomass as feedstock in the United States, the most recent survey and estimation being undertaken by Perlack et al. (2005). Their findings are summarized in this section for land biomass resources.

The land base of the United States is approximately 2,263 million acres, including the 369 million acres of land in Alaska and Hawaii (Perlack et al. 2005). The land area is classified according to forest land, grassland pasture and range, cropland, special uses like public facilities, and other miscellaneous uses like urban areas, swamps, and deserts. The distribution of the total land areas according to these categories is given in Fig. 19. About 60 % of the total land base in the lower 48 states having some potential for growth of biomass.

The two major categories of biomass resources availability are forest resources obtained from forest land and agricultural resources obtained from crop land (or agricultural land). The detailed classification of the biomass resources is given in Fig. 20. The primary resources are often referred to as virgin biomass, and the secondary and tertiary are referred to as waste biomass. Currently, slightly more than 75 % of biomass consumption in the United States (about 142 million dry tons) comes from forestlands. The remainder (about 48 million dry tons), which includes biobased products, biofuels, and some residue biomass, comes from cropland.

Table 8 Land capability classification (Source: USDA)

Class	Description
Class I	Contains soils having few limitations for cultivation
Class II	Contains soils having some limitations for cultivation
Class III	Contains soils having severe limitations for cultivation
Class IV	Contains soils having very severe limitations for cultivation
Class V	Contains soils unsuited to cultivation, although pastures can be improved and benefits from proper management can be expected
Class VI	Contains soils unsuited to cultivation, although some may be used provided unusually intensive management is applied
Class VII	Contains soils unsuited to cultivation and having one or more limitations which cannot be corrected
Class VIII	Contains soils and landforms restricted to use as recreation, wildlife, water supply, or aesthetic purposes

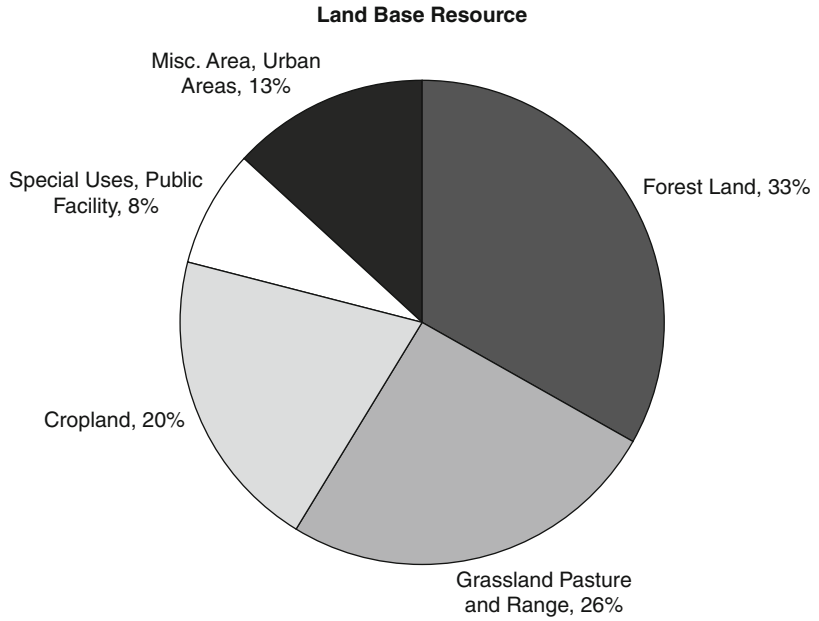

Fig. 19 United States land-based resource (Perlack et al. 2005)

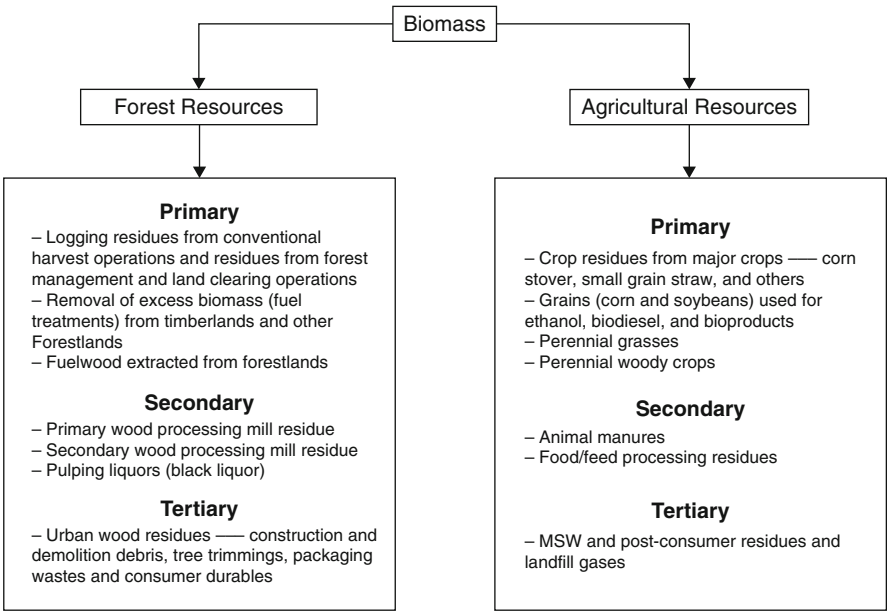

Fig. 20 Biomass resource base (primary, secondary, and tertiary biomass) (Adapted from Perlack et al. (2005))

Forest Resources

Forest Land Base

The total forest land resource base in the United States is approximately 749 million acres (one-third of the total land resource). The forest land is grouped into unreserved "timberland," "reserved land," and "others." The 749 million acres is divided into 504 million acres of timberland capable of growing 20 ft^3 per acre of wood annually, 166 million acres of forestland classified as "other" (incapable of growing 20 ft^3 per acre of wood annually and hence used for of livestock grazing and extraction of some nonindustrial wood products) and 78 million acres of reserved forestland used for parks and wilderness. "Timberland" and the "other" land are considered as the resource base that can be utilized for forest biomass resources.

Types of Forest Resource

The primary forest resources include logging residues and excess biomass (not harvested for fuel treatments and fuelwood) from timberlands. Logging residues are the unused portions of growing-stock and non-growing-stock trees cut or killed by logging and left in the woods. Fuelwood is the wood used for conversion to some form of energy, primarily for residential use.

The processing of sawlogs and pulpwood harvested for forest products generates significant amounts of mill residues and pulping liquors. These are secondary forest resources and constitute the majority of biomass in use today. The secondary residues are used by the forest products industry to manage residue streams, produce energy, and recover chemicals. About 50 % of current biomass energy consumption comes from the secondary residues.

The various categories in which primary and secondary forest resources can be grouped are given below (Fig. 21):

- *Logging residue*: The recovered residues generated by traditional logging activities and residues generated from forest cultural operations or clearing of timberlands. These constitute about 67 million dry tons of residues, of which 41 million is currently available for bioenergy and biobased products.
- *Fuel treatments* (*forest land*): The recovered residues generated from fuel treatment operations on timberland and other forestland. Fuel treatments are the procedures by which forests are treated so as to reduce the fuel value in the wood. The amount of biomass potentially available as feedstock for bioenergy and biobased products is 60 million dry tons per year.
- *Fuelwood*: The direct conversion of roundwood to energy (fuelwood) in the residential, commercial, and electric utility sectors currently includes 35 million dry tons per year and used for space and process heating applications.
- *Forest products industry residues and urban wood residues*: These include the utilization of unused residues generated by the forest products industry, urban residues including those discarded from construction and demolition operations,

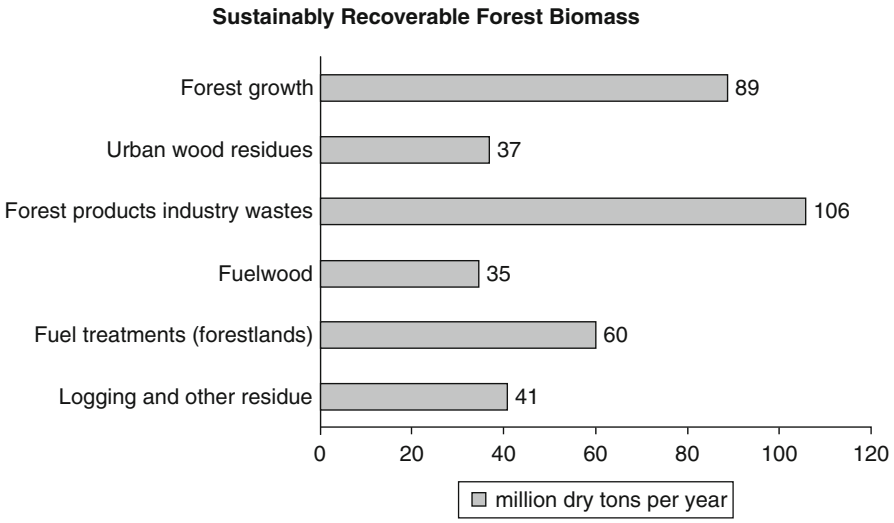

Fig. 21 Estimate of sustainably recoverable forest biomass (Adapted from Perlack et al. (2005))

and residues from tree trimmings, packaging residues, and wood-based consumer durables giving a total of 143 million dry tons per year.

- *Forest growth*: Forest growth and increase in the demand for forest products will increase the contribution of forest biomass by an additional 89 million dry tons annually.

The estimate of currently recoverable forest biomass is given in Fig. 21. The approximate total quantity is 368 million dry tons annually. This includes about 142 million dry tons of biomass currently being used primarily by the forest products industry and an estimated 89 million dry tons that could come from a continuation of demand and supply trends in the forest products industry.

Limiting Factors for Forest Resource Utilization

The 368 million tons of potential forest biomass feedstock base is constrained by some restrictions for exploitation. For forest resources inventory, development in forest utilization relationships and land ownership is expected to play a major role in utilizing the resource. There are three major limiting factors for forest residues from fuel treatment thinning resource, namely, accessibility (having roads to transport the material and operate logging/collection systems, avoiding adverse impacts on soil and water), economic feasibility (value of the biomass compared against the cost of removing the material), and recoverability (function of tree form, technology, and timing of the removal of the biomass from the forests).

Forest products industry processing residues include primary wood processing mills, secondary wood processing mills, and pulp and paper mills. Residues from these sources include bark, sawmill slabs and edgings, sawdust, and peeler log cores,

residues from facilities which use primary products and black liquor. A significant portion of this residue is burnt or combusted to produce energy for the respective industries. Excess amount of residue remain unutilized after the burning and combustion and can be used in biomass processes. Urban wood residues include municipal solid wastes and construction and demolition debris. A part of it is recovered, and a significant part is unexploited. Finally, future forest growth and increased demands in forest products are likely to affect the availability of forest resources for biomass feedstock base. In summary, all of these forest resources are sustainably available on an annual basis, but not currently used to its full potential due to the above constraints. For estimating the residue tonnage from logging and site clearing operations and fuel treatment thinning, a number of assumptions were made by Perlack et al. (2005):

- All forestland areas not currently accessible by roads were excluded.
- All environmentally sensitive areas were excluded.
- Equipment recovery limitations were considered.
- Recoverable biomass was allocated into two utilization groups – conventional forest products and biomass for bioenergy and biobased products.

Summary for Forest Resources

Thus, biomass derived from forestlands currently contributes about 142 million dry tons to the total annual consumption in the United Sates of 190 million dry tons. With the increased use of potential and currently unexploited biomass, this amount of forestland-derived biomass can increase to approximately 368 million dry tons annually. The distribution of the forest resource potential is summarized in Fig. 22. This estimate includes the current annual consumption of 35 million dry tons of fuelwood extracted from forestland for residential, commercial, and electric utility purposes; 96 million dry tons of residues generated and used by the forest products industry; and 11 million dry tons of urban wood residues. There are relatively large amounts of forest residue produced by logging and land clearing operations that are currently not collected (41 million dry tons per year) and significant quantities of forest residues that can be collected from fuel treatments to reduce fire hazards (60 million dry tons per year). Additionally, there are unutilized residues from wood processing mills and unutilized urban wood. These sources total about 36 million dry tons annually. About 48 % of these resources are derived directly from forestlands (primary resources). About 39 % are secondary sources of biomass from the forest products industry. The remaining amount of forest biomass would come from tertiary or collectively from a variety of urban sources.

Agricultural Resources

Agricultural Land Base

The agricultural land resource base for the United States is approximately 455 million acres, approximately 20 % of the total land base in the country. Out of this, 349 million acres is actively used for crop growth, 39 million acres constitutes idle

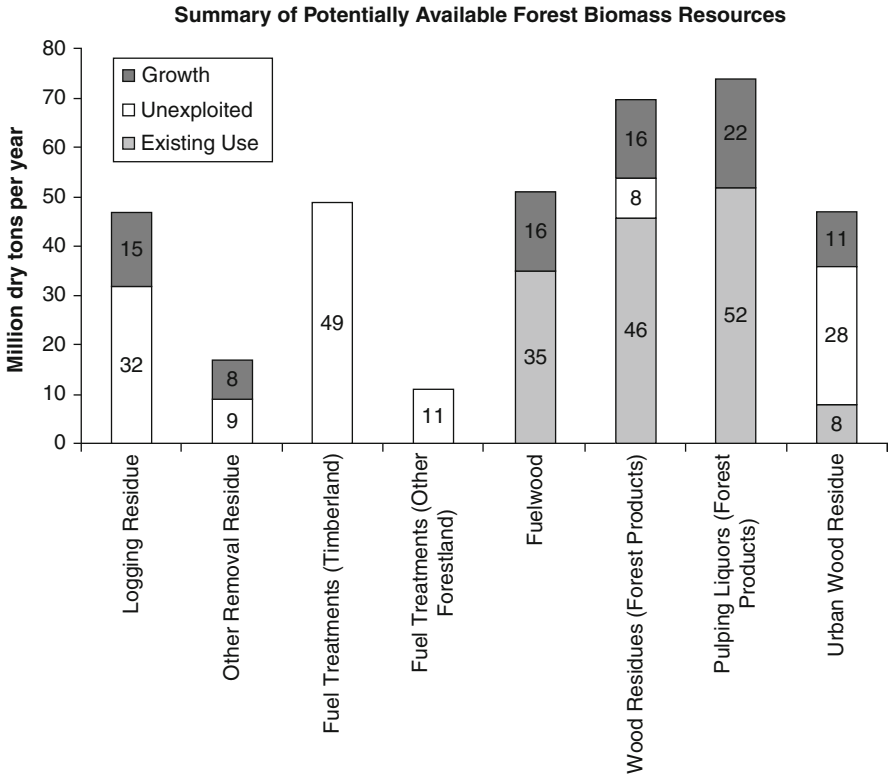

Fig. 22 Summary of potentially available forest biomass resources (Adapted from Perlack et al. (2005))

cropland, and 67 million acres is used for pasture. Cropland utilization is affected by soil and weather conditions, expected crop prices, and government incentives. Crop land is also lost due to conversion of the land for other uses like urban development, etc. The major food crops planted acreage constitutes wheat, soybeans, and rice. The feed crops include corn, sorghum, and hay. The fallow and failed land is a part of cropland. Apart from cropland, there is idle land which includes acreage diverted from crops under the Acreage Reduction Program (ARP), the Conservation Reserve Program (CRP), and other federal acreage reduction programs. The cropland used only for pasture is also separately accounted for. The distribution of agricultural land base and planted crop acreages in the United States is shown in Fig. 23.

Types of Agricultural Resource

The agricultural resource base is primarily comprised of grains and oilseeds in the United States. Currently, grains are primarily used for cattle feed. Grains, primarily corn, can be used for producing ethanol, and oilseeds, primarily soybeans, can be used to produce biodiesel. Approximately 93 % of the total US ethanol is produced from corn. Apart from these, agricultural residues, like corn stover, can also be used

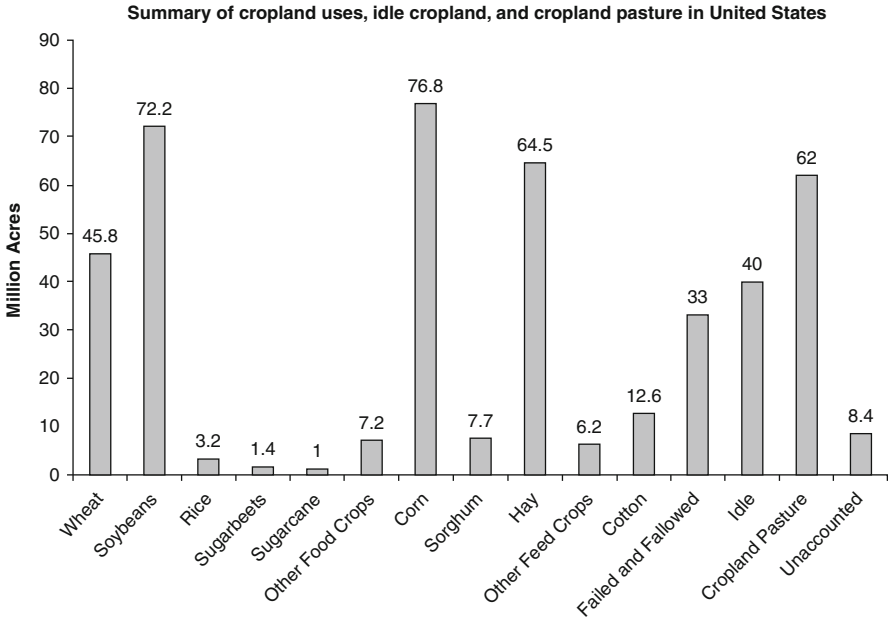

Fig. 23 Summary of agricultural land usage by major crops in United States (Adapted from Perlack et al. (2005))

for producing ethanol. In the United States, approximately 428 million dry tons of annual crop residues, 377 million dry tons of perennial crops, 87 million dry tons of grains, and 106 million dry tons of animal manures, process residues, and other miscellaneous feedstocks can be produced on a sustainable basis (Perlack et al. 2005). This resource potential was evaluated based on changes in the yields of crops grown on active cropland, crop residue-to-grain or crop residue-to-seed ratios, annual crop residue collection technology and equipment, crop tillage practices, land use change to accommodate perennial crops (i.e., grasses and woody crops), biofuels (i.e., ethanol and biodiesel), and secondary processing and other residues. Three scenarios were evaluated for availability of crop biomass, and they are given below.

Current Availability of Biomass Feedstocks from Agricultural Land

The current availability scenario studies biomass resources current crop yields, tillage practices (20–40 % no-till for major crops), residue collection technology (~40 % recovery potential), grain to ethanol and vegetable oil for biodiesel production, and the use of secondary and tertiary residues on a sustainable basis. The amount of biomass currently available for bioenergy and bioproducts is about 194 million dry tons annually as shown in Fig. 24. The largest source of this current potential is 75 million dry tons of corn residues or corn stover, followed by 35 million dry tons of animal manure and other residues.

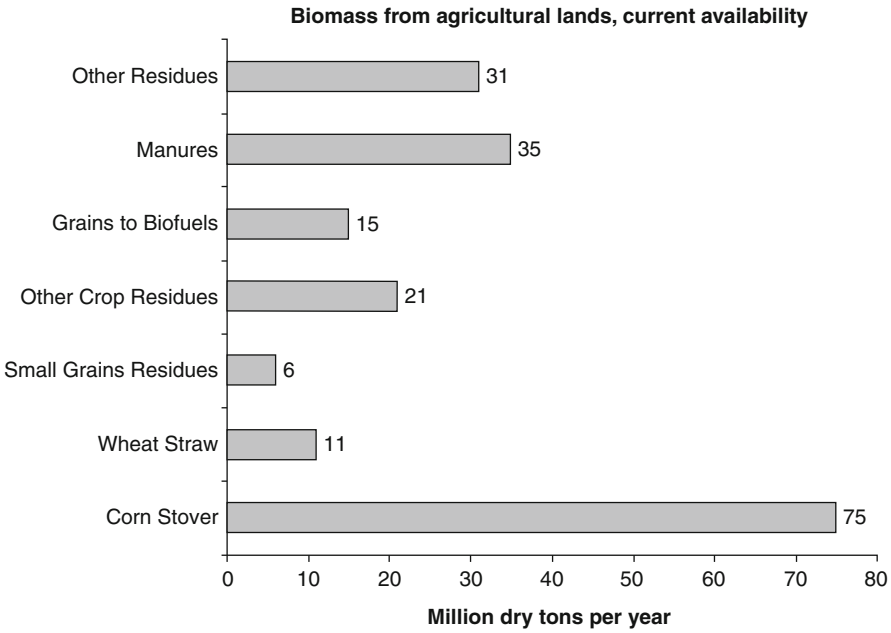

Fig. 24 Current availability of biomass from agricultural lands (Perlack et al. 2005)

Biomass Availability Through Technology Changes in Conventional Crops with No Land Use Change

This scenario analyzed the biomass availability of conventional crops achieved through technology changes. The land utilization for conventional crops projected for 2014 was used for this analysis. Technology changes to increase crop yields and improve collection equipment, and sustainable agricultural practices were considered in this scenario. Corn yields were assumed to increase by 25–50 % from 2001 values, while yields of wheat and other small grains, sorghum, soybeans, rice, and cotton are assumed to increase at rates lower than for corn. The increased production of corn contributed to increase in corn stover as residue. Soybeans contributed no crop residue under a moderate yield increase of about 13 % but made a small contribution with a high yield increase of about 23 %. The collection of these residues from crops was increased through better collection equipment capable of recovering as much as 60 % of residue under the moderate yield increases and 75 % under the high yield increases, but the actual removal amounts depend on the sustainability requirements. No-till cultivation method was assumed to be practiced on approximately 200 million acres under moderate yield increases and all of active cropland under high yields. The amount of corn and soybeans available for ethanol, biodiesel production, or other bioproducts was calculated by subtracting amounts needed to meet food requirements plus feed and export requirements from total quantities. All remaining grain was assumed to be available for bioproducts. Further, about 75 million dry tons of manure and other secondary and tertiary residues and wastes and 50 % of the biomass

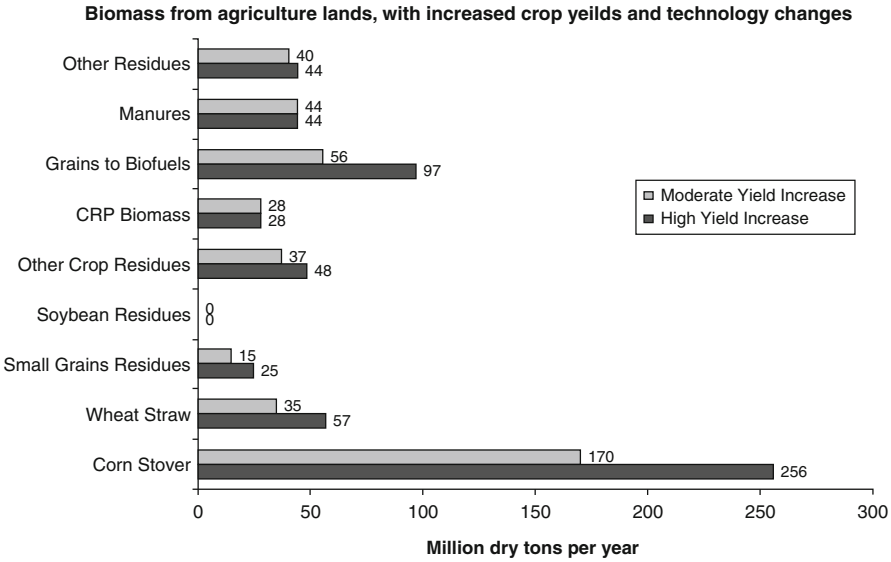

Fig. 25 Availability of biomass for increased crop yields and technology changes (Perlack et al. 2005)

produced on CRP lands (17–28 million dry tons) were assumed to be available for bioenergy production. Thus, this scenario for the use of crop residue results in the annual production of 423 million dry tons per year under moderate yields and 597 million dry tons under high yields. In this scenario, about two-thirds to three-fourths of total biomass are from crop residues, as can be seen in Fig. 25.

Biomass Availability Through Technology Changes in Conventional Crops and New Perennial Crops with Significant Land Use Change

This scenario assumes the addition of perennial crops, land use changes, and changes in soybean varieties, as well as the technology changes assumed under the previous scenario. Technology changes are likely to increase the average residue-to-grain ratio of soybean varieties from 1.5 to a ratio of 2.0. The land use changes considered in this scenario included the conversion of land for growth of perennial crop on 40 million acres for moderate yield increase or 60 million acres for high yield increase. Woody crops produced for fiber were expanded from 0.1 million acres to 5 million acres, where they can produce an average annual yield of 8 dry tons per acre. Twenty-five percent of the wood fiber crops are assumed to be used for bioenergy and the remainder for other, higher-value conventional forest products. Perennial crops (trees or grasses) grown primarily for bioenergy expand to either 35 million acres at 5 dry tons per acre per year or to 55 million acres with average yields of 8 dry tons per acre per year. Ninety-three percent of the perennial crops are assumed available for bioenergy and the remainder for other products. A small fraction of the available biomass (10 %) was assumed as lost during the harvesting

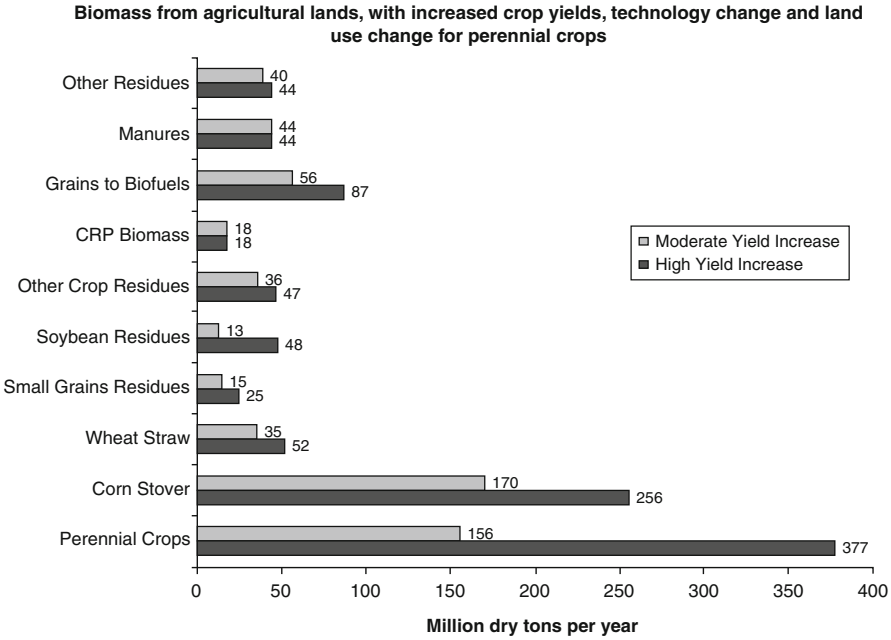

Fig. 26 Availability of biomass for increased crop yields and technology changes and inclusion of perennial crops (Perlack et al. 2005)

operations. This scenario resulted in the production of 581 (moderate yield) to 998 million (high yield) dry tons as shown in Fig. 26. The crop residues increased even though conventional cropland was less because of the addition of more soybean residue together with increased yields. The single largest source of biomass is the crop residue, accounting for nearly 50 % of the total produced. Perennial crops account for about 30–40 % depending on the extent of crop yield increase (i.e., moderate or high).

Limiting Factors for Agricultural Resource Utilization

The annual crop residues, perennial crops, and processing residues can produce 998 million tons of potential agricultural biomass feedstock. The limiting factors for the utilization of crop residues and growth of perennial crops for the purpose of feedstock generation will require significant changes in current crop yields, tillage practices, harvesting and collection technologies, and transportation. Agricultural residues serve as a land cover and prevent soil erosion after harvesting of crops. The removal of large quantities of the residue can affect the soil quality by removal of soil carbon and nutrients and may need to be replenished with fertilizers. The fertilizers, in turn, require energy for production, and hence the optimum removal of the residues needs to be evaluated. Perennial crops require less nutrient supplements and are better choices for preventing soil erosion compared to annual crops, and they are considered for planting.

Important assumptions made for this evaluation of agricultural biomass availability by Perlack et al. (2005) included the following:

- Yields of corn, wheat, and other small grains were increased by 50 %.
- The residue-to-grain ratio for soybeans was increased to 2:1.
- Harvest technology was capable of recovering 75 % of annual crop residues (when removal is sustainable).
- All cropland was managed with no-till methods.
- Fifty five million acres of cropland, idle cropland, and cropland pasture were dedicated to the production of perennial bioenergy crops.
- All manure in excess of that which can applied on-farm for soil improvement under anticipated EPA restrictions was used for biofuel.
- All other available residues were utilized.

Summary for Agricultural Resources

Thus, biomass derived from agricultural lands currently available for removal on a sustainable basis is about 194 million dry tons. This amount can be increased to nearly one billion tons annual production through a combination of technology changes, adoption of no-till cultivation, and land use change to grow perennial crops. The amount of biomass available without the addition of perennial crops but high crop yield increase would be 600 million dry tons. Approximately the same amount of biomass would be produced on agricultural lands with moderate crop yield increase and addition of perennial crops. The distribution of the agricultural resource potential is summarized in Fig. 27.

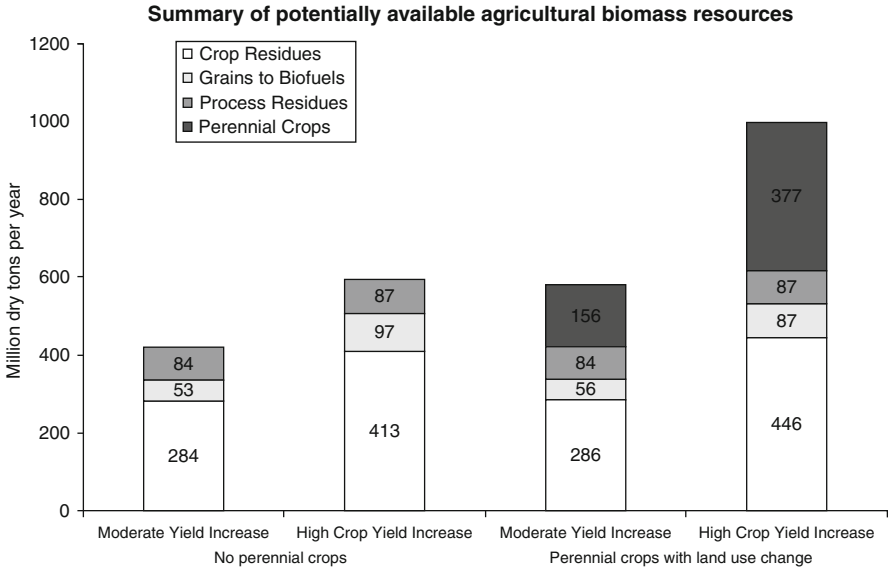

Fig. 27 Summary of potentially available agricultural biomass resources (Perlack et al. 2005)

Aquatic Resources

The previous sections discussed conventional biomass feedstock options grown on land. Apart from the crop and forest biomass resources, other organisms that undergo photosynthesis are cyanobacteria and algae. There are several ongoing attempts to find the ideal growth conditions for cultivating algae on a sustainable basis. Key areas of research interests in algae include high per-acre productivity compared to typical terrestrial oilseed crops, non-food-based feedstock resources, the use of otherwise nonproductive, non-arable land for algae cultivation, utilization of a wide variety of water sources (fresh, brackish, saline, and wastewater), and production of both biofuels and valuable coproducts. The Energy Efficiency and Renewable Energy Laboratory at the Department of Energy commissioned a working group assess the current state of algae technology and to determine the next steps toward commercialization (DOE 2010a). The workshop addressed the following topics and technical barriers in algal biology, feedstock cultivation, harvest and dewatering, extraction and fractionation of microalgae, algal biofuel conversion technologies, coproducts production, distribution and utilization of algal-based fuels, resources and siting, corresponding standards, regulation and policy, systems and techno-economic analysis of algal biofuel deployment, and public-private partnerships. This section aims to capture some of those efforts. A model algal lipid production system with algae growth, harvesting, extraction, separation, and uses is shown in Fig. 28. Methods to convert whole algae into biofuels exist through anaerobic digestion to biogas, supercritical fluid extraction and pyrolysis to liquid or vapor fuels, and gasification process for production of syngas-based fuels and chemicals. Algae oil can supplement refinery diesel in hydrotreating units or be used as feedstock for the biodiesel process. The research on algae as a biomass feedstock is a very dynamic field currently, and the potential of algae seems promising as new results are presented continuously.

Methods to cultivate algae have been developed over the years. Recent developments in algae growth technology include vertical reactors (Hitchings 2007) and bag reactors (Bourne 2007) made of polythene mounted on metal frames, eliminating the need for land use for cultivation. The NREL Aquatic Species Program (Sheehan et al. 1998) mentions "raceway" ponds design for growth of algae. This method required shallow ponds built on land area and connected to a carbon dioxide source

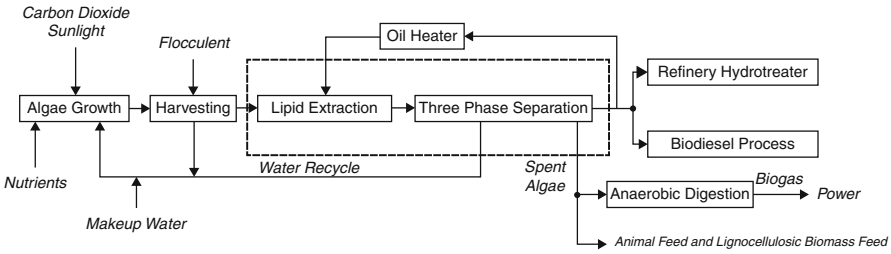

Fig. 28 Model algae lipid production system (Adapted from Pienkos and Daezins (2009))

Table 9 Comparison of productivity between algae and soybean (Pienkos and Daezins 2009)

Productivity	Soybeans	Algae		
		Low productivity (10 g/m^2/day) 15 % TAG	Med. productivity (25 g/m^2/day) 25 % TAG	High productivity (50 g/m^2/day) 50 % TAG
Gallons/acre	48	633	2,637	10,549
Total acres	63.6 million	63.6 million	25 million	6.26 million
Gallons/year	3 billion	40 billion	66 billion	66 billion
Petrodiesel (%)	4.5	61	100	100

such as a power plant. Productivity in these pond designs was few grams/m^2/day. Other designs include tubular cultivation facilities, and the semi-continuous batch cultures gave improved production rates of algae. For example, the 3D Matrix System of Green Fuel Technologies Corporation have an average areal productivity of 98 g/m^2/day (ash free, dry weight basis), with highs of over 170 g/m^2/day achieved during a run time of 19 days (Pulz 2007).

Algae have the potential for being an important source of oil and carbohydrates for production of fuels, chemicals, and energy. Carbon dioxide and sunlight can be used to cultivate algae and produce algae with 60 % triglycerides and 40 % carbohydrates and protein (Pienkos and Daezins 2009). A comparison in productivity between algae and soybean is given in Table 9. The table shows that even at low productivity of algae, yields are more than 10 times in gallons per acre when all the United States soybean acreage is utilized for algae. Higher yields are obtained at medium and high productivity levels of algae (higher triacylglycerols) with reduced acreage requirements. The algae oil resulting from low productivity can replace approximately 61 % of the total United States diesel requirements, as compared to only 4.5 % for soybean oil-based diesel. The other advantage, at these yields, algae can capture up to 2 billion tons of carbon dioxide while photosynthesis.

However, the growth of algae on a large scale for production of oil and chemicals seems to be the most important barrier at this stage. The following technologies developed seem promising ways to cultivate algae, apart from traditional open pond systems. These are discussed on a per case basis, with the companies that have developed these technologies. Some of the current research trends in algae bioreactor systems are presented in the following sections.

Raceway Pond Systems

"Raceway" design for algae growth included shallow ponds in which the algae, water, and nutrients circulate around a "racetrack" as shown in Fig. 29 (inset) (Sheehan et al. 1998). Motorized paddles help to provide the flow and keep algae suspended in water and circulated back up to the surface on a regular frequency. The ponds are shallow to ensure maximum exposure of sunlight (sunlight cannot penetrate beyond certain depths). The ponds are operated as continuous reactors with

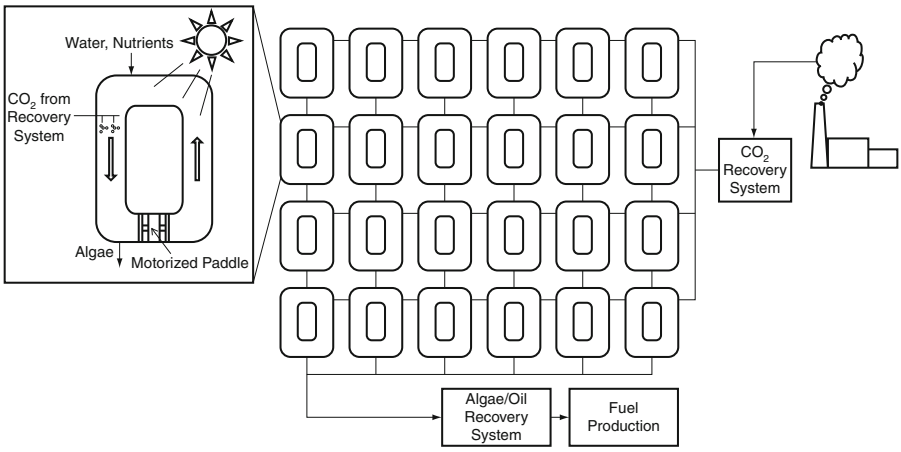

Fig. 29 Algae raceway design (inset) and algae farm system for algae growth (Adapted from Sheehan et al. (1998))

water and nutrients fed to the pond and carbon dioxide bubbled through the system. The algae containing water is removed at the other end of the pond. The algae is then harvested and processed for oil extraction.

The concept of the raceway design for algae growth can be extended to an algae farm as shown in Fig. 29. This consists of numerous ponds similar to the raceway in which algae is grown and harvested. The size of these ponds is measured in terms of surface area (as opposed to volume) as the surface area is critical to capturing sunlight. The productivity is measured in terms of biomass produced per day per unit of available surface area. These designs required large acres of land and thus obtained the scale of farms. The open bioreactor system for a 50 square meters and width 1.2 m algae cultivation facility at the microalgal culture facility of UH Marine Center is shown in Fig. 30.

Algenol Biofuels: Direct to Ethanol^{TM} Process

Algenol biofuels have developed metabolically engineered algae species to produce ethanol in closed bioreactor systems. The proprietary Capture Technology^{TM} bioreactors hold single-cell cyanobacteria in closed and sealed plastic bag units preventing contamination, maximize ethanol recovery, and allow fresh water recovery. The advantage of the process lies in the fact that it is a one-step process where the cyanobacteria utilize the carbon dioxide to convert it to ethanol and secrete the ethanol from the cell (Voith 2009). There is a requirement for strict maintenance of growth parameters such as CO_2, nutrients, water, pH, temperature, salinity, and other environmental conditions for the engineered species of microorganism. The process to make ethanol from algae utilizes 1.5 million tons of carbon dioxide per 100 million gallons of ethanol produced. Algenol, The Dow Chemical Company, and the Department of Energy have teamed to produce ethanol using this technology at

Fig. 30 Microalgal culture facility at the UH Marine Center (Photo: Dr. Edward Laws, LSU School of the Coast and Environment)

Dow's Freeport, Texas, site. Dow would contribute with 25 acres of their site, carbon dioxide source, and technical expertise for the $25 million project. Dow plans to utilize their expertise in film technology to device ideal bioreactor for the system with optimum sunlight penetration.

ExxonMobil Algae Research

ExxonMobil is funding $600 million for algae research partnered with Synthetic Genomics, Inc. to identify and develop algae strains to produce bio-oils at low costs (Kho 2009). The research will also determine the best production systems for growing algal strains, for example, open ponds or closed photobioreactor systems. The company also plans for scale-up to large amounts of CO_2 utilization and developing integrated commercial systems.

Shell Algae Research

Shell and HR Biopetroleum formed a joint venture company in 2007, called Cellana, to develop an algae project for a demonstration facility on the Kona Coast of Hawaii

Island. The site was leased from the Natural Energy Laboratory of Hawaii Authority (NELHA) and is near existing commercial algae enterprises, primarily serving the pharmaceutical and nutrition industries.

The facility will grow only nonmodified, marine microalgae species in open-air ponds using proprietary technology. Algae strains used for the process are indigenous to Hawaii or approved by the Hawaii Department of Agriculture.

Green Fuels Technology

GreenFuel Technologies developed a process that grows algae in plastic bags using CO_2 from smokestacks of power plants via naturally occurring species of algae. The CO_2 source can also come from fermentation or geothermal gases. Algae can be converted to transportation fuels and feed ingredients or recycled back to a combustion source as biomass for power generation. Industrial facilities do not need any internal modifications to host a GreenFuel algae farm. In addition, the system does not require fertile land or potable water. Water used can be recycled, and wastewater can be used as compared to oilseed crops' high water demand. With high growth rates, algae can be harvested daily.

Valcent Products

32A vertical reactor system is being developed by Valcent Products, Inc. of El Paso, Texas, using the 340 annual days of sunshine and carbon dioxide available from power plant exhaust.

Enhanced Biofuel Technology and A2BE Carbon Capture, LLC, are some of the firms that use the concept of raceway pond design and algae farm for production of algae for biofuels. Research is underway to determine the species of algae for oil production and the best method of extracting the oil. Extraction methods being evaluated include expeller/press, hexane solvent extraction, and supercritical fluid extraction and are the more costly step in the process. Approximately 70–75 % of algae oil can be extracted using expeller press, while 95 % oil can be extracted by hexane solvent oil extraction and 100 % oil extracted using supercritical fluid extraction.

Algae Species

Algae are plant-like microorganisms that preceded plants in developing photosynthesis, the ability to turn sunlight into energy. Algae range from small, single-celled organisms to multicellular organisms, some with fairly complex differentiated form. Algae are usually found in damp places or bodies of water and thus are common in terrestrial as well as aquatic environments. Like plants, algae require primarily three components to grow: sunlight, carbon dioxide, and water. Microalgae are the most efficient in photosynthesis, with 60–70 % of each cell's volume capable of photosynthesis (Arnaud 2008). The algae also do not have roots, stems, or leaves, which diverts resources to produce hydrocarbons. Algae cells contain light-absorbing chloroplasts and produce oxygen through photosynthesis. Biologists have categorized microalgae in a variety of classes, mainly distinguished by their pigmentation,

life cycle, and basic cellular structure. The four most important (in terms of abundance) are (Sheehan et al. 1998):

- The diatoms (Bacillariophyceae): These algae dominate the phytoplankton of the oceans, but are also found in fresh and brackish water. Approximately 100,000 species are known to exist. Diatoms contain polymerized silica (Si) in their cell walls. All cells store carbon in a variety of forms. Diatoms store carbon in the form of natural oils or as a polymer of carbohydrates known as chrysolaminarin.
- The green algae (Chlorophyceae): This type of algae is abundant in freshwater, for example, in a swimming pool. They can occur as single cells or as colonies. Green algae are the evolutionary progenitors of modern plants. The main storage compound for green algae is starch, though oils can be produced under certain conditions.
- The blue-green algae (Cyanophyceae): This type of algae is closer to bacteria in structure and organization. These algae play an important role in fixing nitrogen from the atmosphere. There are approximately 2,000 known species found in a variety of habitats.
- The golden algae (Chrysophyceae): This group of algae is similar to the diatoms. They have more complex pigment systems and can appear yellow, brown, or orange in color. Approximately 1,000 species are known to exist, primarily in freshwater systems. They are similar to diatoms in pigmentation and biochemical composition. The golden algae produce natural oils and carbohydrates as storage compounds.

The program initially looked into over 3,000 strains of organisms, which was then narrowed down to about 300 species of microorganisms. The program concentrated not only on algae that produced a lot of oil, but also with algae that grow under severe conditions – extremes of temperature, pH, and salinity.

Algal biomass contains three main components: carbohydrates, proteins, and natural oils. Algae contains 2–40 % of lipids/oils by weight. The composition of various algal species is given in Table 10. These components in algae can be used for fuel or chemicals production in three ways, mainly production of methane via biological or thermal gasification, ethanol via fermentation, or conversion to esters by transesterification (Sheehan et al. 1998). *Botryococcus braunii* species of algae has been engineered to produce the terpenoid C30 botryococcene, a hydrocarbon similar to squalene in structure (Arnaud 2008). The species has been engineered to secrete the oil, and the algae can be reused in the bioreactor. A further modification to the algae is smaller light collecting antennae, allowing more light to penetrate the algae in a polythene container reactor system. A gene, tla1, is responsible for the number of chlorophyll antennae and can be modified to reduce the chlorophyll molecules from 600 to 130. Botryococcene is a triterpene and, unlike triglycerides, cannot undergo transesterification. It can be used as feedstock for hydrocracking in an oil refinery to produce octane, kerosene, and diesel.

Dry algae factor is the percentage of algae cells in relation with the media where is cultured, e.g., if the dry algae factor is 50 %, one would need 2 kg of wet algae

Table 10 Percentage composition of protein, carbohydrate, lipids, and nucleic acid composition of various strains of algae (Sheehan et al. 1998)

Strain	Protein	Carbohydrates	Lipids	Nucleic acid
Scenedesmus obliquus	50–56	10–17	12–14	3–6
Scenedesmus quadricauda	47	–	1.9	–
Scenedesmus dimorphus	8–18	21–52	16–40	–

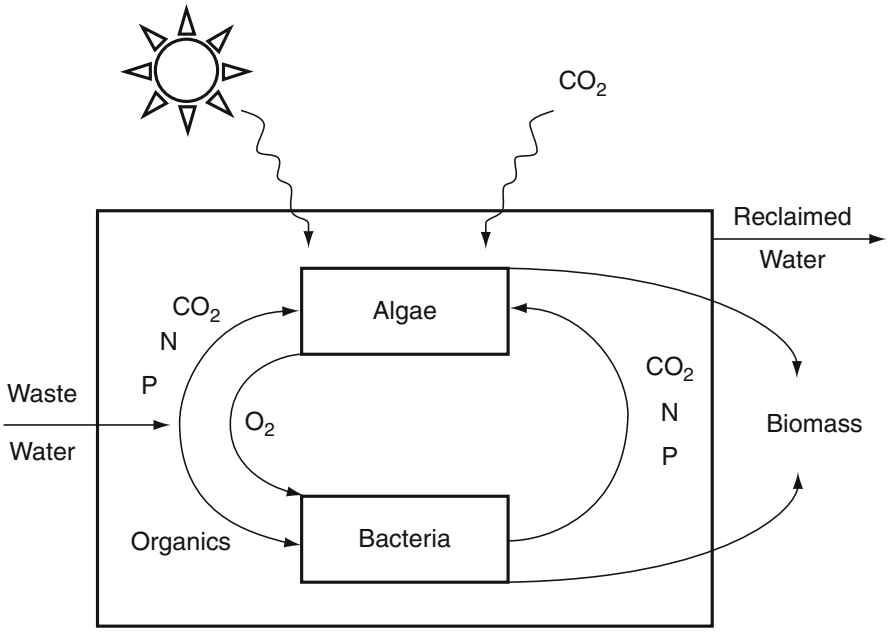

Fig. 31 Schematic diagram for wastewater treatment with algae and production of biomass (Lundquist 2011)

(algae in the media) to get 1 kg of algae cells. Lipid factor is the percentage of vegoil in relation with the algae cells needed to get it, i.e., if the algae lipid factor is 40 %, one would need 2.5 kg of algae cells to get 1 kg of oil.

Carbon dioxide sources for algae growth can be from pipelines for CO_2, flue gases from power plants, or any other sources rich in carbon dioxide. The flue gases from power plants were previously not considered as suitable algae cultivation land was not found near power plants. However, with newer designs of algae reactors linked with power plants, the flue gases can be suitable sources for algae cultivation. Water usage for algae growth is also a concern for design. In an open pond system, the loss of water is greater than in closed tubular cultivation or bag cultivation methods. The water can be local industrial water and recycled after harvesting algae.

Algae can be used in wastewater treatment, as wastewater contains nutrients for algae growth. The advantages for wastewater treatment using algae include the production of oxygen with low-energy input, removal of soluble nitrogen and phosphorus, fixation of atmospheric carbon dioxide, and the production of biomass (Lundquist 2011). The simple schematic in Fig. 31 shows how algae and bacteria can be used to produce biomass.

Conclusion

The chapter aimed to give an overview of the use of biomass as the next-generation feedstock for energy, fuels, and chemicals. The formation of biomass gave the methods in which atmospheric carbon dioxide is fixed naturally to different types of biomass. The classification of biomass into starch, cellulose, hemicellulose, lignin, lipids and oils, and proteins helped to understand the chemical composition of biomass. Biomass species are available in nature as a combination of the components, and it is important to separate the components for the use as energy, fuels, and chemicals. Various conversion technologies are employed for the separation of the components of biomass to make it more amenable, and these include pretreatment, fermentation, anaerobic digestion, transesterification, gasification, and pyrolysis.

The availability of biomass on a sustainable basis is required for the uninterrupted production of energy, fuels, and chemicals. The current forest biomass feedstock used per year is 142 million metric tons. This can be potentially increased to 368 million metric tons which include currently unexploited and future growth of forest biomass. The agricultural biomass currently available per year on a sustainable basis is 194 million dry tons. This amount can be potentially increased to 423–527 million metric tons per year with technology changes in conventional crops and 581–998 million metric tons with technology and land use changes in conventional and perennial crops.

Apart from crop and forest biomass, research in algae and cyanobacteria is ongoing for the production of carbohydrate-based and oil-based feedstock. These processes are currently constrained primarily by the successful scale-up to meet the biomass needs. However, recent advances in photo-bioreactors and algae ponds show considerable potential for large-scale growth of algae as biomass feedstock.

Future Directions

The biomass resource base is capable of producing feedstock for a sustainable supply of fuels, energy, and chemicals. However, technological challenges, market drivers, fossil feedstock cost fluctuations, and government policies and mandates play a significant role in utilizing the full potential of the biomass resources. Ideally, the biomass is regenerated over a short period of time when compared to fossil resources. This period can be few years for forest resources, seasonal for agricultural crops, and days for algae and cyanobacteria. Biomass is the source for natural atmospheric carbon dioxide fixation. Thus, with the use of biomass as feedstock for energy, fuels, and chemicals, the dependence on fossil resources can be reduced, and climate change issues related to resource utilization can be addressed.

Biochemical Conversion of Biomass to Fuels

Swetha Mahalaxmi and Clint Williford

Contents

Abstract

Biomass can provide both hydrocarbon fuels and chemical compounds such as alcohols, gums, sugars, lipid-based products, etc. Biomass-derived fuels have acquired a lot of attention during recent years because of the abundance of supply of resources and lower green house gas emissions. Grasses, agricultural residues, animal residues and waste, used oils, etc., can be used as starting materials in the production of biofuels. Ethanol and biodiesel have found greatest application and contribute significantly to fuels. However, there is growing interest in other alternatives: hydrogen, methane, butanol, renewable diesel, and petroleum compatible fuels from advanced catalytic biotech processes. Characteristics of various feedstocks and fuels, processes for conversion of biomass to biofuels,

the physical, chemical factors, and limitations affecting the conversion of biomass to fuels are discussed in this chapter. Process parameters include pH, temperature, and residence time. Additionally, chemical parameters include carbon source, nutrients, acid and alkaline hydrolysis agents, and phenolic inhibitors and sugars generated within the process. Several limitations to bioconversion of biomass are described such as size reduction, crystallinity, byproduct inhibition to fermentation, deactivation of cellulases, ethanol tolerance by yeast, and cofermentation of various sugars. Recent innovations and future developments in recombinant DNA technology and protein engineering are aimed at overcoming limitations to bioconversion. Understanding the limitations and applying suitable biotechnological applications will support future developments for producing biofuels.

Introduction

With increasing demands for transportation fuel, renewable sources of energy content, have gained importance in the recent years. Important fuel parameters are energy content, combustion quality such as octane or cetane number, volatility, freezing point, toxicity, and its adaptability to current combustion engines (Lee et al. 2008c). Biofuels such as hydrogen, methane, ethanol, butanol, and biodiesel are of current interest in replacing (in partial or complete) gasoline to mitigate greenhouse gas emissions.

Table 1 presents comparative data for various fuels against gasoline and can be produced from biochemical conversion of biomass. Current working status of these fuels is also mentioned in the Table 1. Among the fuels mentioned in the table, butanol and biodiesel (biodiesel from pure vegetable oils) can be used in existing gasoline and diesel engines respectively with a little modification. For others, engine modification is required. For ethanol, lower blends in gasoline do not require engine modification. Use in higher blends requires engine modification. Engine modification is required for some nongasoline fuels due to difference in their air-fuel ratio, latent heat of evaporation, and corrosiveness. Air-fuel ratio of gasoline is 14.6 kg air for 1 kg of fuel. However, 10 % v/v ethanol blend of gasoline has 3.5 % w/w oxygen in the fuel which influences the air-fuel ratio at which the engine performs. Engine management systems in modern vehicles adjust the air-fuel ratio to maintain the stoichiometric oxygen in the fuel. Absence of engine management system or use of higher blend gasolines/biodiesel alters the air-fuel ratio, therefore requiring engine modification. Ethanol and biodiesel have higher latent heat of evaporation compared to gasoline, which may present difficulties with starting in cold conditions. To avoid cold start difficulties, vehicles require a small tank fitted to accommodate gasoline to initiate combustion. Moreover, viscosity of biodiesel increases during cold conditions requiring alternative starting methods for vehicles using higher blends of biodiesel. Higher blends of ethanol are known to be corrosive on fuel lines and tanks; therefore, vehicles using 20 % v/v ethanol blend gasoline require to have nickel-plated steel fuel lines and tank.

Table 1 Properties of various biofuels (Adapted from sources Lee et al. (2008c) and http://en.wikipedia.org/wiki/Energy_density)

	Hydrogen	Methane	Ethanol	Butanol	Biodiesel	Gasoline
Heat of vaporization (KJ/Kg)	451.9	760	920	430	2,639.9	360

Various sources such as agricultural residues, municipal waste, animal waste, perennial grasses, etc., are used for conversion to biofuels. In this chapter, processes of production of biofuels, hydrogen, methane, ethanol, butanol, and biodiesel are described with recent progress. Applications of recombinant DNA technology and bioengineering to overcome production bottlenecks and enhance fuel production are discussed.

Sources

Biomass represents all materials derived from plant, animal, and microbial origins. Classification of biomass used in conversion to biofuels may be based on the origin (plant/animal), carbon source (woody/herbaceous), and physical and chemical characteristics. However, biomass from plant origin is considered highly desirable for its abundance and potential to mitigate emission of greenhouse gases. Carbohydrate monomers in plants are formed through photosynthesis, in which the atmospheric carbon dioxide is converted by sunlight to chemical energy. Moreover, the same amount of carbon dioxide is released, when biomass-derived fuels for energy are used, as taken up during the plant growth using sustainable means, therefore, production of more biomass, consequently mitigates and not add up to the atmospheric carbon dioxide (McKendry 2002).

Biomass can be majorly divided into woody plants, herbaceous plants or grasses, aquatic plants, and manures. Among these, some herbaceous plants, aquatic plants, and manures contain high moisture content and are suitable for wet processing or biochemical processing. Aqueous processing or wet processing is generally initiated through enzyme action. This method is suitable for high moisture content biomass because of challenged efficiency of overall energy retrieval, compared to the energy required for drying involved in dry processing. Moisture content, carbon source, and cellulose to lignin ratio are the most important factors affecting the wet process. Biomass with low moisture content is subjected to dry process or thermal treatment such as gasification, pyrolysis, and combustion. Factors that influence the dry processes are ash content, alkali, and trace components as they adversely affect the thermal conversion processes (McKendry 2002).

The products of wet processes are ethanol, butanol, and biogas. Ethanol and butanol products majorly depend on the plant composition – cellulose, hemicellulose, and lignin. Cellulose, hemicellulose, and lignin are the three main components of any plant material. Cellulose is a polymer of glucose with linear chains of (1,4)-D-glucopyranose units in β-configuration with an average molecular weight of around 100,000. Another polymer of glucose with linear chains of (1,4)-D-glucopyranose units in α-configuration, called amylose constitute about 20 % of starch. Starch also includes amylopectin, a branched polymer chain of D-glucose molecules called α-1,6 glycosidic linkage (Shuler and Kargi 2008). Starch can be more easily digested to sugars compared to cellulose due to the beta configuration and high crystallinity offered by cellulose linear structure. Starch can be obtained

from any of the food storage units of plants, while cellulose constitutes all the other parts of the plant.

Hemicellulose is a heterogeneous polymer of pentoses (xylose and arabinose) primarily xylose, hexoses (mannose, glucose, and galactose), and sugar acids. Although it is not covalently bonded, it is tightly bonded to the surface of each cellulose microfibril. Cellulose digestibility to sugars partially depends on the hemicellulose content.

After cellulose and hemicellulose, lignin is the third most abundant biopolymer, consisting primarily of phenylpropane units most commonly linked by ether bonds. It provides structural support , through its hydrophobic nature impermeability, and resistance to microbial and oxidative attack (Feldman 1985; Chang and Holtzapple 2000). Additionally, woody plants have higher lignin than herbaceous plants, thus imparting lesser strength in the latter due to loosely bound fibers (Saha 2004). Lignin also inhibits the conversion of carbohydrates to ethanol making it imperative to maximize the elimination of lignin in biomass. However, woody plants having higher lignin proportions resist moderately severe treatments, unlike herbaceous biomass. Some herbaceous plants like switch grass and miscanthus (*Miscanthus*) require less severe treatments for lignin removal. Since lignin alone causes inhibition to conversion of sugars and to ethanol, cellulose to lignin ratio is an important factor effecting conversion. Removed lignin can be used for combustion in boilers for energy generation.

For dedicated energy crops, cultivation of herbaceous plants is greatly encouraged for biochemical conversion to fuels compared to the woody biomass for several reasons such as, lesser harvest time, ease of harvesting, usage of surplus land, less intensive agricultural practices, less lignin content, and less severe treatment for conversion. Selection of plants for energy production depends on the climatic conditions, geographical location, and availability and type of treatment employed (either thermal or biochemical).

In the UK, a perennial crop, *miscanthus*, has attained a lot of attention for energy production through biochemical conversion due to the ease in growing, harvesting, and good annual yield. This thin-stemmed crop has been considered a good energy crop due to its annual harvest and low mineral content and is grown in ten countries in Europe. In the USA, another thin-stemmed crop, switch grass, is a model crop for the Oak Ridge National Laboratory, as it yields high ethanol from fermentation with the existing technologies. Its low ash and alkali content allow it to be used for combustion. Brazil, one of the pioneers for the production of ethanol, for fuel uses sugarcane as the source (McKendry 2002). Sources of biomass other than herbaceous plants include agricultural residues such as wheat straw, rice straw, corn fiber, corn stover, baggase, etc. Animal residues such as pig slurry (Murphy and McCarthy 2005), cattle dung, horse dung (Kalia and Singh 1998), etc., are used for biogas production, which upon upgrading to >97 % methane, can be used as transport fuel. Marine algae have gained importance as potential sources for biofuel production, both as substrates for fermentation to hydrogen, ethanol, and butanol, and as oil-rich sources for biodiesel production. Due to their less energy and water requirement, higher carbon dioxide capture and negligible lignin, they are considered as superior

to terrestrial biomass (Tran et al. 2010; Jung et al. 2011). However, several factors including availability, moisture content, and cellulose/lignin ratio impact the biochemical production of biofuels.

Process Overview

Major processes involved in the biochemical production of biofuels are biomass handling, biomass pretreatment, hydrolysis, and fermentation. However, depending on the source of biomass, the route of conversion to biofuel and the type of biofuel, the series of processes can alter. Figure 1 shows a schematic representation of some common unit operations and processes for the biofuels mentioned in section "Biofuels."

Handling

Biomass, either grown or obtained from various sources, needs to be transported to the production sites for biochemical conversion to fuels. Postharvest it is prepared as bales, pellets, and briquettes for which the biomass has to be size reduced. Size reduction is an important mechanical preprocessing step to increase the bulk density and flowability of particles for transportation. Biomass is generally ground to 3–8 mm particles to compact it into pellets or briquettes of higher density. Important parameters in evaluating the efficiency of size reduction are particle size, particle size distribution, shape, surface area, density, and energy efficiency of mill used (Miao et al. 2011). Due to the unavailability of a continuous supply of biomass feedstocks, storage of biomass becomes important to ensure uninterrupted supply for continuous production of biofuels. Although outdoor storing of wood chunks is a commonly practiced method, studies show that terpenes are emitted from wood due to the exposure of direct heat from sunlight (Rupar and Sanati 2005). Large silos and specially constructed facilities are used for biomass storage

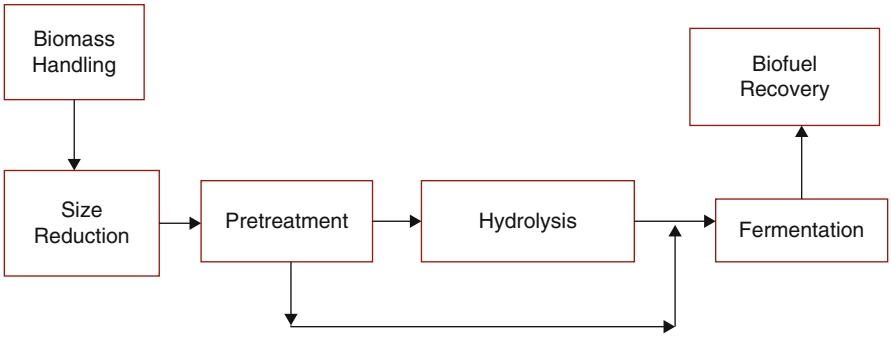

Fig. 1 Schematic representation of processes in biochemical conversion of biomass to fuels

to protect feedstock from the effects of weather, rodents, and microbial growth. Microbial growth during storage causes loss of substrate and also has the potential to result in self-ignition due to exothermic reactions. Therefore, it is required to maintain dry conditions to allow little microbial activity in the biomass during storage. Field drying postharvest is a common method for drying in sunny regions. However, thermal or mechanical drying techniques using drum driers are available for drying biomass after harvest and before storage in colder regions (Venturi et al. 1999).

Pretreatment

Pretreatment plays an important role in the biochemical conversion yields of biofuels. Complex structures in biomass are broken down into oligomeric subunits through pretreatment. These oligomers are further broken down into monomeric units during hydrolysis and fermentation. Pretreatment enhances the product yields by disrupting and solubilizing the hemicelluloses and lignin structures in biomass. Key properties affecting the conversion of lignocellulose are the crystallinity of cellulose, degree of polymerization, moisture content, available surface area, and lignin content (Chang and Holtzapple 2000). The aim of pretreatment is to disrupt the lignocellulosic structure by (1) removing hemicellulose, increasing mean pore size, and facilitating the entrance of enzymes and hydrolysis; (2) removing or redistributing lignin to reduce its "shielding" effect (Alvira et al. 2010).

Pretreatment processes will ideally achieve the following (Yang and Wyman 2008):

- High yields for multiple crops, sites ages, and harvesting times
- Highly digestible pretreated solid
- Minimum amount of toxic compounds
- Biomass size reduction not required
- Operation in reasonable size and moderate cost reactors
- Nonproduction of solid-waste residues
- Effective at low moisture content
- Obtains high sugar concentration (from hydrolysis)
- Fermentation compatibility (minimal production of inhibitors)
- Lignin recovery
- Minimum heat and power requirements

Main Classes of Pretreatment

The main classes of pretreatment covered in this chapter are mechanical, chemical, physiochemical, and biological. Mechanical pretreatment is discussed at this point as it applies to most process trains for biomass conversion. Chemical, physiochemical, and biological pretreatments are described in section "Pretreatment," as they pertain most closely to bioethanol production. At that point, characteristics making acid and alkali pretreatments suitable for methane production are also discussed.

Mechanical

Milling uses grinding to reduce particle size and crystallinity. Specific surface area is increased and degree of polymerization gets decreased. Numerous milling systems can be employed: ball, hammer, roller, colloid, and vibro energy milling (Alvira et al. 2010; Taherzadeh and Karimi 2008). Coupled with other pretreatment, milling can increase hydrolysis yield for lignocellulose by 5–25 % and reduces digestion time by 23–59 % (Delgenes et al. 2003; Hartmann and Ahring 2000). There are limits to effectiveness. Size reduction below #40 mesh does not improve hydrolysis yield or rate (Chang and Holtzapple 2000). Power requirements are large, which will limit economic feasibility (Hendriks and Zeeman 2009).

- Chemical (section "Pretreatment")
  - Acid pretreatment – concentrated and dilute
  - Alkali pretreatment – NaOH, $Ca(OH)_2$, or ammonia
- Physiochemical (section "Pretreatment")
  - Thermal processes include liquid hot water (LHW) and steam pretreatment
  - Steam explosion
  - Ammonia explosion (and CO_2 explosion)
  - Other physiochemical methods include organosolv and wet oxidation
- Biological pretreatment – brown and white soft-rot fungi (section "Pretreatment")

Alvira et al. conclude that chemical and thermochemical methods are the most effective and promising technologies for industrial applications (Alvira et al. 2010). They suggest combination of different pretreatments should be considered for optimal fractionation of components and high yields. They also stress the need for additional fundamental research plant cells to better understand the reactions induced by pretreatment.

Taherzadeh and Karimi (2008) concluded that concentrated acids, wet oxidation, solvents, and metal complexes are effective, but too expensive (Fan et al. 1987; Mosier et al. 2005a). They concluded that steam pretreatment, lime pretreatment, LHW systems, and ammonia-based pretreatments have a high potential. Eggeman and Elander (2005) presented an economic evaluation showing only small differences in cost for five different pretreatment technologies (dilute acid, hot water, ammonia fiber explosion (AFEX), ammonia recycle percolation (ARP), and lime). This analysis appears in the special issue "Coordinated development of leading biomass pretreatment technologies" (Wyman et al. 2005). Optimizing enzyme blends and hydrolysate conditioning may better differentiate process economics.

Hydrolysis and Fermentation

During hydrolysis, breaking down of polymeric and oligomeric cellulosic structure, to simpler molecules such as glucose, cellobiose, xylose, galactose, arabinose, and mannose, takes place. It is done by the action of either chemical or enzymatic agents. Enzymatic hydrolysis is a complex process that takes place at the solid/liquid

interphase. Several processes such as chemical and physical changes in the solid biomass, primary hydrolysis of soluble intermediates from the surface, and secondary hydrolysis to ultimately simpler molecules such as glucose take place simultaneously (Balat 2007). More discussion about enzymes used in hydrolysis is provided in section "Hydrolysis."

Conversion of simpler carbohydrates to alcohol through action of microbes is called as fermentation. Fermentation is both substrate and microbe specific, more details about fermentation are mentioned in section "Biofuels" for each biofuel, hydrogen, methane, ethanol, butanol, and biodiesel.

A combination of hydrolysis and fermentation is another process where simultaneous breaking down of complex carbohydrates to simpler ones and converting to alcohol takes place. This process is commonly called as simultaneous saccharification and fermentation (SSF). Product yields from SSF are higher than separate hydrolysis and fermentation (SHF), as the end product inhibition during hydrolysis of higher carbohydrates to glucose and cellobiose, is relieved by simultaneous fermentation of glucose to ethanol (Balat 2007).

Hydrolysis and fermentation are carried out in both batch and continuous modes. Batch reactors require higher reactor volume compared to the continuous reactors to achieve similar product yields. Two basic types of continuous reactors used in biochemical reactions are continuously stirred tank reactor (CSTR) and plug flow reactor (PFR). Most commonly, CSTR is used for hydrolysis and fermentation during the biochemical production of biofuels. Studies show usage of a packed bed reactor (PBR) in comparison with upflow anaerobic sludge bed (UASB) for the production of hydrogen from organic fraction of municipal solid waste, where the PBR was packed with municipal solid waste. The retention times of 50 and 24 h gave maximum hydrogen yields of 23 % v/v and 30 % v/v (based on volume of waste) for PBR and UASB, respectively (Alzate-Gaviria et al. 2007). Another study investigated combined or sequential two-stage processes involving coproduction of hydrogen and methane since hydrogen is an intermediate byproduct of methane production (Park et al. 2010; Zhu et al. 2008; Koutrouli et al. 2009). Dissolved oxygen and heat transfer are known to be limited by reactor volume. Fermentation for hydrogen, methane, ethanol, and butanol production is anaerobic, and the reactor volume is not limited by the dissolved oxygen and heat transfer when run in continuous mode. Therefore, CSTR fermentation systems with recycling of cell mass are sufficient to overcome solvent toxicity and limited cell growth (García et al. 2011).

Biofuels

Hydrogen

Biohydrogen is considered as a potential biofuel for the future, it is produced from biomass through different routes and their combinations. Gasification of biomass is one of the routes; refer to the chapters on thermal conversion of biomass, integrated

gasification for combined cycle (IGCC), and conversion of syngas to fuels in this handbook for more details about the gasification process. Hydrogen is a natural byproduct of many microbial processes under anaerobic conditions. Certain microbes release hydrogen from water in the presence of sunlight and/or carbon dioxide. Microbes that derive carbon from carbohydrates and need sunlight as a source of energy to release hydrogen are called phototrophic or photosynthetic organism (e.g., *Rhodobacter*) and those that derive their carbon from carbon dioxide and energy from sunlight are called photoautotrophic organisms (e.g., green microalgae and cyanobacteria) (Wukovits et al. 2009). Different fermentative processes, based on different sources of energy and their combinations, are anaerobic fermentation, dark fermentation, photo fermentation, direct photolysis, indirect biophotolysis, and fermentative water-gas shift reaction. The majority of these processes combine microbiological routes led by several microbes.

Anaerobic fermentation is a four-stage process carried out by a consortium of microbes. In the first stage, the complex organic components are converted to simpler components (e.g., sugars) by hydrolysis. In the second stage, the products of hydrolysis are further broken down to short-chain fatty acids by acidogenic bacteria. During the third stage, acidogenesis, the products of second stage are converted to acetic acid, hydrogen, and carbon dioxide. In the final stage, methanogenesis, the products from the third stage are used by the methanogenic bacteria to produce methane. Thus, hydrogen in this process is an intermediate product and its production can be increased by increasing the substrate content in the raw material used.

Figure 2 represents three different two-stage routes that are under active investigation. In the first stage, optimized technologies of above-mentioned conventional methods are used to convert biomass to organic acids and hydrogen. In the second stage, additional energy such as light, electricity, and methane and hydrogen from the first stage are used for achieving stoichiometric conversions. Although this combination of two stages produces a mixture of methane and hydrogen, the process can be developed to achieve hydrogen stream. Dark fermentation is carried out by the anaerobes that convert biomass substrate to hydrogen under the absence of light and is shown in Fig. 2. This process is similar to the first three stages of anaerobic fermentation where the initial raw substrate is simpler carbohydrate. For a complex substrate, hydrolysis such as a chemical/physical pretreatment of biomass is required to break down the complex polymeric biomass substrate to simpler monomeric and oligomeric carbohydrates, which can be later converted to organic acid, carbon dioxide, and hydrogen by anaerobes during dark fermentation. Reaction (1) represents a general formula for hydrogen metabolism from glucose. It is evident that in the presence of hydrogenase enzyme, 4 moles of hydrogen are released for every 1 mole of glucose. Thermophilic bacteria, that grow at high temperatures (above 60 °C) ferment biomass, produce hydrogen at higher rates than the mesophilic bacteria that grow at moderate temperatures (below 50 °C), due to aseptic conditions maintained at high temperatures. Additionally, hydrogen production depends on the other byproduct organic acids present in the effluent. Acetic acid and other organic acids have an inhibitory effect on the growth of microbes, consequently influencing

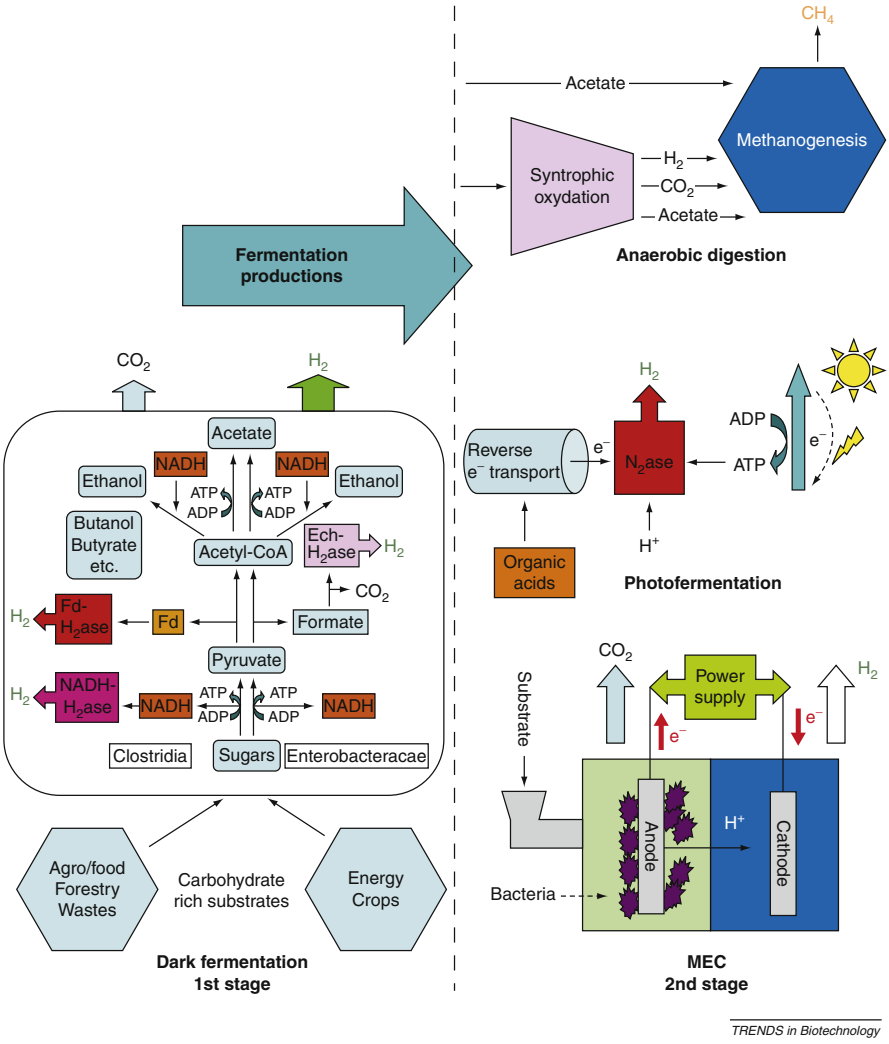

Fig. 2 Different two-stage routes for conversion to hydrogen and methane (Hallenbeck and Ghosh 2009)

hydrogen yield. Besides its inhibitory effect, acetic acid influences the pH of the system, thus affecting the activity of hydrogenase enzyme responsible for the production of hydrogen.

$$C_6H_{12}O_6 + 2H_2O \rightarrow 2CH_3COOH + 2CO_2 + 4H_2 \quad (1)$$

Photo fermentation involves a series of biochemical reactions such as anaerobic digestion. However, unlike dark fermentation, it requires light for energy during the process of hydrogen production. Simple, short-chain fatty acids are converted to

carbon dioxide and hydrogen catalyzed by nitrogenase enzyme in the absence of nitrogen by purple nonsulfur bacteria or green micro algae. Reaction (2) describes the conversion process. Theoretically, 4 moles of hydrogen are produced for every mole of acetic acid but, in practice, part of the acetic acid is used for the production of cells. Moreover, large surface area is required to capture the necessary light energy, making it practically challenging in terms of bioreactor design. Transparent tubular reactors and flat panel reactors consisting of transparent rectangular boxes are under investigation (Wukovits et al. 2009).

$$CH_3COOH + 2H_2O + \text{light energy} \rightarrow 4H_2 + 2CO_2 \quad (2)$$

Combination of the above-mentioned fermentations enhances the yield of hydrogen production. One such combination is dark fermentation and anaerobic digestion in which the monomeric components of the polymeric biomass are converted to biohydrogen. Dark fermentation and photo fermentation is another combination process that theoretically yields 12 moles of hydrogen for every mole of hexose sugar. This approach, called "Hyvolution," would allow complete digestion of biomass, enhancing small-scale, cost-effective production of hydrogen, which otherwise is limited by thermodynamic considerations (Wukovits et al. 2009).

Another approach mentioned in the second stage (lower right of Fig. 2) employs microbial electrohydrogenesis cells (MECs). In this method, electricity is applied to a microbial fuel cell that provides the necessary energy to convert the byproducts (typically organic acids) of the first stage into hydrogen (Hallenbeck and Ghosh 2009).

Several raw materials such as kitchen waste, animal waste, agricultural residues, etc., are used as substrates for biohydrogen production. Fermentation of kitchen waste devoid of plastic and bones was used to produce hydrogen with a maximum efficiency of 4.77 LH_2/(L reactor day) in a continuous stirred tank reactor (Shi et al. 2009). Use of second-generation feedstocks that are of cellulose origin such as corn stalks, wheat straw, switch grass, and *miscanthus* further enhance economical production of hydrogen. Pretreated lipid extracted microalgal biomass residue (LMBR) showed threefold hydrogen yields compared to the untreated LMBR (Yang et al. 2010). However, noncellulosic components such as xylose require conversion by a fermentative organism. High-thermophilic mixed culture was developed for xylose fermenting to biohydrogen at 1.36 ± 0.03 mol H_2/mol xylose consumed (Kongjan et al. 2009).

Organisms belonging to genus *Clostridium* such as *Clostridium butyricum*, *C. acetobutylicum*, *C. saccharoperbutylacetonicum*, and *C. pasteurianum* are often used in the anaerobic production of hydrogen. Anaerobic thermophilic bacterial fermentation to hydrogen is the most suitable option due to increasing chemical and enzymatic reaction rates at high temperatures. Additionally, thermophilic processes yield lesser undesirable products as compared to mesophilic processes (Koskinen et al. 2008). An optimized fermentation of hydrolysate obtained from treating sugarcane bagasse with 0.5 % H_2SO_4 under 121 °C and 1.5 kg/cm^2 in autoclave for 60 min was obtained at initial pH 5.5 and initial total sugar

concentration of 20 g/L at 37 °C (Pattra et al. 2008). Thus, initial pH and total sugar concentration are important factors for an optimal hydrogen yield. However, an increase in hydrolysate (sugar) concentrations from 25 % (v/v) to 30 % (v/v) led to no hydrogen production. Further, an increase in lag time was observed from 11 to 38 h for an increase in hydrolysate concentrations from 20 % (v/v) to 25 % (v/v) for a mixed thermophilic dark fermentation process (Kongjan et al. 2010). Supplemental glucose and xylose with a ratio of 2:3 along with suitable pH control and inoculum concentration are realized to be the key factors for enhanced hydrogen production (Prakasham et al. 2009).

Finally, biophotolysis is a low productivity method for hydrogen gas production. It involves dissociation of water by solar energy using green micro algae. The process takes place in two ways, direct biophotolysis and indirect biophotolysis. In direct biophotolysis, the microbes split the water into oxygen and hydrogen using sunlight by releasing two photons, which can either reduce carbon dioxide or form hydrogen in the presence of hydrogenase enzyme. However the released oxygen has an inhibitory effect on the hydrogenase enzyme which can be overcome by indirect biophotolysis. Indirect biophotolysis is carried out by cyanobacteria, in which water and carbon dioxide form carbohydrates and oxygen via photosynthesis. The second stage involves either dark fermentation or a combination of dark and photo fermentation to produce hydrogen. Fermentative water-gas shift reaction is another biological route in which carbon monoxide in the presence of water is converted to carbon dioxide and hydrogen (Wukovits et al. 2009).

Methane

Methane is the main component of natural gas which is used as an energy carrier and raw material all over the world (Seiffert et al. 2009). Biogas produced from anaerobic digestion of biomass contains methane which can be used for energy purposes. The biochemical conversion of manure and other biomass to methane involves three stages.

In the first stage, hydrolysis, enzymes produced by strict anaerobes such as *Clostridia*, *Bactericides*, and *Streptococci*, break up the complex molecules such as lipids, polysaccharides, proteins, fats, nucleic acids, etc., to simpler molecules such as monosaccharides, amino acids, fatty acids, etc. In the second stage, acidogenesis, a group of bacteria ferment the byproducts of hydrolysis to acetic acid, propionic acid, and butyric acid. In the third stage, methanogenesis, methanogens convert the acetic acid, hydrogen, and carbon dioxide into methane and carbon dioxide.

Figure 3 shows a block diagram of biogas production from manure. Biogas production is greatly affected by temperature. Anaerobic fermentation is effective mostly at mesophilic (15–40°C) and thermophilic (50–60°C) temperature ranges. Therefore, the reactors are coated with biomass residues such as charcoal and even constructed in a sun-facing direction to avoid cold winds and make maximum use of heat available from nature (Anand and Singh 1993). Reactors have been designed to have a polythene sheet covering the top of it to utilize the energy from sun to heat up the reactor contents even during winter (Bansal 1988).

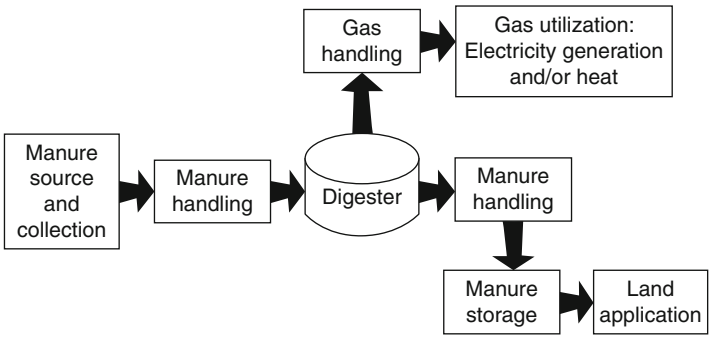

Fig. 3 Block diagram of biogas production from manure (Source: http://pubs.ext.vt.edu/442/442-881/442-881.html)

As acetic acid and hydrogen produced during the process decrease the pH of the system, pH maintenance is another important parameter affecting the methane production, the desired pH being 6.8–7.2. Several techniques are involved in enhancing the production of biogas, such as addition of organic and inorganic additives, microbial strains, recycling of digested slurry, and maintaining C:N ratio. Additives, such as powdered green leaves, allow adsorption of substrate to increase localized concentration and enhance microbial growth. Addition of Ca and Mg salts act as microbial energy supplements and avoid foaming. Recycling of slurry avoids loss of active culture which otherwise occurs through the effluent stream. As the microbes tend to utilize carbon 25–30 times faster than nitrogen for the production of methane, maintaining C:N ratio is another critical factor in efficient production of biogas (Yadvika et al. 2004).

Biomethane can be distributed into the natural gas grid. In the case of existing pipelines in UK, Italy, and Germany, this concept is called the "green gas concept" (Åhman 2010). However, to employ biogas as a transportation fuel, concentration of biogas to 97 $\pm$ 1 % of methane by removing the carbon dioxide is required (Power and Murphy 2009). About 30–60% of the wet biomass can be converted to methane by anaerobic digestion, while the remaining residue can be used as biofertilizer (Åhman 2010). Coproduction of methane and hydrogen using a two-stage anaerobic digestion process is another way to optimize simultaneous production of methane and hydrogen (Zhu et al. 2008).

An energy input approximating 22 % of the fuel value is utilized in the production of biomethane, compared to approximately 57 % in the production of bioethanol (Power and Murphy 2009). The majority of the difference arises from the thermal energy consumption involved in the distillation of ethanol and drying of the residue obtained from fermentation. Thus methane's gaseous nature has an added advantage over liquid biofuels. However, biomethane losses during digestion and upgrading constitute about 7.41 % of total biogas produced. Minimizing these losses and improving infrastructure efficiency for biomethane is needed to enhance the utility of methane relative to ethanol (Power and Murphy 2009).

Ethanol

Ethanol is the most extensively studied biofuel to date and has gained great attention as sustainable biofuel. Bioethanol production and utilization is estimated to reduce green house gas emissions, improve agricultural economy, enhance rural employment, and increase national security (Mabee and Saddler 2009). Bioethanol has higher octane number, broader flammability limits, higher flame speeds, and higher heats of vaporization than gasoline, which allow for higher compression ratio, shorter burn time, and leaner burn engine. A major problem with ethanol is its water solubility and azeotropic mixture formation with water, limiting separation during distillation, consequently intensifying the cost of the separation process. Other major disadvantages include lower energy density than gasoline, low vapor pressure (making cold starts difficult), and toxicity to ecosystems (Balat 2007). However, ethanol is a 35 % oxygenated fuel and reduces particulate and NO_x emissions. It increases combustion efficiency as it provides a reasonable antiknocking value. It can be blended with gasoline in various amounts, ranging from 5 % to 85–100 %, for use in the existing internal combustion engines, where 85 % (E85, meaning 85 % ethanol in gasoline) blends are used in flexible fuel vehicles (FFVs). Table 2 shows various blends of ethanol in gasoline used in different countries worldwide. In pure ethanol cars, sulfur emissions have totally disappeared; gasoline-driven cars with ethanol replacing lead have negligible carbon monoxide emissions (Goldemberg et al. 2008).

Substrates used for the production of bioethanol vary with the availability of feedstock and geographical location. The USA and Brazil are the two major bioethanol producers in the world. Sugarcane and cane molasses are the substrates for the ethanol production in Brazil as is cornstarch in the USA (Almeida et al. 2007). Other substrates used are cassava, sugar beet, wheat, etc. However, use of food products like corn and cassava for ethanol production has an inflating effect on the prices of these staple crops and an effect on their supply. Additionally, storage of high concentration sugar substrates is liable to microbial contamination

Table 2 Common gasoline ethanol blends available in various countries (Balat 2007)

	Common vehicles	Flexible fuel vehicles (FFVs)
USA	E10	E85
Canada	E10	E85
Sweden	E5	E85
India	E5	–
Australia	E10	–
Thailand	E10	–
China	E10	–
Columbia	E10	–
Peru	E10	–
Paraguay	E7	–
Brazil	E20, E25	Any blend available

and requires sophisticated storage methods, such as refrigeration, which in turn requires energy use over long periods (Dodic et al. 2009). Work by Dodic et al. suggests the use of intermediate products such as thick juice in sugar beet production as substrates for ethanol production, in order to reduce storage volume and microbial contamination. Use of lignocellulosic materials such as switch grass, *miscanthus*, sorghum, and corn stover is highly encouraged due to high substrate availability, economic feasibility of production, and storage, and due to other reasons mentioned in section "Sources" of this chapter. Waste mushroom logs have been studied for their potential as substrates for ethanol production where 12 g/L ethanol concentration was obtained as against 8 g/L concentration for normal logs (Lee et al. 2008b). Mahua flowers were investigated for their potential as substrates for ethanol fermentation, with ethanol productivity of 3.13 g/kg flower/h at 77.1 % efficiency (Mohanty et al. 2009).

Lignocellulosic biomass consists of majorly cellulose, hemicelluloses, and lignin of which cellulose is the most desired component for ethanol production. Ethanol is produced from the sugars that are present in the cellulose in polymeric form. Biomass is initially preprocessed, such as size reduced and washed for ease of handling and removal of soil. As shown in Fig. 4, the first major stage requires release of sugars from the cellulose-hemicellulose-lignin matrix; the second major stage involves the hydrolysis of higher sugars and fermentation of the monomeric sugars to ethanol; and the third stage involves the separation of ethanol from the fermentation broth.

Pretreatment

Pretreatments for bioethanol production may be performed using chemicals such as sulfuric acid, sodium hydroxide, ammonium hydroxide, supercritical ammonia, and supercritical carbon dioxide at both high and low temperature and pressure conditions to separate undesirable components such as lignin from biomass. Pretreatment disrupts the biomass structure and increases the surface area to enhance enzyme

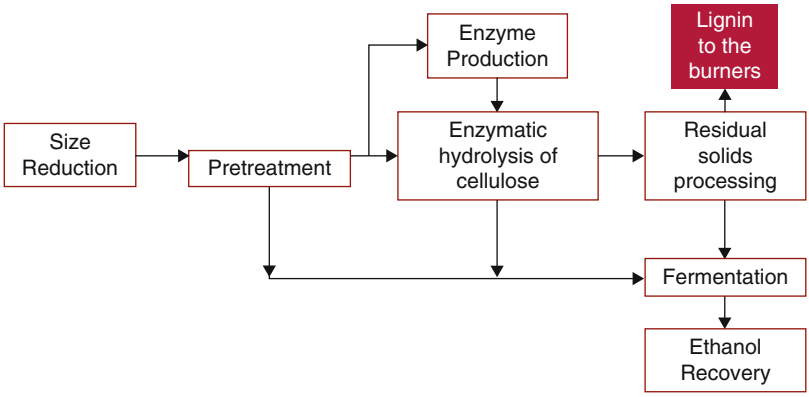

Fig. 4 Cellulosic ethanol "sugar platform"

access during the hydrolysis stage. Several pretreatment methods such as hot water treatment, steam explosion, dilute sulfuric acid treatment, and ammonia fiber expansion can be employed to remove lignin and/or depolymerize lignocelluloses structure in biomass.

Thermal processes include liquid hot water (LHW) and steam pretreatment. At temperatures above 150–180°C, hemicellulose and then lignin begin to dissolve (Bobleter 1994a; Garrote et al. 1999). Hot water pretreatment primarily dissolves hemicellulose to increase access for enzyme hydrolysis and to limit formation of inhibitors (Mosier et al. 2005a). Liquid hot water has removed up to 80 % of the hemicellulose to improve enzymatic hydrolysis by increasing the accessible surface area of the cellulose (Mosier et al. 2005a; Laser et al. 2002). pH should be kept between 4 and 7 to maintain hemicellulosic sugars in oligomeric, reducing formation of degradation products and thus inhibitors (Mosier et al. 2005a). Hemicellulose can be hydrolyzed to form acids which further hydrolyze the hemicelluloses (Gregg and Saddler 1996). The main advantages for LHW are recovery of pentoses, minimization of inhibitors, compared to steam explosions and minimal need for chemical and neutralization as compared to dilute acid pretreatment (Taherzadeh and Karimi 2008). Hot water pretreatment of lignocellulosic biomass has three types of reactor configurations, cocurrent, counter current, and flow through. In cocurrent pretreatment, biomass and water are heated to a desired temperature and held in the reactor for a controlled residence time before cooling. In counter current flow system, biomass slurry and water are allowed to flow in opposite directions into the reactor. In flow through configuration, hot water is allowed to flow through a stationary bed of biomass (Mosier et al. 2005b). Therefore, pretreatment technologies have been developed to be carried out in both batch and continuous flow reactor configurations.

Steam explosion has been widely tested in lab and pilot-scale systems. Biomass is pressurized with steam at 160–260°C for several seconds to minutes and pressure is rapidly released. Mechanical forces separate fibers and the high temperature promotes conversion of acetyl groups to acetic acid (Alvira et al. 2010; Taherzadeh and Karimi 2008). The main action of the acetic acid is probably to catalyze the hydrolysis of soluble hemicellulose oligomers (Bobleter 1994b). Lignin is redistributed and some removed (Pan et al. 2005). Removing hemicellulose increases accessibility of enzymes to the cellulose (Alvira et al. 2010). The advantages of steam explosion include use of larger chip size, reduced need for acid catalyst, high sugar recovery, and feasibility for industrial-scale use (Alvira et al. 2010). The primary disadvantages include partial hemicellulose degradation and generation of inhibitory compounds (Oliva et al. 2003). Steam explosion can be combined with addition of sulfur dioxide and sulfuric acid to enhance recovery of cellulose and hemicellulose. It improves the solubilization of hemicelluloses, lowers optimal treatment temperatures, and partially hydrolyzes cellulose (Brownell et al. 1986; Tengborg et al. 1998). Acid addition is particularly effective with softwoods, which have a low content of acetyl groups (Sun and Cheng 2002).

Acid pretreatment removes hemicellulose to make cellulose more accessible. It can also hydrolyze fermentable sugars. Acid pretreatment can be practiced using

high concentrations of acid (generally sulfuric) at low temperatures or low concentrations at high temperatures (Taherzadeh and Karimi 2008). Use of concentrated acid requires corrosion resistant process equipment. Recovery of the acid is energy intensive and produces degradation products inhibitory to fermentation (Alvira et al. 2010; Taherzadeh and Karimi 2008; Chisti 1996). Use of dilute acid is more promising, for example at 0.1–1 % sulfuric acid at 140–190°C. This achieves almost total hemicellulose removal and high cellulose conversion (Taherzadeh and Karimi 2008). Production of inhibitory compounds is lessened (Hendriks and Zeeman 2009). Addition of nitric acid greatly improves solubilization of lignin in newspaper (Xiao and Clarkson 1997). The use of acid pretreatment for methane production is more forgiving because methanogens can tolerate the inhibitory compounds (Xiao and Clarkson 1997; Benjamin et al. 1984).

Alkali pretreatment uses NaOH, $Ca(OH)_2$, or ammonia. Lime is very effective (Hendriks and Zeeman 2009). It removes acetyl groups and has lower cost and less safety concerns. Solvation and saponification reactions (Hendriks and Zeeman 2009) lead to swelling. The swelling increases internal surface area of cellulose, decreases polymerization and crystallinity, and disrupts lignin structure and removes some lignin and hemicellulose (Taherzadeh and Karimi 2008), increasing accessibility to enzymes enhancing saccharification (Kassim and El-Shahed 1986). Processing can be done at low (ambient) temperature (Xu et al. 2007) for long time periods (24 h) or at elevated (120–130°C) levels for minutes to hours (Silverstein et al. 2007). Production of inhibitory compounds is significantly less (Taherzadeh and Karimi 2008). But, solubilization and redistribution of lignin and modifications in crystalline state of lignin can counteract the benefits of the method (Gregg and Saddler 1996). Addition of hydrogen peroxide to alkaline pretreatment enhances lignin removal and improves enzymatic hydrolysis (Carvalheiro et al. 2008). Alkaline pretreatment, as with acid, is more forgiving for production of methane versus ethanol (Pavlostathis and Gossett 1985).

Ammonia fiber explosion or "expansion" (AFEX) is analogous to the steam expansion method. Anhydrous ammonia is added to biomass at approximately 1 kg NH_3: 1 kg dry and held at temperatures of approximately 100–120°C for several minutes. Pressure is rapidly released, swelling and disrupting the lignocellulose structure (Alvira et al. 2010; Taherzadeh and Karimi 2008). Only a solid residue is produced and a little hemicellulose and lignin are removed (Wyman et al. 2005). Enzyme hydrolysis yields and ethanol production are increased (Alizadeh et al. 2005). AFEX does not produce inhibitors, although some lignin may remain on the biomass surface (Alvira et al. 2010). It is more effective on lower-lignin crop residues and herbaceous crops than woody material (Wyman et al. 2005).

CO_2 explosion uses CO_2 at high pressure to penetrate the pores of lignocellulose. Explosive depressurization disrupts the cellulose and hemicellulose structure and improves enzymatic hydrolysis. Supercritical conditions at 35 °C and 73 bar remove lignin and increase digestibility more effectively (Alvira et al. 2010). However, pretreatment with appropriate conditions is a highly desirable step for lignocellulosic biomass to improve its digestibility.

Other physiochemical methods include organosolv and wet oxidation. Organosolv uses organic solvents to dissolve lignin. Solvent recovery is essential, and inexpensive, low molecular weight alcohols are favored. The recovery of low molecular weight lignin as a coproduct is potentially a significant advantage (Pan et al. 2005). Wet oxidation uses water and oxygen under elevated pressure and temperature (Taherzadeh and Karimi 2008). Hydrogen peroxide can be used at ambient temperature can also be used to enhance enzymatic hydrolysis (Azzam 1989). Batch treatment of corn stover using $FeCl_3$ in tubular reactors resulted in the hydrolysis yield of 98 % compared to 22.8 % yield for the untreated corn stover (Liu et al. 2009).

Biological pretreatment primarily uses brown and white soft rot fungi that degrade lignin and hemicelluloses (Taherzadeh and Karimi 2008). White rot fungi in particular have been evaluated and several shown to have high delignification efficiency (Kumar et al. 2009). Increase in total sugar yields during hydrolysis has been reported for switch grass preprocessed with *Phanerochaete chrysosporium* for 7 days (Mahalaxmi et al. 2010). Advantages include low energy and chemical requirements and ambient conditions. However, hydrolysis rates after biological pretreatment are low, and more research is needed (Alvira et al. 2010).

Hydrolysis

Hydrolysis of the pretreated biomass can be performed both chemically and biochemically. Chemical hydrolysis uses a continuous two-step dilute sulfuric acid process. The first step involves low temperature treatment and the second step, a high temperature treatment, as hemicellulose depolymerizes at lower temperature than the cellulose polymer. In the first step, the hemicellulosic fraction is removed, followed by the second step in which hexose release occurs. A batch process, using concentrated sulfuric acid, is also used for biomass hydrolysis; however, the use of concentrated acid requires high capital investment due to the requirement of corrosive resistant process equipment. Additionally, it requires acid recycling and recovery for economic viability of the process (Balat 2007).

Biochemical hydrolysis is the most sought out process in recent years and is commonly called as saccharification. It is initiated by enzymes that cleave the cellulose-lignin matrix into various monomeric, dimeric, and oligomeric sugars. Most common enzymes that act synergistically for cellulose hydrolysis, called cellulases, are endoglucanases or endo-1,4-β-glucanases (EG), exoglucanases or cellobiohydrolases (CBH), and β-glucosidases (BGL). While endoglucanases cleave the intramolecular bonds of the cellulose polymer, CBH and BGL catalyze the release of cellobiose and glucose from oligomeric ends and glucose from cellobiose respectively as shown in the Fig. 5. A synergistic effect of an enzyme component system consisting of at least endo-β-glucanases, exo-β-glucanases, and β-glucosidases results in hydrolytic efficiency (Sun and Cheng 2002; Maeda et al. 2011).

Enzymes related to hemicellulose hydrolysis, hemicellulases, are majorly endo-1,4- β-xylanase, β-xylosidase, α-glucuronidase, α-L-arabinofuranosidase, and acetylylan esterase as shown in Fig. 6. Therefore, the hydrolysate contains both

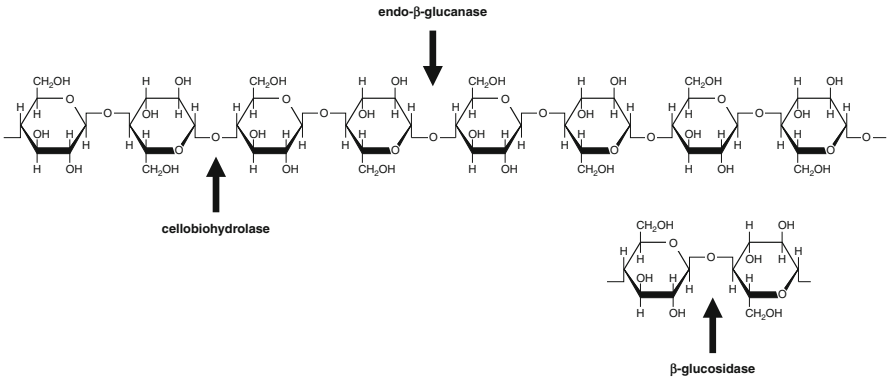

Fig. 5 Molecular structure of cellulose and site of action of endoglucanase, cellobiohydrolase, and β-glucosidase (Kumar et al. 2008)

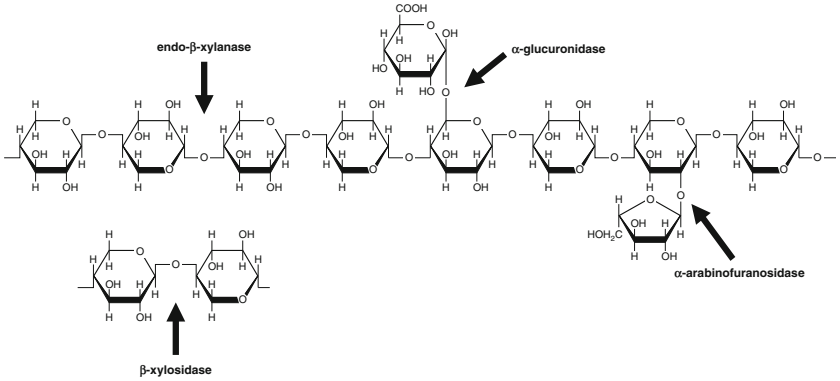

Fig. 6 Polymeric chemical structure of hemicellulose and targets of hydrolytic enzymes involved in hemicellulosic polymer degradation (Kumar et al. 2008)

hexoses and pentoses and their oligomeric forms depending on the treatment (Kumar et al. 2008).

Various bacteria such as *Clostridium*, *Cellulomonas*, *Bacillus*, *Thermomonospora*, *Ruminococcus*, *Bacteriodes*, *Erwinia*, *Acetovibrio*, *Microbispora*, and *Streptomyces* produce these enzymes to hydrolyze lignocelluloses. Fungi such as *Trichoderma*, *Ceriporiopsis*, *Aspergillus*, and *Sporotrichum* also possess the cellulolytic abilities to hydrolyze lignocellulosic biomass. Therefore, enzyme extracts from these cultures are used for hydrolyzing biomass and recent developments in enzyme technology have reduced their price of production significantly.

The factors that influence the enzymatic hydrolysis are mainly temperature, pH, and substrate concentration. At low substrate concentration, increase in substrate concentration increases the yield and the reaction rate of hydrolysis. However, at

high substrate concentration, yield and reaction rate decrease due to substrate inhibition of enzymes (Sun and Cheng 2002; Chisti 1996). Temperature and pH for enzyme activity varies by the microbe source from which it is derived. However, most commonly used industrial cellulases are derived from wild and modified strains of *Trichoderma reesei* and have an optimum temperature between 45 °C and 50 °C. Hydrolysis yields are also increased by addition of surfactants such as Tween-20. It is reported that the addition of Tween-20 resulted in 8 % increase in ethanol and 50 % reduction in cellulases dosage, increase in enzyme activity and the hydrolysis rate (Sánchez and Cardona 2008).

Consolidated microbial treatment of biomass is another method of saccharification of biomass. Loss of sugars during the process is inevitable, due to the consumption by microbes, which makes the use of enzyme extracts advantageous for hydrolysis. Enzyme hydrolysis is limited byproduct inhibition, which requires continuous removal of hydrolysis products apart from the use of BGL for subsequent conversion of the generated cellobiose to glucose. Therefore, simultaneous saccharification and fermentation (SSF) is a potential solution for product inhibition, where release of glucose using enzyme hydrolysis and its subsequent fermentation to ethanol by yeast take place in the same system (Balat 2007).

Fermentation

Fermentation of biomass to ethanol is commonly carried out using yeast such as *Saccharomyces* and *Pichia*, bacteria such as *Zymomonas* and *Escherichia*, and fungi such as *Aspergillus.* Products of hydrolysis and sugars are converted to ethanol producing carbon dioxide as byproduct and energy for cell growth. The most commonly used microbe *Saccharomyces cerevisiae* ferments sugars to ethanol at almost anaerobic conditions, although it requires a certain amount of oxygen for essential polyunsaturated fats and lipids. Figure 7 depicts the ethanol fermentation pathway of *Saccharomyces* from glucose. It briefly describes the conversion of glucose to ethanol through intermediate biochemical reactions involving NAD^+ and NADH (Nicotinamide adenine dinucleotide – oxidized and reduced forms, respectively). Since lignocellulosic biomass consists of several components such as pentoses, hexoses, and acids (acetic acid), degradation products derived from the pretreatment stage could inhibit the fermentation process. Chemical, physical, and biological methods have been developed to overcome the inhibition effect of these compounds by detoxification. *Trichoderma reesei* has been reported to degrade the inhibitors present in willow hydrolysate after steam pretreatment. Overnight extraction of spruce hydrolysate with diethyl ether at pH 2 showed detoxification effects with ethanol yields comparable to the reference fermentation. Detoxification by alkali treatment at pH 9 using $Ca(OH)_2$ and readjustment of pH to 5.5 allowed better fermentability due to precipitation of toxic compounds (Palmqvist and Hahn-Hägerdal 2000).

Usually, the temperature of operation is in the mesophilic range (15–40°C) for most of the species mentioned above. Increases in temperature beyond the optimum condition result in a decrease in ethanol yield and eventually in cell death. Another important factor in maintaining good cell growth is pH, generally a pH range of 6.5–7.5 (Aminifarshidmehr 1996) is suitable for ethanol fermentation for most of the

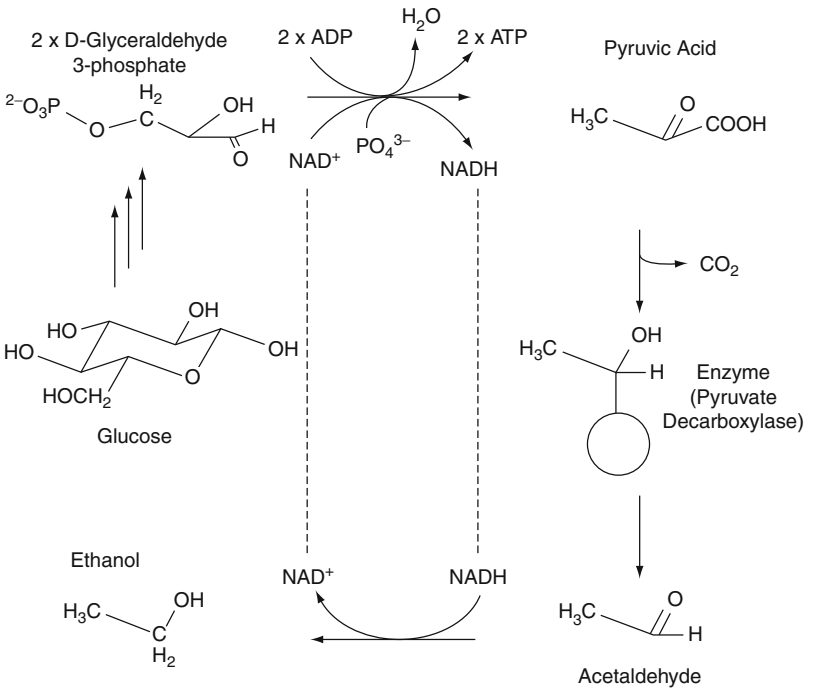

Fig. 7 Ethanol fermentation pathway of *Saccharomyces*

strains, although, yeast and fungal strains can tolerate up to 3.5–5.0. pH below 4.0 reduces the potential of bacterial contamination thus alleviating the requirement of severe aseptic techniques (Balat 2007).

Fermentation of biomass is affected by several other factors such as ethanol tolerance, substrate concentration, and byproduct inhibition. Ethanol tolerance is one of the factors which determine the maximum ethanol concentration that can be reached during fermentation, as most of the microbes responsible for fermentation cannot tolerate high concentrations of ethanol, eventually leading to cell death. *Zymomonas* has higher ethanol tolerance and achieves 5 % higher ethanol yields, as compared to the other yeast strains (Mohagheghi et al. 2002). Increase in substrate concentration decreased the ethanol yield. However, batchwise charging of substrate reduces this kind of inhibition. Therefore, fed-batch reactors are more suitable for industrial applications. Byproduct inhibition is overcome by chemical, mechanical, or biological detoxification as mentioned above (Balat 2007).

Butanol

Butanol is a colorless liquid which causes a narcotic effect at high concentrations. It is used as a solvent in biopharmaceutical, chemical, and cosmetic applications because of its high solubility in organic solvents and low water miscibility. Its physical properties very closely resemble those of gasoline, making it a potential

additive in partial or complete to transportation fuel (Lee et al. 2008c). Butanol can also be used as a replacement fuel to gasoline-driven engines with minimum or no changes; it can also be blended with gasoline at much higher composition than ethanol as butanol has similar energy content as that of gasoline. It can be added to gasoline at the refinery and distributed through existing gasoline pipeline unlike ethanol, as butanol is less corrosive and does not absorb water (Dürre 2008).

Butanol, a four carbon primary alcohol, can be synthesized both chemically and biochemically; chemical synthesis of butanol is conducted majorly by three methods, namely, Oxo synthesis, Reppe synthesis, and crotonaldehyde hydrogenation. However, the discussion of this chapter is limited to biochemical conversion of biomass to butanol.

In biochemical route, butanol is a fermentation product of anaerobic bacteria *Clostridium acetobutyliticum*, *Clostridium butyricum*, etc. Industrial production of butanol dates back to 1914 during World War I, as a byproduct in the production of acetone (which was used in war ammunition) by fermentation using *C. acetobutyliticum*. Although there was no immediate application of butanol during that time, later in 1920s in the USA, it was used to replace amyl acetate, a product from amyl alcohol, a solvent for lacquers in the automobile industry. By the 1950s, 66 % of the butanol used in the world was produced biochemically. However, due to increased biomass cost and low crude oil prices, crude oil replaced butanol as a transportation fuel (Dürre 2007). Substrates used for butanol production can be of both starch and cellulose origin such as molasses, corn fiber, wheat straw, etc. However, the conflict of using food substrates for fuel production regulates the usage of starch-based substrates. Figure 4, which depicts the flow of processes for ethanol, can also be applied for butanol. However, fermentation of biomass is carried out by butanol producing bacteria.

The biochemical routes involved in butanol formation are given in Fig. 8 (Lee et al. 2008c). Butanol formation takes place through the glucose-pyruvate-butyraldehyde route. Butanol fermentation is a biphasic transformation consisting of an acidogenic phase which occurs during exponential growth phase and solventogenic phase. During the acidogenic phase, acid-forming pathways are activated, and acetate, butyrate, hydrogen, and carbon dioxide are produced as major products. Acetone, butanol, and ethanol/propanol are the products of solventogenic phase which occurs after the exponential growth phase (Lee et al. 2008c). Both acidogenic and solventogenic phases can be seen in the Fig. 8 based on the final products produced in the two phases. The solventogenic phase is a response to the increased acid production after acidogenic phase, which if not initiated, would lead to a decrease in the extracellular pH, and finally to cell death due to increasing proton gradient between inner and outer cellular environments (Dürre 2008). Therefore, pH control has a very crucial effect on butanol production, and it requires being in the acidic range for the solventogenic phase.

Solvent toxicity is another major concern that causes cell death, due to cell wall weakening in the presence of acetone, ethanol, and butanol (the most toxic compound), leading to low product concentrations and productivity (Lee et al. 2008c). Solvent toxicity can be overcome by continuous removal of the solvents through

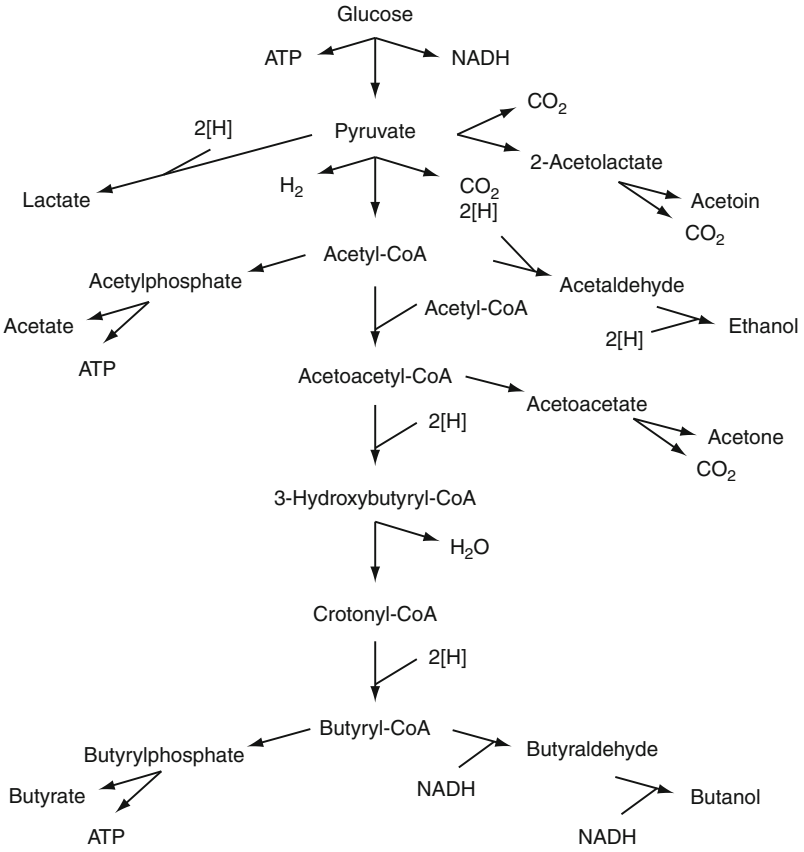

Fig. 8 Butanol fermentation pathway of *Clostridium acetobutylicum* (Dürre 2008)

various unit operations. Traditionally, butanol formed is separated by distillation which is a cost-intensive operation due to its high boiling point. Alternative methods for butanol separation are adsorption, gas stripping, liquid-liquid extraction, perstraption, pervaporation, and reverse osmosis (Dürre 2007). Each of these processes has certain limitations, among which, gas stripping is simple and successful in spite of low selectivity, as it can be used in a continuous operation for removing butanol. Liquid-liquid extraction requires use of a solvent that is noninhibitory to the microbes. In pervaporation, butanol is selectively diffused through a membrane and evaporated without removing the medium components necessary for the microbial growth (Qureshi et al. 1999). However, it is limited by fouling of membranes by the particles present in the fermentation broth.

Biodiesel

Biodiesel is a biofuel derived from transesterification of fats and oils with properties similar to the petroleum diesel. It can be blended with diesel or used directly in the

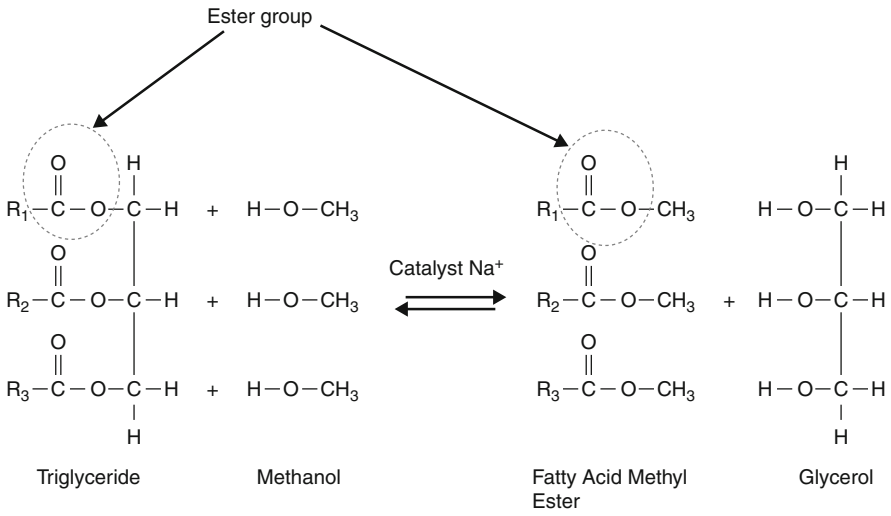

Fig. 9 Formation of biodiesel (Fatty acid methyl ester)

existing diesel engines without significant modifications. The main advantage of biodiesel is that, as a biomass-derived fuel, it produces 78 % less (net) carbon dioxide emissions, compared with that for petroleum-derived diesel fuel. Because its structure is nonaromatic, it combusts more efficiently, producing 46.7 % less carbon monoxide emissions, 66.7 % less particulate emissions, and 45.2 % less unburned hydrocarbons compared to conventional diesel. Therefore, it can be used in highly sensitive environments such as marine and mining environments (Helwani et al. 2009). Additionally, its high boiling point (about 150 °C) and presence of fatty acids impart lesser volatility and higher lubricating effect respectively, on engines, eventually reducing wear and tear and enhancing longer service life (Al-Zuhair 2007).

Biodiesel is conventionally produced from transesterification of oil (triglycerides) with alcohol (methanol) in the presence of an acid, base, or enzyme catalyst with glycerin as byproduct as shown in Fig. 9.

The sources of oil include oil seed plants such as palm, rapeseed, soybean, castor, and jatropha, used oils, lard, animal fat residue, etc. Palm oil having the highest yield of around 4,000 kg of oil per hectare is considered to be the best source of oil for biodiesel production (Al-Zuhair 2007). However, the majority of the cost involved in biodiesel production arises from the cost of the feedstock oil. Further, with the increasing edible oil consumption, it is more economical and environmentally sustainable to employ used oils and nonedible oils for biodiesel production. The major differences between the fresh and used oils are the moisture and free fatty acid (FFA) content, with used oils having high moisture and FFA content, which affect the acid- and alkaline-catalyzed transesterification, respectively. Alternatively, animal fats from waste residues are a useful source of oils. However, the heat at their high melting points denatures the enzymes used during enzyme-catalyzed

transesterification. Other sources of oil are oleaginous yeasts and filamentous fungi which on their outer surface secrete oil (Miao and Wu 2006).

As mentioned earlier, biodiesel production process can be alkali, acid, or enzyme catalyzed depending on the amount of FFAs and moisture present in the oil feedstock. The stoichiometry from Fig. 9 suggests oil to methanol ratio to be 1:3. However, for equilibrium to proceed toward the formation of biodiesel, use of excess alcohol is suggested.

During an alkali-catalyzed reaction, the oils in the presence of excess methanol are converted to fatty acid methyl esters and glycerin (Fig. 10). Alternately, during an acid-catalyzed reaction the triglycerides are esterified followed by a transesterification process (Fig. 11) (Schuchardt et al. 1998). Low FFA-containing feedstock is more suitable for alkali-catalyzed transesterification and high FFA-containing ones for acid-catalyzed reaction. FFAs present in oils during base-catalyzed reaction react with the oils to form soap and emulsions that hinder the purification processes of biodiesel apart from base consumption (Basu and Norris 1996). Alkaline methoxides are high biodiesel yielding base catalysts with short reaction times, even at very low (0.5 mol%) concentrations. However, they are more expensive than metal hydroxides (KOH and NaOH) (Helwani et al. 2009). On the other hand, acid-catalyzed reactions are 400 times slower than the alkali-catalyzed transesterification (Al-Zuhair 2007) and less sensitive to FFA content. The presence of water greatly inhibits the conversion due to catalyst deactivation.

The major reaction parameters affecting the biodiesel conversion are temperature, oil/methanol ratio, FFA, and moisture contents. An increase in temperature will increase the conversion the most appropriate range being 60–70°C, the alcohol boiling range at atmospheric pressure.

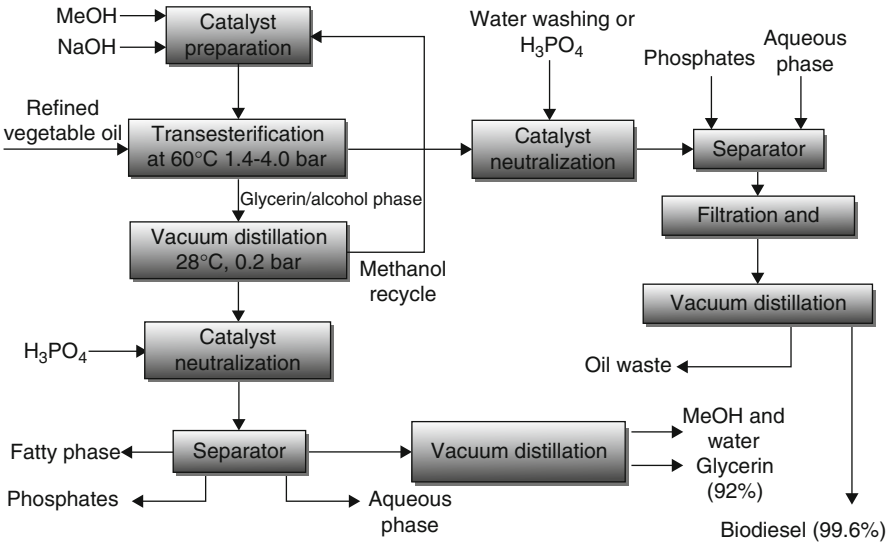

Fig. 10 Block diagram for base-catalyzed production of biodiesel (Helwani et al. 2009)

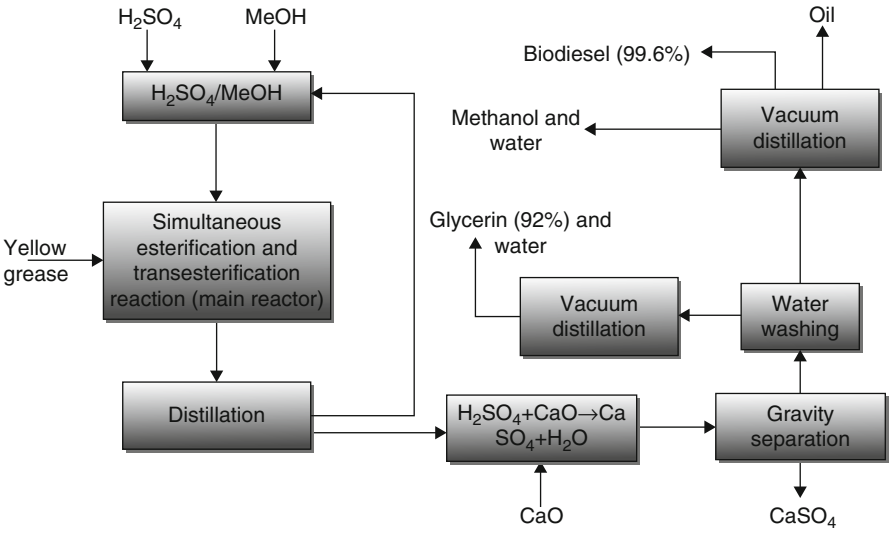

Fig. 11 Block diagram for acid-catalyzed production of biodiesel (Helwani et al. 2009)

Enzyme-catalyzed transesterification is achieved using lipases obtained from organisms such as *Candida rugosa*, *Pseudomonas fluorescens*, *Rhizopus oryzae*, *Burkholderia cepacia*, *Aspergillus niger*, *Thermomyces lanuginosa*, and *Rhizomucor miehei* (Al-Zuhair 2007). Enzymes are more compatible in terms of usage of a wide range of feedstocks, fewer processing steps, and fewer separation steps. Enzymes do not form soaps with the FFAs present in the feedstock, which allows the use of spent oils and animal fats for biodiesel production. They can convert both FFAs and triglycerides (TAG) simultaneously without another pretreatment step for converting FFAs to TAG (Fjerbaek et al. 2009). An increase in temperature increases the enzymatic conversion of biodiesel due to increased rate constants and lesser mass transfer limitations (Al-Zuhair et al. 2003). Additionally, optimal water content increases the biodiesel conversion as lipase acts as an interface between the aqueous and organic phases which allow its activation by rendering suitable conformation for transesterification (Panalotov and Verger 2000). However, they are currently facing challenges related to lower reaction rate, high cost, and loss of activity.

Methanol is the most widely used alcohol for biodiesel production due to its availability from syngas. However, it is required to use an alcohol produced from a renewable source, such as ethanol, to make biodiesel production a completely green process. Additionally, methanol is toxic and renders lipases inactive at high concentrations. Therefore, methyl acetate can be used as a methyl acceptor in place of methanol, as it still has no negative effects on Novozyme 435, the only commercial lipase known, used for biodiesel production from soybean oil (Du et al. 2004). Immobilization of lipases is considered an economical process to overcome the

limitations of using a batch process and employing a continuous process to enable glycerol separation for higher conversion rates (Watanabe et al. 2002).

Genetic Engineering Approaches

With the above background of conversion of biomass to fuels, it is evident that several factors such as biomass composition, pH, temperature, by-products, etc., have a potential impact on the biofuel production. Process factors such as pH and temperature can be maintained using appropriate reactor and process conditions. Intrinsic factors such as biomass composition, product tolerance such as ethanol and butanol tolerance, specific binding of enzymes, and byproduct inhibition will remain potential challenges without recombinant DNA technology.

Recombinant DNA technology is comprised of five general procedures (Nelson and Cox 2008):

1. A desired segment of the microbe DNA of interest is cut using sequence-specific endonucleases which are nucleotide cleaving enzymes, otherwise called restriction endonucleases. These endonucleases act as molecular scissors to obtain the required nucleotide sequence.
2. A small molecule of DNA capable of self-replication is selected. These molecules, called cloning vectors, are generally plasmids or viral DNA which can be coupled with the nucleotide sequence obtained from the previous step.
3. The two segments are incubated in the presence of DNA ligase to obtain a recombinant DNA.
4. Recombinant DNA is introduced into the host cell for replication. The most common host cell used is *E. coli* for its well-understood DNA metabolism and its well-characterized bacteriophages (viruses that live on bacteria) and plasmids.
5. After cell replication, the host cells with recombinant DNA are identified and used for expression.

The most commonly used host cells for metabolic engineering are *Escherichia coli*, *Zymomonas mobilis*, and *Saccharomyces cerevisiae* as their genetic maps are the most well studied (Banerjee et al. 2010). They are facultative anaerobes with fast growth rates and viability (Lee et al. 2008a). Incorporation and expression of pyruvate decarboxylase and alcohol dehydrogenase II genes from *Z. mobilis* into *E. coli* has resulted in high yields of ethanol from the utilization of both pentoses and hexoses, as against only hexoses (Banerjee et al. 2010). Although the recombinant strains are helpful in exploring the solutions for pathway-related problems, their industrial sustenance is limited due to the lack of robustness. Recombinant *E. coli* can produce isopropanol, n-butanol, and fatty acid ethyl esters through various engineered pathways (Atsumi and Liao 2008).

Modification of enzymes used in hydrolysis of biomass to produce sugars is generating immense interest. However, it is noticed that the enzymes belonging to the same class have different amino acid sequences conferring low level of

homogeneity, for example CBH1 (*T. reesei*) has <65 % amino acid identity in the nonredundant database. Additionally, cellulases from fungal origin have different optimized conditions than those from the prokaryotic origin and to predict a better choice between them is a challenge. Prediction of biochemical activity of an enzyme from its amino acid sequence is unreliable, and the only better way to evaluate it is to employ the extracted cellulase for hydrolysis and test it on various substrates (Banerjee et al. 2010). Alternatively, manipulation of plant species is directed toward altering its components such as lignin. Rastogi and Dwivedi discussed altering the lignin of woody species by introducing *omt* or *f5h* gene to introduce syringyl units in lignin to increase the paper pulping capability (Rastogi and Dwivedi 2008). Modification of lignin can be a potential area of research to increase the enzymatic digestibility and hydrolysis for enriching animal feed and enhancing biofuel production respectively.

Another area where genetic engineering principles can be applied is biomass cultivation. It is understood that by increasing the light interception efficiency and solar energy conversion to biomass, the productivity and yield of cultivation can be increased. Genetic engineering techniques can be applied to identify and manipulate the genes related to light reception and energy conversion to biomass in plants for dual interest, mitigation of elevated levels of atmospheric carbon dioxide, and increasing crop yield (Jansson et al. 2010).

Recombinant DNA technology is also used as a means to identify various enzymatic activities present in an organism. Two β-glucosidases were identified from *Pichia etchellsii* by cloning and expression of the corresponding genes in *E. coli* (Wallecha and Mishra 2003).

Advanced Fuels from Biochemical Conversion

Algal biofuels are of growing interest, where microalgae are grown in either closed or open photobioreactors to produce fatty acids. Although, algae use the sunlight with the same photosynthetic efficiency as that of land plants, the productivity of algal systems is much higher than plant biomass, as they do not produce roots, stems, and other structures. However, the extraction and processing costs during oil extraction from algae are challenging and require being minimized (Kaparaju et al. 2009). In an alternative use of algae, macro algae cells are used to tap the sunlight, and the tapped energy is converted to electricity. The excited electrons in the chloroplasts of the algae are intercepted through gold electrodes to create a tiny electrical current (Alternative energy).

The University of California, Los Angeles, is conducting research on microbes producing fuels from proteins rather than utilizing them for their growth. The microbes are induced to produce certain kind of proteins, which can be converted to fuels (Alternative energy).

Modified cyanobacteria utilize atmospheric carbon dioxide and sunlight to produce isobutanol which can be used as biofuel. Bacteria-powered battery is a very recent development, contrary to the belief that bacteria cannot produce electricity.

The byproducts of bacterial metabolism produce ions which pass through an ion filtering membrane, and then through an external circuit, converting the chemical energy provided by the bacteria to electrical energy (Alternative energy).

Isobutene, a fuel additive is produced through natural enzyme, rather than from the traditional petroleum-based route, by Prof. Thomas Bobik and his doctoral student David Gogerty. They have identified a new natural enzyme which can convert glucose found in plants to isobutene and is called as Bobik's enzyme. A limitation with the enzyme is the time taken to convert glucose to isobutene. However, efforts are in progress to reduce the conversion time for industrial feasibility (Alternative energy).

Qteros and Applied Clean Tech are working together to produce ethanol from wastewater and have developed technologies to handle the sludge remaining from the wastewater plant. Tobacco oil is another promising biofuel that is being studied by the researchers in Biotechnology Foundation Labs at Thomas Jefferson University. Current research is being conducted on improving the oil production from the tobacco leaves. Tobacco is a very attractive source for biofuel as it is not used in food production. Two genes in the plant have been modified to result in 6.8 % of oil per dry weight in leaves (Alternative energy).

Future Directions

It is evident from the above discussion that biofuels have high potential for meeting the needs of the transportation sector and supporting fuel independence and greener living. Choice of biomass and its properties are critical for optimum production of biofuel. Biomass selection depends on its availability, type of pretreatment employed, and the biofuel desired for production and their economics. Exploring various sources of biomass and improving the system of biomass collection and handling can improve the availability of biomass. Chemical, physical, or microbial techniques that can enrich the biomass composition are very desirable. Improvements in reactor design, process conditions, and other engineering aspects help optimize the biofuel production process. Adaptation and modifications of engine systems to biofuel use and innovation of newer ones is another important area of interest. Application of biotechnological tools such as recombinant DNA technology and genetic engineering can be used to overcome the bottlenecks of biochemical conversion and microbial robustness.

Thermal Conversion of Biomass

Zhongyang Luo and Jingsong Zhou

Contents

Abstract

Bioenergy is presently the largest global contributor of renewable energy. Biomass thermal conversion has significant potential to expand in the production of heat, electricity, and fuels for transport. In addition, energy from biomass can contribute significantly toward the objectives of reducing greenhouse gas emissions and alleviating problems related to climate change. There are three main thermal processes – combustion, gasification, and pyrolysis – to convert the biomass into various energy products.

Combustion is well established and widely practiced with many examples of dedicated plant and co-firing applications. At present, biomass co-firing in modern coal power plants is the most cost-effective biomass use for power generation. Due to feedstock availability issues, dedicated biomass plants for combined heat and power (CHP) are typically of smaller size.

Gasification provides a competitive way to convert diverse, highly distributed, and low-value lignocellulosic biomass to syngas for combined heat and power generation, synthesis of liquid fuels, and production of hydrogen (H_2). A number of gasifier configurations have been developed. Biomass integrated gasification combined cycles (BIGCC) using black liquor are already in use. Gasification can also coproduce liquid fuels, and such advanced technologies are currently being investigated in research and pilot plants.

Pyrolysis is thermal destruction of biomass in the absence of air/oxygen to produce liquid bio-oil, syngas, and charcoal. Fast pyrolysis for liquid fuel production is currently of particular interest because liquid fuel can be stored and transported more easily and at lower cost than solid biomass. Pyrolysis technology is currently at the demonstration stage, and technologies for upgrading the bio-oil to transport fuels are applied at the R&D and pilot stage.

This chapter provides an overview of the state-of-the-art knowledge on biomass thermal conversion: the recent breakthrough in the technology, the current research and development activities, and the challenges associated with its increased deployment.

Introduction

Due to the rapid outgrowth of population and urbanization, renewable energy is of growing importance in responding to concerns over the environment and the security of energy supplies. Among the renewable energies, one of the most important energy sources in near future is biomass. In general, any organic non-fossil fuel can be considered a biomass fuel. These are the substances in which solar energy can be stored. Plants produce biomass continuously by the process of photosynthesis. Currently biomass is gaining more and more attention worldwide. Because of its potential in neutral in relation to global warming, biomass fuels are considered environmentally friendly. There is no net increase in CO_2 for the utilization of biomass if it is replanted. And biomass is the fourth largest source of energy in the world, accounting for about 15 % of the world's primary energy consumption (Chen et al. 2003). The potential of biomass to help to meet the world energy demand has also been widely recognized. Today biomass contributes about 10–15 % (or 45 $\pm$ 10 EJ) of the energy demand. On average, in the industrialized countries biomass contributes about 9–14 % to the total energy supplies, but in developing countries this is as high as one-fifth to one-third (Khan et al. 2009).

Usual composition of biomass comprises cellulose, hemicellulose, lignin, extractives, and inert ash. Biomass resources can be divided into two categories, i.e., natural and derived materials. These categories can further be subdivided as agriculture waste, forest products, and energy crops. Biomass fuels and residues can be converted to energy via thermochemical, biological, and mechanical or physical processes. Thermochemical conversion processes, a significant way used for the recovery of energy from biomass, draw the most attention of the world. The three basic approaches of different thermochemical processing are combustion,

gasification, and pyrolysis. Combustion burns biomass directly with excess oxygen in the temperature of 800–1,000 °C to obtain a range of outputs like heat, mechanical power, or electricity. It is already a worldwide and well-established commercial technology with applications in most industrialized and developing countries. And combustion systems are widely available at domestic, small industrial, and utility scales. Gasification converts biomass to a combustible gas mixture through partial oxidation of biomass at high temperatures of 800–900 °C. It has traditionally received the most R&D support as it offers potentially higher efficiencies compared with combustion. Generally, comparing to coal gasification systems, most of the available biomass gasifiers are still in the development or early demonstration process. Pyrolysis is thermal destruction of biomass in the absence of air/oxygen. Pyrolysis of biomass starts at 350–500 °C and goes to 700 °C with the liquid oil, gases, and solid products. Different condition leads to the formation of products in different proportions. Fast pyrolysis is still at a relatively early stage of development but offers the benefits of a liquid fuel with concomitant advantages of easy storage and transport as well as comparable higher power generation efficiencies at the smaller scales of operation that are likely to be achieved from bioenergy systems compared to fossil-fueled systems.

Biomass Thermal Conversion

Combustion

Of all thermochemical conversion technologies available for biomass, combustion is the most developed and most frequently applied because of its low costs and high reliability. Its commercial availability is high, and there is a multitude of options for integration with the existing infrastructure on both large- and small-scale levels (van Loo 2004).

Combustion Process of Biomass

During combustion, the biomass first loses its moisture at temperatures up to 100 °C, using heat from other particles that release their heat values. As the dried particle heats up, volatile gases containing hydrocarbons, CO, CH_4, and other gaseous components are released. In a combustion process, these gases contribute about 70 % of the heating value of the biomass. Finally, char oxidizes and ash remains.

Combustion characteristics for different types of biomass vary slightly depending upon the particular chemical composition, physical properties, and ash characteristics of the given fuel. One of the most important properties of biomass fuel that must be considered during the combustion process is the fuel moisture content. In most cases, the moisture contents of the residues are determined by the process of separating the residues from the crop product. High moisture content can lead to poor ignition and reduction of the combustion temperature, which in turn hinders the combustion of the reaction products and consequently affects the quality of combustion (Demirbas 2004; Werther et al. 2000; Jenkins et al. 1998).

Compared to solid fossil fuels, the properties of biomass are of great difference, which may result in different combustion behaviors. The differences may be summarized as follows:

1. Biomass fuels generally have higher volatile contents, less carbon and more oxygen, and lower specific heating value than coal.
2. Pyrolysis starts at a lower temperature for biomass fuels.
3. The fractional heat contribution by volatiles in biomass is of the order of ~70 % compared to ~36 % for coal.
4. Biomass fuels, for example, straw, have more free alkali in ash, which may aggravate the slagging and fouling problems.
5. Compared to coal chars, biomass chars have higher oxidation reactivity, probably as a result of the presence of alkalis (catalytically active) in the char matrix.

All these have significant influence on the thermal utilization of biomass fuels and the choice of the appropriate combustion technology.

Status of Biomass Combustion Technology

Biomass combustion power plants differ mainly in the areas of boiler designs, fuel composition, and environmental regulations. Pretreatment facilities are designed according to the difference between characteristics of the biomass and the demands by the boiler system, while flue gas cleaning is designed according to the difference between the environmental demands and the emissions of the boiler flue gases. Steam turbines and generators that are used in the different plants do not show many differences in basic design, except for differences between condensing and combined heat and power technology (CHP) applications.

Different biomass combustion systems are available for industrial purposes. Broadly, they can be defined as fixed-bed combustion, fluidized-bed combustion, and dust combustion. Boiler capacity of each combustion technology is different, with the corresponding value shown in Table 1.

The two most common types of boilers for biomass combustion are fixed-bed systems and fluidized-bed combustors, both of which have good fuel flexibility and

Table 1 The corresponding capacity range of biomass combustion boilers

Biomass combustion boilers		Capacity
Fixed bed	Stoves	2–12 KW
	Boilers	5–35 KW
	Pellets	5–100 KW
	Understoker	5 KW–2 MW
	Moving grate	200 KW–50 MW
Fluidized bed	Bubbling fluidized bed	5–100 MW
	Circulating fluidized bed	5–100 MW
Dust	Dust	5–14 MW
	Co-firing with pulverized coal	10–250 MW

can be fueled entirely by biomass or co-fired with coal. Suspension burners are often used to co-fire milled biomass pellets or raw biomass with pulverized coal or natural gas, in which the air-dried biomass fuels (with relatively low moisture content, e.g., <25 wt%) must be finely pulverized (e.g., particle feed size <6 mm) and have a relatively low share (e.g., less than 25 % on energy basis). The following description is in accordance with the combustion form (van den Broek et al. 1995).

Fixed-Bed

Fixed-bed combustion systems include grate furnaces and underfeed stokers. Primary air passes through a fixed bed, where drying, gasification, and charcoal combustion take place in consecutive stages. The combustible gases are burned in a separate combustion zone using secondary air.

Grate Furnace

Grate furnaces are appropriate for burning biomass fuels with high moisture content, different particle sizes, and high ash content. Usually, the capacity goes up to around 20 MWth. Mixtures of wood fuels can be used but straw, cereals, and grasses may cause problems due to their different combustion behavior, low moisture content, and low ash melting point. The fuel burns in a fixed or mobile grate, and in a relatively static state, the air required during combustion comes from the bottom through the grate. The combustion time of fuel after entering the furnace can be controlled by the movement or vibration of the grate, and finally, the ash left falls below the grate into the pit at the tail. The grate and walls can be air-cooled or water-cooled to avoid slagging problems. The design and control of the grate are aimed at guaranteeing smooth transportation and even distribution of the fuel and a homogeneous primary air supply over the whole grate surface. Irregular air supply may cause slagging and higher amounts of fly ash and may increase the oxygen needed for complete combustion.

Grate combustion is divided into chain grate, reciprocating grate, vibrating grate, and so on. The chain grate boilers are now less used because the fuel is hard to burn out, resulting from the uneven fuel layer and air distribution. Among the different types of grates, vibrating grates may have the longest life and highest availability. It is made of panel walls with drilled holes in the fins for the primary air. The grate is part of the boiler pressure system and connected to furnace walls by flexible connection pipes, designed for the vibrations. Instead of a continuous ash discharge in a traveling grate, a vibrating grate utilizes an intermittent ash removal system where the grate surface vibrates at high frequency and low amplitudes for about 2 % of the time to move the solids forward and discharge the ash at the end of the grate. This type of grate uses very few moving parts, and the drive mechanism is outside the heat and flame, which increases grate life, reduces maintenance costs, and results in high equipment availability (Yin et al. 2008).

After many years of exploration and development, Denmark has had mature experience with the grate combustion technology, and pure straw power generation and combined heat and power have been spread across the country. The most famous technology is water-cooled vibrating grate combustion boiler, which has been

applied in many other countries such as Sweden, Spain, Finland, England, and China. In Denmark, crops are packed according to uniform standards to bales when harvesting and trucked to warehouse of power plants and then the crop bales transported by belt to the furnace.

Crop bales have two main combustion ways when feeding into the furnace: one is "cigar burning," where big bales are pushed continuously into the combustion chamber where they burn from the end, and the other, bales are broken up and chopped before feeding into furnace.

Underfeed Stoker

Underfeed stokers represent a cheap safe technology for small- and medium-scale systems up to about 6 MWth. The fuel is fed into the combustion chamber by screw conveyors from below and is transported upward on a grate. Underfeed stokers are suitable for biomass fuels with low ash content (wood chips, sawdust, pellets) and small particle sizes (up to 50 mm). Underfeed stokers have a good partial load characteristics and simple load control. Load changes can be achieved more easily and quickly than in grate furnaces because of its better control of the fuel supply.

Fluidized Bed

Among the available technologies, fluidized beds are proving to be one of the best because of their flexibility, stability, and efficiency. They are used worldwide to combust both coal and biomass. Depending on the fluidization velocity, bubbling and circulating fluidized-bed combustion can be distinguished. Circulating fluidized-bed combustion technology has been widely used in small-scale thermal power-generating unit and develops quickly toward large-scale and high parameter (Khan et al. 2009).

Biomass generally has high water content and low calorific value. The inherent advantages of fluidized beds make them an attractive option for the combustion of biomass. In a fluidized bed, biomass fuel is burned in a self-mixing suspension of gas and solid bed material (usually silica sand and dolomite) in which air for combustion enters from below. The intense heat transfer and mixing provide good conditions for complete combustion with low excess air demand. Using internal heat exchanger surfaces, flue gas recirculation, or water injection, a relatively low combustion temperature is maintained in order to prevent ash sintering in the bed. Due to the good mixing achieved, fuel flexibility is high, although attention must be paid to particle size and impurities contained in the fuel. Fluidized-bed combustion plants usually operate at full load.

At present, utilization of biomass by fluidized-bed combustion technology has a considerate scale worldwide. The fuel is mainly forestry waste and other low-alkali biomass. There are lots of companies working at the development and application of this technology (Jana 2004), typical ones are AE & E, Foster Wheeler, B & W, and Kvaerner, with its main applications in Europe and the USA. The fluidized boilers developed by B & W have been in operation since late 1980s. In Sweden, with branches, leaves, and other forest wastes as fuels of large fluidized-bed boilers, the thermal efficiency can reach 80 %. Applying the circulating fluidized bed of Foster

Wheeler, the moist content of biomass residues burned can reach as high as 60 % in Finland. In China, there are abundant biomass resources of high potassium content such as rice and wheat straw. In addition to the water-cooled vibrating grate technology introduced from Denmark, Zhejiang University developed a new fluidized combustion technology based on particular boiler design and combustion organization. Through a series of different-scale thermal experiments and industrial practices, it proved to be a successful combustion technology using crop residues (Yu et al. 2010).

Suspension Combustion

Dust combustion is suitable for fuels available as small, dry particles such as wood dust. A mixture of fuel and primary combustion air is injected into the combustion chamber. Combustion takes place while the fuel is in suspension; the transportation air is used as primary air. Gas burnout is achieved after secondary air addition. An auxiliary burner is used to start the furnace. When the combustion temperature reaches a certain value, biomass injection starts and the auxiliary burner is shut down. Due to the explosion-like gasification process of the biomass particles, careful fuel feeding is essential. Since the fuel and air are well mixed, only a small amount of excess air is required. This results in high combustion efficiency.

However, there is irreconcilable conflict between the high temperature needed by suspension combustion and the high-alkali characteristic of some special biomass such as straw. Few practical projects directly carried out the suspension burning of biomass, most co-fired it with coal in a small blending ratio in the existing coal-fired plants.

Problems Related to Biomass Combustion

The most problems during biomass combustion are ash related. Biomass usually has high contents of alkali oxides and salts, the low melting points of which may lead to various problems during combustion (Werther et al. 2000; Demirbas 2005).

Agglomeration

During the combustion of agricultural residues in fluidized beds, a major problem is bed agglomeration. Agglomeration begins when part of the fuel ash melts and causes adhesion of bed particles. In addition to the adhesion effect of the sintered ash, the alkali oxides or salts can react with Si compounds of the bed material to form eutectic mixtures with low melting points. Beginning of agglomeration in the fluidized bed is often indicated by the occurrence of temperature gradients in the bed and the presence of large fluctuation of the bed pressure. When the feeding of the fuel continues, the extent of agglomeration will increase and may eventually lead to defluidization of the whole bed (Demirbas 2005; Bartels et al. 2008; Chirone et al. 2006; Elisabet et al. 2005).

Fouling and Slagging

The constituents of the ash formed as a result of the combustion process reacting with flue gases or with other components, in a complex mechanism, forming a

variety of compounds that may be in gaseous, liquid, or solid state. Gaseous or liquid-phase constituents form deposits on the cooled surfaces or furnace walls leading to slagging and fouling, respectively. The term "slagging" characterizes deposits on furnace walls or other surfaces exposed to predominantly radiant heat. Fouling refers to deposits on surfaces in the heat recovery section. Fouling is generally associated with reduction in heat-transfer rates and corrosion (Werther et al. 2000; Baxter 1993).

Corrosion

Ash deposition from biomass fuels that contain certain chemicals can also create corrosion and erosion of metals. The two most abundant inorganic elements in wheat straw are Si and K, which form silicates with a low melting point. The combustion of the straw leads to the condensation of molten silicates, which are likely to cause fouling and corrosion in combustion systems. Metals in combustion systems are exposed to chemical attack when silicates are present because protective layers of oxides can be relatively soluble and/or reactive in silicate slags (Werther et al. 2000; Nielsen et al. 2000).

Some Measures

In the process of biomass combustion and utilization, there have been some efficient ways to solve fouling, slagging, and corrosion problems such as reducing fuel alkali metal content (co-firing with coal or appropriate pretreatment); raising the melting point of fuel ash by additives such as kaolinite, bauxite, and emalthite; and applying new type of bed material (non-SiO_2 bed material: feldspar, dolomite, and magnesite as well as ferric oxide and alumina). Meanwhile, to reduce the combustion temperature appropriately without influencing normal operation of fluidized bed is also a good option (Khan et al. 2009; Elisabet et al. 2005).

Co-firing Coal and Biomass

Biomass can be directly fired in dedicated boilers. However, co-firing biomass and coal has technical, economical, and environmental advantages over the other options. By co-firing biomass with coal, a continuous supply of biomass would not be an issue, since the boiler plant would always have the primary fuel, coal, for 100 % utilization (Baxter 2005).

Technology Options for Co-firing

Co-firing is a family of technologies. These include blending biomass with coal on the fuel pile, separately injecting biomass into a boiler, and gasifying biomass for subsequent firing in an electricity-generating system (Tillman 2000; Sami et al. 2001).

Blending Biomass with Coal on the Fuel Pile

This simple approach to blending biomass with coal for subsequent introduction into the boiler is the least-cost approach to co-firing. It provides good mixing, high combustion efficiencies, and low emissions. When this approach to co-firing is

employed in pulverized combustion boilers, it will have significant impact on the pulverizer. And the percentage of biomass that can be added to the total fuel blend is at very low levels. Also it is important to note that the type of biomass blended with coal is limited. For example, bark can cause significant problems because it can be very stringy. Usually, wood chips, sawdust, and straw are used for this kind of co-firing. And wood chip was found to be the most favorable co-firing fuel in terms of ease of combustion and reduced emissions of NO_x and SO_2.

Co-firing with Separate Injection

This approach involves separately preparing the biomass and then firing it in the boiler. The biomass is introduced simply at another injection point. This approach, which involves more equipment than blending on the coal pile, can accomplish higher percentage co-firing in pulverized combustion boilers. It has the advantage of better control over fuel flow rates. Thermal output similar to coal-only firing requires higher biomass feed rates. Thus, separate feeders facilitate controlling the biomass feed rate independent of the coal feed rate. Using a single feed line for a blend fuel has the risk of agglomeration occurring in the supply line, which may lead to a disconnection or blockage in the fuel supply. On the other hand, separate feed lines and separate burners increase capital and maintenance costs.

Gasification-Based Co-firing

The gasification approach to co-firing has significant potential, for it permits the use of biomass in other solid fuel combustion systems without significant influence on it. In gasification-based co-firing, biomass is first fed to a gasifier in order to generate a producer gas. The gas is then fired in a boiler or in a duct burner between a combustion turbine and a heat recovery steam generator. Gasification-based co-firing addresses several issues commonly associated with co-firing including accomplishing complete combustion in a furnace with a very short gas residence time, separating biomass ash from coal ash, and providing a means for co-firing in natural gas-fired electricity-generating systems. While it is the most capital-intensive approach to co-firing, it is also the most flexible in terms of the base fuel considered (coal, oil, natural gas) and the electricity-generating system appropriate to its application.

Major Technical Considerations When Co-firing Biomass with Coal

Co-firing biomass with coal, in comparison with single coal firing, helps reduce the total emissions per unit energy produced. Coal and biomass fuels are quite different in composition. Co-firing biomass with coal has the capability to reduce both NO_x and SO_x levels from the existing pulverized coal-fired power plants. In addition, biomass ash with notable carbon content has been used as effective reburning fuel for NO reduction, and it was reported that about 85 % of NO reduction efficiency appears achievable at a stoichiometric ratio 0.945 (Chen and Gathitu 2006). This can be considered a special co-firing process. Biomass offers important advantages as a combustion feedstock due to the high volatility of the fuel and the high reactivity of both the fuel and the resulting char. However, it should be noticed that in comparison

with solid fossil fuels, biomass contains much less carbon and more oxygen and has a low heating value (Baxter 2005; Tillman 2000; Demirbas 2003). There are still many important issues that are yet unanswered regarding coal-biomass blend combustion.

Fuel Preparation and Handling

Because biomass fuels are hygroscopic, have low densities, and have irregular shapes, they should generally be prepared and transported using equipment designed specifically for that purpose. In some cases, however, they can be directly metered on the coal belt conveyor. Care must be taken to prevent skidding, bridging, and plugging in pulverizers, hoppers, and pipe bends.

Ash Deposition

Rates of ash deposition from biomass fuels can greatly exceed or be considerably less than those from firing coal alone. This is attributable only partially to the total ash content of the fuels. Deposition rates from blends of coal and biomass are generally lower than indicated by a direct interpolation between the two rates. Experimental evidence supports the hypothesis that this reduction occurs primarily because of interactions between alkali (mainly potassium) from the biomass and sulfur from the coal.

Fly Ash Utilization

The majority of the fly ash generated from coal combustion worldwide is used either as a concrete additive or for other purposes. However, current standards preclude the use of fly ash as a concrete additive from any source other than coal. The technical case for precluding the use of fly ash from co-firing wood with coal appears to be unjustified. However, the less comprehensive data available for herbaceous biomass fuels suggest that alkali, chorine, and other properties may compromise several important concrete properties. Strict interpretation of many standards that are the basis for regulations and policy for many institutions would preclude all fly ash from use in concrete if it contains any amount of non-coal-derived material, including co-fired fly ash. Though these standards are under active revision, this may take many years to complete (van Loo and Koppejan 2008).

Gasification

Biomass gasification is a thermal conversion technology that converts biomass into a combustible gas through high-temperature partial oxidation reaction. The product gas mainly consists of carbon monoxide (CO), carbon dioxide (CO_2), hydrogen (H_2), methane (CH_4), and water (H_2O) but also contains contaminants such as char particles, tars, and ash. The syngas can be used to produce a wider variety of outputs: electricity, heat and power, liquid fuels, and synthetic chemicals. Hence, different demands of the market can be met. The utilization of biomass gasification technology mainly depends on syngas purification technologies and syngas quality control technologies. At present, biomass gasification system is undergoing the transformation from demonstration to commercialization. The well-known manufacturers of

commercial biomass gasifiers are Bioneer, PRM Energy, Foster Wheeler, and Lurgi Umwelt.

Gasification Process of Biomass

The gasification process is a sequence of interconnected reactions: the first step is quick drying. The second step is fast pyrolysis at 300–500 °C. Char, condensable hydrocarbons, tars, and gases are produced. The following step is gasification, namely, partial oxidation reaction between pyrolysis production and oxygenant. During gasification, part of the biomass is converted to char and tar instead of syngas. Reduction and conversion of char and tar can also increase syngas yield and overall conversion efficiency. Hence, the product syngas quality depends on: raw material composition, water content, temperature, heating rate, type of gasifier, and oxidation of pyrolysis products. The reaction process is as follows:

Oxidation: $C + O_2 \rightarrow CO_2,\ 2C + O_2 \rightarrow 2CO$
Boudouard: $C + CO_2 \rightarrow 2CO$
Steam reforming: $CH_4 + H_2O(g) \rightarrow CO + 3H_2$, $CH_4 + 2H_2O(g) \rightarrow CO_2 + 4H_2$
Water-gas reaction: $C + H_2O(g) \rightarrow CO + H_2$, $C + 2H_2O(g) \rightarrow CO_2 + 3H_2$
Water-gas shift reaction: $CO + H_2O(g) \rightarrow CO_2 + H_2$

In the gasification process, the oxidant can be air, pure O_2, steam, CO_2, air/steam, O_2/steam, CO_2/steam. The advantages and technical challenges of different gasifying agents are listed in Table 2. In addition, CO_2 gasification is very promising. CO_2 from the gasification or combustion can be used as gasifying agent. But there are few operational examples.

Table 2 Advantages and technical challenges of different gasifying agents

Method	Gas composition	LHV	Advantages	Technical challenges
Air gasification	CO, CO_2, H_2, CH_4, N_2, tar	~3–6 MJ/m^3 (Gabra et al. 2001; Zainal et al. 2002)	Simple equipment, easy operation and maintenance, low cost	Syngas with high N_2 content (>50 %) and low heating value, combustion problems (especially gas turbine)
Oxygen gasification	CO, CO_2, H_2, CH_4, tar	~10–12 MJ/m^3	Good syngas quality	High cost of operation and air separation
Steam gasification	CO, CO_2, H_2, CH_4, tar	~10–15 MJ/m^3 (Rapagna et al. 2000; Gil et al. 1999)	High H_2 content (>50 %), high heating value	An indirect or external heat supply, corrosion, and high tar content
Pyrolytic gasification	CO, CO_2, H_2, CH_4, tar	~15–20 MJ/m^3	Syngas with medium heating value	Low system efficiency

Status of Biomass Gasification Technology

The gasifier is the core component of biomass gasification equipment. There are three main types of gasifiers: fixed bed, fluidized bed, and entrained-flow bed. According to a recent survey about the gasifier manufacturers, 75 % of gasifiers offered commercially were downdraft fixed bed, 20 % were fluidized bed (including circulating fluidized beds), 2.5 % were updraft fixed bed, and 2.5 % were other types (Knoef 2000).

Fixed-Bed Gasifier

Working characteristics: the chopped biomass materials are put into the reactor from the top. The gasification reactions occur slowly in the gasifier. Fixed-bed reactors have countercurrent (updraft), cocurrent (downdraft), and very seldom crosscurrent mass flow.

Due to its simple design, easy operation, and reliable performance, fixed-bed gasifier is widely applied. However, compared with other types of reactors, low and nonuniform heat and mass transfer in the fixed-bed reactors (Wang et al. 2008) lead to large quantities of tars and char in the syngas. That increases the system complexity and investment of subsequent processing. Therefore, small-scale gasifiers are more economical.

Updraft gasifiers are mainly used for heating (Kurkela 2000). Its upper size is around 2.5 MWe. The most well-known manufactures of updraft fixed-bed gasifiers are Bioneer and PRM Energy. About 10 Bioneer gasifiers are operational for district heating in Finland and Sweden. PRM Energy has 18 units in operation producing heat for industrial drying application or low-pressure steam (Knoef 2001–2003). Downdraft gasifiers are more attractive for small-scale application up to around 1.5 MWe. In principle, downdraft gasifier is suitable for electric power generation. But it has not achieved industrialization.

Fluidized-Bed Gasifier

Working characteristics: the pulverized raw material and inert sands are put into the reactor. The material particles, sands, and gasifying agents can be heated evenly by good contacting among each other under the blowing of gasifying agent. A certain state of "boiling" is presented in the reactor. Therefore, fluidized beds have fast heat up, high gasification rate, great production capacity, and high syngas yield. Tar content is low since its secondary cracking under the high temperature and uniform temperature field. But high dust content is in the gas phase. Due to the complicated structure and large equipment investment of fluidized-bed reactor, large-scale gasification system is more economical.

The types of fluidized-bed gasifiers can be divided into single fluidized-bed gasifier, double fluidized-bed gasifier, and circulating fluidized-bed gasifier.

Atmospheric bubbling fluidized-bed gasifiers at pilot scale and commercial application in small to medium scales ($\sim$25 MWth) can be in reliable operation. Circulating fluidized-bed gasifiers are more suitable for large scale ($-$100 MWe) with attractive market. Examples include the TPS (Termiska Processer AB)

atmospheric process (Waldheim et al. 2001) and the Varnamo pressurized system (Stahl et al. 2001). The world's most mature biomass gasification technology is "fast internal circulating fluidized-bed" (FICFB) technology. The most successful biomass gasifier for power generation is "Güssing" gasifier in Australia, which is based on the high-temperature pyrolysis to produce syngas with medium heating value. It has been successfully run >15,000 h to generate electricity 2 MWe.

According to the blowing pressure of gasification agent, gasifiers have atmospheric gasifiers (0.11 ~ 0.15 MPa) and pressurized gasifiers (1.8 ~ 2.25 MPa). The pressurized gasifier with high-temperature and high-pressure outgas is suitable for the large-scale system for power generation. A gas compression process in the downstream system for the gas turbine or liquefaction could be avoided in the pressurized gasification process, in the short term, either pressurized circulating fluidized-bed, bubbling bed, or pressurized bubbling bed gasifiers have the lack of market appeal mainly due to the complex system and high construction cost of large pressure shell. And the pressurized gasification process often uses pure O_2 as gasifying agent to improve the gas quality. Hence, special security measures are required to guarantee safe operation.

Entrained-Flow-Bed Gasifier

Work characteristics: fine biomass powder as raw material carried by the high-speed air flow is injected into the gasifier with gasifying agent. In the reactor, solid particles are dragged along with the gas stream. Their properties of dispersing and flowing in the airflow are similar to the flow of mass points of gas. This generally means short residence times (typically 1 s) and high temperatures (typically 1,300 ~ 1,500 °C). Hence, entrained-flow gasification is of high reaction rate, large capacity, high carbon conversion, and improved syngas without tar and phenol and little environmental pollution.

Now entrained-flow gasification technology is mainly used in coal gasification industry. The most mature technology of entrained-flow gasification is Koppers-Totzek (KT) technology, which is in the atmospheric pressure operation. And pressurized entrained-flow gasification technology is successfully developed: Shell and Prenflo technology can feed dry coal powder, and Texaco and Destec technology can feed water-coal slurry or oil.

Although there are many commercial coal-based entrained-flow gasifiers, the experience in the biomass-based gasifiers is still little. Experimental results show: biomass ash in the entrained-flow gasifiers is difficult to melt under the operating temperature (1,300 ~ 1,500 °C), due to ash containing high contents of CaO and alkali metal generally found in the gas phase, which can reduce the ash melting point. However, a slagging gasifier is preferred over a non-slagging gasifier: (1) little slagging can never be avoided and (2) a slagging gasifier is more fuel flexible, but it needs to add a fluxing material (silica or clay) to achieve melting properties at required temperature.

Currently, the research on biomass entrained-flow gasification is at the stage of experimental study and numerical simulation. The CARBO-V system of Colin (CHOREN) in the German city of Freiburg, Saxony, is the most advanced biomass

gasification system for bio-oil production in the industrial level. Energy Research Centre of the Netherlands (ECN) studied the feasibility of biomass entrained-flow gasification, ash melting properties, the feeding device, pressurization methods, and the selection of gasification routes (Drift et al. 2004). Biomass Technology Group of the Netherlands (BTG) investigated the bio-oil entrained-flow gasification (Venderbosch and Prins 1998). Zhejiang University of China designed the reactor, investigated biomass gasification characteristics, residual carbon properties, the volatile issue of alkali metal, and pretreatment of raw materials; and established a dynamic model about the gasification process (Zhao 2007).

In recent years, countries in the world usually pressurized entrained-flow gasifiers for the research on the biomass gasification using powder materials. As a potential gasification technology, pressurized gasification has become a hot research spot. How to effectively realize the pressurized entrained-flow gasification of biomass is the focus of future research.

Syngas Quality Control and Cleaning Technology

Any gasification process for synthesis gas will produce pollutants: particulate, condensable tars, alkali metal compounds, H_2S, HCl, NH_3, HCN, COS, etc. (Van et al. 1995). So deep purification is needed according to the requirements of the downstream gas appliances and the use restrictions of catalyst. In general, Fischer-Tropsch synthesis demands higher standards of gas cleaning than biomass integrated gasification combined cycle (BIGCC). At present, the common feedstock for Fischer-Tropsch synthesis is the relatively clean natural gas. Hence, actual cleaning specifications for some specific biomass contaminants are not known. Some specifications for biomass gasification are estimated based on the practical experience.

Ash Particles

Ash particles in the product gas can be mainly purified by mechanical clarification. The particle reduction of different methods can be seen in Table 3. Most of them are operated at low temperatures. Some are at high temperatures, such as the operation temperature of ceramic filters which is 600 °C. Ceramic filter according to its structure types can be divided into bag-type ceramic filters, webbing ceramic filters, tubular ceramic filters, cross flow ceramic filters, cellular-type ceramic filter, and so on. Low-temperature cleaning technology has been realized in industrialization and

Table 3 The particle reduction of different methods

Method	Particle reduction (%)	Particle size
Wash tower	95–98 %	>1 μm
Jet scrubber	95–99 %	>1 μm
Granular-bed filter	99 %	
Bag filter	99 %	>0.1 μm
Cyclone separator	90 %	>10 μm
Inertial dust separator	≤70 %	20–30 μm
Wet electrostatic precipitator	>99	

Table 4 The tar yield of different gasification processes

Gasification method	Tar content in syngas (g/Nm^3)
An air-blown circulating fluidized-bed (CFB) biomass gasifier	10
Updraft fixed-bed gasifier	100
Downdraft fixed-bed gasifier	1
Other gasifier	0.5 ~ 100

Table 5 The effect of different methods on removing tars

Method	Tar reduction (%)
Water scrubber	10–25
Venturi scrubber	50–90 (Hasler 1997)
Fabric filter	0–50
Rotating particle separator	30–70
Wet electrostatic precipitator	40–70 (Paasen and Rabou 2004)

more mature than high-temperature cleaning. But the pollution problems of low-temperature cleaning are more serious, such as secondary pollution caused by wastewater from washing and wet ESP. Compared with low-temperature cleaning, high-temperature cleaning can improve system energy efficiency, can reduce the operating cost from the utilization of high-temperature syngas, and also can be combined with the high-temperature fuel cells for heat and power generation (Ma et al. 2005).

Tar

Biomass tar is a light hydrocarbon and phenolic mixture. "Naphthalene" is the most difficult compound to reform.

Tar will cause many severe problems. It will condense into liquid below its dew point temperature to lead to clogged, blockage, or corrosion in the downstream pipeline, filters, or equipment. It is difficult to completely burn tar. Gas facilities such as internal combustion engines and gas turbines would be damaged. Table 4 shows the tar yield of different gasification processes.

Tar removal, conversion, or destruction has been one of the greatest technical challenges for the successful development of commercial gasification technologies (Dayton 2002). For this reason, most applications require the product gas with a low tar content, of the order 0.05 g/m^3 or less.

The methods to remove tar are mechanical cleaning, low-temperature cleaning, high-temperature cleaning, thermal cracking, and catalytic cracking. The operation and economical analysis shows that mechanical cleaning and catalytic cracking are suitable for small-scale plants and large-scale plants, respectively.

Mechanical Cleaning

The common mechanical methods are considerably efficient in removing tar accompanied with effective particles capture (Hasler and Nussbaumer 1999). Table 5

shows the effect of different methods on removing tars. However, the cost of mechanical cleaning system is usually high. And it only removes the tar from the product gas, while the energy in the tar is lost. Now a new tar removal system called OLGA (OLGA is the Dutch acronym for oil-based gas washer) is developed. In this system, heavy tars, 99 % phenol, and 97 % of the heterocyclic tars can be removed (Boerrigter 2005). The lab test results (Hasler 1997) show that active carbon has good removal efficiency for high-boiling hydrocarbons and phenols. Meanwhile, the "tar" and the active carbon itself can be recycled as a feedstock. But the tars' accumulation on the carbon is difficult to clean completely to cause the blockage of active carbon filters.

Thermal Cracking

In thermal cracking method, the raw gas derived from gasification or pyrolysis is heated to high temperatures. The tar molecules can be cracked into lighter gases.

Biomass-derived tar is very refractory and hard to crack by high temperature alone. Three ways are beneficial for tar's splitting decomposition reaction. The first method is to increase the residence time such as the utilization of fluidized-bed reactor. But the improving effect is not obvious. The second method is increasing the area of the heating surfaces, but it depends on the mixture grade of various compositions. The last method is adding oxygen or air to strengthen the partial oxidation of tar, which increases the CO content at the expense of conversion efficiency decrease and operation cost enhancement.

Catalyst Cracking

At present, the catalytic cracking is the most effective way to remove the tar. It is divided into low-temperature catalytic reforming (350 $\sim$ 600 °C) and high-temperature catalytic reforming (500 $\sim$ 800 °C). Catalysts are as follows: nickel-based catalyst, dolomite, alkali metals, and nano-catalyst.

Nickel-based catalyst supported on SiO_2 and Al_2O_3 can be used at low temperatures or at high temperatures for catalytic cracking. Although nickel-based catalyst has good effect on cracking tars, it is very expensive and easy to lose activation because of the carbon deposition, H_2S poisoning, and catalyst attrition.

Compared to nickel-based catalyst, the abundant naturally occurring catalysts such as dolomite $CaMg(CO_3)_2$ are cheaper. And it is the most common and effective catalyst for tar removal (Rapagna et al. 2000). However, the conversion of tars over dolomite cannot reach 90–95 % or more (Zhang 2003). And it is difficult for dolomite to crack the heavy tar components (Karlsson and Ekström 1994). In addition, due to its low melting point, dolomite is very easy to melt to cause deactivation.

Adding inexpensive alkali metal catalyst to biomass raw material can significantly reduce tar content through dry mixing or wet impregnation. Many studies (Brown et al. 2000; Kumar et al. 1997; Elliott and Baker 1986) suggest that potassium has a better catalytic effect on tar cracking compared to other alkali metals (such as Na, Li, Ca, etc.). But the alkali metal in the furnace would lead to

agglomeration, sintering, fluidization performance degradation, blockage in the pipes, and other metal catalyst deactivation.

Currently, some novel metals have been widely used as catalysts for tar cracking. It is found that $Rh/CeO_2/SiO_2$ has the best catalytic performance: little carbon deposition at low temperatures and high and stable activity even under the presence of high concentrations of H_2S (280 ppm) (Tomishige et al. 2005). In addition, nano-Ni catalyst ($NiO/\gamma\text{-}Al_2O_3$) also can improve the quality of synthesis gas and reduce the tar in the gasification process (Li et al. 2008).

Plasma Methods

Some studies demonstrated that corona discharge could also decompose the organic components, which can be used to reduce the tar content. Tests (Heesch and Paasen 2000) were carried out on a wood gasifier, which was designed to produce a 100 kW electrical output. The dust removal efficiency was about 72–95 %. Conversion efficiencies of heavy tar components and light tar components were 68 % and ~50 %, respectively. In addition to capturing dust and tar, plasma technology can operate at high temperatures.

Alkali Metal

In the biomass gasification process, the problems associated with alkali metals are mainly caused by the main nonmetallic components: Si and alkali metal potassium in the ash. Si reacts with K at temperature less than 900 °C. For this reason, Si-O-Si bond is broken to form silicate or to react with sulfur to form sulfate. The melting points of silicate and sulfate are lower than 700 °C. So they are easy to deposit on the walls of reactors or pipes to cause sintering, corrosion, anti-fluidization, or blockage. These problems can be mitigated by leaching and fractionation as the two main pretreatments (Arvelakis et al. 2002, 2005; Arvelakis and Koukios 2002). However, mechanical fractionation could reduce up to 50 % of the ash content in the biomass. The remaining ash would still produce such problems (Arvelakis et al. 2005). Eighty percent of the alkali metals in the syngas can be separated together with the coke through the cyclone.

Syngas Utilization

Gas Centralized Supply

In the developing countries, in addition to the heat and power supply, biomass gasification technology has been mainly applied for domestic cooking in the way of gas centralized supply.

The process of biomass gasification system project for central gas supply: straw is put into the gasifier and converted into combustible gas through pyrolysis and gasification reactions. The dust and tars in the combustible gas are removed by the downstream cleaner. Then the clean gas stored in the air storage can be delivered to the every user of this system.

The main types of gasifiers used in the biomass gasification system project for central gas supply are pyrolysis gasifiers, updraft fixed-bed gasifiers, pressurized

updraft fixed-bed gasifiers, downdraft fixed-bed gasifiers, and fluidized-bed gasifiers. Downdraft fixed-bed gasifier is the most often used reactor in all of them.

But the operation rate of village-level straw gasification system for centralized cooking gas supply is still very low. There are many reasons for this. Technically the syngas quality is low due to the low heating value and the high contents of CO and N_2. Contents of tars and dust in the combustible gas are high. The whole centralized gas supply system is not fully used. The syngas should be utilized in many ways to improve the utilization rate of system such as power generation, preheating, and drying grain and other agricultural products. From a policy and economic point of view: limited by the capital cost, the system needs to be as simple as possible. Therefore, the system cannot be perfectly designed, leaving some operation difficulties and environmental problems (Bridgwater et al. 1999a). Therefore, most of the domestic cooking fuel projects need government financial support now.

Combined Heat and Power Generation

Due to its properties of energy saving and environmental conservation, combined heat and power generation (CHP) technology has been the focal point of worldwide attention as an alternate energy source for traditional source.

The major conversion technologies of biomass-based CHP systems are combustion, gasification, pyrolysis, biochemical/biological processes, and chemical/mechanical processes. Combustion technology is widely used at large- and medium-scale systems. Although gasification technology is still developing, this technology has great potential for CHP. The main types of gasifiers for CHP systems are updraft/downdraft fixed-bed gasifiers, fluidized-bed gasifiers, circulating fluidized-bed gasifiers, and entrained-flow gasifiers. Internal combustion engines and turbine can use cleaned product gas to produce heat and power. Gasification-based CHP system potentially has higher electricity efficiency than a direct combustion-based CHP system. Moreover, syngas from biomass gasification can increase the bio-based fuel percentage used in the existing pulverized combustors without any concern about plugging of the coal-feeding system during co-firing of biomass coal. But gasification-based CHP systems have not been realized in commercialization till now. The unstable gasification process leads to the great changed quality of the synthetic gas and higher content of tars, which seriously damage engines. And to reduce system cost, the gasification-based system is short of automatic measurement and control measures to result in the varied system performance.

According to CHP capacity, it can be divided into large-scale, medium-sized, small-scale, and microscale CHP. Biomass is best suited for decentralized, small-scale, and microscale CHP systems due to its intrinsic properties. On one hand, small-scale and microscale biomass CHP systems can reduce transportation cost of biomass and provide heat and power where they are needed. On the other hand, it is more difficult to find an end user for the heat produced in larger CHP systems. Generally speaking, the concept “small-scale CHP” means combined heat and power generation systems with electrical power less than 100 kW. “Microscale CHP” is also often used to denote small-scale CHP systems with an electric capacity smaller

than 15 kWe. Biomass-based CHP systems are generally smaller than coal-based systems. And the power efficiency of biomass-based CHP is also lower, only about 85–90 %, as 30–34 % and 22 % of electricity will be used for biomass drying and solid-waste treatment, respectively. A typical CHP system at large scale is biomass integrated gasification combined cycles (BIGCC). The overall efficiency of the BIGCC system is about 86 % and the electrical efficiency is about 33 % (Miccio 1999). "VEGA" gasification system developed by Sydkraft AB Company of Sweden uses BIGCC technology for district heat and power supply. Buggenum IGCC system in the Netherlands uses the mixtures of biomass and coal to generate power (250 MW). Currently small- and medium-scale CHP systems have not been commercialized due to high investment, low return, and some technical barriers.

Synthesis Techniques

Syngas can be converted to a liquid fuel or chemicals through synthesis technology.

The major synthesis technologies are methanol synthesis, Fischer-Tropsch synthesis, methane synthesis, hydroformylation of olefins synthesis, and hydrogen in organic synthesis. The features of different technologies are in Table 6.

Fischer-Tropsch synthesis is one of the biomass indirect liquefaction technologies. Under the appropriate condition (20 $\sim$ 40 bar, 180 $\sim$ 250 °C), syngas as raw material is synthesized into the liquid fuels (hydrocarbons with different chain lengths). Fischer-Tropsch synthetic oil can be divided into three categories according to different raw materials (see Table 7). The synthesis process includes gasification, gas purification, transformation and reforming, synthesis, and upgradation. The optimal molar ratio of H_2 and CO for Fischer-Tropsch synthesis is 2 $\sim$ 2.5, preferably 2.1. Currently the cheap Fe-based catalyst is commonly used for industrial Fischer-Tropsch synthesis. However, it will strengthen the water-gas reaction to produce too much useless CO_2 at the expense of large CO consumption. Moreover, when it is used in slurry bed reactors at low temperatures, the small particles of Fe-based catalyst are hardly separated from the product wax. The Co-based catalyst precisely overcomes these deficiencies. Hence, the current developed catalysts are mostly cobalt-based catalysts with high activity, high factor of chain elongation, and long life. The main reactors are fixed bed and circulating fluidized bed. The F-T synthesis is used on a technical scale nowadays only at SASOL (coal based) in South Africa and at Shell (natural gas based) in Malaysia. However, biomass synthesis gas for the Fischer-Tropsch synthesis is still of less attention.

Obstacles to Commercialization

The application obstacles are divided into technical and nontechnical barriers to obstruct development of biomass gasification technology.

Technical barriers are shown as follows:

1. *Biomass resources*: As a resource with the properties of low density and dispersion, there are substantial logistical problems in collection and transport as well as high costs. Moreover, biomass has the characteristic of its seasonality. So it is difficult to achieve large-scale gasification plants for power generation.

Table 6 The features of different synthesis technologies (Wang et al. 2008; Reinhard 2002)

Synthesis	Product	Principle	Catalyst	Industrialization
Methanol synthesis	Methanol	$CO + 2H_2 \rightarrow CH_3OH + 90$ kJ/mol	High-pressure process: copper-containing catalysts	Yes
		$CO_2 + 3H_2 \rightarrow CH_3OH + H_2O + 49.6$ kJ/mol	Low-pressure process: CuO/ZnO/M (M = Al, CrO, mixed oxide of zinc and aluminum)	
F-T synthesis	F-T oil	$CO + 2H_2 \rightarrow [-CH_2-] + H_2O - 165$ kJ/mol	Cobalt or iron	Yes
Methane synthesis	Methane	$CO + 3H_2 \rightarrow CH_4 + H_2O + 206.4$ kJ/mol	Mg-promoted Ni catalysts with diatomaceous earthenware as carrier	Yes
Hydroformylation	Aldehyde		Cobalt carbonyl hydride, cobalt- or rhodium-phosphine complexes	Yes
Hydrogen in organic synthesis	Chemicals	$A + nH_2 \rightarrow BH_2n$	Raney nickel, copper, molybdenum, especially inert metals (Pt, Pd)	No

Table 7 The features of different Fischer-Tropsch synthetic oil

Fisher-Tropsch synthesis fuels	Advantages	Disadvantages	Commercialization
Coal-based oil (coal to liquid)	Oil quality is better than the products of direct liquefaction	High content of arene, a low cetane number for diesel oil product, no applications for CO_2 zero emission	Sasol in Malaysia
Natural gas-based oil (gas to liquid)	A high cetane number, does not contain aromatic compound and sulfur	No applications for CO_2 zero emission	Shell in South Africa
Biomass-based oil (biomass to liquid)	A neutral carbon fuel, does not contain the impurities that are always in mineral oil		No
	A high cetane number, can be used as additives or used as clean fuel for diesel engines		

2. *Feeding*: In the feeding process, the problems with bridging, blockage, and instability are often caused due to low-dense materials and mixed residues with varying characteristics.
3. *Gasification technology*: There is a need to improve the equipment reliability. The immature technology makes it difficult to open market and commercialize.
4. *Purification*: The difficulties of purifying tail gas are how to solve the fouling and corrosion of the heat exchanger and pipes, tar removal/cracking, and continuous operation.
5. *Prime mover*: Experience about biomass syngas utilized in operation of prime mover is little, such as allowable contamination, allowable emissions, engine, fuel cell, Stirling, and turbine (specifications to product gas).

Nontechnical barriers are shown as follows:

1. *Emission standard*: The standards of allowable emissions differ from country to country.
2. *Public perception*: At present, due to large investment, small return, and no significant effect of gasification technology on social benefits, the public are rather negative with no confidence.
3. *Infrastructure*: Many aspects affect economy of biomass gasification – investment channel, collection and transportation cost, and so on. To take the power generation for an example, some countries do not have regulations regarding the incorporation of electricity derived from biomass into the existing grid network.
4. *Capital cost*: Investment cost of gasification projects are high, particularly the cost of collection and transportation of raw materials. Sometimes in order to

reduce costs, the system has to be as simple as possible. Therefore, this results in some sectors such as tar treatment, and gas cleaning cannot be perfectly designed, leaving some operation difficulties and environmental problems.

5. *Environmental protection*: In recent years, countries in the world advocate environmental protection energetically, as well as energy saving and emission reduction. But the real fact is that not all the biomass gasification technology can meet environmental requirements. Although some techniques, such as centralized gas supply systems for domestic cooking in rural areas, can achieve obvious social benefits, in practice gasification stations are difficult to really make a profit from it due to the high cost of antipollution measures.

Pyrolysis

Pyrolysis is the initial chemical stage of combustion and has been used for charcoal production from wood since ancient Egyptian times. And biomass pyrolysis is a process in which biomass is heated in the absence of oxygen to decompose into char, gaseous products, and liquid product "bio-oil." The significant development of biomass pyrolysis happens in the 1980s, when many researchers began to observe an increasing liquid product yield obtained from fast pyrolysis with a rapid heating rate and a short cooling time (Graham et al. 1984). Crude bio-oils have a high water content of about 15–30 %, a high acidity (PH value of 2.8–3.8), a high density of about 1,200 kg/m^3, a low heating value of 14–18.5 MJ/kg, and a large range of viscosities depending on the feedstock and pyrolysis conditions (Zhang et al. 2007). And they are multicomponent mixtures of different chemical families, such as acids, ketones, alcohols, aldehydes, esters, sugars, and phenols (Garcia-Perez et al. 2007). The deleterious properties of corrosiveness, high viscosity, and thermal instability limit the high-quality applications of bio-oils, but corresponding upgrading technologies are developed to explore promising ways for substituted transport fuel production (Xu et al. 2008; Balat and Balat 2009). Moreover bio-oils from this conversion technology have a positive environmental effect compared to most coal- or petroleum-derived fuels due to the low levels of aromatics and sulfur.

Pyrolysis Process of Biomass

The physical conditions of biomass pyrolysis, such as temperature, heating rate, and residence time, have been identified to have a profound influence on the product yields and composition. As shown in Table 8, pyrolysis is classified as slow, conventional, fast, and flash pyrolysis mainly depending on the temperature and heating rate. The terms of "slow pyrolysis" and "fast pyrolysis" are somewhat arbitrary and have no precise definition of the times or heating rates involved in each. Conventional pyrolysis may be in the range of slow pyrolysis, and flash pyrolysis is also termed as fast pyrolysis. Slow pyrolysis is similar to carbonization and produces large amounts of charcoal. This charcoal as a solid fuel is cleaner than that from fossil fuels without the impurities of lead, sulfur, or mercury, which is the best option in the process of iron reduction and sugar refinement and as the absorbent

Table 8 Classification of biomass pyrolysis technologies (Huber et al. 2006; Mohan et al. 2006)

Pyrolysis type	Temperature (°C)	Heating rate	Residence time	Main products
Carbonization	400	Very low	Days	Charcoal
Slow pyrolysis	400–600	Low	Hours	Charcoal, liquids, gases
Conventional pyrolysis	600	Low	5–30 min	Charcoal, liquids, gases
Fast pyrolysis	400–650	High	0.1–2 s	Liquids
Flash pyrolysis	<650	Very high	<1 s	Liquids or chemicals and gases
Vacuum pyrolysis	400	Medium	2–30 s	Liquids

or soil amendment (Peláez-Samaniego et al. 2008). Fast pyrolysis produces 60–75 wt% of liquid bio-oil, 15–25 wt% of solid char, and 10–20 wt% of noncondensable gases varied with the feedstock used. The maximum bio-oil yield of up to 80 wt% dry feed is obtained from wood fast pyrolysis at 500–520 °C with residence times not more than 1 s (Bridgwater et al. 1999b). In order to obtain a high liquid bio-oil yield, fast pyrolysis is well in research and development in recent years among the whole world. The suitable conditions include (1) very high heating and heat-transfer rate and a finely ground biomass feedstocks, (2) carefully controlled pyrolysis temperature of about 420–550 °C, and (3) short vapors residence times in reactors and rapid vapors cooling times (Huber et al. 2006; Mohan et al. 2006). A number of fast pyrolysis technologies have been commercialized mainly by Ensyn Technologies (seven Rapid Thermal Processing plants used circulating fluidized bed have been built in the USA and Canada; the largest has the capacity to process 100 t of dry residual wood per day), Dynamotive (three fast pyrolysis plants which adopted fluidized bed are in operation and the largest is 200 t/day plant in Guelph), and BTG (the Empyro plant, the largest pyrolysis plant in Europe, can convert 5 t dry wood into oil, steam, and electricity per hour in the rotary cone reactor).

Status of Biomass Fast Pyrolysis Technology

Fast Pyrolysis for Bio-oil Production from Various Feedstocks

Various feedstocks have been used in fast pyrolysis process for bio-oil production, ranging from bark, wood, agricultural wastes/residues, nuts, seeds, algae, grasses, and forestry residues to energy crops such as *Miscanthus* and *Sorghum*. Wood materials are widely used for bio-oil production due to the high bio-oil yield and quality. Luo et al. (2004) conducted the fast pyrolysis of wood feedstock such as *Pterocarpus indicus*, *Cunninghamia lanceolata*, and *Fraxinus mandshurica* in a fluidized-bed reactor and obtained the optimum bio-oil yield of about 56 % at the temperature 500 °C. Park et al. (2008) obtained a bio-oil yield of about 50 wt% of the product from Radiata pine sawdust fast pyrolysis at 400–450 °C in a bubbling fluidized bed. In addition to wood residues, agricultural waste and algae are also rich in raw materials. The highest bio-oil yield of about 55 wt% was obtained from rice husk and cotton stalk fast pyrolysis in a fluidized bed at 465 °C and 510 °C, and

these products could be directly used as a fuel oil in a boiler or a furnace on the basis of heat value, stability, miscibility, and corrosion characteristics analysis (Zheng 2007; Zheng et al. 2008). Miao et al. (2004) investigated the fast pyrolysis of microalgae (*Chlorella protothecoides* and *Microcystis aeruginosa*) in a fluidized bed at 500 °C with a heating rate of 600 °C/s and a vapor residence time of 2–3 s. The yield of bio-oil was 18 % and 24 %, respectively, and the properties were considered more suitable for fuel oil usages than bio-oil from lignocelluloses materials, with a higher heating value of 29 MJ/kg, a density of 1.16 kg/L, and a viscosity of 0.10 Pa s.

Reactors for Fast Pyrolysis

Besides the influence of biomass feedstocks, the types of reactor are the dominant factor, which directly determine the yield and physicochemical properties of bio-oils. The breakthrough of fast pyrolysis technology is the development of reactors. During the last two decades, several kinds of reactors have been explored to meet the rapid heat-transfer requirements. The main highlights of the important reactors that are available for the commercialization of pyrolysis technology will be discussed below.

Bubbling Fluidized-Bed Reactors

Bubbling fluidized-bed reactors are usually used in biomass pyrolysis for bio-oil production. They are easy to construct, operate, and even be scaled up, providing good temperature control and efficient heat transfer to biomass particles due to high solid density all along. Heating can be achieved in a variety of ways such as hot wall, hot tubes, hot inert gases, hot fluidizing gas, hot sand, etc. However, heat transfer to bed at large scales of operation has to be considered carefully due to scale-up limitations of different methods of heat transfer. A key feature of fast pyrolysis is the need to separate the by-product char from the vapors as quickly and completely as possible because char is a vapor-cracking catalyst and can significantly reduce the bio-oil yields. The rapid and effective char separation is usually achieved by ejection and entrainment followed by separation in one or more cyclones, so careful design of sand and biomass/char hydrodynamics is important. Fluidized-bed reactors give good and consistent performance with high liquid yields of typically 70–75 wt% from wood on a dry-feed basis, when biomass particle sizes are as small as less than 2–3 mm. Therefore, fluidized-bed reactors are commonly used for bio-oil production, including the academic researches in the Waterloo laboratory, Aston University, Leeds University, and National Renewable Energy Laboratory (NREL) and all the demonstration projects of Dynamotive. However, relatively low bio-oil yields of about 50–55 wt% are obtained in the same type of reactors in recent years (Luo et al. 2004; Park et al. 2008; Miao et al. 2004; Bridgwater 2003). The detailed different configuration of reactors is one of the reasons, but the main reason may be caused by the different efficiencies of quench coolers. So the R&D of condensation devices is very important to further improvement of the reactors.

Circulating Fluidized-Bed/Transported-Bed Reactors

Circulating fluidized bed (CFB) has many similar features to bubbling fluidized bed except that the residence time for the char is almost the same to it for vapors and gas (Bridgwater 2003). The advantage of CFBs is that they are suitable for very large throughputs, even though the hydrodynamics are complex and heat-transfer modes are not identified. The disadvantages are related to the separation of attrited char particles from pyrolysis vapors and careful control of closely integrated char combustion reactor to ensure that the temperature and heat flux match the process and feed requirements. Heat supply is usually from recycled heated sand through 80 % conduction, 19 % gas-solid convective transfer, and 1 % radiation (Bridgwater 1999), so their heat-transfer rates are not as high as fluidized beds and obviously affected by the biomass/sand ratio. In addition, impurities imported from hot char or adhered in recycled sand are mainly composed of alkali metals, which decrease the liquid product yield, increase the char yield, and improve the thermal stability of bio-oils (Nowakowski et al. 2007; Wang et al. 2006).

Ablative Pyrolysis Reactor

Ablative pyrolysis is substantially different in concept compared to the other methods of fast pyrolysis, which must adopt small biomass particles to ensure the high heat-transfer rate. The mode of reaction in ablative pyrolysis is completed by the high relative motion between particles and reactor wall. So heat is transferred from the hot reactor wall surface to melt biomass in virtue of high pressures, achieved due to centrifugal force in NREL or mechanically in Aston University. The wall temperature has to be limited to a maximum of about 625 °C to ensure the production of a liquid film between the wall and the particles which then vaporizes and leaves the reactor and to avoid severe coke deposition at the wall (Bridgwater and Peacocke 2000). The reactions in ablative pyrolysis are limited by heat-supply rate to the reactor rather than heat-transfer rate to the particles, so large feed sizes can be used without the requirement for fluidizing gas. Usually, ablative reactors are small and intensive but hard to scale up economically. The original design capacity of the vortex reactor in NREL is 50 kg/h biomass but the factual maximum throughput is 36 kg/h. Development focuses of ablative reactors are on the improvements of the bio-oil quality rather than reactor throughput currently. One of few researches related to the reactor configuration is the comparison of contact ablative pyrolysis and radiant ablative pyrolysis, on the basis of the values of ablation thickness and velocity and of product fractions and compositions, to show their advantages and drawbacks (Lédé 2003).

Vacuum Pyrolysis Reactor

Vacuum pyrolysis reactor is actually not a true fast pyrolysis, as the heat-transfer rate both to and through the solid biomass is much slower than that observed in other reactors and the solid residence time is very high. Vacuum pyrolysis can produce larger particles of biomass than most fast pyrolysis, which decompose into primary fragments when heated in the reactor and then quickly vaporize under reduced pressure. The properties of rapid volatilization and no carrier gas of vacuum

pyrolysis directly cause a less content of char particles in liquid product due to lower gas velocities. A pilot vacuum reactor with continuous feed rate of 15 kg/h, operated at 500 °C under 15 kPa, was used to produce bio-oil and investigate the characterization of bio-oils from softwood and hardwood (Garcìa-Pérez et al. 2007). Liquid yields of 45 wt% and 53 wt% on dry feed were obtained from softwood and hardwood with higher char yields than fast pyrolysis systems. However, there are no successful large throughput demonstrations that adopted vacuum pyrolysis technologies due to the complicated mechanics and poor heat-mass transfer rates.

Auger Reactor

Auger pyrolysis is a novel pyrolysis technology compared with other pyrolysis technologies (Brown 2009). The main features are that it is compact and does not require carrier gas and can continuously decompose biomass at low temperature of about 400 °C. Augers are used to transport feedstocks through an oxygen-free cylindrical heated tube. Hot sand as a heat-transfer medium can increase the heat supply from auger reactor. When heated, particles begin to decompose and volatilize followed by the separation of char and vapors. This design consequently reduces energy costs; moreover, the vapor residence time can be modified by increasing the length of the heated zone.

Rotating Cone Pyrolyzer

The rotating cone reactor is developed by Twente University and demonstrated by Biomass Technology Group of the Netherlands (BTG) in the 1990s. Biomass particles are fed into an impeller that is mounted at the base of the heated rotating cone together with an excess flow of inert materials, which have less carrier gas and sand or some catalytic particles (Wagenaar et al. 1994). These are then flung on to the heated surface to be pyrolyzed while being transported spirally upward along the hot cone wall. Produced char and sand drop into a fluidized bed surrounding the cone, from where they are lifted to a separate fluid-bed combustor, where char is burned to heat the sand used as the recycled heat-transfer medium. The reactor is very compact but complex integrated of three subsystems, including rotating cone reactor, riser for sand recycling, and fluidized bed for char combustion. So they are hard to scale up.

Development Recommendations

According to the above-discussed contents, some details should be paid more attention to the improvement of biomass to bio-oil processes, which allow easier scale up and significantly improved energy efficiency.

1. For pyrolysis reactor, it is important to develop an independent heat-supply source, which allows more design flexibility and easier control. Moreover, if the operated temperature can be minimized to about 400–450 °C, energy consumption will be obviously decreased compared to that consumed in 500–550 °C.
2. For the char separation, more efficient cyclones are urgently needed to separate char from pyrolysis vapors or aerosols with the minimum attrition of char

Table 9 Typical properties of the bio-oils (Czernik and Bridgwater 2004; Bridgwater 2004)

Properties	Value		Notes
	Bio-oil	Heavy oil	
Moisture content (wt%)	15–30	0.1	Water comes from moisture in the feed and reaction water and cannot be separated
pH	2.5		The low pH value comes from organic acids, e.g., acetic acid
Density	1.2	0.94	Bio-oil has about 40 % of the energy content of fuel oil on a weight basis but 60 % on a volumetric basis
Elemental composition			Typical elemental composition is affected by both the feedstocks and the produced solid char
C	54–58	85	Typical data is 57
H	5.5–7	11	Typical data is 6
O	35–40	1.0	Typical data is 37
N	0–0.2	0.3	The N content is trace
Ash	0–0.2	0.1	All ash is associated with the char content and affected by char separation
HHV (MJ/kg)	16–19	40	With the consideration of high moisture content of about 25 %, bio-oil has a high heating value
Viscosity, at 500 °C (cP)	40–100	180	Viscosity depends on the feedstocks, water content, light, and aging
Solids (wt%)	0.2–1	1.0	0.1 wt% is a good level, and 1 wt% is often encountered
Distillation residue (wt%)	Up to 50	1.0	Water addition can be tolerated up to about 35 %. Bio-oil is miscible with polar solvents such as methanol but totally immiscible with petroleum-derived fuels

particles, which have significant influence on quenching and applications of bio-oils. And as the by-product, the more clean char is better.

3. For quenching system, a rapid quenching time and a small recycle ratio (i.e., a small gas/biomass feed ratio) are required. It is the weakest part in the biomass-to-bio-oil development.

Properties of Bio-oils

Bio-oil is also called pyrolysis oil, wood oil, liquid smoke, wood distillates, etc., in the related researches and reports. Bio-oils are dark brown, are smelly, have high acidity, and have free-flowing organic liquids, produced from the decomposition and fragment of the main biomass components, namely, cellulose, hemicelluloses, and lignin. The special and complex physicochemical properties of bio-oils require careful characterizations of bio-oils and comprehensive considerations before any applications, storage, upgrading, and utilization.

Physical Properties

The physical properties of bio-oils are well documented in the literatures (Mohan et al. 2006; Lu et al. 2009a; Czernik and Bridgwater 2004; Bridgwater 2004). The

typical properties are described in Table 9, which are significantly different from that of the heavy fuel oil. The moisture content in bio-oils varies over a wide range (15–30 wt%) depending on the feedstocks and process conditions. The presence of water has both negative and positive effects on the oil properties. It lowers the heating value of bio-oils, especially the LHV and flame temperature, and contributes to the increase in ignition delay and decrease of combustion heat release rate. But the existence of water in bio-oils improves flow characteristics during pumping and atomization and leads to lower NO_x emissions. The presence of oxygen in many oil components is the primary reason for differences in the properties and behavior observed between hydrocarbon fuels and biomass pyrolysis oils. The high oxygen content of 35–40 % results in a low energy density that is less than 50 % of that for conventional fuel oils and immiscibility with hydrocarbon fuels. An even more important consequence of the organic oxygen is the thermal instability of bio-oils. The viscosity decreases at higher temperatures much faster than for petroleum-derived oils and a significant reduction can also be observed by addition of polar solvents. The undesired effect is the viscosity increase with time during storage or handling processes due to the chemical reactions between compounds leading to the formation of large molecules. Moreover, the corrosiveness is severe at elevated temperature and with the increase in water content. These properties have a significant influence on the behavior of bio-oils during combustion and consequently applications for energy production in standard equipment. Bio-oils are combustible but not flammable due to the high content of nonvolatile components contained (Hristov et al. 2004).

Chemical Properties

From a chemical point of view, bio-oils are characterized by the presence of oxygenated compounds, such as furan derivatives, carboxylic acids, alcohols, dihydroxyphenols, and dimethoxyphenols, derived from the decomposition of biomass components. Typical components and their yields of commercial wood-derived bio-oils produced from Biomass Technology Group of the Netherlands (BTG), Dynamotive, Ensyn, and Pyrovac (adopted vacuum reactors located in Quebec, Canada) are summarized in Table 10. Major compounds exist in the four kinds of bio-oils except for some differences in yields, which are caused by types of wood material, reactors, liquid collection methods, etc. In addition, properties and compositions of bio-oils from other feedstocks (like agriculture residues and forest residues) are also concluded by many researches (Mohan et al. 2006; Zheng 2007; Branca et al. 2005, 2006; Uzun et al. 2007).

Bio-oils are composed of molecules with different sizes derived from the depolymerization and fragmentation of cellulose, hemicelluloses, and lignin. Moreover, the composition of bio-oils is influenced by various factors, such as reactor type, operating conditions, and feeding materials. For example, the results of conventional fast pyrolysis indicate that faster rates enhance the formation of levoglucosan and hydroxyacetaldehyde with a diminution of carboxylic acids (Branca et al. 2003). Detailed classification systems use categories such as acids, aldehydes, phenols, furans, alkenes, aromatics, ketones, and saccharides (Mohan et al. 2006), and

Table 10 Yields and boiling point temperature of bio-oil components (Branca et al. 2005)

Compound	T_b (K)	BTG (wt %)	Dynamotive (wt %)	Ensyn (wt%)	Pyrovac (wt %)

representative compounds include acetic acid, formic acid, levoglucosan, hydroxypropanone, 2-furaldehyde, and hydroxyacetaldehyde (Garcia-Perez et al. 2007). The chemical composition of bio-oil can be manipulated by changing the thermal conditions of pyrolysis, but complex bio-oils are recalcitrant to complete

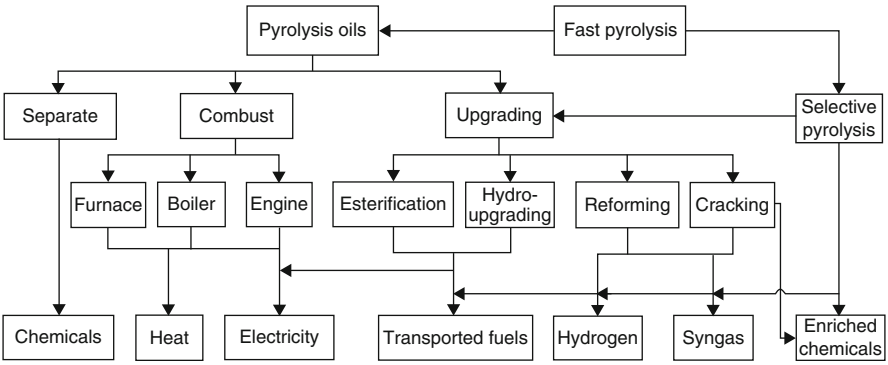

Fig. 1 Applications of bio-oils from fast pyrolysis process

chemical characterization, which is hindered by the limitations of modern analytical equipment.

Applications of Bio-oils

The most significant issues of bio-oils as fuels are poor volatility, high viscosity, coking, corrosiveness, and cold-flow problems. Though these problems limit the utilization of bio-oils, they also have many applications, mainly including direct combustion in boilers or furnaces to supply heat or to generate electricity and substitution for transported fuels after upgrading. Figure 1 summarizes some existing concepts of bio-oil applications, which can be divided into two classes: primary and high-grade applications.

Primary Applications of Bio-oils

Bio-oils are renewable liquid fuel, with a lower heating value of about 18 MJ/kg compared with 43 MJ/kg for diesels. They can be used as fuels in boilers, engines, or gas turbines for the production of heat, power, and combined heat and power (CHP). Compared to combustion and gasification of biomass, fast pyrolysis has the advantage that a liquid intermediate is produced, stored, and then transported to centralized locations economically. Thus, bio-oil production and heat or power generation can be carried out independently at different locations and times and at good efficient scales (Brammer et al. 2006).

Heat Generation

As discussed above, bio-oils have lower heating values compared with fossil fuels due to the high content of oxygenated compounds and water, but their combustion characteristics are similar to light fuel oils. So direct combustion of bio-oils can supply residential or industrial heating, which have been under operations in many regions. Currently, the consideration and improvement of this application are referred to three major issues. Bio-oils are too acidic to be used in the existing residential boilers, meaning that bio-oils should have to be processed or stainless

steel used; the modification of nozzles or burners is also necessary to ensure efficient ignition or combustion. Researches on the removal of oxygenated compounds and part of water are essential to improve the combustion behaviors.

Power Generation

One of the common applications for bio-oils is as a fuel for power generation. But attentions should be paid that boilers, especially engines and turbines, are specially designed to use bio-oils, rather than the conventional commercial engines. Organizations testing bio-oil in engines include Wartsila Diesel in Finland, Onnrod Diesel in Great Britain, and Orenda in Canada. One of the alterations to the turbine includes changing the fuel system and nozzle to handle a higher flow rate. Because of the high viscosity of bio-oils, the efficiency of fuel atomization is also an issue that must be addressed to achieve complete combustion. All these changes in the fuel pump, feed linings, and the injection system provide opportunities for applications for bio-oils to replace natural gas, diesel, and other fossil fuels in the industrial equipment.

As bio-oils are insoluble with petro-derived fuels, it is not possible to mix the fuels before combustion without emulsification. Emulsions of bio-oil and standard diesel or other fossil fuels have been produced and tested in diesel engines. Some researches investigate the emulsification effect on thermal stability of the fuel blends and observe that the emulsions are more stable than the crude bio-oils; the higher the bio-oil content, the higher the viscosity of the emulsion; and the optimal range of emulsifier to provide acceptable viscosity is between 0.5 % and 2 % (Chiaramonti et al. 2003a, b). Moreover, suitable emulsification can decrease the viscosity and corrosiveness of the fuel blends compared with original bio-oils (Ikura et al. 2003). Emulsification does not demand redundant chemical transformations, but the high cost and energy consumption input cannot be neglected. The accompanying corrosiveness to the engine and the subassemblies is inevitably serious.

Chemical Separation

More than 400 kinds of compounds have been identified in bio-oils. Some enriched compounds, such as acetic acid, hydroxyacetaldehyde, and phenols, can be separated by adding solvents into bio-oils. Phenols, consisting of relatively small amounts of phenol, eugenol, and cresols and much larger quantities of alkylated phenols, which are also called lignin-derived fractions, are present in high concentrations. The lignin-derived fraction is comprised of a total phenolic content of about 30–80 % and is considered more reactive in usage as an extender within resin formulations without requiring any further extraction or fractionation procedures. Many attractive results about pyrolyzed phenol substitution for resins have been reported (Wang et al. 2009a, b). However, resin producers want to market the reproducible, precisely tailored resin compositions that the end users demand. So the variability of chemical compositions has gained resin producers' attention in developing commercial resins from bio-oils.

Table 11 Properties of bio-oils after hydrodeoxygenation (Elliott 2007)

Properties	High-pressure liquefaction	Flash pyrolysis	Hydrodeoxygenation bio-oils
Elemental analysis			
C	72.6	43.5	85.3–89.2
H	8.0	7.3	10.5–14.1

IBP-225 °C	8	44	97–36
225–350 °C	32	Coked	0–41

Bio-oils Upgrading for High-Grade Applications

Hydrodeoxygenation (Hydro-upgrading)

Crude fossil fuel oil processing techniques typically focus on the removal of nitrogen and sulfur, as well as molecular weight reduction. In contrast, treatment of bio-oils will mainly be more focused on oxygen removal and molecular weight reduction. Hydrodeoxygenation of bio-oils involves treating bio-oils at moderate temperature of 250–400 °C with high-pressure H_2 (10–18 MPa) and continuous H_2 feed rate (volume ratio of H_2/bio-oil, 100–700) (Peterson et al. 2008). Processes refer to hydrotreating and hydrocracking, often in the presence of some catalysts. A number of different catalysts are employed, including nickel, cobalt, molybdenum, and platinum. Comprehensive reviews on hydrodeoxygenation have been written by Furimsky (2000) and Elliott (2007). As shown in Table 11, the energy content and the stability of bio-oils after upgrading are significantly increased. The high-pressure liquefaction is a method for bio-oil upgrading, which takes place in a water-rich phase, rather than an oil-rich phase, which eliminated the need for recycle but employed subsequent alkaline and acid treatments (Davis et al. 1982). The disadvantages are that it consumes H_2 and even requires high-pressure H_2. Moreover, hydrodeoxygenation process needs complicated equipments, advanced techniques, and excess cost and usually is forced to stop due to catalyst deactivation and reactor clogging. Future work in hydrodeoxygenation may be focused on developing decreased H_2 combustion system modified through mass and energy balance calculation and exploring and texting novel high-efficiency catalysts.

Catalytic Steam Reforming

The strategy of catalytic steam reforming is based on producing hydrogen from bio-oils in conjunction with other products that have greater value and can reduce the cost of hydrogen, which firstly start to develop in the 1990s by NREL. The original concept is that bio-oils are fractionated into two fractions based on water solubility. The water-soluble fraction is to be used for hydrogen production, and the water-insoluble fraction could be used in adhesive productions. Bio-oils are usually steam reformed using a nickel-based catalyst at 750–850 °C, followed by a shift reaction to convert CO to CO_2. The reactions in catalytic steam reforming of bio-oils are described as follows. The yield of hydrogen is limited with a maximum of only 8.6 g H_2/100 g bio-oil (Milne et al. 2001). Control of coke formation is a key aspect of this process. Loss of activity of the nickel catalysts after a few hours forces periodic regeneration. It is well known that CO_2 from a pressure swing absorption step can effectively remove the coke. There are currently no commercial deployment opportunities for hydrogen production, but this method remains viable. Several model compounds were successfully steam reformed, such as acetic acid, ethyl alcohol, acetone, phenol, cresol, and aqueous fraction of bio-oil.

$$\text{Biomass} + \text{Energy} \rightarrow \text{Bio} - \text{oil} + \text{Char} + \text{Gas impurities (pyrolysis)}$$
$$\text{Bio} - \text{oil} + \text{Water} \rightarrow \text{CO} + \text{H}_2\text{(reforming)}$$
$$\text{CO} + \text{Water} \rightarrow \text{CO}_2 + \text{H}_2\text{(shift reaction)}$$
$$\text{CH}_{1.9}\text{O}_{0.7} + 1.26\,\text{H}_2\text{O} \rightarrow \text{CO}_2 + 2.21\,\text{H}_2$$

Steam reforming of bio-oils can also produce syngas, composed of CO and H_2. Then syngas is converted into a range of fuels depending on the ratio of CO/H_2. The fuels include hydrogen by the water-gas shift reaction, methanol by methanol synthesis, alkanes by Fischer-Tropsch synthesis, ethanol by fermentation, etc.

Catalytic Cracking

Catalytic cracking is one of the routes for obtaining gasoline and other lighter products from fast pyrolysis oils. The initial catalysts were clays and amorphous silica alumina and were evolved with time to zeolites, specially the use of rare earth-Y (REY) and finally to the ultrastable-Y (USY), REUSY, and multi-zeolite catalysts used today (Tamunaidu and Bhatia 2007). Bio-oils can be upgraded using zeolite catalysts to reduce oxygen content and improve thermal stability. Zeolite upgrade is operated in the temperature range of 350–500 °C, atmospheric pressure, and gas hourly space velocities of around 2. The products are consisted of hydrocarbons, water-soluble organics, water, oil-soluble organics, gases, and coke. A number of chemical reactions occur including dehydration, cracking, polymerization, deoxygenation, and aromatization. By alternation cracking steps, bio-oils can be mainly decomposed into H_2, CO or CO_2, and coke. Then the coke is burnt by O_2 addition in the regeneration step. Catalytic cracking provides an interesting means of controlling the coke formed during bio-oil cracking. Moreover, the process may run autothermally. Different chemical compounds in bio-oils have a significant difference in reactivity and coke formation rates. Therefore, separation prior to reaction is

a positive prevention method for coke formation and catalyst attrition. It is necessary to incorporate the reactor and catalyst design as well as optimum process operation conditions in order to further improve the bio-gasoline production (Ong and Bhatia 2010).

Selective Pyrolysis of Biomass

In recent years, selective pyrolysis has aroused a great interest due to the advantages of operating at atmospheric pressure and in the absence of hydrogen. Selective pyrolysis is different from conventional fast pyrolysis, which is usually aimed at the maximum bio-oil yield and is to drive the pyrolysis of biomass toward the products of interest (Zhu and Lu 2010). The application of proper catalysts can effectively optimize the distribution of bio-oil composition and improve the quality of bio-oil as well as produce value-addition chemicals. Many studies have been focused on the catalysts of acids and alkali metal salt. The application of sulfated metal oxides (SO_4^{2-}/TiO_2, SO_4^{2-}/ZrO_2, SO_4^{2-}/SnO_2) significantly decreases or completely eliminates the formation of levoglucosan due to the enhancement of dehydration reactions (Lu et al. 2009b), while suitable concentration of phosphoric acid can govern levoglucosan/levoglucosenone ratio produced from cellulose pyrolysis (Dobele et al. 2005). Alkali metal salts such as K_2CO_3, NaCl, KCl, $MgCl_2$, and $CaCl_2$ have an obvious influence on gaseous products resulting in an increase in gas yield and a decrease in tar yield (Nishimura et al. 2009; Shimada et al. 2008). Currently catalytic upgrading of pyrolysis vapors using zeolites and noble metals is a potentially promising method for removing oxygen from organic compounds and converting them to hydrocarbons (French and Czernik 2009). Zeolites (Y and ZSM type) exhibit a strong influence on pyrolysis behavior of cellulose, reducing the overall yields of anhydrosugars to convert into hydrocarbons (Fabbri et al. 2007). Noble metals, for example, Pt and Ni, are widely applied in bio-oil catalytic reforming to improve the yields of gaseous products especially hydrogen (Zhao et al. 2009; Iojoiu et al. 2007).

Application of Biochar

Biochar as the by-product of biomass pyrolysis is of increasing interest because of concerns about climate change caused by emissions of carbon dioxide (CO_2) and other greenhouse gases (GHG).

Biochar is a stable charcoal of rich carbon produced by biomass pyrolysis under fully or partially anoxic conditions and at relatively low temperature (below 700 °C). The carbon content of biomass char varies as the pyrolysis temperature changes (Bruun et al. 2010). Biochar has a high surface area, high nutrient-retention capacity, and high water-retention capacity due to its porous structure (Zhang et al. 2009).

Biochar as a Potent Soil Amendment

Biochar has a large surface area because of its pore structure just as charcoal. Therefore, biochar has a high water-retention capacity. Application of biochar will increase the water-holding capacity of agricultural soil. In addition, the application of biochar is related to soil moisture and soil texture (Zhang et al. 2009). But further

studies are needed to clarify whether this may help balance fluctuations in water availability to plants (Karhu et al. 2011).

There are several ways for biochar to improve soil fertility. In the first place, biochar in the soil has a high nutrient-retention capacity because biochar can increase soil cation exchange capacity to enhance cation adsorption and improve pH of the soil. For example, rice hull char can increase pH in both soils to some extent, mainly by decreasing the contents of exchangeable acid and exchangeable Al, and increase the content of exchangeable bases and the base saturation (Yuan and Xu 2010). Furthermore, biochar addition benefits for the growth of fungus and nitrogen-fixing microbial groups, improving soil fertility and increasing crop yields (Song and Gong 2010; Diana et al. 2010). So, as a soil amendment, biochar makes soil more fertile, preserves cropland diversity, and reduces the need for some chemical and fertilizer inputs, which indirectly boosts food security and reduces water pollution.

Application of biochar could not only improve the physical and chemical properties of soil and increase soil fertility but also adsorb heavy metals (such as cadmium, arsenic, etc.), prevent the plant from uptaking of pollutants, and improve the effect of environmental remediation to a certain extent. The effects on the mobility, bioavailability, and toxicity of specific elements vary with the applying amendments to multielement contaminated soils (Luke et al. 2010; Luke and Marta 2011).

Biochar as a Powerful Tool to Combat Climate Change

The carbon in biochar resists degradation and can hold carbon in soils for hundreds to thousands of years. Biochar is produced through pyrolysis or gasification – processes that heat biomass in the absence (or under reduction) of oxygen.

In addition to creating a soil enhancer, sustainable biochar practices can produce oil and gas by-products that can be used as fuel, providing clean, renewable energy. When the biochar is buried in the ground as a soil enhancer, the system can become "carbon negative."

Biochar and bioenergy coproduction can help combat global climate change by displacing fossil fuel use and by sequestering carbon in stable soil carbon pools. It may also reduce emissions of nitrous oxide.

Future Directions

Combustion

At present, large-scale biomass combustion power generation projects were mainly concentrated in Europe and the USA and other developed countries. However, due to the variety of resources, most of the applied projects are using wood-based raw materials such as branches, wood chips, and waste wood as the main fuel, only a small part blending a small part of the crop stalks. In the area of crop stalk combustion power generation, Denmark has made outstanding achievement, represented by water-cooled vibrating grate technology of BWE. In 1988, the first crop stalk combustion power plant was constructed in Denmark. Since then, more

than 100 plants have been established in the past years, and it makes biomass become the very important energy resource in Denmark. In order to overcome the biomass fuel supply fluctuations, large-scale power plants generally co-fire it with coal. Meanwhile, in order to improve the economics of biomass power plants and thermal efficiency, now the combined heat and power technology (CHP) is widely used.

After many years of development, there have been no major technical obstacles of biomass combustion power generation. However, lots of work still need to be done. The biomass resources are of great varieties and scattered, which result in difficult collection and transportation. At present, the equipments and processing flow for collection, transportation, and pretreatment of biomass are not perfect, which is the key factor of scale-up biomass power generation.

In the future, the utilization of high-alkali biomass will become more and more important. In order to improve the share of electricity generation from biomass combustion, co-firing represents a cost-effective, short-term option at large scale.

Gasification

Among the different gasification technologies, the biomass gasification is the most promising biomass technology that has great potential to be further developed. Though there is a great achievement in the research and development of this technology, several developmental constraints exist including pollution issues, competitiveness with electricity generated by conventional fuel, and system scale. Environmental protection and energy conservation may be a driving force of further development of the biomass gasification technologies.

1. *Scale*: At present, due to financing problems, the development of small-scale gasification plants is restricted. But the development of large-scale plants is also restricted because of the problems with collection and transportation. To handle the relations of the two issues is the great impetus for gasification development.
2. *Feeding*: Because of the seasonality of biomass, it is necessary to improve the feasibility of the gasification equipment for different raw materials either separately or in mixed form. Compared to the direct gasification of raw biomass materials, the overall efficiency of oil/gas gasification is low. But it is easier to realize continuous oil and system compression using oil as raw material, which can effectively reduce costs and achieve economy. Hence, it is necessary to research and develop the pyrolysis oil/gas gasification technology.
3. *Combined heat and power (CHP) technology*: Although large- and medium-scale CHP plants have been commercialized, small- and microscale plants used for heat supply for buildings are easier to find an end user than larger CHP systems. So small- and microscale plants need more research.
4. *Contamination*: Some specifications for biomass gasification are estimated based on the practical experience. So it is necessary to investigate the rules of pollutant emission in the biomass gasification process.

5. *Purification*: A complete set of specific specification for pollutants in the product gas is needed. For example, the requirements for Fischer-Tropsch synthesis are very stringent. And the relatively clean natural gas is the common feedstock for Fischer-Tropsch synthesis. But the actual cleaning specifications are not known for some specific biomass contaminants.
6. *Policy*: Since the industrialization process of biomass gasification would take a long period to reflect the importance of biomass gasification in an environmental protection field, the government should offer sustainable assistance for development, such as increasing support funds, setting up of special project assessment institute, and setting up of special funds with an aim to drive society investment and cultivate mature market.

Pyrolysis

Bio-oils have the considerable advantages of being storable and transportable as well as the potential to supply the amount of valuable chemicals; there are many challenges facing fast pyrolysis that relate to technology, product characterization, and applications.

The challenges are as follows:

1. Design a well-integral fast pyrolysis system, making the reactor in perfect cooperation with char separation, liquid quenching, liquid collection, and fuel applications.
2. Decrease the cost of bio-oil production and increase the energy efficiency.
3. Set up standards for testing the physicochemical properties of bio-oil.
4. Develop widely the applications of bio-oils before and after upgrading.
5. Bio-oil is incompatible with conventional fuels and its users are unfamiliar with this material.
6. Dedicated fuel handing systems are needed.
7. Develop environmental health and safety issue evaluation in handing, transport, and usage.
8. Encourage developers to implement bio-oil and by-product applications.

Chemicals from Biomass

Debalina Sengupta and Ralph W. Pike

Contents

Abstract

The different biomass conversion routes to chemicals will be described in this chapter. Chapter "► Biomass as Feedstock," gives an overview of the methods used to obtain chemicals from biomass. These processes along with some other chemical conversions can be used for the manufacture of chemicals from biomass. A list of chemicals compiled based on the carbon number in the chemicals will be discussed in this chapter. Some of these chemicals are presently made

from nonrenewable feedstock like natural gas and petroleum, while others are new chemicals that have potential to replace nonrenewable feedstock-based chemicals. Transesterification process is used to produce propylene chain of chemicals from glycerin. Fermentation is used to produce ethanol which is converted to ethylene and can be used for ethylene chain of chemicals. The chemicals discussed in this chapter include recent advances in chemistry, and processes discussed include new frontiers for research in biomass to chemical production.

Introduction

Crude oil is the single largest source of energy for the USA, followed by natural gas and coal. Approximately 3 % of the total crude oil is used as feedstock for the production of chemicals (Banholzer et al. 2008). Natural gas is used for the production of fertilizers and supplies energy to the production processes. Petroleum refineries extract and upgrade valuable components of crude oil using various physical and chemical methods into a large array of useful petroleum products. While the USA is one of the world's largest producers of crude oil, the country relies heavily on imports to meet the demand for petroleum products for consumers and industry. This reliance on international ties to petroleum trade has led to numerous upheavals in the industry over the last four decades, the most recent being when crude oil prices reached $134 per barrel in 2008 (Banholzer et al. 2008), as shown in Fig. 1. Natural disasters such as hurricanes in the Gulf Coast region (Katrina and Rita in 2005 and Gustav in 2008) caused major damages to offshore oil-drilling platforms and disruption of crude oil supply. The natural gas prices, shown in Fig. 2, have also varied from $4 per cubic feet in 2001 to $13 per cubic feet in 2008 (EIA 2010b).

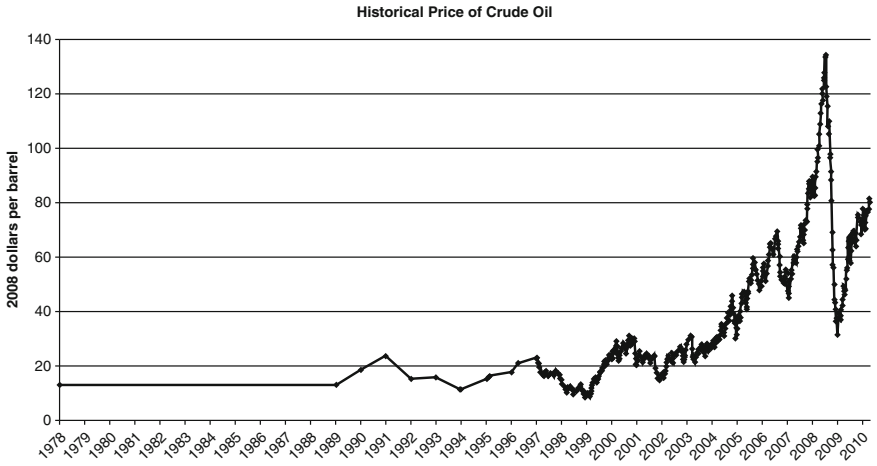

Fig. 1 Historical crude oil prices (EIA 2010a)

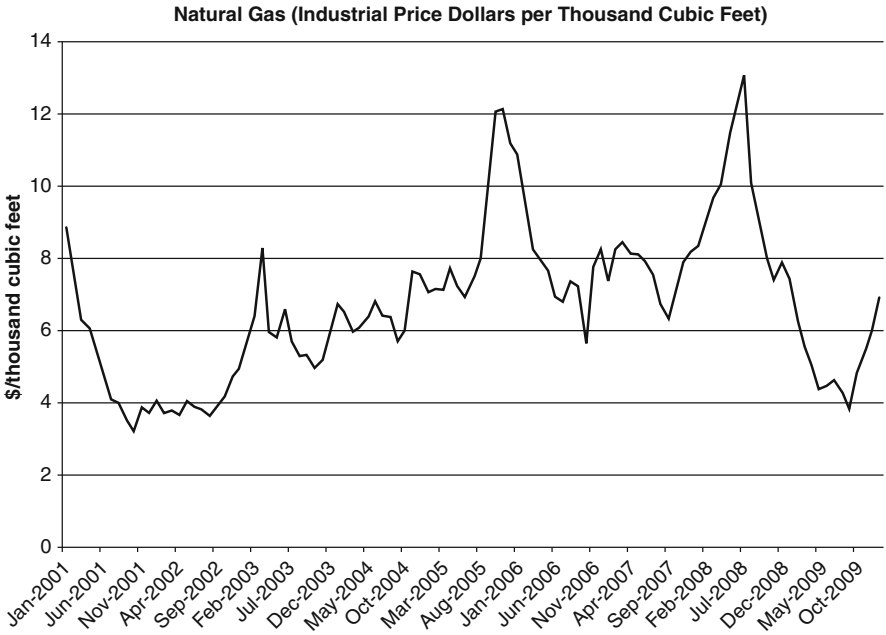

Fig. 2 Natural gas prices (EIA 2010b)

The consumption of energy resources in the world added 30.4 billion tons of carbon dioxide in 2008, an increase of approximately 12 billion tons higher than 1980 figures (EIA 2010c). The rate of carbon dioxide emissions is expected to go higher, unless alternate methods for obtaining energy, fuels, and chemicals are developed. Renewable resources are considered for supplementing and eventually substituting the dependence on oil and natural gas. These resources include biomass, wind, hydroelectric, and solar energy. These resources convert an alternate form of energy (different from fossil resource) into power, fuels, or chemicals. Some of these resources (wind, solar, hydroelectric) do not emit large quantities of carbon dioxide during resource utilization and thus are cleaner choices compared to fossil resources. This also reduces the dependence on foreign oil imports.

The processes for the production of chemicals involve the conversion of traditional or conventional forms of energy (petroleum and natural gas) to materials by rearranging the atoms from the components, mainly carbon, hydrogen, and oxygen. The shift to renewable resources for the production of chemicals offers biomass as the only choice of raw material because only biomass can provide the necessary carbon, hydrogen, and oxygen atoms. The rest of the renewable resources can be used as supplement for energy requirements for the conversion processes. Also, carbon dioxide utilized in photosynthetic processes to produce biomass is released when biomass is used. This allows the immediate use of atmospherically fixed carbon dioxide to be released to the environment, which in turn will be used for biomass formation. The transition from fossil feedstock to biomass feedstock

requires extensive process technology changes, market penetration of new chemicals from biomass replacing existing chemicals, and process energy requirements.

Chemicals from Nonrenewable Resources

The chemical industry in the USA is an integral part of the country's economy, producing more than 70,000 products each year. About 24 % of the chemicals produced become raw materials for other products within the industry. For example, ethylene is the fourth largest produced chemical in the USA, with 24 million short tons produced in 1997 (Energetics 2000). The Department of Energy gives an extensive list of chemicals and allied products manufactured in the USA, identified by SIC (Standard Industrial Classifications) codes. The major US chemical industry SIC codes and their corresponding products are given in Table 1.

Based on the classifications of industrial chemicals in Table 1, they can be divided into five chains of chemicals. These include the ethylene chain, the propylene chain,

Table 1 Major US chemical industry SIC codes and their products (Adapted from Energetics (2000))

SIC	Major products
281 Industrial inorganic chemicals	
2812 Alkalies and chlorine	Caustic soda (sodium hydroxide), chlorine, soda ash, potassium, and sodium carbonates
2813 Industrial gases	Inorganic and organic gases (acetylene, hydrogen, nitrogen, oxygen)
2819 Industrial inorganic chemicals (not otherwise classified)	Compounds of aluminum, ammonium, chromium, magnesium, potassium, sodium, sulfur, and numerous other minerals; inorganic acids
282 Plastics and rubbers	
2821 Plastic materials and resins	Synthetic resins, plastics, and elastomers (acrylic, polyamide, vinyl, polystyrene, polyester, nylon, polyethylene)
2822 Synthetic rubber	Vulcanizable rubbers (acrylic, butadiene, neoprene, silicone)
286 Industrial organic chemicals	
2865 Cyclic crudes and intermediates	Distilling coal tars; cyclic intermediates, i.e., hydrocarbons, aromatics (benzene, aniline, toluene, xylenes); and organic dyes and pigments
2869 Industrial organic chemicals (not otherwise classified)	Aliphatic/acyclic organics (ethylene, butylene, organic acids), solvents (alcohols, ethers, acetone, chlorinated solvents), perfumes and flavorings, rubber processors and plasticizers
287 Agricultural chemicals	
2873 Nitrogenous chemicals	Ammonia fertilizer compounds, anhydrous ammonia, nitric acid, urea, and natural organic fertilizers
2874 Phosphatic chemicals	Phosphatic materials, phosphatic fertilizers

the benzene–toluene–xylene (BTX) chain, the agricultural chemicals chain, and the chlor-alkali industry (Energetics 2000). Among these, the production of ethylene, the building block for the ethylene chain of chemicals, depends on the availability of petroleum feedstock. Propylene, a building block for the propylene chain of chemicals, is almost entirely produced as a coproduct with ethylene in the steam cracking of hydrocarbons. The BTX chain of chemicals is coproduced by the catalytic reforming of naphtha. The agricultural chemicals, like ammonia, urea, ammonium phosphate, etc., are primarily dependent on natural gas for the production of hydrogen. Thus, the present chemical industry is almost entirely dependent on fossil resources for the production of chemicals. A significant amount of carbon dioxide and other greenhouse gases is also released during the production of these chemicals.

Historically, there had been no governmental regulations on carbon dioxide emissions by chemical industries. However, the increased concerns due to global warming, climate change, and pollution reduction programs prompted the US Government House of Representatives to pass the American Clean Energy and Security Act of 2009 (ACES 2010). This bill, if passed, would introduce a cap and trade program aimed at reducing the greenhouse gases to address climate change. The Environmental Protection Agency issued the Mandatory Reporting of Greenhouse Gases Rule in December 2009 (EPA 2010). The rule requires reporting of greenhouse gas (GHG) emissions from large sources and suppliers in the USA and is intended to collect accurate and timely emission data to inform future policy decisions. Under the rule, suppliers of fossil fuels or industrial greenhouse gases, manufacturers of vehicles and engines, and facilities that emit 25,000 t or more per year of GHG emissions are required to submit annual reports to EPA.

With the government initiatives and increased global concerns for greenhouse gas emissions, alternate pathways for production of chemicals from biomass are required. This chapter focuses on the use of biomass as feedstock for chemicals. This is an ongoing research area, and the chemicals discussed in this chapter are not an exhaustive list; however, an attempt is made to include the most promising chemicals from biomass that have the potential for commercialization and can replace the existing chain of chemicals from fossil resources.

Chemicals from Biomass as Feedstock

The world has a wide variety of bio-feedstocks that can be used for the production of chemicals. Biomass includes plant materials such as trees, grasses, agricultural crops, and animal manure. The components of biomass are shown in Fig. 3, and it can be seen that all the biomass components are molecules of carbon, hydrogen, and oxygen atoms. Biomass can be divided into five major categories as shown in the figure: starch, cellulose, hemicellulose, lignin, and oils. Cellulose, hemicellulose, and lignin are components of woody biomass, grasses, stalks, stover, etc. Starch and cellulose are both polymeric forms of hexose, a 6 carbon sugar. Hemicellulose is a polymer of pentose. Lignin is composed of phenolic polymers, and oils are

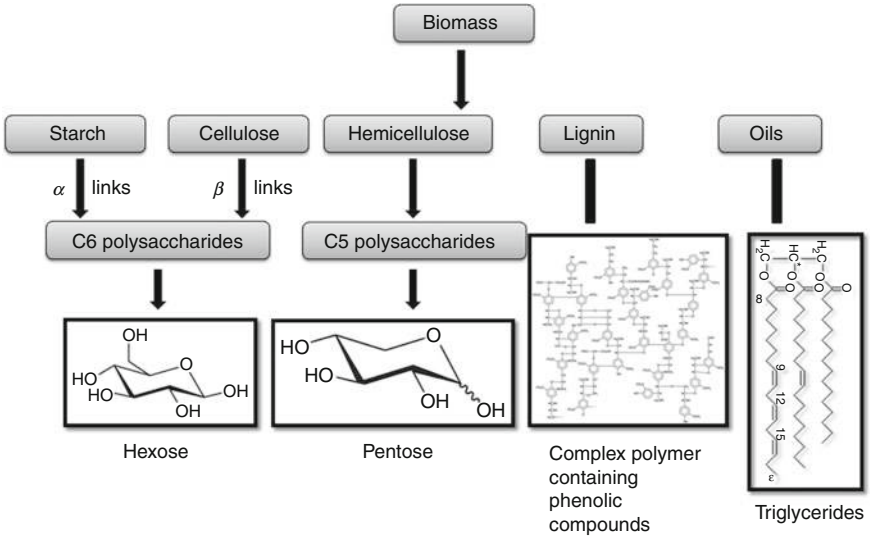

Fig. 3 Biomass classifications and components

triglycerides. Starch is primarily found in corn, sweet sorghum, and other crops. Sugarcane contains the sugar in monomeric form, but extraction of juice is required. Other biomass components, which are generally present in minor amounts, include sterols, alkaloids, resins, terpenes, terpenoids, and waxes.

The feedstock availability in the USA currently includes 142 million dry tons per year of forest biomass with a possibility of increasing it to 368 million dry tons per year (Perlack et al. 2005). The agricultural biomass currently available is 194 million dry tons per year with a possible increase to 998 million dry tons per year. Forest biomass is the biomass obtained from forestland (land having at least 10 % tree cover) and is naturally or artificially regenerated. Agricultural biomass is the biomass obtained from cropland designated for the harvested row crops and closely sown crops, hay and silage crops, tree fruits, small fruits, berries, tree nuts, vegetable and melons, and other minor crops. Apart from forest and agricultural biomass, algae can be produced from power plant exhaust carbon dioxide and used for chemical synthesis.

Figure 4 shows the different routes for the production of chemicals from biomass. The feedstock base includes natural oils, sugars, and starches as carbohydrates, cellulose, and hemicellulose. The main conversion technologies used are transesterification, fermentation, anaerobic digestion, acid dehydration, gasification, and pyrolysis. The primary products given in the figure are not an exhaustive list, but some representative chemicals.

There are primarily two different platforms of conversion technologies for converting biomass feedstock to chemicals, the biochemical platform and the thermochemical platform (DOE 2010a). The biochemical platform focuses on the

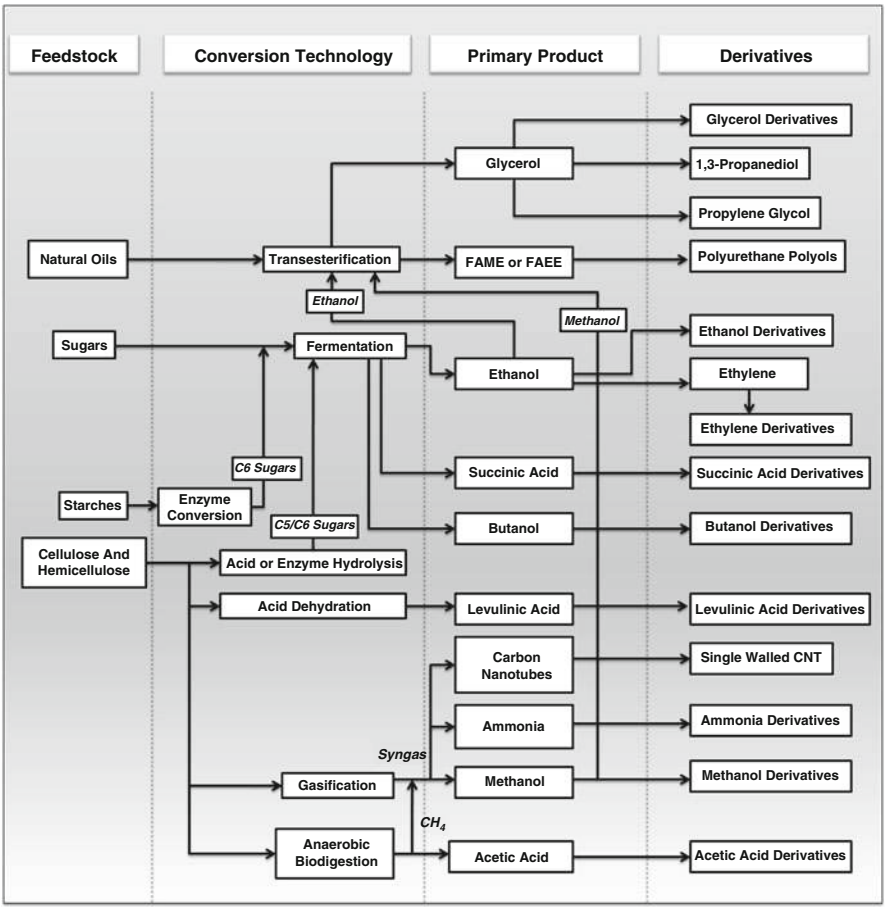

Fig. 4 Biomass feedstock conversion routes to chemicals

conversion of carbohydrates (starch, cellulose, hemicellulose) to sugars using biocatalysts like enzymes and microorganisms and chemical catalysts. These sugars are then suitable for fermentation into a wide array of chemicals. Apart from this, chemical catalysis used in transesterification reaction can produce fatty acid methyl and ethyl esters (FAME and FAEE) and glycerol. The fermentation products such as ethanol and butanol can be a starting material for numerous chemicals, for example, ethanol can be converted to ethylene and introduced to the propylene chain of chemicals. The glycerol produced as by-product in the transesterification process can be converted to produce the propylene chain of chemicals. The thermochemical platform uses technology to convert biomass to fuels, chemicals and power via thermal and chemical processes such as gasification and pyrolysis. Intermediate products in the thermochemical platform include clean synthesis gas or syngas (a mixture of primarily hydrogen and carbon monoxide) produced via gasification

and bio-oil and biochar produced via pyrolysis. Synthesis gas is conventionally manufactured from natural gas, so the gasification procedure to produce synthesis gas from biomass is a possible replacement for the fossil resource.

The various chemicals that can be manufactured from biomass are compiled based on carbon numbers and given in the following section. Some of these chemicals are presently made from nonrenewable feedstock like natural gas and petroleum, while others are new chemicals that have potential to replace nonrenewable feedstock-based chemicals. This description is not exhaustive but serves as a starting point for identifying the processes and feedstocks for conversion to chemicals.

Biomass Conversion Products (Chemicals)

Biomass can be converted to chemicals using the routes described in the previous section. The Biomass Research and Development Act of 2000 had set up a Biomass R&D Technical Advisory Committee which has fixed a goal of supplying the USA with 25 % of its chemicals from biomass by the year 2030 (Perlack et al. 2005). Bulk chemicals can be defined as those costing $1.00–$4.00 per kg and produced worldwide in volumes of more than 1 million metric tons per year (Short 2007). The production cost of these chemicals can be reduced by 30 % when petrochemical processes are replaced by biobased processes. Some of these chemicals are discussed in the following sections.

Single Carbon Compounds

Methane

Methane from natural gas is an important industrial raw material for the production of acetylene, synthesis gas, methanol, carbon black, etc. (Austin 1984). Natural gas is a nonrenewable source, and ways to produce methane from biomass are needed.

Methane can be produced from the anaerobic digestion of biomass, primarily waste biomass (e.g., corn stover, sewage sludge, municipal solid waste, etc.). Methanogenic bacteria are comprised of mesophilic and thermophilic species that convert biomass in the absence of oxygen. Anaerobic digestion of biomass is the treatment of biomass with a mixed culture of bacteria to produce methane (biogas) as a primary product. The four stages of anaerobic digestion are hydrolysis, acidogenesis, acetogenesis, and methanogenesis. In the first stage, hydrolysis, complex organic molecules are broken down into simple sugars, amino acids, and fatty acids with the addition of hydroxyl groups. In the second stage, acidogenesis, volatile fatty acids (e.g., acetic, propionic, butyric, valeric) are formed along with ammonia, carbon dioxide, and hydrogen sulfide. In the third stage, acetogenesis, simple molecules from acidogenesis are further digested to produce carbon dioxide, hydrogen, and organic acids, mainly acetic acid. Then in the fourth stage, methanogenesis, the organic acids are converted to methane, carbon dioxide, and water. The last stage produces 65–70 % methane and 35–30 % carbon dioxide

(Brown 2003). Anaerobic digestion can be conducted either wet or dry where dry digestion has a solid content of 30 % or greater and wet digestion has a solid content of 15 % or less. Either batch or continuous digester operations can be used. In continuous operations, there is a constant production of biogas, while batch operations can be considered simpler; the production of biogas varies. Advantages of anaerobic digestion for processing biomass include the ability to use non-sterile reaction vessels, automatic product separation by outgassing, and relatively simpler equipment and operations. The primary disadvantages for the process are slow reaction rates and low methane yields.

The methanation chemistry from carbon monoxide and carbon dioxide is given by the reactions in Eqs. 1 and 2 (NETL 2011). Synthetically, the methanation process takes place over nickel catalyst fixed-bed reactors, known as methanators. The reactions are highly exothermic, and a catalyst system that can maintain its activity after prolonged exposure to high temperatures is required. Three types of methanation reactor configurations include equilibrium-limited fixed-bed reactors in series, throughwall-cooled fixed-bed reactor, and slurry bubble reactor (NETL 2011):

$$CO + 3H_2 \rightarrow CH_4 + H_2O \quad (1)$$

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O \quad (2)$$

An innovative process using pyrolytic gasification for methane production from biomass is given by Klass (1998) and shown in Fig. 5. Biomass is fed to the pyrolysis reactor operating at 800 °C. The reactor temperature is maintained at this temperature by sand fed from the combustion reactor at 950 °C. The biomass decomposes into pyrolysis gas (~40 % CO, ~30 % H_2, and others) which exits from the top of the reactor. Char is deposited on the sand which is sent to the combustion reactor, and air is fed to this reactor to maintain the temperature at

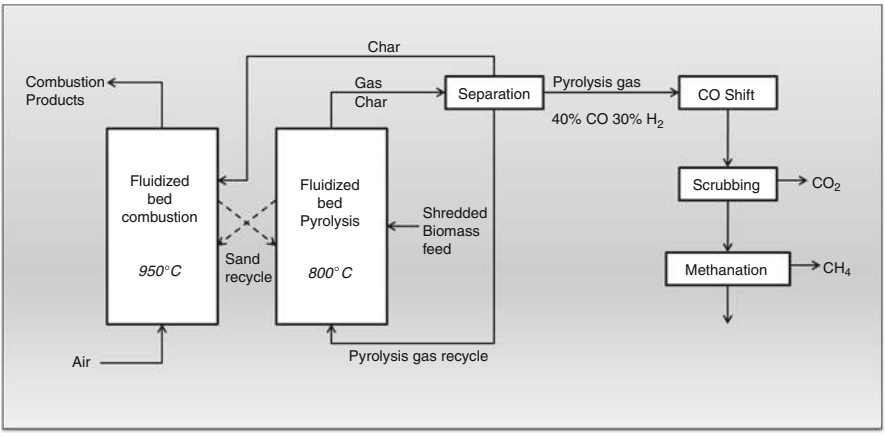

Fig. 5 Pyrolytic gasification process using two fluidized bed reactors (Adapted from Klass (1998))

950 °C from combustion of the char. The pyrolysis gas can then be sent to a methanation reactor as shown in Fig. 5.

Methanol

Methanol was historically produced by the destructive distillation of wood (Wells 1999). Currently, 97 % of methanol production is based on natural gas, naphtha, or refinery light gas. Large-scale methanol manufacture processes based on hydrogen–carbon oxide (carbon mono- and dioxides) mixtures were introduced in the 1920s. In the 1970s, low-pressure processes replaced high-pressure routes for the product formation. Currently, methanol is produced using adiabatic route of ICI and isothermal route of Lurgi. Capacities of methanol plants range from 60,000 to 2,250,000 t/year. Nearly 12.2 billion pounds of methanol are produced annually in the USA, and around 85 % of it is converted to higher-value chemicals such as formaldehyde (37 %), methyl tertiary butyl ether (28 %), and acetic acid (8 %) (Paster et al. 2003).

Synthesis gas, an intermediate in the conventional methanol process from natural gas, can be produced from gasification of biomass (Spath and Dayton 2003). The details of gasification process have been discussed in an earlier chapter. The conventional process for methanol synthesis and the process modification for utilizing biomass as feedstock are given in Fig. 6.

Two Carbon Compounds

Ethanol

Ethanol has been produced by fermentation of carbohydrates for many thousands of years (Wells 1999). Economic, industrial manufacture of ethanol began in the 1930s.

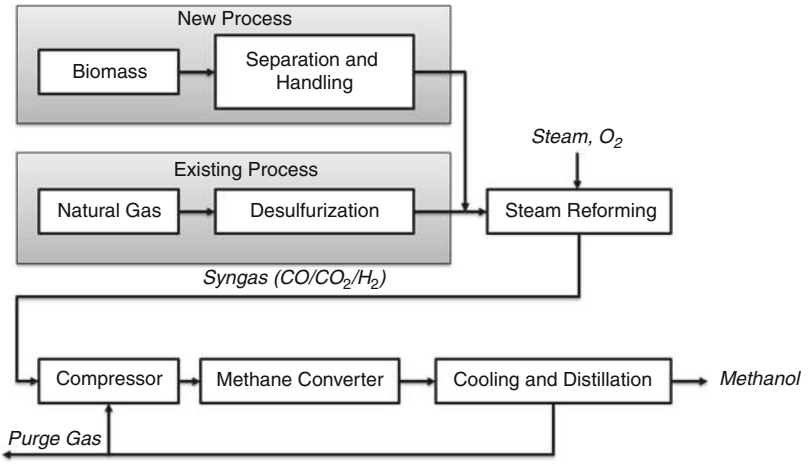

Fig. 6 Conventional methanol process with modification for biomass-derived syngas (Adapted from Spath and Dayton (2003))

Current processes to produce ethanol in the industry include direct and indirect hydration of ethylene and carbonylation of methyl alcohol and methyl acetate. Industrial uses of ethanol include use as solvents and in the synthesis of chemicals (Wells 1999). Forty-five percent of total industrial ethanol demand is for solvent applications. It is a chemical intermediate for the manufacture of esters, glycol ethers, acetic acid, acetaldehyde, and ethyl chloride, and this demand as intermediate accounts for 35 % of its production. Ethanol can also be converted to ethylene and that serves as a raw material for a wide range of chemicals that are presently produced from petroleum-based feedstock. Since ethylene is an important building block chemical and ethanol is its precursor, the processes for manufacture of ethanol are discussed in details in this section. There are four case studies presented for conversion of lignocellulosic biomass to ethanol.

Increasing prices of crude petroleum has prompted the research for manufacture of ethanol from biomass sources. Ethanol can be produced by the fermentation of starch (corn), sugar (sugarcane), or waste lignocellulosic biomass like corn stover or switchgrass. The processes for conversion depend on the feedstock used. The reaction for fermentation of glucose to ethanol is given by Eq. 3:

$$C_6H_{12}O_6 \rightarrow 2C_2H_5OH + 2CO_2 \tag{3}$$

Sugars can be directly converted to ethanol using *Saccharomyces cerevisiae* without any pretreatment (Klass 1998). For starch-containing grain feedstock, the cell walls must be disrupted to expose the starch polymers so that they can be hydrolyzed to free, fermentable sugars as yeast does not ferment polymers. The sugar polymers in grain starches contain about 10–20 % hot-water-soluble amylases and 80–90 % water-insoluble amylopectins. Both substances yield glucose or maltose on hydrolysis. Cellulosic or lignocellulosic biomass is mainly composed of crystalline and amorphous cellulose, amorphous hemicelluloses, and lignin as binder. The main problems associated with using this feedstock lie in the difficulty of hydrolyzing cellulosics to maximize glucose yields and the inability of yeasts to ferment the pentose sugars which are the building blocks of the hemicelluloses.

Capacities of biomass feedstock-based ethanol plants range from 1.5 to 420 million gallons per year in the USA (EPM 2010). Currently, 60 % of the world's biobased ethanol is obtained from sugarcane in Brazil. Sugar from sugarcane is used directly as a solution from the grinding of the cane, and it is sent directly to fermentor rather than proceeding with clarification, evaporation, and crystallization to produce raw sugar that is sent to a sugar refinery. The corn dry-grind process for the production of ethanol is described by (Klass 1998) and shown in Fig. 7. The production of ethanol in the USA increased from nearly 2 billion gallons in 1999 to over 13 billion gallons in 2010 (DOE 2010b; EPM 2010) as shown in Fig. 8.

Cellulosic biomass refers to a wide variety of plentiful materials obtained from plants, including certain forest-related resources (mill residues, precommercial thinning, slash, and brush), many types of solid wood waste materials, and certain agricultural wastes (including corn stover, sugarcane bagasse), as well as plants

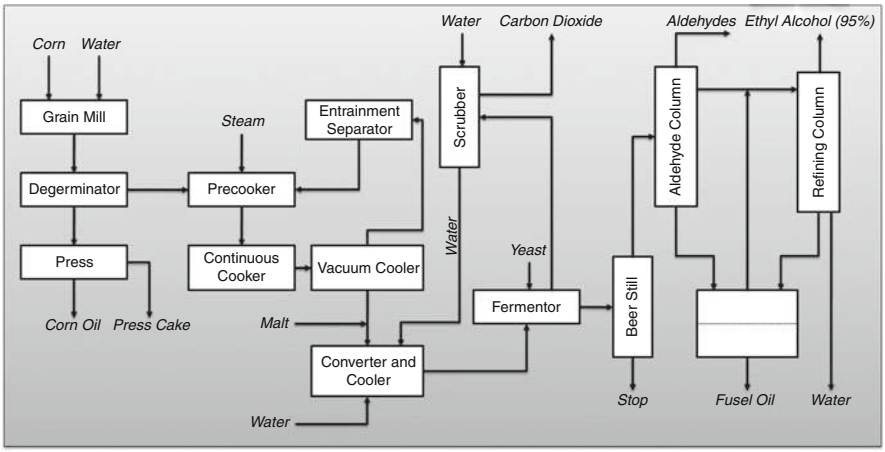

Fig. 7 Corn dry-grind operation to ethanol (Adapted from Klass (1998))

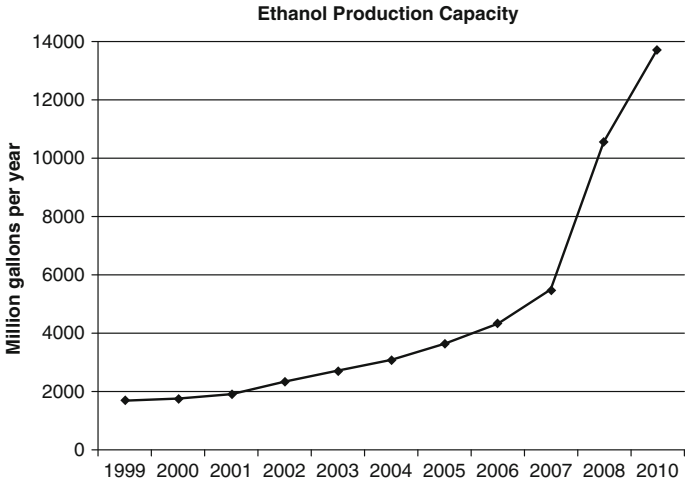

Fig. 8 Production of ethanol in the USA from 1999 to 2010 (EPM 2010; DOE 2010a)

that are specifically grown as fuel for generating electricity. These materials can be used to produce ethanol which is referred to as "cellulosic ethanol." The cellulosic biomass contains cellulose, hemicellulose, and lignin. The cellulose and hemicellulose are converted to sugars using enzymes, which are then fermented to ethanol. Figure 9 gives the BCI process for the conversion of cellulosic biomass (sugarcane bagasse) to ethanol.

Six plants were selected by DOE to receive federal funding for cellulosic ethanol production (DOE 2007). These plants received a sum of $385 million for biorefinery

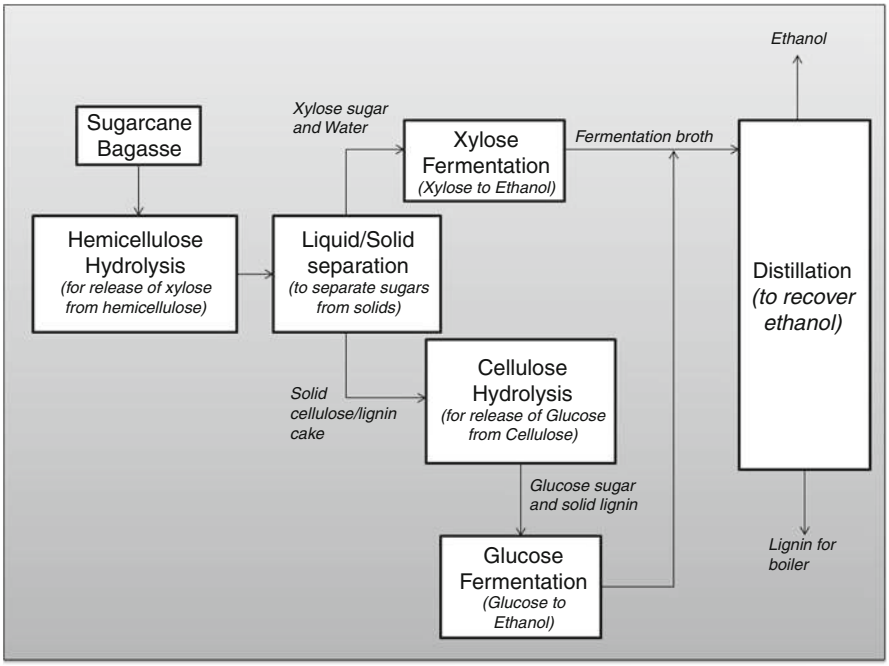

Fig. 9 BCI process for converting sugarcane bagasse to ethanol (Adapted from Smith (2005))

projects for producing more than 130 million gallons of cellulosic ethanol per year. Table 2 gives a list of these plants with their capacity of producing ethanol.

Four case studies are given in this section where biomass is converted to ethanol. The first two cases are production of ethanol from cellulosic biomass, the third case is a fermentation process of glycerol to produce ethanol, and the fourth case discusses fermentation of syngas to ethanol. There are several other methods to produce ethanol from biomass including corn, sugarcane, sugarcane bagasse, etc. The fermentation of corn to ethanol is a well-established process (Klass 1998), and detailed descriptions of corn wet milling and dry milling procedures have been given by Johnson (Johnson 2006). Approximately 93 % of the ethanol currently produced in the USA comes from corn, and 3 % comes from sorghum (DOE 2010b). Other feedstocks include molasses, cassava, rice, beets, and potatoes. However, these are primarily food and feed crops, and there is considerable debate on their usage, for example, the use of corn as feed versus feedstock. Cellulosic biomass to ethanol production is not yet fully developed for large-scale production, and some of these attempts are discussed in the following cases. The first two cases are discussed on the basis of selection on raw material and the optimum selection of plant size. These are currently the major concerns for a cellulosic feedstock-based ethanol industry, and research is ongoing to reduce the cost of ethanol for these factors.

Table 2 DOE-funded cellulosic ethanol plants (DOE 2007)

Plant name/ location/start-up year	Feedstock	Feedstock capacity (t/day)	Products	Notes
Abengoa Bioenergy Biomass of Kansas LLC Colwich, Kansas, 2011	Corn stover Wheat straw Sorghum Stubble Switchgrass	700	Ethanol: 11.4 million gal/year Syngas	Thermochemical and biochemical processing
ALICO, Inc. LaBelle, Florida 2010	Yard Wood Vegetative wastes (citrus peel)	770	Ethanol: 7 million gal/year (first unit) 13.9 million gal/year (second unit) Power: 6,255 KW Hydrogen Ammonia	Gasification fermentation of syngas to ethanol
BlueFire Ethanol, Inc. Southern California 2009 (plant in Fulton, MS)	Sorted green waste and wood waste from landfills	700	Ethanol: 19 million gal/year	Concentrated acid processing fermentation
Broin Companies Emmetsburg, Palo Alto County, Iowa 2010	Corn fiber Corn stover	842	Ethanol: 125 million gal/year Chemicals Animal feed	Fermentation of starch and lignocellulosic biomass (25 %)
Iogen Biorefinery Partners, LLC Shelley, Idaho 2010	Agricultural residues: wheat straw, barley straw, corn stover, switchgrass, and rice straw	700	Ethanol: 18 million gal/year (first plant) 250 million gal/year (future plants)	Enzymatic process converting cellulose to ethanol
Range Fuels, Inc. Near Soperton, Treutlen County, Georgia 2011	Unmerchantable timber and forest residues	1,200	Ethanol: 10 million gal/year (first unit) ~40 million gal/year (commercial unit) Methanol: 9 million gal/year (commercial unit)	Thermochemical Catalytic syngas conversion

Case Study 1: Iogen Process for Ethanol Production from Wheat Straw and Corn Stover

Tolan (2006) discussed Iogen's process for the production of ethanol from cellulosic biomass. Iogen was one of the six companies identified by DOE to receive federal funding to produce ethanol from lignocellulosic feedstock. Iogen's facility produces 2,000 gal/day of ethanol from wheat straw in a pilot plant, with proposal to scale up to 170,000 gal/day (60 million gal/year). The Iogen process uses steam explosion pretreatment for chopped, milled wheat straw mixed with corn stover. High-pressure steam and 0.5–2 % sulfuric acid are added to the feedstock at a temperature of 180–260 °C. The acid hydrolysis releases the hemicellulose and converts it to xylose. The residence time in the pretreatment reactor is 0.5–5 min. The pressure is released rapidly to enable the steam explosion process. Hemicellulose reacts first in the process according to the reaction given in Eq. 4. The dilute sulfuric acid produces xylose monomer, which dehydrates to furfural according to the reaction given in Eq. 5 under further pretreatment conditions. Similar reactions occur for arabinose. Small amounts of cellulose react to glucose according to the reaction given in Eq. 6 and further degrade to hydroxymethylfurfural according to the reaction given in Eq. 7. The lignin depolymerizes in this process but is insoluble in the acid or water:

$$(C_5H_8O_4)_n + H_2O \rightarrow (C_5H_8O_4)_{n-1} + C_5H_{10}O_5 \tag{4}$$

$$C_5H_{10}O_5 \rightarrow C_5H_4O_2 + 3H_2O \tag{5}$$

$$(C_6H_{10}O_5)_n + H_2O \rightarrow (C_6H_{10}O_5)_{n-1} + C_6H_{12}O_6 \tag{6}$$

$$C_6H_{12}O_6 \rightarrow C_6H_6O_3 + 3H_2O \tag{7}$$

The next step is the preparation of cellulase enzymes and cellulose hydrolysis. In the Iogen process, *Trichoderma*, a wood-rotting fungus, is used to produce cellulase enzymes. The cellulases are prepared in submerged liquid cultures in fermentation vessels of 50,000 gal. The liquid broth contains carbon source, salts, complex nutrients like corn steep liquor, and water. The carbon source is important and includes an inducing sugar (like cellobiose, lactose, sophorose, and other low molecular weight oligomers of glucose) promoting cellulase growth as opposed to glucose which promotes growth of the organism. The nutrient broth is sterilized by heating with steam. The fermenter is inoculated with the enzyme production strain once the liquid broth cools down. The operating conditions of the fermenter are 30 °C at a pH 4–5. The temperature is maintained using cooling coils of water, and pH is maintained using alkali. Constant stream of air or oxygen is passed to maintain aerobic conditions required for *Trichoderma*. The cellulase enzyme production process requires about one week and, at the end of the run, is filtered across a cloth to remove cells. The spent cell mass is disposed in landfills. Cellulase enzymes can be directly used at Iogen's ethanol manufacturing facility. The enzymes can also be stored provided that it is sterilized against microbial contamination by using sodium benzoate and protein denaturation by using glycerol. Iogen reduces the cost

of their ethanol manufacture by having an on-site cellulase manufacture facility, reducing costs due to storage and transportation of enzymes. The cellulase enzymes are conveyed to hydrolysis tanks to convert cellulose to glucose.

The slurry from pretreatment containing 5–15 % total solids is fed into hydrolysis tanks having a volume of 200,000 gal. Crude cellulase enzymes broth is added in dosages of 100 l/t of cellulose. The contents are agitated to keep material dispersed in the tank. The hydrolysis proceeds for 5–7 days. The viscosity of the slurry decreases, and lignin remains as insoluble particles. The cellulose hydrolysis process yields 90–98 % conversion of cellulose to glucose. Enzymatic hydrolysis of cellulose occurs according to Eqs. 8 and 9:

$$(C_6H_{10}O_5)_n + H_2O \rightarrow (C_6H_{10}O_5)_{n-2} + C_{12}H_{22}O_{11} \tag{8}$$

$$C_{12}H_{22}O_{11} + H_2O \rightarrow 2C_6H_{12}O_6 \tag{9}$$

The cellulose hydrolysis is followed by sugar separation and fermentation using recombinant yeast capable of fermenting both glucose and xylose. The hydrolysis slurry is separated from lignin and unreacted cellulose using a plate-and-frame filter. The filter plates are washed with water to ensure high sugar recovery. The sugar stream from pretreatment section is pumped into fermentation tanks. The lignin cakes can be used for power generation by combustion, and excess electricity can be sold to neighboring plants.

The sugar stream is fermented with genetically modified *Saccharomyces* yeast capable of fermenting both glucose and xylose. The yeast is well developed for plant operations with good ethanol tolerance. The rates and yields of xylose fermentation are not high in the current process leaving scope for further improvement. The fermentation broth obtained after fermentation is pumped into a distillation column. Ethanol is distilled out at the top and dehydrated. The yield of ethanol obtained in the process is 75 gal/t of wheat straw.

The feedstock selection for the Iogen process depended on the following considerations:

- *Low cost*: Desired feedstock should be available and delivered to plant at low cost. Primary and secondary tree growth, sawdust, and wastepaper have existing markets and were not considered for the process.
- *Availability*: Feedstock availability should be consistent and in the order of 800,000 t/year which is not generally available from sugarcane bagasse.
- *Uniformity*: Feedstock availability should be consistent, and hence municipal waste containing foreign matter was discarded.
- *Cleanliness*: High levels of silica can cause damage to equipment. Microbial contamination and toxic or inhibitory products should be prevented from the feedstock.
- *High potential ethanol yield*: Cellulose and hemicellulose should be present in high percentage in the feed to yield maximum ethanol by fermentation. Wood and forestry waste has high lignin content which inhibits fermentation.

- *High efficiency of conversion*: The efficiency of conversion in the Iogen process depended on arabinan and xylan content in feedstock. These are constituent hemicelluloses, and low content of these required high quantities of enzyme for conversion to cellulose, thereby increasing the process cost.

Case Study 2: NREL Process for Conversion of 2,000 t/day of Corn Stover

Aden et al. (2002) and Humbird and Aden (2009) discuss the use of lignocellulosic biomass for the production of ethanol from corn stover. The plant size was such that 2,000 t/day of corn stover was processed in the facility. The overall plant diagram is given in Fig. 10. The cost estimate is based on the assumption that the plant developed is an "nth" plant of several plants that are already built using the same technology and are operating. The target selling price of ethanol is $1.07 per gallon with a start-up date for plant in 2010. This cost was increased in an updated report (Humbird and Aden 2009) to $1.49 per gallon of ethanol. The conceptual design for this plant includes equipment design, corn stover handling, and purchase of enzymes from commercial facilities like Genencor International and Novozymes Biotech. The design did not take into account the sale of by-products which are important commodity and specialty chemicals, but the report mentions that reduction of price of ethanol is possible with the sale of these chemicals. The design of the facility is divided into eight sections: feedstock storage and handling; pretreatment and hydrolyzate conditioning; saccharification and co-fermentation; product, solids, and water recovery; wastewater treatment; product and feed chemical storage; combustor, boiler, and turbogenerator; and utilities. The process description for conversion of biomass is similar to the Iogen process for corn and wheat straw as raw material.

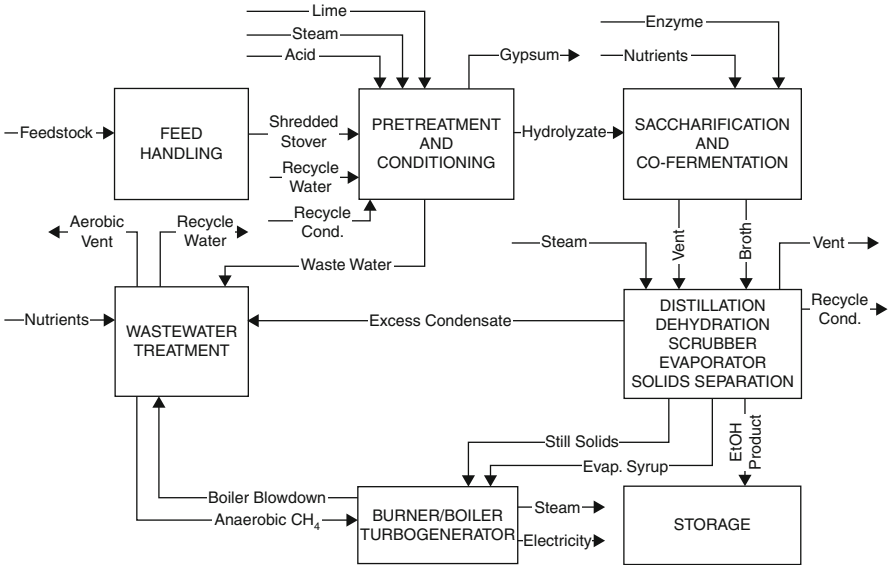

Fig. 10 Overall process diagram for corn stover conversion to ethanol (Aden et al. 2002)

The NREL report gave the following considerations for the selection of plant size between 2,000 and 4,000 t/day. These are listed below:

- *Economies of scale*: The capital cost for equipment varies with equipment size according to the Eq. 10. If exponential, "exp," equals 1, linear scaling of plant size occurs. However, if the exponential value is less than 1, then the capital cost per unit size decreases as the equipment becomes larger. The NREL uses a cost scaling exponent of 0.7:

$$\text{New cost} = \text{Original cost}\left(\frac{\text{New size}}{\text{Old size}}\right)^{\exp} \tag{10}$$

- *Plant size and collection distance*: The distance traveled to collect corn stover increases as the plant size increases because more stover is required for feed. This collection distance is estimated as the radius of a circle around the plant within which the stover is purchased. This area around the plant is calculated using the Eq. 11:

$$\text{Area}_{\text{collection}} = \left(\text{D}_{\text{strover}} / \left(\text{Y}_{\text{strover}} * \text{F}_{\text{available acres}} * \text{F}_{\text{land in crops}}\right)\right) \tag{11}$$

  where
  $\text{Area}_{\text{collection}}$ is the circle of collection around the plant
  D_{stover} is the annual demand for stover by an ethanol plant
  Y_{stover} is metric tons stover collected per acre per year
  $\text{F}_{\text{available acres}}$ is the fraction of total farmland from which stover can be collected
  $\text{F}_{\text{land in crops}}$ is the fraction of surrounding farmland containing crops.

  The fraction of available acres takes into account the land use due to roads and buildings within the farmland. For example, if the farm area has 25 % roads and other infrastructure, then the fraction of available land, $\text{F}_{\text{available acres}}$, is 0.75. The $\text{F}_{\text{land in crops}}$ is a variable parameter depending on the ability of farms around the ethanol plant to contribute to the corn stover demand. The parameter is used to vary the dependence of plant size on collection distance. The radius of collection is calculated from the $\text{Area}_{\text{collection}}$. The price of ethanol is also a function of plant size and percentage of available acres.
- *Corn stover cost*: The corn stover raw material cost depends on two direct costs: the cost of baling and staging stover at the edge of the field and the cost of transportation from the field to the plant gate. Apart from these, a farmer's premium and cost for fertilizers also add up to the direct costs for corn stover as a raw material. A life cycle analysis of the corn stover represents that 47 % of cost was in the staging and baling process, 23 % was for transport of stover to plant, 11 % was farmer premium for taking the risk of added work of collecting and selling the residue, and the rest 12 % for fertilizer supplement for the land. This method of analysis gave a value of $62 per dry metric ton of corn stover. The report suggests that this cost will be reduced considerably over time with new technology for collecting and transporting stover, and an assumption of $33 per

dry metric ton of corn stover was taken for further analysis. However, the update to the report in 2009 suggested that the cost for feedstock increased to $69.60 per dry ton of corn stover in 2007, which can be reduced to reach $50.90 per dry ton in 2012 (Humbird and Aden 2009).

- *Corn stover hauling cost*: The corn stover hauling cost (cost for farm to gate of plant) depended on distance from plant. The hauler cost is a function of radial distance from the plant. An increase in hauling cost shows the optimum plant size range to decrease. For 50 % increase in hauling costs per ton-mile, plant size range decreases from 2,000 to 8,000 t/day to 2,000–5,000 t/day. For a 100 % increase, the optimal plant size is at around 3,000 t/day, and the price of ethanol increases drastically above or below this price.
- *Total cost of ethanol as a function of plant size*: The total cost of ethanol as a function of plant size was determined with the total feedstock and non-feedstock costs. The analysis was done with two plant sizes of 2,000 and 10,000 t/day of stover. A net savings occurred for plant sizes between 6,000 and 8,000 t/day of stover. Below 2,000 t/day, the selling price per gallon of ethanol increased rapidly. A minimum optimal plant size between 2,000 and 4,000 t/day of corn stover was obtained for collection from 10 % corn acres around a conversion plant.

Case 3: Ethanol from Fermentation of Glycerol

Ito et al. (2005) described a process where ethanol is produced from glycerol-containing waste discharged after transesterification process. *Enterobacter aerogenes* HU-101 microorganism is used to ferment the glycerol-rich waste, and yields of 63 mmol/l/h of H_2 and 0.85 mol/mole glycerol of ethanol were reported using porous ceramics as support to fix cells in the reactor. There are no reports of scale-up of this process.

Case 4: Ethanol from Synthesis Gas Fermentation

Synthesis gas can be used as feed to a fermentor that uses anaerobic bacteria to produce ethanol. Although it uses some of the oldest biological mechanisms in existence, technical barriers to be overcome include organism development, gas–liquid mass transfer, and product yield (Spath and Dayton 2003; Phillips et al. 2007; Snyder 2007).

Spath and Dayton (2003) give a description of the process for conversion of synthesis gas to ethanol. The first step in the process is to convert biomass to synthesis gas, and the syngas is then converted to ethanol using fermentation. The feedstock for this process was wood chips derived from forests. Wood chips are primarily composed of cellulose, hemicellulose, and lignin. However, this process can use any biobased feedstock as feed, which can be gasified to syngas. The overall schematic diagram is given in Fig. 11.

The feed is received and placed in temporary storage on-site. It is then sent to the gasifier where it is converted into a raw syngas mixture rich in carbon monoxide and hydrogen. The indirect BCL/FERCO process gasifier was used for the production of syngas from biomass (Spath and Dayton 2003). The equipment include an indirectly heated gasifier with operating temperature at 700–850 °C and pressures slightly

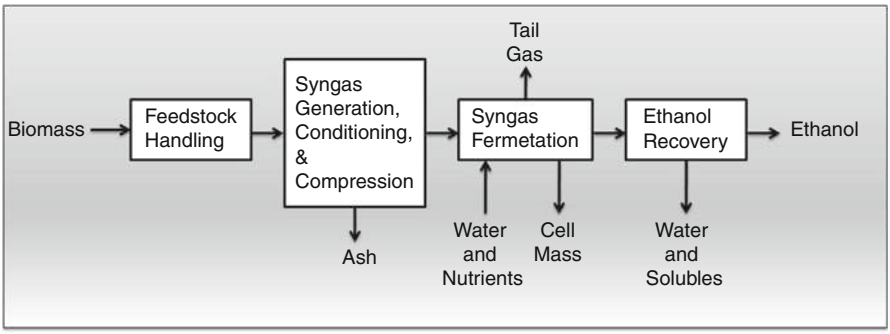

Fig. 11 Synthesis gas to ethanol process (Adapted from Spath et al. (2003))

greater than atmospheric. The biomass feed is dried and then fed to a fast fluidized bed where it is converted into a raw syngas. The resulting syngas contains significant amounts of methane, ethylene and other light hydrocarbons, and tars which can be removed in the gas-conditioning steps. The conditioned syngas is then fed to fermentation reactor where it is converted to ethanol using bacteria. The resulting fermentation broth is diluted, typically containing 2 % or less of ethanol. The ethanol can be recovered from the broth using recovery schemes (distillation, molecular sieves) used in the existing corn ethanol industry. The cell mass produced can be recycled as a portion of the feed to the gasifier. One advantage of the syngas fermentation route is that the chemical energy stored in all parts of the biomass, including the lignin fraction, contributes to the yield of ethanol. Equation 12 gives the method to calculate the capacity of ethanol produced by this process:

$$\mathrm{P} = \frac{F \times \mathrm{HHV}_F \times \eta_{\mathrm{Gas+Cond}} \times X_{\mathrm{CO+H_2/EtOH}}}{1.5 \times 10^5} \tag{12}$$

where

P, production of ethanol, million gal/year
F, feed rate, tons/day (dry basis)
HHVF, higher heating value of the feed in Btu/lb (dry)
$\eta_{\mathrm{Gas+Cond}}$, cold gas efficiency of gasifier + conditioning steps (a fraction less than 1)
$X_{\mathrm{CO + H2/EtOH}}$, average conversion of CO and H_2 to ethanol, as a fraction of theoretical

Spath and Dayton (2003) give the overall reactions for the process as given in Eqs. 13, 14, 15, and 16. The microorganisms used for ethanol production from syngas mixtures are anaerobes that use a heterofermentative version of the acetyl-CoA pathway for acetogenesis. Acetyl-CoA is produced from CO or H_2/CO_2 mixtures in this pathway. The acetyl-CoA intermediate is then converted into either acetic acid or ethanol as a primary metabolic product. Carbon monoxide is a better

substrate than carbon dioxide and hydrogen because the change in free energy is more favorable as shown in Eqs. 13, 14, 15, and 16:

$$6CO + 3H_2O \rightarrow CH_3CH_2OH + 4CO_2 \quad \Delta G = -48.7 \text{ kcal/mol} \tag{13}$$

$$2CO + 6H_2 \rightarrow CH_3CH_2OH + 3H_2O \quad \Delta G = -28.7 \text{ kcal/mol} \tag{14}$$

$$4CO + 2H_2O \rightarrow CH_3COOH + 2CO_2 \quad \Delta G = -39.2 \text{ kcal/mol} \tag{15}$$

$$2CO_2 + 4H_2 \rightarrow CH_3COOH + 2H_2O \quad \Delta G = -25.8 \text{ kcal/mol} \tag{16}$$

The ratio of ethanol to acetate produced depends upon the strain and fermentation conditions. The organisms are inhibited by low pH and acetate ion concentration. Typically, the pH is kept at 4.5 for the production of ethanol (Spath and Dayton 2003).

The organisms used are mesophilic or thermophilic bacteria, with temperature optimums ranging from room temperature to 90 °C. High operating temperatures, low carbohydrate levels, low pH, and high CO levels (inhibitory to methanogens) reduce the risk of contamination (Spath and Dayton 2003).

The fermentor can be a simple gas-sparged tank reactor, operating in batch or continuous mode. A two-stage fermentation system with cell recycle has been suggested as a better alternative. The syngas fermentation performance is not tied to a specific H_2/CO mixture, but organisms prefer CO more than H_2 (Spath and Dayton 2003).

Spath and Dayton (2003) also report the cost analysis for the gasification process and fermentation. A facility for gasification processing 2,000 t (dry) per day of wood would produce 48.5 million gal/year of ethanol based on an ethanol yield of 71 gal/t. Fixed capital was estimated at $153.6 million or $3.17 per annual gallon of capacity. Cash costs were $0.697 per gallon with feedstock cost at $25 per ton. The price required for a zero net present value for the project with 100 % financing and 10 % real after-tax discounting, known as rational cost, was $1.33 per gallon.

Phillips et al. (2007) described the feasibility of a forest resource-based thermochemical pathway conversion to ethanol and mixed alcohols. Hybrid poplar was used as feed for the indirect gasification process. The detailed design included seven sections, namely, feed handling and drying, gasification, gas cleanup and conditioning, alcohol synthesis, alcohol separation, steam cycle, and cooling water. The syngas was heated to 300 °C and 1,000 psi pressure and converted to the alcohol mixture across a fixed-bed catalyst. The minimum cost of ethanol based on the operating cost was $1.01 per gallon. A similar study with syngas from high-pressure oxygen blown direct gasifiers gave a minimum cost of ethanol based on the operating cost as $1.95 per gallon (Dutta and Philips 2009).

Acetic Acid

Acetic acid was first made by the fermentation of ethyl alcohol, and a very dilute solution of it is used as vinegar (Wells 1999). Small quantities of acetic acid are recovered from pyroligneous acid liquor obtained from the destructive distillation

of hardwood. The modern acetic acid industry began with the commercial availability of acetylene which was converted to acetaldehyde and then oxidized to acetic acid. The three commercial processes for the manufacture of acetic acid are oxidation of acetaldehyde, liquid phase oxidation of *n*-butane or naphtha, and carbonylation of methyl alcohol. The carbonylation of methyl alcohol is the dominant technology because of low material and energy costs and the absence of significant by-products. Capacities of acetic acid plants range from 30,000 to 840,000 t/year.

Synthesis gas is the raw material for the carbonylation process at low temperature and pressure using a proprietary catalyst, rhodium iodide, developed by BASF and Monsanto. The synthesis gas can be produced alternately from biobased feedstock using gasification and pyrolysis as described in previous chapter. The fermentation of syngas can also be used to produce acetic acid, as shown in Eqs. 15 and 16.

Acetic acid can be produced by the anaerobic digestion of biomass. The four stages of anaerobic fermentation are given in the section for methane. The fourth stage of methane formation can be inhibited by the use of iodoform or bromoform, thus producing carboxylic acids, hydrogen, and carbon dioxide. Biomass is converted to acetic acid (CH_3COOH) under non-sterile anaerobic conditions according to Eq. 17 (Holtzapple et al. 1999). Glucose ($C_6H_{12}O_6$) is used for illustration for this reaction:

$$C_6H_{12}O_6 + 2H_2O + 4NAD^+ \rightarrow 2H_3CCOOH + 2CO_2 + 4NADH + 4H^+ \quad (17)$$

The reducing power of nicotinamide adenine dinucleotide (NADH) may be released as hydrogen using endogenous hydrogen dehydrogenase as shown by the reaction in Eq. 18:

$$NADH + H^+ \rightarrow NAD^+ + H_2 \quad (18)$$

Methanogens are microorganisms that can produce methane by reacting carbon dioxide produced with hydrogen. The reaction is given in Eq. 19:

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O \quad (19)$$

Acetic acid can also be converted to methane in the presence of methanogens. So, the potential to convert all biomass to methane exists. The production of methane according to Eq. 19 can be inhibited by the addition of iodoform or bromoform. Thus, combining reactions in Eqs. 17 and 18, Eq. 20 is obtained where acetic acid is produced from glucose and the production of methane is inhibited:

$$C_6H_{12}O_6 + 2H_2O \rightarrow 2H_3CCOOH + 2CO_2 + 4H_2 \quad (20)$$

Conversion of biomass mixtures of sugarcane bagasse/chicken manure (Thanakoses et al. 2003a), municipal solid waste/sewage sludge (Aiello-Mazzarri et al. 2006), and corn stover/pig manure (Thanakoses et al. 2003b) to carboxylic acids has been reported.

Forty-four percent of acetic acid is converted to vinyl acetate which is used to form polyvinyl acetate and polyvinyl alcohols used for paints, adhesives, and plastics. Twelve percent of acetic acid is converted to acetic anhydride which is used to manufacture cellulose acetate, paper-sizing agents, a bleach activator, and aspirin. Thirteen percent of acetic acid is used to produce acetates and esters used in solvents for coatings, inks, resins, gums, flavorings, and perfumes. Twelve percent of acetic acid is used in the production of terephthalic acid (TPA) used for polyethylene terephthalate (PET) bottles and fibers.

Cellulose acetate is a cellulose derivative prepared by acetylating cellulose with acetic anhydride (Wells 1999). Fully acetylated cellulose is partially hydrolyzed to give an acetone-soluble product, which is usually between a di- and a tri-ester (Austin 1984). The esters are mixed with plasticizers, dyes, and pigments and processed in different ways depending on the form of plastic desired. The important properties of cellulose acetate include mechanical strength, impact resistance, transparency, colorability, fabricating versatility, moldability, and high dielectric strength (Austin 1984). Cellulose acetate is used to manufacture synthetic fibers like rayon, based on cotton or tree pulp cellulose.

Research has been reported using waste cellulose from corn fiber, rice hulls, and wheat straw to produce cellulose acetate (Ondrey 2007a). The raw materials are milled, slurried in dilute sulfuric acid, and pretreated in an autoclave at 121 °C. This is followed by the acetylation to cellulose triacetate under ambient conditions at 80 °C, using acetic acid, acetic anhydride, methylene chloride, and trace amounts of sulfuric acid. The cellulose acetate is soluble in methylene chloride and separated easily from the reaction medium. Conversions of cellulose to cellulose acetate have been 35–40 % in a laboratory study. The incentive to pursue this line of work was the price of cellulose acetate, approximately $2.00 per pound, a more valuable product than ethanol.

Ethylene

Ethylene ranks fourth among chemicals produced in large volumes in the USA with about 48 billion pounds produced in 1997 (Energetics 2000). It is a principal building block for the petrochemicals industry, with almost all of the ethylene produced being used as a feedstock in the manufacture of plastics and chemicals.

Ethylene is used as a raw material in the production of a wide variety of chemicals and polymers as shown in Fig. 12 (Energetics 2000). Polyethylene (PE) is used in the manufacture of plastic films, packaging materials, moldings (e.g., toys, chairs, automotive parts, and beverage containers), wire and cable insulation, pipes, and coatings. The production of polyethylene in USA in 1997 was about 27 billion pounds (Energetics 2000), which increased to 60 billion pounds in 2008 (ICIS 2009). Ethylene dichloride is used to manufacture polyvinyl chloride (PVC) which is used in drainage and sewer pipes, electrical conduits, industrial pipes, wire and cable coatings, wall panels, siding, doors, flooring, gutters, downspouts, and insulation. The US chemical production of ethylene dichloride was over 20 billion pounds in 1997. The US production of PVC was about 14 billion pounds in 1997. Ethylene oxide is used for the production of ethylene glycol which is a commonly

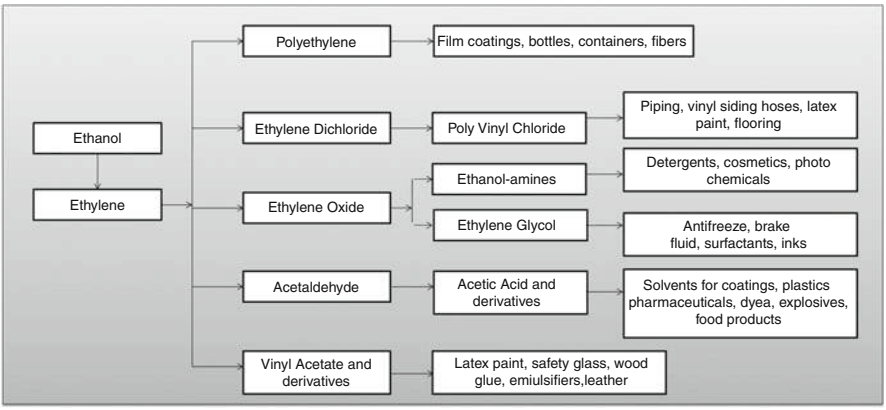

Fig. 12 Ethylene product chain (Adapted from Energetics (2000))

used antifreeze. Ethylene glycol also serves as a raw material in the production of polyester, used for manufacturing textiles. Ethylene oxide and ethylene glycol are both listed among the top 50 chemicals produced in the USA, with ethylene oxide ranking twenty-seventh (7.1 billion pounds in 1997) and ethylene glycol ranking twenty-ninth (5.6 billion pounds in 1997).

World demand for ethylene was about 180 billion pounds in 1998 and was predicted to reach 250 billion pounds by 2005 (Energetics 2000). The polyethylene industry was a 100 billion pound market with over 150 producers worldwide in 1998 (Energetics 2000). The global market for polyvinyl chloride was estimated at about 7.5 billion pounds capacity.

The petroleum refining industry is the major supplier of raw materials for ethylene production, and a large percentage of ethylene capacity is located at petroleum refineries that are in close proximity to petrochemical plants (Energetics 2000). Naphtha and gas oil are the primary sources from which ethylene is obtained. In Western Europe and some Asian countries (South Korea, Taiwan, Japan), naphtha and gas oil account for 80–100 % of the feed to ethylene crackers. Overall, more than 50 % of ethylene production capacity is currently located at refineries. However, the current resources of petroleum are being depleted for use as fuels, and the rising price of petroleum feedstock opens up new areas for research for the production of ethylene.

Ethanol can be used for the production of ethylene by dehydration. Ethanol, for the dehydration process to ethylene, can be produced from biomass feedstock as described in the earlier section. Ethanol is vaporized by preheating with high-pressure steam before passing over a fixed bed of activated alumina and phosphoric acid or alumina and zinc oxide contained in a reactor (Wells 1999). The reaction for dehydration of ethanol to ethylene is given in Eq. 21:

$$C_2H_5OH \rightarrow C_2H_4 + H_2O \tag{21}$$

The reactor can be isothermal or adiabatic, with temperature maintained at 296–315 °C. The reaction is endothermic, and the heat is supplied by condensing vapor latent heat. The temperature control in the reactor is important to prevent the formation of acetaldehyde or ethers as by-products. The gas is purified, dried, and compressed using conventional steps. A fluidized bed modification of this process has been developed with efficient temperature controls and conversions up to 99 %.

Takahara et al. (2005) have discussed the use of different catalysts for the dehydrogenation of ethanol into ethylene. The dehydration of ethanol into ethylene was investigated over various solid acid catalysts such as zeolites and silica–alumina at temperatures ranging from 453 K to 573 K under atmospheric pressure. Ethylene was produced via diethyl ether during the dehydration process. H-mordenites were the most active for the dehydration.

Philip and Datta (1997) reported the production of ethyl tert-butyl ether (ETBE) from biomass-derived hydrous ethanol dehydration over H-ZSM-5 catalyst. Temperatures between 413 K and 493 K were studied for the process, at partial pressures of ethanol less than 0.7 atm and water feed molar ratio less than 0.25.

Varisli et al. (2007) reported the production of ethylene and diethyl ether by dehydration of ethanol over heteropoly acid catalysts. The temperature range studied for this process was 413–523 K with three heteropoly acids, tungstophosphoric acid (TPA), silicotungstic acid (STA), and molybdophosphoric acid (MPA). Very high ethylene yields over 0.75 were obtained at 523 K with TPA. Among the three HPA catalysts, the activity trend was obtained as STA > TPA > MPA.

Tsao and Zasloff (1979) describe a detailed patented process for a fluidized bed dehydration with over 99 % yield of ethylene. Dow Chemical and Crystalsev, a Brazilian sugar and ethanol producer, announced the plans of 300,000 t/year ethylene plant in Brazil to manufacture 350,000 t/year of low-density polyethylene from sugarcane-derived ethanol. Braskem, a Brazilian petrochemical company, announced their plans to produce 650,000 t of ethylene from sugarcane-based ethanol which will be converted to 200,000 t/year of high-density polyethylene (C&E News 2007).

Three Carbon Compounds

Glycerol

Glycerol, also known as glycerine or glycerin, is a triol occurring in natural fats and oils. About 90 % of glycerol is produced from natural sources by the transesterification process. The rest 10 % is commercially manufactured synthetically from propylene (Wells 1999).

Glycerol is a major by-product in the transesterification process used to convert the vegetable oils and other natural oils to fatty acid methyl and ethyl esters. Approximately 10 % by weight of glycerol is produced from the transesterification of soybean oil with an alcohol. Transesterification process is used to manufacture fatty acid methyl and ethyl esters which can be blended in refinery diesel. As the production of fatty acid methyl and ethyl esters increases, the quantity of glycerol

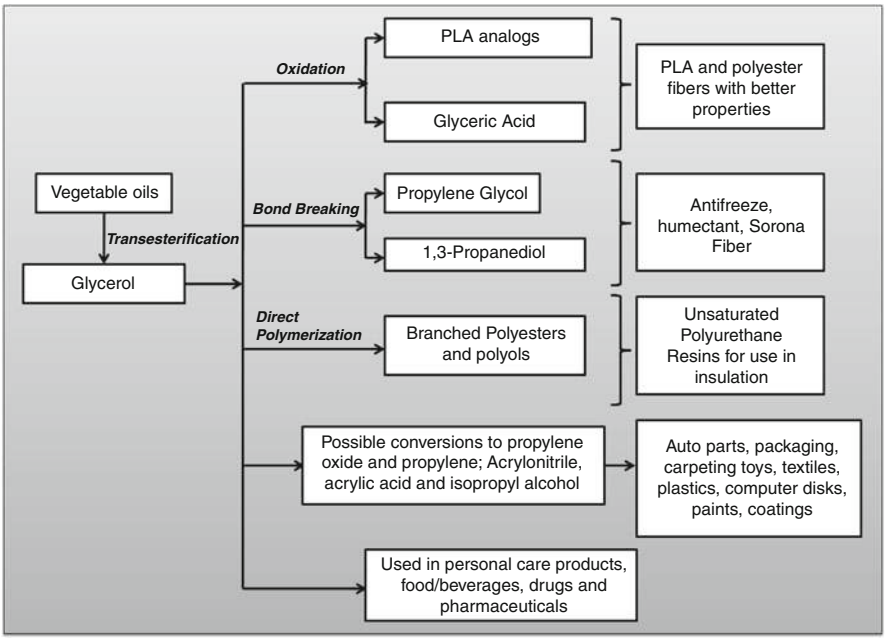

Fig. 13 Production and derivatives of glycerol (Adapted from Energetics (2000) and Werpy et al. (2004))

manufactured as a by-product also increases the need to explore cost-effective routes to convert glycerin to value-added products.

Glycerol currently has a global production of 500,000–750,000 t/year (Werpy et al. 2004). The USA is one of the world's largest suppliers and consumers of refined glycerol. Referring to Fig. 13, glycerin can potentially be used in a number of paths for chemicals that are currently produced from petroleum-based feedstock. The products from the glycerol are similar to the products currently obtained from the propylene chain. Uniqema, Procter & Gamble, and Stepan are some of the companies that currently produce derivatives of glycerol such as glycerol triacetate, glycerol stearate, and glycerol oleate. Glycerol prices are expected to drop if biodiesel production increases, enabling its availability as a cheap feedstock for conversion to chemicals. Small increases in fatty acid consumption for fuels and products can increase world glycerol production significantly. For example, if the USA displaced 2 % of the on-road diesel with biodiesel by 2012, almost 800 million pounds of new glycerol supplies would be produced.

Dasari et al. (2005) reported a low pressure and temperature (200 psi and 200 °C) catalytic process for the hydrogenolysis of glycerol to propylene glycol that is being commercialized and received the 2006 EPA Green Chemistry Award. Copper chromite catalyst was identified as the most effective catalyst for the hydrogenolysis of glycerol to propylene glycol among nickel, palladium, platinum, copper, and copper chromite catalysts. The low pressure and temperature are the advantages for

the process when compared to traditional process using severe conditions of temperature and pressure. The mechanism proposed forms an acetol intermediate in the production of propylene glycol. In a two-step reaction process, the first step of forming acetol can be performed at atmospheric pressure, while the second requires a hydrogen partial pressure. Propylene glycol yields >73 % were achieved at moderate reaction conditions.

Karinen and Krause (2006) studied the etherification of glycerol with isobutene in liquid phase with acidic ion exchange resin catalyst. Five product ethers and a side reaction yielding C_8-C_{16} hydrocarbons from isobutene were reported. The optimal selectivity toward the ethers was discovered near temperature of 80 °C and isobutene/glycerol ratio of 3. The reactants for this process were isobutene (99 % purity), glycerol (99 % purity), and pressurized with nitrogen (99.5 % purity). The five ether isomers formed in the reaction included two monosubstituted monoethers (3-*tert*-butoxy-1,2-propanediol and 2-*tert*-butoxy-1,3-propanediol), two disubstituted diethers (2,3-di-*tert*-butoxy-1-propanol and 1,3-di-*tert*-butoxy-2-propanol), and one trisubstituted triether (1,2,3-tri-*tert*-butoxy propane). *Tert*-butyl alcohol was added in some of the reactions to prevent oligomerization of isobutene and improve selectivity toward ethers.

Acrylic acid is a bulk chemical that can be produced from glycerol. Shima and Takahashi (2006) reported the production of acrylic acid involving steps of glycerol dehydration, in gas phase, followed by the application of a gas-phase oxidation reaction to a gaseous reaction product formed by the dehydration reaction. Dehydration of glycerol could lead to commercially viable production of acrolein, an important intermediate for acrylic acid esters, superabsorber polymers, or detergents (Koutinas et al. 2008). Glycerol can also be converted to chlorinated compounds such as dichloropropanol and epichlorohydrin. Dow and Solvay are developing a process to convert glycerol to epoxy resin raw material epichlorohydrin (Tullo 2007a).

Several other methods for conversion of glycerol exist; however, commercial viability of these methods is still in the development stage. Some of these include catalytic conversion of glycerol to hydrogen and alkanes and microbial conversion of glycerol to succinic acid, polyhydroxyalkanoates, butanol, and propionic acid (Koutinas et al. 2008).

Lactic Acid

Lactic acid is a commonly occurring organic acid, which is valuable due to its wide use in food and food-related industries and its potential for the production of biodegradable and biocompatible polylactate polymers. Lactic acid can be produced from biomass using various fungal species of the *Rhizopus* genus, which have advantages compared to the bacteria, including their amylolytic characteristics, low nutrient requirements, and valuable fermentation fungal biomass by-product (Zhang et al. 2007).

Lactic acid can be produced using bacteria also. Lactic acid-producing bacteria (LAB) have high growth rate and product yield. However, LAB have complex nutrient requirements because of their limited ability to synthesize B-vitamins and

amino acids. They need to be supplemented with sufficient nutrients such as yeast extracts to the media. This downstream process is expensive and increases the overall cost of production of lactic acid using bacteria.

An important derivative of lactic acid is polylactic acid. BASF uses 45 % corn-based polylactic acid for its product ecovio®.

Propylene Glycol

Propylene glycol is industrially produced from the reaction of propylene oxide and water (Wells 1999). Capacities of propylene glycol plants range from 15,000 to 250,000 t/year. It is mainly used (around 40 %) for the manufacture of polyester resins which are used in surface coatings and glass fiber-reinforced resins. A growing market for propylene glycol is in the manufacture of nonionic detergents (around 7 %) used in petroleum, sugar, and paper refining and also in the preparation of toiletries, antibiotics, etc. Five percent of propylene glycol manufactured is used in antifreeze.

Propylene glycol can be produced from glycerol, a by-product of transesterification process, by a low pressure and temperature (200 psi and 200 °C) catalytic process for the hydrogenolysis of glycerol to propylene glycol (Dasari et al. 2005) that is being commercialized and received the 2006 EPA Green Chemistry Award.

Ashland Inc. and Cargill have a joint venture underway to produce propylene glycol in a 65,000 t/year plant in Europe (Ondrey 2007b, c). Davy Process Technology Ltd. (DPT) has developed the glycerin to propylene glycol process for this plant. The plant is expected to start up in 2009. The process is outlined in Fig. 14. This is a two-step process where glycerin in the gas phase is first dehydrated into water and acetol over a heterogeneous catalyst bed, and, then, propylene glycol is formed in situ in the reactor by the hydrogenation of acetol. The per pass glycerin conversion is 99 %, and by-products include ethylene glycol, ethanol, and propanols.

Huntsman Corporation plans to commercialize a process for propylene glycol from glycerin at their process development facility in Conroe, Texas (Tullo 2007a).

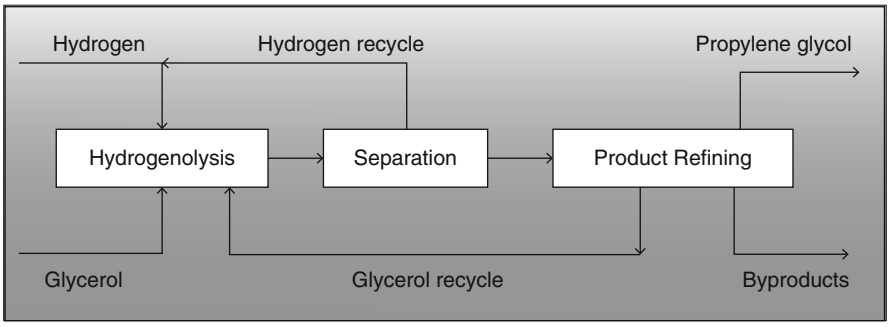

Fig. 14 DPT process for manufacture of propylene glycol from glycerol by hydrogenolysis (Ondrey 2007c)

Dow and Solvay are planning to manufacture epoxy resin raw material epichlorohydrin from a glycerin-based route to propylene glycol.

1,3-Propanediol

1,3-Propanediol is a derivative that can be used as a diol component in the plastic polytrimethylene terephthalate (PTT), a new polymer comparable to nylon (Wilke et al. 2006). Two methods to produce 1,3-propanediol exist, one from glycerol by bacterial treatment and another from glucose by mixed culture of genetically engineered microorganisms.

A detailed description of various pathways to microbial conversion of glycerol to 1,3-propanediol is given by Liu et al. (2010). Mu et al. (2006) give a process for conversion of crude glycerol to propanediol. They conclude that a microbial production of 1,3-propanediol by *Klebsiella pneumoniae* was feasible by fermentation using crude glycerol as the sole carbon source. Crude glycerol from the transesterification process could be used directly in fed-batch cultures of *K. pneumoniae* with results similar to those obtained with pure glycerol. The final 1,3-propanediol concentration on glycerol from lipase-catalyzed methanolysis of soybean oil was comparable to that on glycerol from alkali-catalyzed process. The high 1,3-propanediol concentration and volumetric productivity from crude glycerol suggested a low fermentation cost, an important factor for the bioconversion of such industrial by-products into valuable compounds. A microbial conversion process for propanediol from glycerol using *K. pneumoniae* ATCC 25955 was given by Cameron and Koutsky (Cameron and Koutsky 1994). With a $0.20/lb of crude glycerol raw material, a product selling price of $1.10/lb of pure propanediol, and a capital investment of $15 MM, a return on investment of 29 % was obtained. Production trends in biodiesel suggest that the price of raw material (glycerol) is expected to go down considerably, and a higher return on investment can be expected for future propanediol manufacturing processes.

DuPont Tate and Lyle Bio Products, LLC, opened a $100 million facility in Loudon, Tennessee, to make 1,3-propanediol from corn (CEP 2007). The company uses a proprietary fermentation process to convert the corn to Bio-PDO, the commercial name of 1,3-propanediol used by the company. This process uses 40 % less energy and reduces greenhouse gas emissions by 20 % compared with petroleum-based propanediol. Shell produces propanediol from ethylene oxide, and Degussa produces it from acrolein. It is used by Shell under the name Corterra to make carpets and DuPont under the name Sorona to make special textile fibers.

Acetone

Acetone is the simplest and most important ketone. It is colorless, flammable liquid miscible in water and a lot of other organic solvents such as ether, methanol, and ethanol. Acetone is a chemical intermediate for the manufacture of methacrylates, methyl isobutyl ketone, bisphenyl A, and methyl butynol, among others. It is also used as solvent for resins, paints, varnishes, lacquers, nitrocellulose, and cellulose acetate. Acetone can be produced from biomass by fermentation of starch or sugars

via the acetone–butanol–ethanol fermentation process (Moreira 1983). This is discussed in detail in the butanol section below.

Four Carbon Compounds

Butanol

Butanol or butyl alcohol can be produced by the fermentation of carbohydrates with bacteria yielding a mixture of acetone and butyl alcohol (Wells 1999). Synthetically, butyl alcohol can be produced by the hydroformylation of propylene, known as the oxo process, followed by the hydrogenation of the aldehydes formed yielding a mixture of *n*- and *iso*-butyl alcohol. The use of rhodium catalysts maximizes the yield of *n*-butyl alcohol. The principal use of *n*-butyl alcohol is as solvent. Butyl alcohol/butyl acetate mixtures are good solvents for nitrocellulose lacquers and coatings. Butyl glycol ethers formed by the reaction of butyl alcohol and ethylene oxide are used in vinyl and acrylic paints and lacquers and to solubilize organic surfactants in surface cleaners. Butyl acrylate and methacrylate are important commercial derivatives that can be used in emulsion polymers for latex paints, in textile manufacturing, and in impact modifiers for rigid polyvinyl chloride. Butyl esters of acids like phthalic, adipic, and stearic acid can be used as plasticizers and surface-coating additives.

The process for the fermentation of butanol is also known as Weizmann process or acetone–butanol–ethanol fermentation (ABE fermentation). Butyric acid-producing bacteria belong to the *Clostridium* genus. Two of the most common butyric acid-producing bacteria are *C. butylicum* and *C. acetobutylicum*. *C. butylicum* can produce acetic acid, butyric acid, 1-butanol, 2-propanol, and H_2 and CO_2 from glucose, and *C. acetobutylicum* can produce acetic acid, butyric acid, 1-butanol, acetone, H_2, CO_2, and small amounts of ethanol from glucose (Klass 1998). The acetone–butanol fermentation by *C. acetobutylicum* was the only commercial process of producing industrial chemicals by anaerobic bacteria that uses a monoculture. Acetone was produced from corn fermentation during World War I for the manufacture of cordite. This process for the fermentation of corn to butanol and acetone was discontinued in 1960s for unfavorable economics due to chemical synthesis of these products from petroleum feedstock.

The fermentation process involves conversion of glucose to pyruvate via the Embden–Meyerhof–Parnas (EMP) pathway; the pyruvate molecule is then broken to acetyl-CoA with the release of carbon dioxide and hydrogen (Moreira 1983). Acetyl-CoA is a key intermediate in the process serving as a precursor to acetic acid, ethanol. The formation of butyric acid and neutral solvents (acetone and butanol) occurs in two steps. Initially, two acetyl-CoA molecules combine to form acetoacetyl-CoA, thus initiating a cycle leading to the production of butyric acid. A reduction in the pH of the system occurs as a result of increased acidity. At this step in fermentation, a new enzyme system is activated, leading to the production of acetone and butanol. Acetoacetyl-CoA is diverted by a transferase system to the production of acetoacetate, which is then decarboxylated to acetone. Butanol is produced by reducing the butyric acid in three reactions. Detailed descriptions of

batch fermentation, continuous fermentation, and extractive fermentation systems are given by Moreira (1983).

DuPont and BP are working with British Sugar to produce 30,000 t/year or biobutanol using corn, sugarcane, or beet as feedstock (D'Aquino 2007). UK biotechnology firm Green Biologics has demonstrated the conversion of cellulosic biomass to butanol, known as Butafuel. Butanol can also be used as a fuel additive instead of ethanol. Butanol is less volatile, not sensitive to water, less hazardous to handle, less flammable, has a higher octane number, and can be mixed with gasoline in any proportion when compared to ethanol. The production cost of butanol from biobased feedstock is reported to be $3.75/gal (D'Aquino 2007).

Succinic Acid

Succinic acid was chosen by DOE as one of the top 30 chemicals which can be produced from biomass. It is an intermediate for the production of a wide variety of chemicals as shown in Fig. 15. Succinic acid is produced biochemically from glucose using an engineered form of the organism *Anaerobiospirillum succinici-producens* or an engineered *Escherichia coli* strain developed by DOE laboratories (Werpy et al. 2004).

Zelder (2006) discusses BASF's efforts to develop bacteria which convert biomass to succinate and succinic acid. The bacteria convert the glucose and carbon dioxide with an almost 100 % yield into the C4 compound succinate. BASF is also developing a chemistry that will convert the fermentation product into succinic acid derivatives, butanediol and tetrahydrofuran. Succinic acid can also be used as a monomeric component for polyesters.

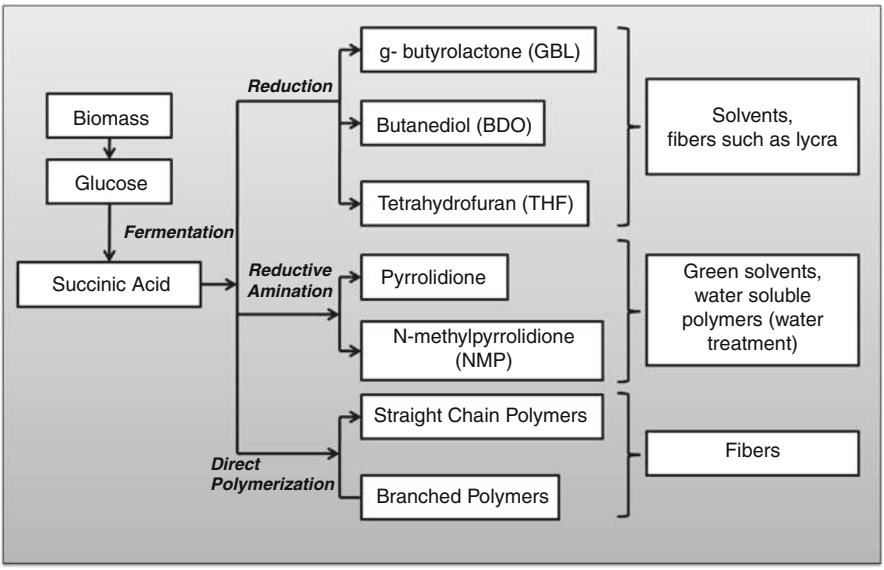

Fig. 15 Succinic acid production and derivatives (Werpy et al. 2004)

Snyder (2007) reports the successful operation of a 150,000 fermentation processes that use a licensed strain of *E. coli* at the Argonne National Laboratory. Opportunities for succinic acid derivatives include maleic anhydride, fumaric acid, dibasic esters, and others in addition to the ones shown in Fig. 15. The overall cost of fermentation is one of the major barriers to this process. Low-cost techniques are being developed to facilitate the economical production of succinic acid (Werpy et al. 2004).

BioAmber, a joint venture of Diversified Natural Products (DNP) and Agro Industries Recherche et Development, will construct a plant that will produce 5,000 t/year of succinic acid from biomass in Pomacle, France (Ondrey 2007d). The plant is scheduled for start-up in mid-2008. Succinic acid from BioAmber's industrial demonstration plant is made from sucrose or glucose fermentation using patented technology from the US Department of Energy in collaboration with Michigan State University. BioAmber will use patented technology developed by (Guettler et al. 1996), for the production of succinic acid using biomass and carbon dioxide.

Aspartic Acid

Aspartic acid is an α-amino acid manufactured either chemically by the amination of fumaric acid with ammonia or the biotransformation of oxaloacetate in the Krebs cycle with fermentative or enzymatic conversion (Werpy et al. 2004). It is one of the chemicals identified in DOE top 12 value-added chemicals from biomass list. Aspartic acid can be used as sweeteners and salts for chelating agents. The derivatives of aspartic acid include amine butanediol, amine tetrahydrofuran, aspartic anhydride, and polyaspartic with new potential uses as biodegradable plastics.

Five Carbon Compounds

Levulinic Acid

Levulinic acid was first synthesized from fructose with hydrochloric acid by the Dutch scientist G.J. Mulder in 1840 (Kamm et al. 2006). It is also known as 4-oxopentanoic acid or γ-ketovaleric acid. In 1940, the first commercial scale production of levulinic acid in an autoclave was started in the USA by A.E. Stanley, Decatur, Illinois. Levulinic acid has been used in food, fragrance, and specialty chemicals. The derivatives have a wide range of applications like polycarbonate resins, graft copolymers, and biodegradable herbicide.

Levulinic acid (LA) is formed by treatment of 6 carbon sugar carbohydrates from starch or lignocellulosics with acid. Five carbon sugars derived from hemicelluloses like xylose and arabinose can also be converted to levulinic acid by addition of a reduction step subsequent to acid treatment. The following steps are used for the production of levulinic acid from hemicellulose (Klass 1998). Xylose from hemicelluloses is dehydrated by acid treatment to yield 64 wt% of furan-substituted aldehyde (furfural). Furfural undergoes catalytic decarbonylation to form furan. Furfuryl alcohol is formed by catalytic hydrogenation of the aldehyde group in

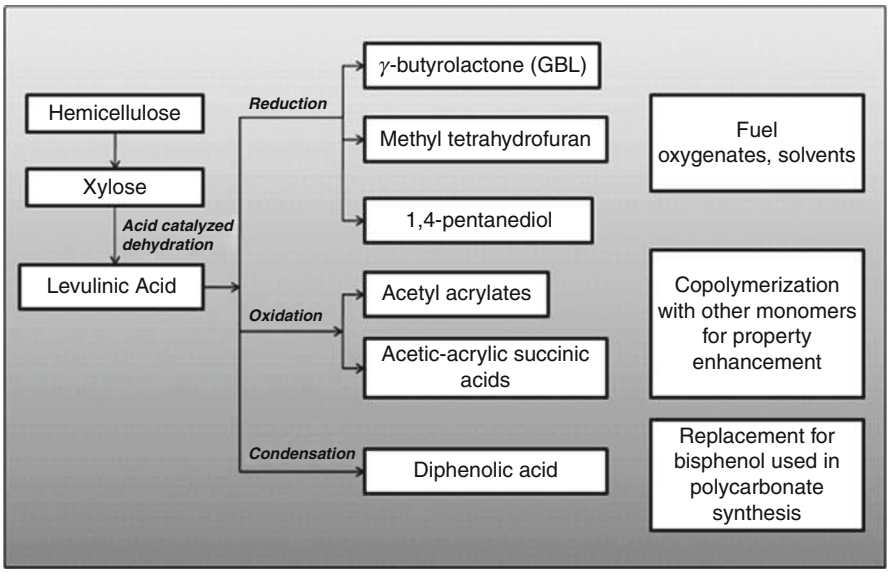

Fig. 16 Production and derivatives of levulinic acid (Adapted from Werpy et al. (2004))

furfural. Tetrahydrofurfuryl alcohol is formed after further catalytic hydrogenation of furfural. Levulinic acid is formed from tetrahydrofurfuryl alcohol on treatment with dilute acid. Werpy et al. (Werpy et al. 2004) report an overall yield of 70 % for the production of levulinic acid.

A number of large-volume chemical markets can be addressed from the derivatives of levulinic acid (Werpy et al. 2004). Figure 16 gives the production of levulinic acid from hemicellulose and the derivatives of levulinic acid. In addition to the chemicals in the figure, the following derivative chemicals of LA also have a considerable market. Methyltetrahydrofuran and various levulinate esters can be used as gasoline and biodiesel additives, respectively. δ-Aminolevulinic acid is a herbicide and targets a market of 200–300 million pounds per year at a projected cost of $2.00–3.00 per pound. An intermediate in the production of δ-aminolevulinic acid is β-acetylacrylic acid. This material could be used in the production of new acrylate polymers, addressing a market of 2.3 billion pounds per year with values of about $1.30 per pound. Diphenolic acid is of particular interest because it can serve as a replacement for bisphenol A in the production of polycarbonates. The polycarbonate resin market is almost 4 billion lb/year, with product values of about $2.40/lb. New technology also suggests that levulinic acid could be used for production of acrylic acid via oxidative processes. Levulinic acid is also a potential starting material for the production of succinic acid. The production of levulinic acid-derived lactones offers the opportunity to enter a large solvent market, as these materials could be converted into analogs of N-methylpyrrolidinone. Complete reduction of levulinic acid leads to 1,4-pentanediol, which could be used for production of new polyesters.

A levulinic acid production facility has been built in Caserta, Italy, by Le Calorie, a subsidiary of Italian construction Immobilgi (Ritter 2006). The plant is expected to produce 3,000 t/year of levulinic acid from local tobacco bagasse and paper mill sludge through a process developed by Biofine Renewables.

Hayes et al. (2006) give the details of the Biofine process for the production of levulinic acid. This process received the Presidential Green Chemistry Award in 1999. The Biofine process involves a two-step reaction in a two-reactor design scheme. The feedstock comprises of 0.5–1.0 cm biomass particles comprised of cellulose and hemicellulose conveyed to a mixing tank by high-pressure air injection system. The feed is mixed with 2.5–3 % recycled sulfuric acid in the mixing tank. The feed is then transferred to the reactors. The first reactor is a plug-flow reactor, where first-order acid hydrolysis of the carbohydrate polysaccharides occurs to soluble intermediates like hydroxymethylfurfural (HMF). The residence time in the reactor is 12 s at a temperature of 210–220 °C and pressure of 25 bar. The diameter of the reactor is small to enable the short residence time. The second reactor is a back-mix reactor operated at 190–200 °C and 14 bar and a residence time of 20 min. LA is formed in this reactor favored by the completely mixed conditions of the reactor. Furfural and other volatile products are removed, and the tarry mixture containing LA is passed to a gravity separator. The insoluble mixture from this unit goes to a dehydration unit where the water and volatiles are boiled off. The crude LA obtained is 75 % and can be purified to 98 % purity. The residue formed is a bone-dry powdery substance or char with calorific value comparable to bituminous coal and can be used in syngas production. Lignin is another by-product which can be converted to char and burned or gasified. The Biofine process uses polymerization inhibitors which convert around 50 % of both 5 and 6 carbon sugars to levulinic acid.

Xylitol/Arabinitol

Xylitol and arabinitol are hydrogenation products from the corresponding sugars xylose and arabinose (Werpy et al. 2004). Currently, there is a limited commercial production of xylitol and no commercial production of arabinitol. The technology required to convert the 5 carbon sugars, xylose and arabinose, to xylitol and arabinitol, can be modeled based on the conversion of glucose to sorbitol. The hydrogenation of the 5 carbon sugars to the sugar alcohols occurs with one of many active hydrogenation catalysts such as nickel, ruthenium, and rhodium. The production of xylitol for use as a building block for derivatives essentially requires no technical development. Derivatives of xylitol and arabinitol are described in Fig. 17.

Itaconic Acid

Itaconic acid is a C5 dicarboxylic acid, also known as methyl succinic acid, and has the potential to be a key building block for deriving both commodity and specialty chemicals. The basic chemistry of itaconic acid is similar to that of the petrochemical-derived maleic acid/anhydride. The chemistry of itaconic acid to the derivatives is shown in Fig. 18.

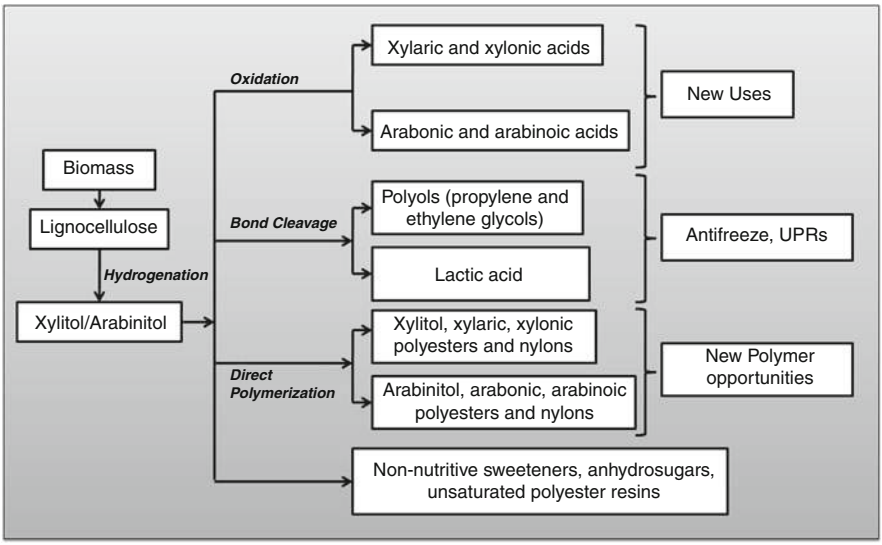

Fig. 17 Production and derivatives of xylitol and arabinitol (Adapted from Werpy et al. (2004))

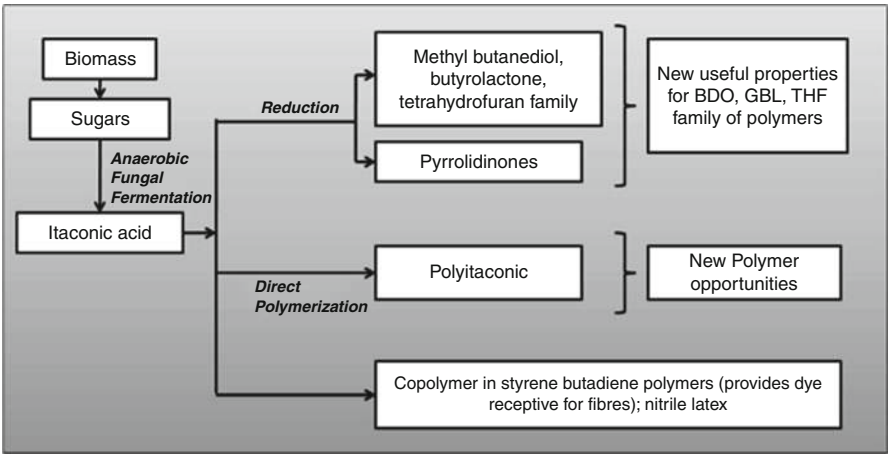

Fig. 18 Production and derivatives of itaconic acid (Adapted from Werpy et al. (2004))

Itaconic acid is currently produced via fungal fermentation and is used primarily as a specialty monomer. The major applications include the use as a copolymer with acrylic acid and in styrene–butadiene systems. The major technical hurdles for the development of itaconic acid as a building block for commodity chemicals include the development of very low-cost fermentation routes. The primary elements of improved fermentation include increasing the fermentation rate, improving the final

titer, and potentially increasing the yield from sugar. There could also be some cost advantages associated with an organism that could utilize both C5 and C6 sugars.

Six Carbon Compounds

Sorbitol

Sorbitol is produced by the hydrogenation of glucose (Werpy et al. 2004). The production of sorbitol is practiced commercially by several companies and has a current production volume on the order of 200 million pounds annually. The commercial processes for sorbitol production are based on batch technology, and Raney nickel is used as the catalyst. The batch production ensures complete conversion of glucose.

Technology development is possible for conversion of glucose to sorbitol in a continuous process instead of a batch process. Engelhard (now a BASF-owned concern) has demonstrated that the continuous production of sorbitol from glucose can be done continuously using a ruthenium on carbon catalyst (Werpy et al. 2004). The yields demonstrated were near 99 % with very high weight hourly space velocity.

Derivatives of sorbitol include isosorbide, propylene glycol, ethylene glycol, glycerol, lactic acid, anhydrosugars, and branched polysaccharides (Werpy et al. 2004). The derivatives and their uses are described in Fig. 19.

2,5-Furandicarboxylic Acid

FDCA is a member of the furan family and is formed by an oxidative dehydration of glucose (Werpy et al. 2004). The production process uses oxygen or electrochemistry. The conversion can also be carried out by oxidation of 5-hydroxymethylfurfural,

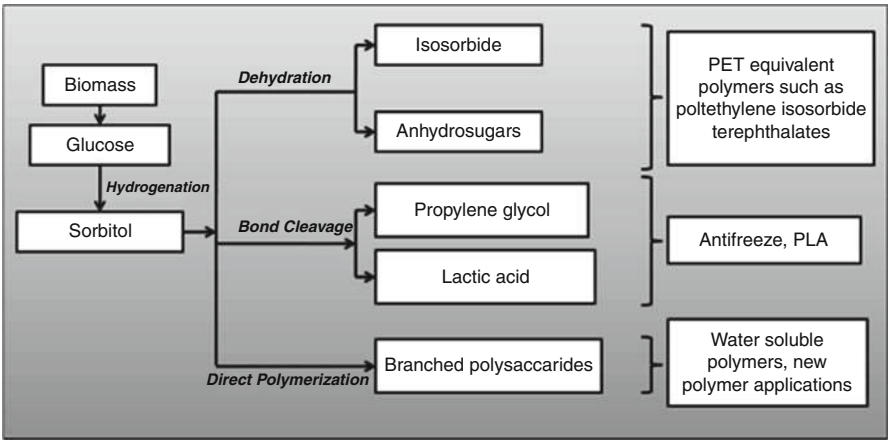

Fig. 19 Production and derivatives of sorbitol (Adapted from Werpy et al. (2004))

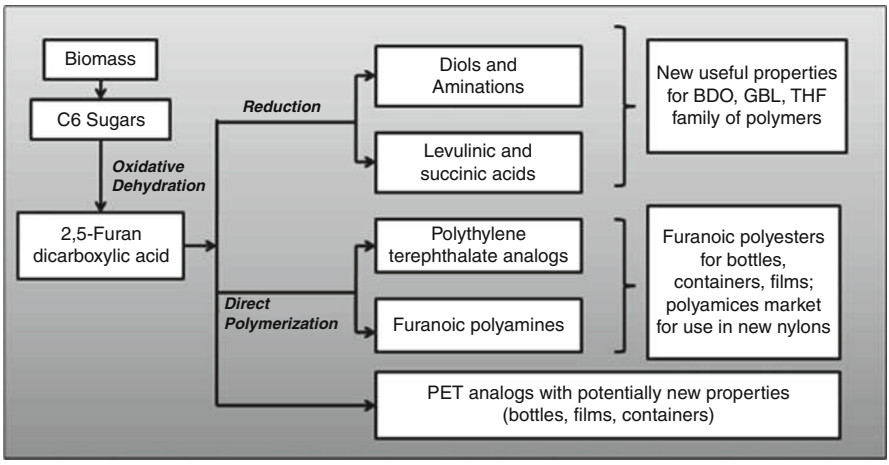

Fig. 20 Production and derivatives of 2,5-FDCA (Werpy et al. 2004)

which is an intermediate in the conversion of 6 carbon sugars into levulinic acid. Figure 20 describes some of the potential uses of FDCA.

FDCA resembles and can act as a replacement for terephthalic acid, a widely used component in various polyesters, such as polyethylene terephthalate (PET) and polybutylene terephthalate (PBT) (Werpy et al. 2004). PET has a market size approaching 4 billion pounds per year, and PBT is almost a billion pounds per year. The market value of PET polymers varies depending on the application, but is in the range of $1.00–3.00/lb for uses as films and thermoplastic engineering polymers. PET and PBT are manufactured industrially from terephthalic acid, which, in turn, is manufactured from toluene (Wells 1999). Toluene is obtained industrially from the catalytic reforming of petroleum or from coal. Thus, FDCA derived from biomass can replace the present market for petroleum-based PET and PBT.

FDCA derivatives can be used for the production of new polyester, and their combination with FDCA would lead to a new family of completely biomass-derived products. New nylons can be obtained from FDCA, either through reaction of FDCA with diamines or through the conversion of FDCA to 2,5-bis(aminomethyl)-tetrahydrofuran. The nylons have a market of almost 9 billion pounds per year, with product values between $0.85 and $2.20 per pound, depending on the application.

Biopolymers and Biomaterials

The previous section discussed the major industrial chemicals that can be produced from biomass. This section will be focused on various biomaterials that can be produced from biomass. Thirteen thousand million metric tons of polymers were made from biomass in 2007 as shown in Fig. 21 out of which 68 % are natural rubber. New polymers from biomass, which attribute to a total of 3 % of the present

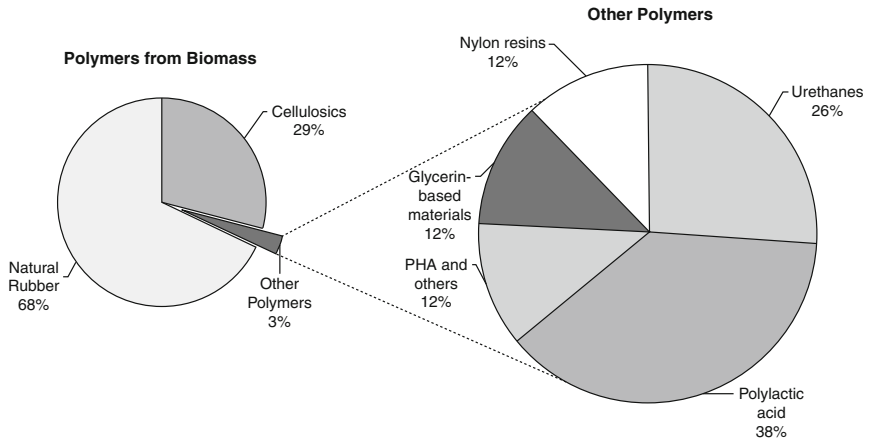

Fig. 21 Production of polymers from biomass in 2007 (13,000 million metric tons) and breakdown of "other polymers" (Tullo 2008)

market share of biobased polymers, consist of urethanes, glycerin-based materials, nylon resins, polyhydroxyalkanoates (PHA), and polylactic acid (PLA) (Tullo 2008). A new product from a new chemical plant is expected to have a slow penetration (less than 10 %) of the existing market for the chemical that it replaces. However, once the benefits of a new product are established, for example, replacing glass in soda bottles with petrochemical-based polyethylene terephthalate, the growth is rapid over a short period of time. Most renewable processes for making polymers have an inflection point at $70 per barrel of oil, above which the petroleum-based process costs more than the renewable process. For example, above $80 per barrel of oil, polylactic acid (PLA) is cheaper than polyethylene terephthalate (PET) (Tullo 2008). Table 3 gives a list of companies that have planned new chemical production based on biomass feedstock along with capacity and projected start-up date. Government subsidies and incentives tend to be of limited time and short-term value. Projected bulk chemicals from biobased feedstocks are ethanol, butanol, and glycerin.

Some of these biomaterials have been discussed in association with their precursor chemicals in the previous section. The important biomaterials that can be produced from biomass include wood and natural fibers, isolated and modified biopolymers, agromaterials, and biodegradable plastics (Vaca-Garcia 2008). These are outlined in Fig. 22. The production process for poly(3-hydroxybutyrate) is given by Rossell et al. (2006), and a detailed review for polyhydroxyalkanoates (PHA) as commercially viable replacement for petroleum-based plastics is given by Snell and Peoples (2009).

Lignin has a complex chemical structure, and various aromatic compounds can be produced from lignin. Current technology is underdeveloped for the industrial scale production of lignin-based chemicals, but there is considerable potential to supplement the benzene–toluene–xylene (BTX) chain of chemicals currently produced

Table 3 Companies producing biobased materials from biomass (Tullo 2008)

Company name	Location	Start-up date	Product	Capacity (t/year)	Notes
Telles	Clinton, Iowa	Q2, 2009	Polyhydroxyalkanoate (PHA) or Mirel	50,000	Joint venture between Metabolix and Archer Daniels Midland, fermented with K-12 strain of *Escherichia coli* genetically modified to produce PHA directly (about 3.5 % lower energy consumption compared to conventional plastics), biodegradable of PHA
Cereplast	Seymour, Indiana	Completed, 2008	Polylactic acid (PLA)-based compound	25,000	Cereplast working with PLA from NatureWorks to make it more heat resistant comparable to polypropylene or polystyrene
PSM North America	China	In production	Plastarch material (PSM)	100,000	80 % industrial starch and 8 % cellulose mixed with sodium stearate, oleic acid, and other ingredients. It can be processed like a petrochemical plastic, can withstand moisture, and is heat tolerant
Synbra	The Netherlands	2009	Polylactic acid (PLA)	5,000	PLA technology developed by Dutch lactic acid maker Purac and Swiss process engineering firm, Sulzer
Green Bioscience	Tianjin, China	–	Polyhydroxyalkanoate (PHA)	10,000	DSM has invested in this firm

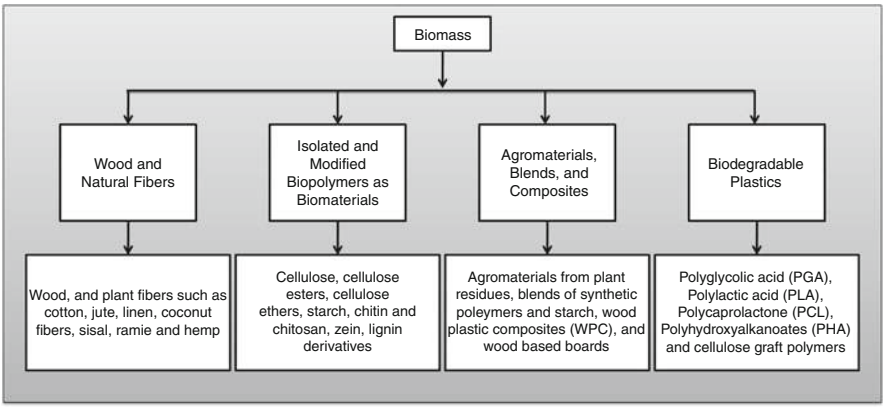

Fig. 22 Biomaterials from biomass (Vaca-Garcia 2008)

from fossil-based feedstock. Osipovs (2008) discusses the extraction of aromatic compounds such as benzene from biomass tar.

Natural Oil-Based Polymers and Chemicals

Natural oils are mainly processed for chemical production by hydrolysis and or transesterification. Oil hydrolysis is carried out in pressurized water at 220 °C, by which fatty acids and glycerol are produced. The main products that can be obtained from natural oils are shown in Fig. 23. Transesterification is the acid-catalyzed reaction in the presence of an alcohol to produce fatty acid alkyl esters and glycerol. Fatty acids can be used for the production of surfactants, resins, stabilizers, plasticizers, dicarboxylic acids, etc. Epoxidation, hydroformylation, and metathesis are some of the other methods to convert oils to useful chemicals and materials. Sources of natural oil include soybean oil, lard, canola oil, algae oil, waste grease, etc.

Soybean oil can be used to manufacture molecules with multiple hydroxyl groups, known as polyols (Tullo 2007b). Polyols can be reacted with isocyanates to make polyurethanes. Soybean oil can also be introduced in unsaturated polyester resins to make composite parts. Soybean oil-based polyols have the potential to replace petrochemical-based polyols derived from propylene oxide in polyurethane formulations (Tullo 2007b). The annual market for conventional polyols is 3 billion pounds in the USA and 9 billion pounds globally.

Dow Chemical, the world's largest manufacturer of petrochemical polyols, also started the manufacture of soy-based polyols (Tullo 2007b). Dow uses the following process for the manufacture of polyols. The transesterification of triglycerides gives methyl esters which are then hydroformylated to add aldehyde groups to unsaturated bonds. This is followed by a hydrogenation step which converts the aldehyde group to alcohols. The resultant molecule is used as a monomer with polyether polyols to build a new polyol. Urethane Soy Systems manufactures soy-based polyols at Volga,

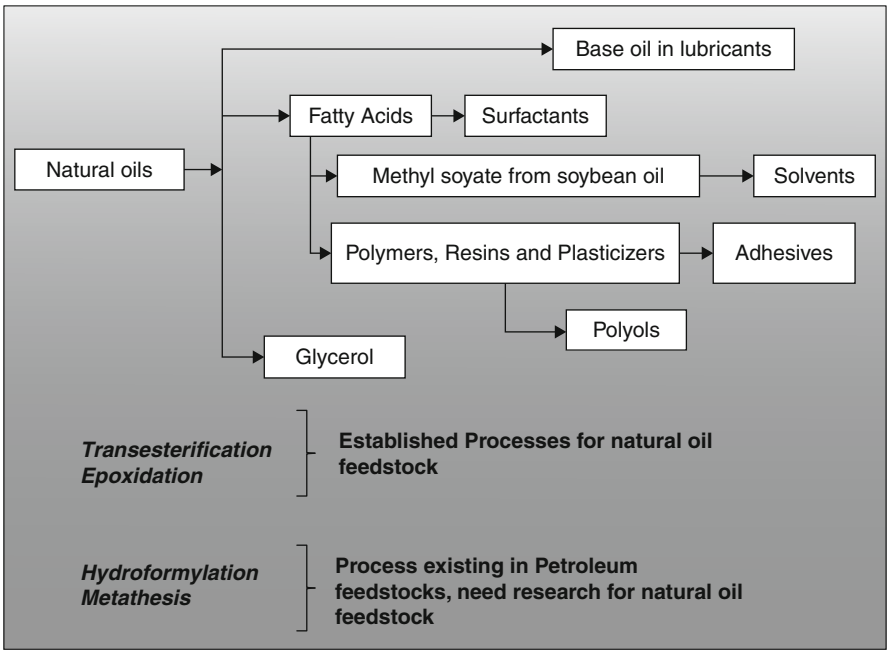

Fig. 23 Natural oil-based chemicals

South Dakota, with a capacity of 75 million pounds per year and supplies them to Lear Corp., manufacturer of car seats for Ford Motor Company. The company uses two processes for the manufacture of polyols: an autoxidation process replacing unsaturated bonds in the triglycerides with hydroxyl groups and a transesterification process where rearranged chains of triglycerides are reacted with alcohols. BioBased Technologies® supplies soy polyols to Universal Textile Technologies for the manufacture of carpet backing and artificial turf. Johnson Controls uses their polyols to make 5 % replaced foam automotive seats. The company has worked with BASF and Bayer MaterialScience for the conventional polyurethanes and now manufactures the polyols by oxidizing unsaturated bonds of triglycerides. The company has three families of products with 96 %, 70 %, and 60 % of biobased content.

Soybean oil can be epoxidized by a standard epoxidation reaction (Wool and Sun 2005). The epoxidized soybean oil can then be reacted with acrylic acid to form acrylated epoxidized soybean oil (AESO). The acrylated epoxidized triglycerides can be used as alternative plasticizers in polyvinyl chloride as a replacement for phthalates.

Aydogan et al. (2006) give a method for the potential of using dense (sub-/supercritical) CO_2 in the reaction medium for the addition of functional groups to soybean oil triglycerides for the synthesis of rigid polymers. The reaction of soybean oil triglycerides with $KMnO_4$ in the presence of water and dense CO_2 is presented in this paper. Dense CO_2 is utilized to bring the soybean oil and aqueous $KMnO_4$

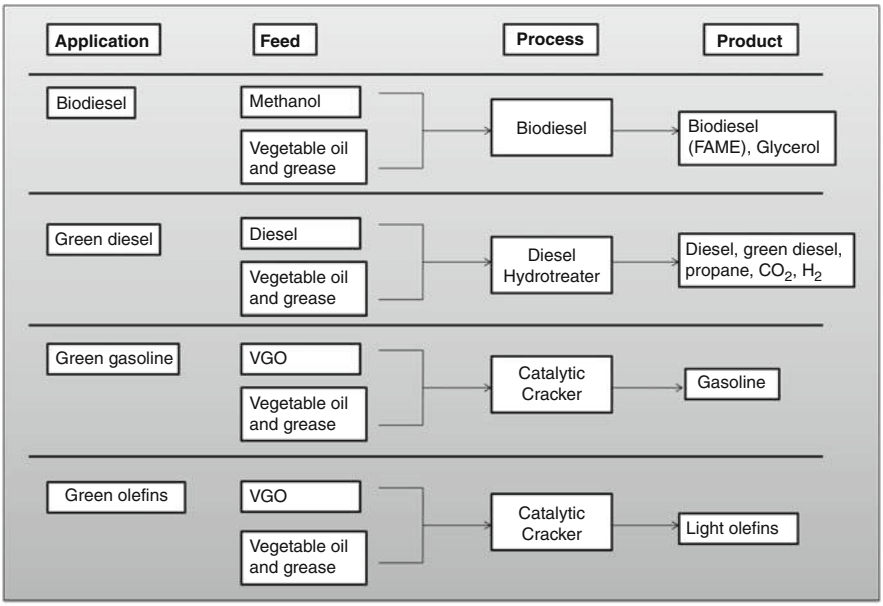

Fig. 24 Processing routes for vegetable oils and grease (Holmgren et al. 2007)

solution into contact. Experiments are conducted to study the effects of temperature, pressure, $NaHCO_3$ addition, and $KMnO_4$ amount on the conversion (depletion by bond opening) of soybean–triglyceride double bonds (STDB). The highest STDB conversions, about 40 %, are obtained at the near-critical conditions of CO_2. The addition of $NaHCO_3$ enhances the conversion; 1 mol of $NaHCO_3$ per mole of $KMnO_4$ gives the highest benefit. Increasing $KMnO_4$ up to 10 % increases the conversion of STDB.

Holmgren et al. (2007) discuss the uses of vegetable oils as feedstock for refineries. Four processes are outlined as shown in Fig. 24. The first process is the production of fatty acid methyl esters by transesterification process. The second process is the UOP/Eni Renewable Diesel Process that processes vegetable oils combined with the crude diesel through hydroprocessing unit. The third and fourth processes involve the catalytic cracking of pretreated vegetable oil mixed with virgin gas oil (VGO) to produce gasoline, olefins, light cycle oil, and clarified slurry oil. Petrobras has a comparable H-Bio process where vegetable oils can also be used directly with petroleum diesel fractions.

Conclusion

As in petroleum and natural gas, various fractions are used for the manufacture of various chemicals; biomass can be considered to have similar fractions. All types of biomass contain cellulose, hemicellulose, lignin, fats, and lipids and proteins as main

constituents in various ratios. Separate methods to convert these fractions into chemicals exist. Biomass containing mainly cellulose, hemicellulose, and lignin, referred to as lignocellulosics, can also undergo various pretreatment procedures to separate the components. Steam hydrolysis breaks some of the bonds in cellulose, hemicellulose, and lignin. Acid hydrolysis solubilizes the hemicellulose by depolymerizing hemicellulose to 5 carbon sugars such as pentose, xylose, and arabinose. This can be separated for extracting the chemicals from 5 carbon sugars. The cellulose and lignin stream is then subjected to enzymatic hydrolysis where cellulose is depolymerized to 6 carbon glucose and other 6 carbon polymers. This separates the cellulose stream from lignin. Thus, three separate streams can be obtained from biomass. The cellulose and hemicellulose monomers, glucose, and pentose can undergo fermentation to yield chemicals like ethanol, succinic acid, butanol, xylitol, arabinitol, itaconic acid, and sorbitol. The lignin stream is rich in phenolic compounds, which can be extracted, or the stream can be dried to form char and used for gasification to produce syngas.

Biomass containing oils, lipids, and fats can be transesterified to produce fatty acid methyl and ethyl esters and glycerol. Vegetable oils can be directly blended in petroleum diesel fractions, and catalytic cracking of these fractions produces biomass-derived fuels. Algae have shown great potential for use as source of biomass, and there have been algae strains which can secrete oil, reducing process costs for separation. Algae grow fast (compared to food crops), fix atmospheric and power plant flue gas carbon sources, and do not require freshwater sources. However, algae production technology on an industrial scale for the production of chemicals and fuel is still in the research and development stage. Growth of algae for biomass is a promising field of research.

The glycerol from transesterification can be converted to propylene glycol, 1,3-propanediol, and other compounds which can replace current natural gas-based chemicals. Vegetable oils, particularly soybean oil, have been considered for various polyols with a potential to replace propylene oxide-based chemicals.

Future Directions

These technologies outlined above can be further developed to produce a wide array of chemicals, and further research is needed for the commercialization of these chemicals.

Nearly 5.6 billion metric tons of carbon dioxide were emitted to the atmosphere in 2008 from utilization of fossil resources (EIA 2010b). The world production of polymers from biomass was 13 billion metric tons. There is opportunity to further convert biomass to chemicals and materials, and further research is required in that direction. The derivatives and market penetration of new chemicals from biomass are needed. The lignin stream from cellulosic biomass is an important source of aromatic chemicals such as benzene, toluene, xylene, etc. and can contribute to the BTX chain of chemicals.

This chapter outlined the various chemicals that are currently produced from petroleum-based feedstock that can be produced from biomass as feedstock. New polymers and composites from biomass are continually being developed which can replace the needs of current fossil feedstock-based chemicals.

Contents

Abstract

Bio-oil is a renewable and carbon-neutral energy source. It is made by the fast pyrolysis of biomass at elevated temperatures followed by condensation of vapors and aerosols that are removed rapidly from the pyrolysis chamber. Raw bio-oil contains significant amounts of oxygenated compounds which reduce its fuel quality. Upgrading raw bio-oil using hydrodeoxygenation (HDO) is one

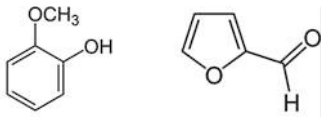
solution to increase fuel quality. Guaiacol and furfural are important model oxygen-containing compounds present in raw bio-oil. HDO of guaiacol and furfural with a dual Cu-based water–gas shift and Mo/Co/K HDO catalyst system in a static catalyst basket was studied in the gas phase in a batch autoclave using H_2/CO at 4.0 MPa (total partial pressure of CO + H_2) and temperatures of 200 °C, 250 °C, and 300 °C. Syngas HDO using two syngas mixtures (H_2/CO/N_2 ratios of 47:47:6 (50/50 syngas) and 18:23:46 (bio-syngas)) was compared to hydrogen alone, which is traditionally used in bio-oil upgrading. Liquid and gas products were analyzed using GC/MS. Temperature and catalyst both exert significant effects on conversion and product selectivity. Guaiacol conversions of 79–86 % were observed in both 50/50 syngas and bio-syngas systems at 300 °C, with 24–29 % cyclohexane formed in 4 h. Furfural exhibited ~100 % conversion in 4 h at 300 °C with both syngas systems. Reaction products from upgrading with syngases had a higher total heat of combustion but lower energy density than the products from reactions with pure H_2. For example, 0.04 mol (4.96 g) of guaiacol has a total heat of combustion of 143.4 kJ with an energy density of 28.9 kJ/g (3.59 MJ/mol). Reaction products from upgrading the same amount of guaiacol with H_2 had a total energy content and energy density of 146.6 ± 0.4 kJ and 38.8 ± 0.2 kJ/g (3.66 MJ/mol), respectively, compared to 153.6 ± 0.4 kJ and 35.8 ± 0.1 kJ/g (3.84 MJ/mol) for the product upgraded with bio-syngas. This, and product selectivity, suggests incorporation of some C from CO in these syngas reactions.



Guaiacol Furfural

Introduction

Worldwide energy consumption began increasing dramatically, beginning with the Industrial Revolution. This trend continues today and energy needs are expected to double in the next 50 years as more of the world becomes developed (Shafiee and Topal 2009). Fossil fuels are a major energy source and continued use of these finite reserves will lead to depletion with time. Greenhouse gas emissions of CO_2 are a harmful consequence of fossil fuel combustion and a major contributor to global warming. Development of alternative fuel sources is needed which will provide energy while reducing CO_2 emissions.

Conversion of biomass into biofuels has been studied to fulfill our clean energy needs (Alonso et al. 2010; Bridgwater 2006; Adjaye and Bakhshi 1995a). A portion of CO_2 emissions produced during formation and use of biofuels is consumed during photosynthesis for plant growth. Biofuel versus fossil fuel use would

lower greenhouse gas emissions. Many currently available "first-generation" (Stöcker 2008) biofuels (ethanol) come from the edible plant carbohydrates and fermentation. This competes with food demand from a rapidly growing population, raising food prices. The so-called "second-generation" technologies for the production of fuels allow the use of a wide range of nonfood "cellulosic" biomass feedstocks (Stöcker 2008). This includes agricultural residues (e.g., straw, bagasse, corn stover), wastes (e.g., paper, manures, cardboard, sawmill residues), and specially grown energy crops (e.g., *Miscanthus*, willow, switchgrass) (Huber and Corma 2007; Huber et al. 2006). Cellulosic-containing biomass consists of biopolymers such as cellulose (35–50 %), hemicelluloses (15–25 %), and lignin (15–30 %) (Mohan et al. 2006).

Thermochemical Conversion of Biomass

Biomass can be converted by gasification to synthesis gas or by fast pyrolysis to raw bio-oil. Catalytic upgrading of these raw materials can lead to transportation-grade fuels. Gasification converts biomass into synthesis gas, consisting of carbon monoxide and hydrogen. Pyrolysis of biomass produces raw bio-oil, which is an unstable complex mixture, consisting of various organic and inorganic compounds and water (Huber et al. 2006; Mohan et al. 2006). An advantage of both these thermochemical approaches is that all of the biomass (cellulose, hemicelluloses, and lignin) can be fed and consumed during conversion without isolating specific components first. A major disadvantage is significant loss of original calories present in the biomass during conversion.

Pyrolysis of Biomass

Biomass pyrolysis is the decomposition of biomass using elevated temperatures while limiting oxygen. During this process, gases, liquids, and solids (chars) are produced (Mohan et al. 2006). The compositions of the product depend on the feedstock, residence time, and pyrolysis temperature. Pyrolytic decomposition of hemicelluloses occurs between 250 °C and 400 °C; cellulose decomposes at a somewhat higher temperature of 310–430 °C, while lignin decomposes at 300–530 °C (Williams and Besler 1996). Dehydration of cellulose begins around 300 °C and produces unsaturated polymers and char. Depolymerization of cellulose to form smaller units begins at ~400 °C (Lange 2007). At higher temperatures, breaking of C–C and C–H bonds produces C_{2-4} oxygenates and gases (CO, CO_2, H_2, and CH_4) (Lange 2007).

Different pyrolysis modes result in different product compositions as reported by Bridgwater (Bridgwater 2006) (Table 1). Commercial value exists in liquid (Alonso et al. 2010), char (Bridgwater 2006), and gas products (Delgado et al. 1997), contributing to the importance of biomass pyrolysis. Biomass pyrolysis production

Table 1 Average product yields formed by different dry wood pyrolysis methods (Bridgwater 2006)

Method	Operation conditions		Liquid (%)	Gas (%)	Char (%)
	Temperature	Residence time			
Fast	Moderate temperature, around 500 °C	Short hot vapor residence time ~1 s	75	13	12
Intermediate	Moderate temperature, around 500 °C	Moderate hot vapor residence times ~10–20 s	50	30	20
Slow (carbonization)	Low temperature, around 400 °C	Very long residence time	30	35	35
Gasification	High temperature, around 800 °C	Long residence times	5	85	10

methods continue to be extensively studied and optimized to increase the value of each component.

Bio-oil yield under optimum fast pyrolysis conditions (typically between 425 °C and 500 °C with a vapor residence time of a 1 s) may reach 70–80 % of the biomass, with 20–25 % water (Delgado et al. 1997). Slow pyrolysis (400 °C with a residence time of ~8 min) (Ashworth et al. 2014) produces more biochar and considerably increases the yield of water (up to 35–40 %) (Bridgwater 2006). Longer residence times of ~1 h (Ashworth et al. 2014) and lower temperatures of around 400 °C reduce bio-oil yields while increasing the yields of char to about 30 wt%. Higher temperatures around 700 °C at very high heating rates produce more gases (up to 80 wt%) (Bridgwater 1994). Salts and acids which are formed during the pyrolysis can influence the quality of the bio-oil.

Oxygenated compounds found in bio-oil derive their oxygen content from the oxygen originally present in the cellulose, lignin, and hemicellulose components of the biomass. This is because the biomass is fed to the reactor either under nitrogen or through a valve which seals the reactor from air. The only oxygen gas that can be fed under those conditions is with the air that enters with the biomass particles or pellets. The biomass fed to the reactor is 2000 or more times as dense as the air occupying the volume between biomass particles. Thus, even if 80 % of this volume is air (~20 % of this is oxygen), the moles of oxygen in the feed are negligible versus what would be needed to measurably influence the product distributions.

Gasification of Biomass

Gasification of biomass is performed under controlled amounts of oxygen and steam at elevated temperature (500–800 °C) to produce bio-syngas (Delgado et al. 1997). Steam use can generate the water–gas shift reaction (Eq. 1) and steam reforming reaction (Eqs. 2 and 3). CO and hydrocarbons produced during gasification can react with water to produce H_2. Equation 1, the water–gas shift

reaction, converts carbon monoxide and water into carbon dioxide and hydrogen. Equations 2 and 3 convert hydrocarbons produced during the gasification process into CO and H_2. Small amounts of added oxygen can reduce coke formation by combustion of the carbonaceous material to CO_2 and other volatile chemicals (van Steen and Claeys 2008). Steam can increase the H_2/CO ratio in the resulting synthesis gas (van Steen and Claeys 2008). Syngas can be used directly for power generation as a methane substitute or converted into fuel-range hydrocarbons by Fischer–Tropsch (FT) synthesis with appropriate catalysts (van Steen and Claeys 2008).

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad (1)$$

$$C_xH_{2y} + xH_2O \rightleftharpoons xCO + (x + y)H_2 \quad (3)$$

Bio-oil Upgrading

Fast pyrolysis of biomass with a residence time of 1 s at moderate temperatures (425–500 °C) can be used to produce bio-oil in high yields (60–75 %). Regardless of the production method, raw pyrolysis bio-oil's high organic oxygen (20–40 %) and water (15–30 %) contents lead to low energy densities, thermal and chemical instabilities, acidity, undesirable odors, and corrosive properties (Bridgwater 1994). Microphases are frequently present in bio-oil and easily observable under magnification (Mohan et al. 2006). Tiny solid char particles are common which catalyzed reactions on their surfaces further enhancing instability (Mohan et al. 2006). Upgrading is required to convert raw fast pyrolysis oil into a useable form for transportation fuels (Mohan et al. 2006; Boateng et al. 2008; Bridgwater et al. 1999). Several approaches (cracking, decarbonylation, decarboxylation, hydrocracking, hydrodeoxygenation, and hydrogenation) were reported for bio-oil upgrading (Adjaye and Bakhshi 1995b; Wildschut et al. 2009). These reactions take place in the presence of catalysts at elevated pressure and temperature. Examples of each reaction type are given in Fig. 1.

Fast pyrolysis oils contain liquid organic components that include organic acids, ketones, aldehydes, furans, phenolic compounds, guaiacol, syringol, sugar-based compounds, and water (Mohan et al. 2006; Ingram et al. 2007). The large phenolic content in bio-oil results from lignin pyrolysis and may reach 30 % of the organic components (Zhang et al. 2007). Guaiacol, among the more abundant fragments from lignin (Mohan et al. 2006; Bridgwater et al. 1999; Ingram et al. 2007; Zhang et al. 2007; Mullen and Boateng 2008; Bridgwater 2003; Bridgwater et al. 2001; Bridgwater and Peacocke 1999; Huber et al. 2005; Bridgwater 1996; Czernik and Bridgwater 2004), is present at levels of approximately 0.94 wt% in pine wood and 0.18–0.51 wt% in switchgrass- and alfalfa-derived pyrolysis oils (Ingram et al. 2007; Mullen and Boateng 2008). Furfural is produced during thermal

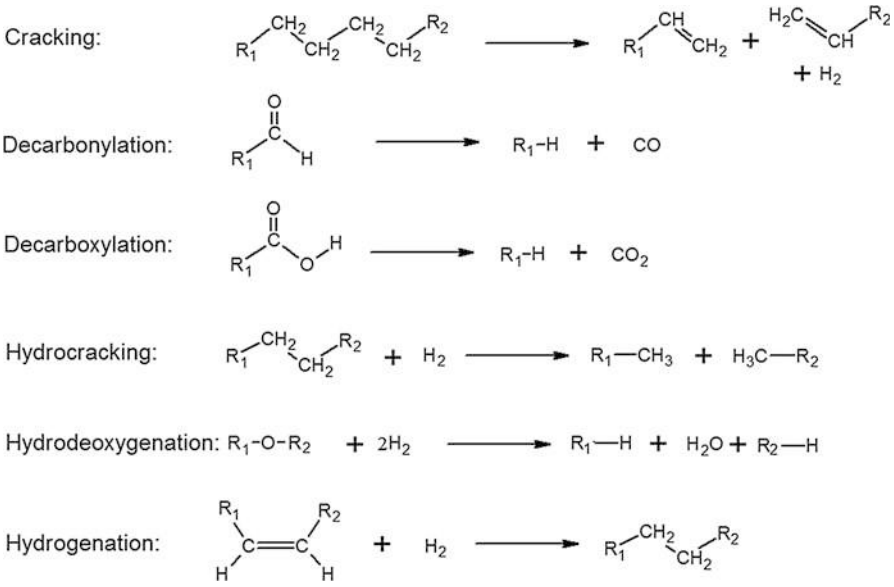

Fig. 1 Bio-oil upgrading reactions

decomposition of glucose, cellulose, and hemicelluloses (Mohan et al. 2006; Bridgwater et al. 1999; Ingram et al. 2007; Zhang et al. 2007; Mullen and Boateng 2008; Bridgwater 2003; Bridgwater et al. 2001; Bridgwater and Peacocke 1999; Huber et al. 2005; Bridgwater 1996; Czernik and Bridgwater 2004).

Hydrodeoxygenation (HDO) is similar to hydrodesulfurization (HDS) which is used extensively in the oil refineries to remove sulfur from organic molecules. During HDO, oxygen is removed from the organic compound as water. Separated organic and aqueous phases are often found after the reaction (Venderbosch et al. 2010).

Deoxygenation upgrading is generally conducted at elevated hydrogen pressure and temperatures (Grange et al. 1996). HDO is generally performed at pressures between 10 and 30 Mpa (Venderbosch and Prins 2010; de Miguel Mercader et al. 2010). Higher pressures increase hydrogen solubility in the bio-oil and H_2 absorption on the catalyst surfaces. This serves to increase rate and decrease coking (Kwon et al. 2011). Theoretically, about 25 mol H_2 per one kg of bio-oil is required to completely deoxygenate the bio-oil. However, excess hydrogen (35–420 mol/kg) typically is used for HDO reactions (Venderbosch et al. 2010; Elliott et al. 2009).

Industrial HDO reactions are typically done in a flow reactor with liquid hourly space velocities (LHSV) of 0.1–1.5 h^{-1} (McCall et al. 2012), while batch reactions, often used for research applications, are typically completed in 2–5 h (Wildschut et al. 2009). HDO is conducted at temperatures between 250 °C and 450 °C (Adjaye and Bakhshi 1995a). Recently, the effect of temperature on upgrading was studied using wood-based bio-oil in a fixed-bed flow reactor at 14 Mpa H_2 with a Pd/C

catalyst. The upgraded liquid product yield decreased from 75 % to 56 % when increasing the temperature from 310 °C to 360 °C. More gas products were produced at the higher temperature. At temperatures over 340 °C, hydrocracking becomes more favorable than HDO (Elliott et al. 2009).

Noble metal (Ru, Rh, Pd, and Pt) catalysts are reported to show good activity for HDO reactions; however, their higher prices make them unattractive (Yakovlev et al. 2009). Ni, Co, Mo, and Cu metals can be used as alternatives to the noble metal catalysts. However, these catalysts are reported to suffer from lost activity due to catalyst coking (Yakovlev et al. 2009).

Several dual metal catalyst systems (Zhao et al. 2009; Zhang et al. 2006), including Co/Mo combinations, have been used to promote bio-oil HDO reactions (Furimsky 2000). Previous HDO studies of the model compound guaiacol under hydrogen followed its conversion into phenol, catechol, and fully deoxygenated cyclohexane, cyclohexene, and substituted benzenes using hydrogen and Mo/Co catalysts (Laurent and Delmon 1994; Bredenberg et al. 1982; Lin et al. 2011). Guaiacol conversion to phenol has also been achieved by removal of methanol via hydrogenolysis of the aromatic C–O bond using Co/Mo, along with a competing formation of catechol by loss of the methyl group (Ferrari et al. 2001; Ferrari et al. 2002). Catalyst acidity promotes both coke formation (Centeno et al. 1995) and guaiacol conversion. Potassium modification of alumina-supported Mo/Co alters the catalyst's acidity and reduces coke formation during guaiacol conversion (Centeno et al. 1995; Wijayapala et al. 2014). Ni/Mo/S and Co/Mo/S catalysts have been widely used for HDO (Elliott 2007). Ni and Co act as promoters by donating electron density to the Mo, weakening the Mo–S bond. Loss of sulfur creates vacant sulfur sites for HDO (Massoth et al. 2006). However, during the electron donation process, Mo–S is converted into Mo–O which reduces catalyst activity (Romero et al. 2010).

Transition metal catalysts for HDO reactions should be bifunctional. Oxygen-containing compounds must be activated during the process and a hydrogen adsorption active site is also needed. A support is often used with transition metals to achieve this bifunctionality. The transition metal can act as the active site for dissociative hydrogen absorption and then it can donate a hydrogen atom to promote the HDO reaction. The supporting material can act as the active site for the oxy-compound complexation as described in Fig. 2 (Mallat and Baiker 2000; Vargas et al. 2004).

Hydrogen gas has been used for almost all bio-oil upgrading studies (Mallat and Baiker 2000; Vargas et al. 2004; Fisk et al. 2009). Upgrading reactions typically include HDO, which induces C–O bond cleavage and produces water (Bridgwater 1996). The water–gas shift (WGS) reaction (Eq. 1) can be used to generate H_2 from CO + H_2O and to vary H_2 and CO compositions (Patt et al. 2000; Sun et al. 2010). *Herein, we examined Mo/Co/K loaded on a ZSM-5 support to catalyze HDO reactions of guaiacol and furfural with 50/50 syngas and bio-syngas (a green and renewable source of hydrogen and carbon monoxide). Mo/Co/K on a ZSM-5 support was also simultaneously used with a Cu-based low-temperature WGS catalyst for HDO reactions of guaiacol and furfural using the same syngas sources.* The reactions were conducted at 200–300 °C and a 4 MPa initial CO + H_2 pressure in batch gas phase reactions.

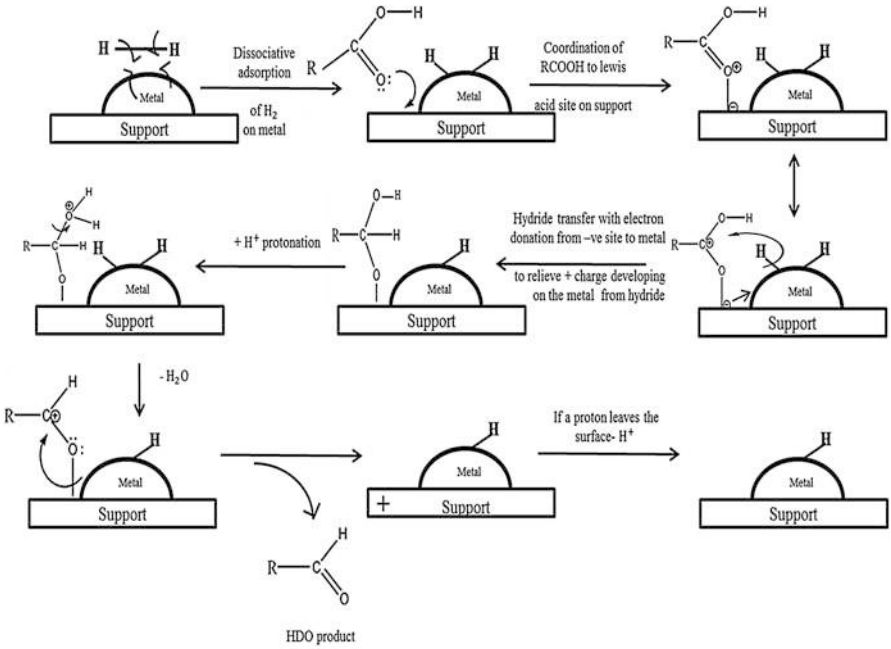

Fig. 2 Schematic diagram of one catalyst process showing the synergistic relationship of the transition metal and the support

The presence of CO and the WGS catalyst can increase H_2 partial pressure by reaction with both H_2O formed during HDO and also the water present in bio-oil. In model compound work, no water will be present at the start. However, the WGS reaction should lower the water content of the products produced by HDO. These upgrading reactions were compared to analogous HDO reactions using only H_2. *It is conceivable that CO may independently remove oxygen from organic compounds, forming CO_2*. Since Mo/Co/K on ZSM-5 is a known Fischer–Tropsch (FT) catalyst (van Steen and Claeys 2008), *it is also possible that syngas-induced HDO of guaiacol and furfural might occur concurrently with FT chemistry*. If so, hydrocarbons formed by FT reactions would enhance the upgraded product's heating value.

Experimental

Catalyst Preparation

Mo/Co/K/ZSM-5 was prepared using incipient wetness impregnation (Liu et al. 2009). The ammonium form of ZSM-5 ($SiO_2/Al_2O_3 = 50$) (50.0 g) obtained from Zeolyst International was impregnated with an aqueous solution of 4.60 g $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ (Sigma-Aldrich). This Mo/ZSM-5 was then impregnated

with an aqueous solution of 12.35 g $Co(NO_3)_2 \cdot 6H_2O$ (Sigma-Aldrich). Finally this Mo/Co/ZSM-5 was impregnated with an aqueous solution of 1.25 g K_2CO_3 (Sigma-Aldrich). The samples were then calcined in air at 500 °C for 3 h and pelletized into 0.45–0.8 mm particles for activity tests. The designated (after calcination) loading was 5 wt% for Co with 5 wt% Mo and 1.4 wt% K. The WGS catalyst was purchased from Alfa Aesar (copper-based low-temperature water–gas shift catalyst, HiFUEL W220 pellets 3.1 × 3.1 mm).

Catalyst Characterization

Catalyst surface areas were determined by N_2 physical adsorption using a BET surface area analyzer (Monosorb Quantachrome). First, the samples were degassed at 280 °C under flow of 30 % nitrogen in helium. Atomic absorption (AAS) analyses were conducted using Mo, Co, Cu, and K standards (Sigma-Aldrich AAS standard) to determine the metal wt% values. Acid digestion was used to extract the metal from the supporting surface prior to analysis. Carbon % of the used catalysts was determined using an elemental analyzer (CE 440; Exeter Analytical, Inc.). Catalyst characterization results are discussed in Results and Discussion.

Catalytic Upgrading Guaiacol and Furfural with Syngas

Guaiacol and furfural HDO reactions with syngas were performed in a 500 mL stainless steel static reactor controlled with a Parr 4843 reactor controller. The combinations of substrate, gases, catalyst, and temperature employed (54 total combinations) are listed in Table 2. The catalyst (2.0 g or 2.0 g of each when using dual catalysts) was used with two different syngas mixtures: syngas 50/50 H_2/CO/N_2 (47:47:6) and bio-syngas (mole% H_2, 17.83 %; CO, 22.66 %; N_2, 46.04 %; CH_4, 1.76 %; C_2H_4, 0.25 %; O_2, 0.88 %; CO_2, 10.60 %) and also with H_2 (99.99 %). Guaiacol (Sigma-Aldrich) or furfural (Sigma-Aldrich) (0.0400 mol) were used as the substrates. They were loaded into the reactor at room temperature. The catalyst was loaded into a static basket mesh holder placed well above the substrate (guaiacol or furfural) liquid level. After purging with the gas to be used, this reactant gas was introduced, pressurizing the reactor at ambient temperature. Then the reactor was heated to the designated reaction temperature (200 °C, 250 °C, or 300 °C) which raised the total pressure to 4.0 MPa in each case.

After the 4 h reaction, the reactor was allowed to cool to ambient temperature before effluent gas was collected into a 1 L Tedlar bag and analyzed using a gas chromatograph (SRI 8610C) equipped with both thermal conductivity (TCD) and flame ionization (FID) detectors. A ShinCarbon ST 100/120 (2 m 1 mm ID 1/16″ OD silicone) packed column and an MXT-1(60 m 0.53 mm ID 5.00 μm) capillary column were employed for separation of inorganic gases and light hydrocarbons. Liquid products were removed and the reactor was washed three times with 5.0 mL

Table 2 Reaction conditions used for each catalyst system

Substrate	Gas	Catalyst	Temperature (°C)[a]
Guaiacol	50/50 syngas	Mo/Co/K	200, 250, 300
		WGS	200, 250, 300
		WGS + Mo/Co/K	200, 250, 300
	Bio-syngas	Mo/Co/K	200, 250, 300
		WGS	200, 250, 300
		WGS + Mo/Co/K	200, 250, 300
	Hydrogen	Mo/Co/K	200, 250, 300
		WGS	200, 250, 300
		WGS + Mo/Co/K	200, 250, 300
Furfural	50/50 syngas	Mo/Co/K	200, 250, 300
		WGS	200, 250, 300
		WGS + Mo/Co/K	200, 250, 300
	Bio-syngas	Mo/Co/K	200, 250, 300
		WGS	200, 250, 300
		WGS + Mo/Co/K	200, 250, 300
	Hydrogen	Mo/Co/K	200, 250, 300
		WGS	200, 250, 300
		WGS + Mo/Co/K	200, 250, 300

[a]In all cases, the reactor was charged at ambient temperature with the reactant gas so that it reached a 4.0 MPa partial pressure (hydrogen + carbon monoxide) once the target temperatures of 200 °C, 250 °C, and 300 °C were achieved

of ethyl acetate (Sigma-Aldrich, LC–MS Grade). The washings were collected and added to the liquid products. An internal standard, chlorobenzene-d_5 (Sigma-Aldrich) (0.100 mL), was added and the mixture diluted to 25.0 ml in a volumetric flask. GC/MS analysis of the mixture was performed on a GC/MS (Agilent 7890A) equipped with DB-1 column (GC, DB-1-60 m 0.32 mm 1.0 μm). Peak area comparisons with the internal standard using product response factors allowed for quantification.

Results and Discussion

Catalyst Characterization

Catalyst surface areas and metal compositions are listed in Table 3. Impregnating ZSM-5 with Mo, Co, and K significantly reduced the surface area from 422 m^2/g to approximately 300 m^2/g, indicating that the added metals block some zeolite channels. A smaller drop in Mo/Co/K/ZSM-5 surface area was observed after the 50/50 syngas catalytic reactions at 300 °C with guaiacol than those with furfural, implying somewhat more catalyst coking occurred during furfural HDO under the same conditions. In contrast, Cu-based WGS catalyst's surface area dropped sharply and coke deposited during both guaiacol and furfural HDO. After HDO

[b]Using an elemental analyzer (CE 440; Exeter Analytical, Inc.)
[c]Catalysts were used in 4 h reactions with syngas 50/50 at 4.0 MPa partial pressure ($CO + H_2$) at 300 °C, prior to BET analysis
[d]No WGS catalyst was used
[e]No HDO catalyst was used

reactions, 4.2 and 8.3 %C were found on the WGS catalyst for these two substrates, respectively. Carbon depositions observed on the used catalysts at 200 °C, 250 °C, and 300 °C are shown for H_2, 50/50 syngas, and bio-syngas reactions in Fig. 3. AAS analysis confirmed the expected Mo/Co composition of the fresh catalyst after calcinations (Table 3).

HDO of Guaiacol and Furfural

HDO of guaiacol and furfural was studied individually with Mo/Co/K and Cu-based WGS catalysts and then with the dual system of both catalysts (Table 2). HDO reactions under hydrogen were used as reference results to compare with the catalyst activity in syngas reactions. Guaiacol and furfural conversions at 200–300 °C were determined (Tables 4 and 5) following their disappearance by GC/MS.

Temperature has a significant impact on the guaiacol conversion with all three reagent gases with the three different catalyst systems (Table 4). At the highest temperature (300 °C) employed, the maximum guaiacol conversions were observed for each gas and each catalyst. The conversions of guaiacol in the presence of the dual catalysts (Mo/Co/K + WGS) were almost the same as the conversions using the single Mo/Co/K catalyst under hydrogen at 200 °C, 250 °C, and 300 °C. However, a significant difference in guaiacol conversion was found with both syngas compositions using Mo/Co/K versus the dual (Mo/Co/K + WGS) catalyst. The dual catalyst system exhibited the higher conversions with both syngases at all three temperatures. However, using only Mo/Co/K resulted in considerably lower conversions with both syngases than with hydrogen only (where the initial hydrogen

[a]All conversions are expressed as percent conversion of furfural conversion

pressure was higher). This illustrates the significance that the WGS catalyst plays in the dual catalyst system for HDO of guaiacol with syngas.

Higher conversions were observed for furfural than guaiacol under these conditions. When the reaction temperature was maintained at or above 250 °C, complete furfural conversion was achieved in 4 h using the dual (Mo/Co/K + WGS) catalyst with each type of syngas (Table 5). HDO rates increased at higher temperatures for all the catalyst systems, with all reagent gases. The products from both guaiacol and furfural HDO treatments were analyzed by GC/MS using chlorobenzene-d_5 as an internal standard and response factors from standards. The product selectivity (S_i) is expressed in Eq. 4, where n_i is the number of moles of product i and c_i is the number of carbon atoms in product i. The selectivity, S_i, is the percentage of the total number of carbon atoms found in the specified product i ($n_i \times c_i$) versus the number of carbon atoms in the starting material ($n_a^0 \times c_a$). This tracks carbon from the amount in either the guaiacol or furfural changed to the reactors to the products. If the sum of all S_i values exceeds 100 %, that would indicate that carbon has entered into the products from the CO of the syngas reagent gas.

$$S_i = \frac{n_i \times c_i}{n_a^0 \times c_a} \times 100\% \tag{4}$$

n_i = Number of moles of product i
c_i = Number of carbon atoms in product i
n_a^0 = Initial number of moles of guaiacol or furfural
c_a = Number of carbon atoms in guaiacol or furfural

These selectivities are obtained from experimental measurements of the product selectivities (S_i) observed in HDO of guaiacol and furfural. These are shown in Table 6.

Guaiacol reactions produced significant amounts of cyclohexane and cyclohexene after 4 h at 300 °C using all three reactant gases. Both syngases converted guaiacol into deoxygenated products, although using only H_2 generated slightly higher cyclohexane and cyclohexene selectivities. Cyclohexane and cyclohexene selectivities decreased at 200 °C and 250 °C. 1,2-Dimethoxybenzene selectivity was significantly higher using either syngas compared to employing H_2 at 300 °C.

A major question of interest is: can carbon from CO be incorporated into the liquid HDO reaction products? Evidence of carbon incorporation into the liquid products from CO was obtained. Guaiacol HDO products from both 50/50 syngas and bio-syngas reactions at 300 °C exhibited product selectivity totals exceeding 100 % (Table 6a). This means more carbon was found in the liquid products than was present in the reagent guaiacol placed into the reaction vessel. Therefore, this carbon could only have come from CO. This was only observed at 300 °C and the amounts were small (see Table 6a). However, three repetitions of each experiment were performed and the amounts of extra carbon beyond the guaiacol charged exceeded the standard deviation in these experiments. Future reactions will be done

Table 6 HDO product selectivities at 200 °C, 250 °C, and 300 °C for all three reagent gases over the Mo/Co/K + WGS dual catalyst after 4 h for (a) guaiacol and (b) furfural

at 325 °C and 350 °C to determine if this additional carbon in the products increases.

Alkyl-substituted phenols appear in guaiacol HDO reaction products (at 300 °C) only when using syngas as shown in Table 6a. Methylation and ethylation of phenol probably occur via Friedel–Crafts alkylation by methanol and ethanol formed by Fischer–Tropsch reaction of syngas on Mo/Co/K, but these FT reactions cannot occur with H_2 (see Eq. 5). The formation of methanol and dimethyl ether was observed from syngas over this catalyst previously (Wijayapala et al. 2014). Char or coke formation or incomplete liquid product collection could explain the missing carbon (totals below 100 % for Table 6a and b). Used catalysts exhibited carbon weight percentages of 2–12 wt%. These are shown in Fig. 3.

$$\mathrm{CO} + \mathrm{H_2} \xrightarrow[\substack{\mathrm{FT} \\ 300\ ^\circ\mathrm{C}}]{\mathrm{Mo/Co/K}} \mathrm{CH_3OH}, \quad \mathrm{CH_3CH_2OH} \tag{5}$$

Furfural reactions exhibited high selectivity to furan and methylfuran. Totally deoxygenated products such as pentane, cyclohexane, and cyclopentene are also formed. Cyclic aliphatic hydrocarbons were found only in furfural/syngas reactions and not in furfural/H_2 reactions, suggesting CO was involved in product formation, perhaps via Fischer–Tropsch (FT) routes.

Two control reactions were performed to probe if FT chemistry was involved. Syngas-only reactions were carried out using the dual Mo/Co/K + WGS catalysts at 300 °C, where no guaiacol or furfural was present. No cyclic aliphatic or olefinic compounds were formed after 4 h (Table 7). This suggests that the cyclic hydrocarbons shown in Table 6 are probably produced from reactions involving guaiacol or furfural. A second experiment reacted guaiacol at 300 °C with only CO (no H_2) over the Mo/Co/K + WGS catalyst for 4 h (Table 8). Very little conversion occurred. This small amount of conversion seen could have resulted from thermal conversion generating small amounts of water, which, in turn, led to some H_2 formation by the WGS reaction.

Oxygen removal is one measure of bio-oil upgrading. Catalyst activity was defined by the degree of deoxygenation (HDO %). HDO % is defined here simply as the percentage of the initial oxygen in the substrate charged to the reactor that remains in the liquid product. This is expressed in Eq. 6 (Bykova et al. 2012), where a_i is the number of oxygen atoms contained in a given component of the product i and n_i is the number of moles of product i. The product of n_i and a_i is summed from all product components over the starting material where n_a^0 is the initial number of moles of guaiacol or furfural. The 2 factor is used because there are two oxygen atoms in each guaiacol and furfural molecule.

$$\mathrm{HDO}\% = \left[1 - \frac{\sum_i n_i a_i}{n_a^0 \times 2}\right] \times 100 \tag{6}$$

HDO % (Table 9) reflects the oxygen removal capability of the catalyst when reactions are compared at identical conditions and reaction times. A higher HDO% indicates less oxygen in the products. The distribution of reaction products with 0, 1, or 2 oxygen atoms from guaiacol HDO over Mo/Co/K + WGS at 300 °C after 4 h can be found in Fig. 4.

The HDO % of guaiacol was higher using hydrogen than using either syngas. The largest difference in product selectivities for guaiacol upgrading at 300 °C (Table 6) was found for 1,2-dimethoxybenzene (8.3, 20.2, and 17.9 % for H_2, 50/50 syngas, and bio-syngas, respectively). The amount of this compound peaks at 4 h and then decreases in hydrogen reactions. 1,2-Dimethoxybenzene is thought to form from the addition of methanol to the guaiacol hydroxyl function (*O*-methylation) with loss of water. Methanol can be produced from syngas via FT processes over Mo/Co/K on ZSM-5 (Wijayapala et al. 2014). However, acid-catalyzed methylation of guaiacol by another guaiacol molecule could also occur.

Table 9 HDO % of guaiacol and furfural reactions catalyzed by Mo/Co/K + WGS at 300 °C for 4 h[a]

Substrate	Hydrogen	50/50 syngas	Bio-syngas
Guaiacol	68.8	53.7	48.9
Furfural	51.8	53.8	55.1

[a]HDO % is the percentage of oxygen that was initially present in the initial substrate removed by the HDO reaction and no longer found in the product

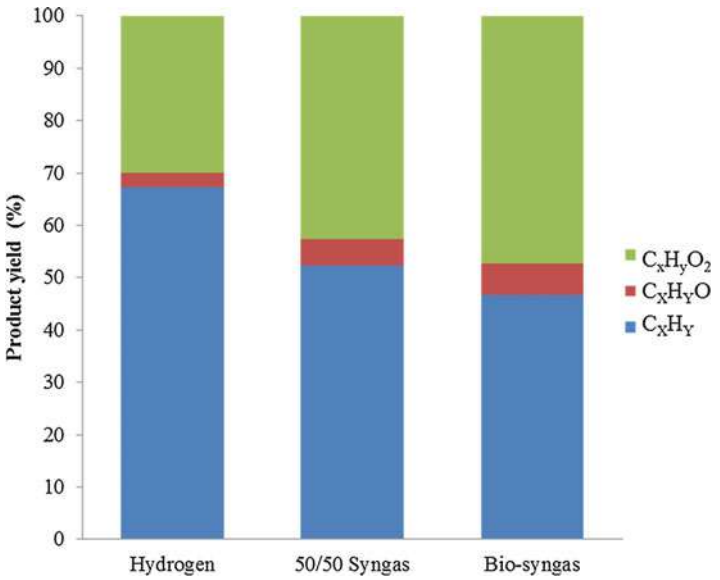

Fig. 4 Yields of compounds with different numbers of retained oxygen atoms for guaiacol HDO over Mo/Co/K + WGS at 300 °C after 4 h (C_xH_yO, single-oxygen-atom-containing oxygenates; $C_xH_yO_2$, dioxygen-atom-containing oxygenates; C_xH_y, products without oxygen)

Product distribution versus time curves was obtained by running identical reactions for different lengths of time before analyzing the products. H_2, 50/50 syngas, and bio-syngas were used individually to upgrade both guaiacol and furfural with the dual catalyst (Mo/Co/K + WGS). Guaiacol conversion (falling curves) and the product selectivities for cyclohexane and 1,2-dimethoxybenzene with the three different gases versus time are shown in Fig. 5.

Guaiacol consumption with H_2, 50/50 syngas, and bio-syngas at 300 °C was essentially complete after 8 h. Reaction with pure hydrogen occurred faster than those with either syngas. However, if the initial hydrogen partial pressure in syngas reactions were adjusted to be equal to these in the pure H_2 cases, this would no longer be true. The product distributions changed little after 8 h with all three gases. The initial partial H_2 pressures in the syngas reactions were lower than with pure H_2. This lower H_2 pressure slows hydrodeoxygenation and hydrogenation. At high initial H_2 pressures, hydrodeoxygenation/hydrogenation is favored and conversion

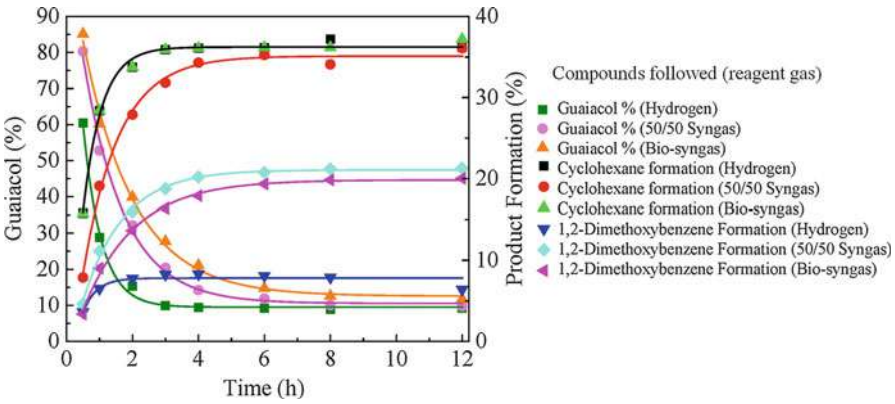

Fig. 5 Guaiacol consumption and cyclohexane and 1,2-dimethoxybenzene formation versus reaction time using the dual catalyst (Mo/Co/K + WGS) at 300 °C for all three reagent gases

is accelerated. The pressure falls with time in these constant volume reactions. The WGS catalyst produces in situ H_2 from water formed during HDO in the syngas reactions. This raises the hydrogen partial pressure and facilitates the HDO and hydrogenation of guaiacol. Cyclohexene formation versus time (not shown in Fig. 4) initially rises, reaches a maximum, and then decreases. Cyclohexane continues to increase as the hydrogenation of cyclohexene generates cyclohexane. The product distributions versus time over the Mo/Co/K + WGS catalyst at 300 °C are shown in Table 10. When 50/50 syngas was reacted alone over the Mo/Co/K + WGS dual catalyst, no cyclohexane or cyclohexene were formed. However, C-1 through C-6 linear and branched alkanes were produced (Table 7). Thus, cyclohexane and cyclohexene formed in guaiacol HDO must be derived from guaiacol.

Furfural was consumed more rapidly (~4 h, Fig. 6) than guaiacol (Fig. 5). The yield of the two main products (furan and 2-methylfuran) reached their maximum values after 3 h using all three reagent gases. Cyclohexane and cyclohexene were formed along with cyclopentene. The product distributions formed as a function of time over the dual catalyst system at 300 °C 50/50 syngas are summarized in Table 11. Since cyclohexene, cyclohexane, and cyclopentene were not formed in 50/50 syngas reaction alone over the dual catalyst from 200 °C to 300 °C, the cyclic hydrocarbons must have originated from furfural. Reaction schemes (Schemes 1 and 2) are proposed for the HDO of guaiacol and furfural based on the product analyses with time (all product formation percentages are shown in Tables 10 and 11).

In guaiacol HDO, the methoxy group is demethylated by hydrogenolysis of the O–CH_3 bond (Scheme 1). This forms catechol and methane. Demethoxylation of guaiacol leads to the formation of phenol and methanol (Nimmanwudipong et al. 2011). Hydrogenolysis of phenol's OH group cleaves the $C_{aromatic}$–OH bond forming benzene. Subsequent hydrogenation of the aromatic ring can result in cyclohexane (Nimmanwudipong et al. 2011). Guaiacol can be converted to phenol

Table 10 Guaiacol reaction product formation verses reaction time using the dual catalyst (Mo/Co/K + WGS) at 300 °C[a]

Products	Product formation %							
	0.5 h	1 h	2 h	3 h	4 h[b]	6 h	8 h	12 h

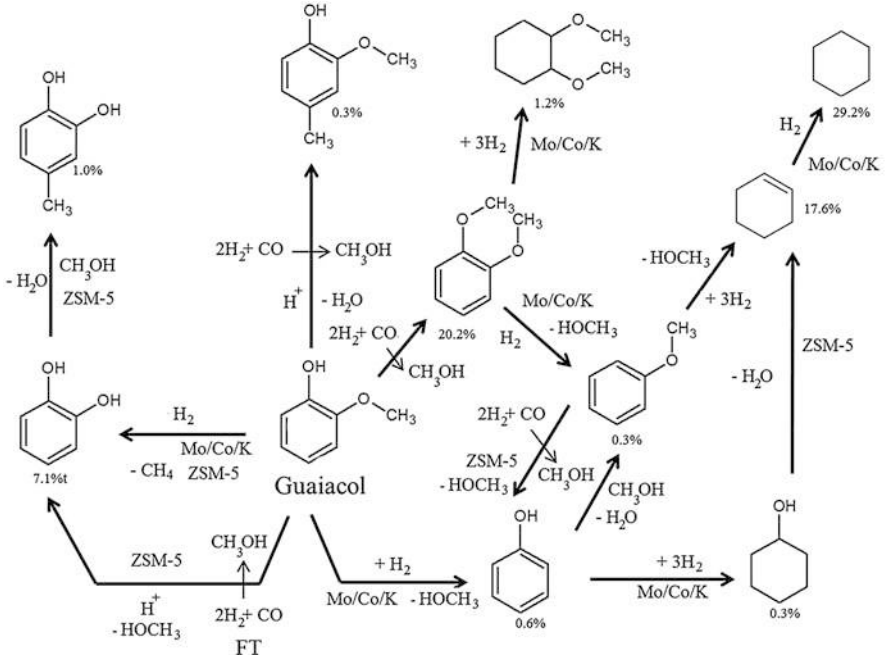
Cyclopentene	–	–	0.4	2.0	2.2	2.5	2.5

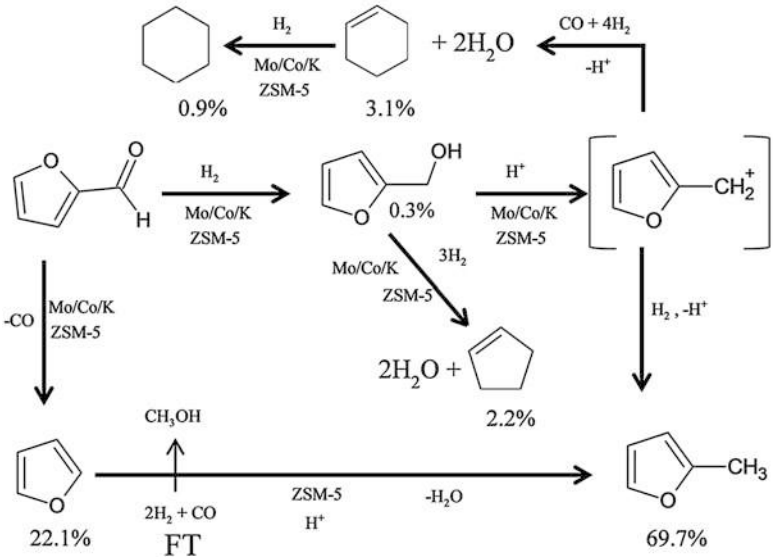
via direct demethoxylation, and/or the observed product, methoxybenzene, can be demethylated to phenol by methanol. Methoxybenzene can also undergo demethoxylation by hydrogen to benzene, followed by hydrogenation to cyclohexene and cyclohexane. Ring hydrogenation of phenol produces cyclohexanol (see Table 10). Then, dehydration to cyclohexene can be followed by hydrogenation to cyclohexane. *O*-Methylation of guaiacol gives dimethoxybenzene.

O-Methylation of phenol or guaiacol readily occurs in the presence of methanol or dimethyl ether (Shen et al. 2005), both of which form from syngas over this catalyst system (Wijayapala et al. 2014). Phenol will readily be *C*-methylated at *ortho* and *para* positions over the Mo/Co/K catalyst which is supported on ZSM-5, a strong catalyst for electrophilic aromatic substitution.

Furfural (Scheme 2, Table 11) produced 2-methylfuran (~70 %) by hydrodeoxygenation of the aldehyde group. This likely occurred through aldehyde hydrogenation to 2-hydroxymethylfuran followed by facile loss of water from the reactive alpha CH_2OH group. The formation of 2-hydroxymethylfuran is seen to rise early



Scheme 1 Proposed scheme for guaiacol conversion to ten observed products with 50/50 syngas over Mo/Co/K + WGS at 300 °C. Product yields are given after 4 h



Scheme 2 Proposed scheme for furfural HDO with 50/50 syngas over Mo/Co/K + WGS at 300 °C after 4 h

and then fall (Table 11). Decarbonylation of the furfural aldehyde function produces furan (Modak et al. 2012). Furan is formed in ~22 % yield between 3 and 8 h. The formation of cyclohexene, cyclohexane, and cyclopentene, each with one carbon more than furfural, was observed with syngas, but not with hydrogen, in furfural HDO (Table 11). Since these three products were not formed from 50/50 syngas over Mo/Co/K + WGS without furfural present, these arose from furfural. The presence of methanol or dimethyl ether, formed in FT routes, could give 2-methylfuran by electrophilic aromatic substitution. Carbon addition to the furan ring, originating from CO, with concurrent removal of the oxygen must occur to convert the C-5 furfural or a product resulting from it to cyclohexene or cyclohexane. However, we have no evidence to support a specific pathway for this or for cyclopentene formation.

The heat of combustion defines the energy content in a fuel. The total heat of combustion of guaiacol and furfural liquid products in kJ is found in Tables 12 and 13, respectively. The energy density (kJ/g) was calculated using the number of moles of each product determined from GC/MS and the standard enthalpy of combustion (ΔH_c°) for each product. The mass of each product mixture was determined from the number of moles and molecular weight for each product. The results for both guaiacol and furfural HDO reactions after 4 and 12 h at 200 °C, 250 °C, and 300 °C can be found in Table 14. Product mixtures obtained by upgrading with all three gases exhibited higher total heats of combustion and energy densities kJ/g than the initial guaiacol and furfural feeds. The guaiacol products from H_2 (300 °C and both 4 and 12 h) upgrading had a lower total energy but higher energy density than upgrading with the bio-syngases. In contrast, the furfural H_2 upgrading product at these same conditions (300 °C, 4 and 12 h) exhibited both lower total energies and lower energy densities than the product upgraded with the bio-syngas.

The heat content (kJ) of the guaiacol product mixture versus reaction time for 300 °C upgrading reactions using the dual catalyst is shown in Fig. 7. A significant gap exists between the hydrogen and syngas upgrading. *Syngas upgrading leads to higher heats of combustion*. After 12 h, products from the 50/50 syngas guaiacol upgrade gave a 156.4 ± 0.5 kJ versus 146.6 ± 0.4 kJ for the product made under hydrogen (9 kJ difference for 0.0400 mol of starting material). *This is due to a product selectivity with syngas that favors higher heat of combustion products*. Reaction products with an increased total energy content are a potential benefit of upgrading with synthesis gas compared to hydrogen particularly when used in fuel applications.

Catalyst recycle was tested both with and without a catalyst washing step. Used catalyst was washed with ethyl acetate and dried for 24 h at 125 °C under air, before reuse. Product selectivities and CO conversions were examined to evaluate loss of activity and the reusability of the Mo/Co/K + WGS catalyst (Fig. 8). Catalysts lose activity more rapidly when reused without washing. About 50 % of the activity was lost after the catalyst had been used twice. However, 98 % activity is retained after three cycles, if the washed catalyst is recycled.

Table 12 Calculation of the heat of combustion of the liquid product obtained by upgrading guaiacol with Mo/Co/K + WGS at 200, 250, and 300 °C for 4 h (number of moles of each product was used with the heat of combustion of each compound found in references (Matos et al. 2003; Linstrom and Mallard))

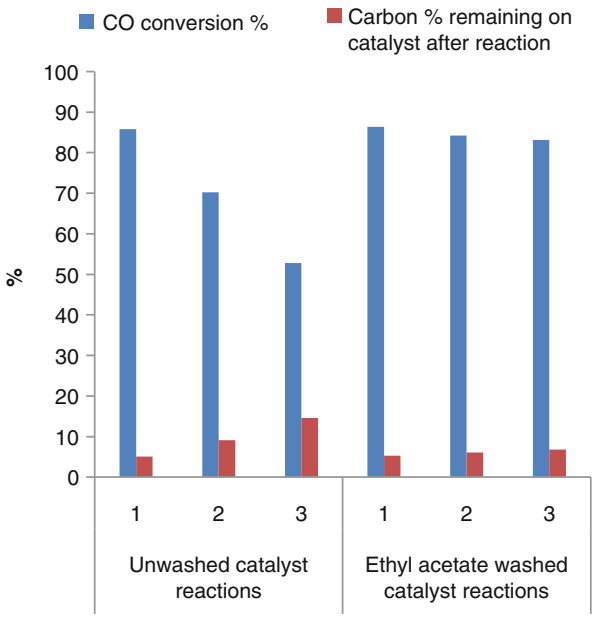

Fig. 8 CO % conversion and C wt% found on the used catalyst (Mo/Co/K + WGS shift catalyst using guaiacol and 50/50 syngas at 300 °C). CO conversion decreased and C wt% on the used catalyst increased in reactions employing recycled unwashed catalyst. Washing the used Mo/Co/K + WGS catalysts with ethyl acetate reduced progressive loss of CO conversion upon recycling the catalyst

Conclusions

The upgrading of bio-oil model compounds, guaiacol and furfural, using syngas or hydrogen and a dual catalyst system (Mo/Co/K + WGS) showed that syngas reactions (same total initial pressure but lower H_2 partial pressure) gave slower but competitive conversions compared to H_2. This occurs even though the H_2 partial pressure was much lower in the syngas reactions. All furfural upgrading reactions, at or above 300 °C, resulted in 100 % conversion of furfural's aldehyde functional group. In raw bio-oil, aldehydes are known to participate in oligomerization and oxidation reactions contributing to raw bio-oil instability. Upgrading reactions that remove this functional group lower oxygen content and increase bio-oil stability. Furfural conversion was complete (primarily producing 2-methylfuran ~70 % and furan ~22 %) after 4 h under hydrogen and both syngases at 250 °C and 300 °C. At 300 °C, furfural HDO% was slightly higher with syngas ~54 % compared to H_2 at 51.8 %. Guaiacol conversion increased with increasing temperature and was faster under hydrogen at 300 °C (~90 % at 3 h) than under the syngases (~90 % at 8 h).

Guaiacol HDO products from both 50/50 syngas and bio-syngas reactions at 300 °C exhibited products with more total carbon than that in the starting guaiacol (e.g., selectivity totals exceeding 100 %, Table 6a). This suggests incorporation of carbon into the liquid products from CO. This incorporation of carbon from syngas resulted in additional products, not found from H_2 upgrading, and a higher heat of combustion using syngas upgrading (156 and 154 kJ) versus hydrogen (147 kJ). Increased product energy content represents a compelling advantage of syngas upgrading, compared to H_2 upgrading, when developing new routes to biomass-derived transportation-quality liquid fuels.

This work identified a catalyst system, which effectively converted a model bio-oil aromatic phenol arising from lignin pyrolysis and a model furan aldehyde derived from cellulose pyrolysis, respectively, to more hydrophobic compounds with less oxygen. Products included alkanes and ethers using bio-syngas as the hydrogen source. The use of syngas, instead of pure hydrogen for HDO reactions, represents a new green bio-oil model upgrading route with considerable oxygen removal and increased energy density products. This represents an endorsement for more bio-oil upgrading research using syngas in place of hydrogen under a much wider range of conditions and substrate feeds.

Future Directions

Future work will focus on studying additional model compounds which are present in raw bio-oil (e.g., furfuryl alcohol, acetic acid, isoeugenol, hydroxyacetone, etc.) with a number of different functional groups including ethers, aldehydes, ketones, alcohols, esters, and carboxylic acids. Raw biomass pyrolysis liquids will also be studied. Once catalysts and conditions are optimized in a static reactor, efforts will shift to optimizing in a flow reactor. The H_2/CO ratio will be varied. Higher

pressures (5–10 MPa), various H_2/CO ratios and higher temperatures (300–400 °C), and gas hourly space velocities will also be investigated. We have demonstrated that model bio-oil compounds can be upgraded from treatment with bio-syngas. The ultimate goal of this work would be the commercial use of catalysts and reaction conditions to upgrade raw bio-oil in a flow system utilizing bio-syngas to produce a commercial-grade liquid fuel with the required heating value, acid value, water content, and density.

Abstract

Biochar is a stable form of carbon produced via the pyrolysis of biomass for use in sustainable environmental and agricultural practices. The concept of biochar was originally triggered from the ancient practice in which humans deliberately mixed carbonized biomass into soils to enrich the soil quality and fertility. According to the International Biochar Initiative (IBI), biochar can be defined as "A solid material obtained from the thermo-chemical conversion of biomass in an oxygen-limited environment." Biomass-derived biochar production has been demonstrated as a potentially viable strategy for developing negative carbon emission technologies for climate change mitigation and also as a material for effective amendment of relatively poor agricultural soils. Most interestingly, ongoing biochar research work has expanded broadly, stretching from its traditional core in the environmental and agricultural science to include studies in the use of biochar for energy generation and as adsorbents for pollution treatment applications. However, the use of biochar for carbon sequestration and soil amendment has attracted more interests by research scientists globally. The use of biochar as a material for soil amendment is closely linked with its potential for climate change mitigation by carbon sequestration. Specifically, the properties of biochar include resistance to microbial degradation and chemical transformations, high surface areas, high water retention capacity, cation-exchange capacity, and its effectiveness as support and substrate for soil microbes. These characteristics endow biochar with a greater potential to become a highly useful source of materials for improving agricultural productivity through soil quality enhancement while simultaneously sequestering CO_2 from the atmosphere to mitigate climate change. On a separate front, a recent study of acoustic and photochemical interactions of CO_2 with carbonaceous materials seems to warrant feasibility research in the future for exploring novel routes of CO_2 utilization and CO_2 capture. Moreover, biochar's ability to absorb electromagnetic radiation and emit far-infrared wavelength radiation has promoted research, development, and commercialization of biochar's applications in medical and health therapies.

Introduction

For decades, significant interest has been paid to research activities on biomass-derived biochar for environmental and agricultural purposes. The key properties such as resistance to microbial degradations, chemical transformations, and preservation for geological time periods have provided recognition for biochar application as a potential strategic material for carbon sequestration and soil improvement. The concept of biochar originated from the ancient practice in which humans were deliberately

mixing burned biomass into soils to enrich the soil quality (O'Neill et al. 2009). These enriched soil deposits, known as terra preta and found in the Amazonian Basin, appear to have substantially altered soil properties and led to long-term carbon storage and crop improvement (Lehmann 2003; Lehmann et al. 2009).

Biochar, being a thermochemically derived recalcitrant carbon, has multiple definitions based on its production conditions and intended applications. The International Biochar Initiative (IBI 2012) provided a standardized definition for biochar as "A solid material obtained from the thermo-chemical conversion of biomass in an oxygen-limited environment." Lehmann and Joseph (2009) described biochar as "A carbon-rich product obtained when biomass such as wood, manure or leaves is heated in a closed container with little or unavailable air" (Lehmann and Joseph 2009), whereas two more definitions given by Shackley et al. (2012) and Verheijen et al. (2010) were "The porous carbonaceous solid produced by the thermo-chemical conversion of organic materials in an oxygen depleted atmosphere that has physicochemical properties suitable for safe and long-term storage of carbon in the environment" (Shackley et al. 2012), and "Biomass that has been pyrolyzed in a zero or low oxygen environment applied to soil at a specific site that is expected to sustainably sequester carbon and concurrently improve soil functions under current and future management, while avoiding short- and long-term detrimental effects to the wider environment as well as human and animal health"(Verheijen et al. 2010).

Biomass-derived biochar has been increasingly discussed by experts as a potential strategy for developing negative carbon emission technologies, climate change mitigation, soil quality, and food security (Lal 2004; Lehmann et al. 2009; Lehmann and Joseph 2009; Manya 2012; Paustian et al. 2000; Xu et al. 2012; Zhao et al. 2013a). To mitigate global climate change and ensure food security for a growing global population, biochar-based techniques have been extensively used for many years to improve the environment by carbon sequestration, reduce greenhouse gas emissions, and enhance soil quality and crop productivity (Laird 2008; Lehmann 2007; Lehmann et al. 2006; Sohi et al. 2010). The multiple benefits associated with biochar are shown diagrammatically in Fig. 1.

Figure 1 shows how human activities impact global climate change and this is represented in two categories and designated carbon negative and carbon positive. Carbon negative is a phrase used to describe any activity that removes more carbon or CO_2 from the atmosphere. For example, the process of photosynthesis is a classic carbon neutral phenomenon. Ultimately, the world will need to become carbon negative if the increasing buildup of atmospheric CO_2 is to be reversed. Thus, a sustainable global environmental future requires strategies to facilitate the use of energy resources that enable the reduction of concentrations of CO_2 and other greenhouse gases in the atmosphere. Low-cost and sustainable ways to achieve net negative carbon emissions from human activities involve the use of technologies such as the hydrogen fuel cell, solar and wind power, and other renewable energy sources. They are critical to achieving the net negative emission goal. On the contrary, carbon positive processes are those which add carbon to the environment. Whereas the thermochemical transformation of biomass into biochar is carbon positive with respect to the atmosphere, the addition of biochar to soil is carbon

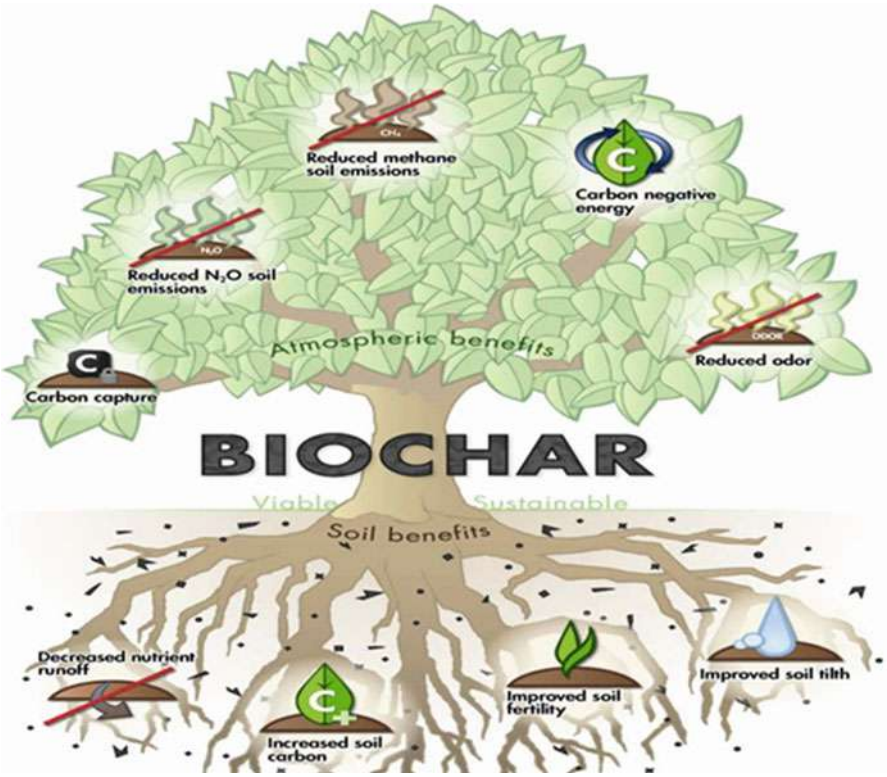

Fig. 1 Environmental and agricultural benefits associated with biochar (Source: International Biochar Initiative (IBI); http://www.biocharinternational.org/)

negative and desirable. Converting biomass carbon to biochar carbon is known to help in sequestering 50 % of the initial carbon compared to the low amounts retained after burning or normal biological decomposition. The stabilization of biomass carbon to carbonized biochar under sustainable procedures is an imperative component in a multi-phased strategy to reduce and offset GHG emissions globally. An added benefit to this solution is the potential for simultaneous enhancement in agricultural production through increased soil carbon content, improved soil fertility and soil tilth, water retention capacity, and reduced nutrient depletion. The physical properties of biochar contribute to its intrinsic multifunctional ability as a tool for environmental management. When biochar is present in the soil, its contribution to the physical nature of the system may involve significantly influencing texture, structure, porosity, and consistency through changing the bulk surface area, pore-size distribution, particle-size distribution, density, and packing. The effect of biochar on soil physical properties may then have a direct impact on plant growth because the penetration depth and availability of air and water within the root zone is determined largely by the physical makeup of soil horizon (Downie et al. 2009). In this chapter, the authors have summarized information related to biochar production

techniques, characterization methods, and its potential benefits for carbon sequestration and soil amendment purposes.

Biochar Production Pyrolysis

Pyrolysis is a thermochemical process involving conversion of organic material into a carbon rich solid (char/biochar/charcoal) and volatile materials such as gases (syngas) and liquids (bio-oil) by heating in the absence of oxygen (Demirbas and Arin 2002). The solid product obtained in pyrolysis process is known as char/biochar or charcoal and contains around half of the carbon of the original organic matter. A simple schematic representation of main products of pyrolysis is shown in Fig. 2. Pyrolysis process has been used for decades. Production of charcoal as an unintentional residue from cooking fires by Cro-Magnon man has been reported 38,000 years ago (Antal and Grønli 2003). Pyrolysis and gasification methods have been used for the production of synthetic crude oil from coal since Victorian times.

Based on the heating rate applied to the biomass in order to reach the intended pyrolysis temperature, pyrolysis is classified into slow pyrolysis and fast pyrolysis. Techniques such as intermediate pyrolysis, flash pyrolysis, and hydrothermal carbonization and gasification methods have also been employed but less frequently compared to slow and fast pyrolysis.

Slow Pyrolysis

Slow pyrolysis involves slower heating rates and longer solid and vapor residence times. The temperatures used in slow pyrolysis are typically 400 °C and the heating rate is about 5–7 °C/min. In slow pyrolysis, the yield of biochar is higher compared

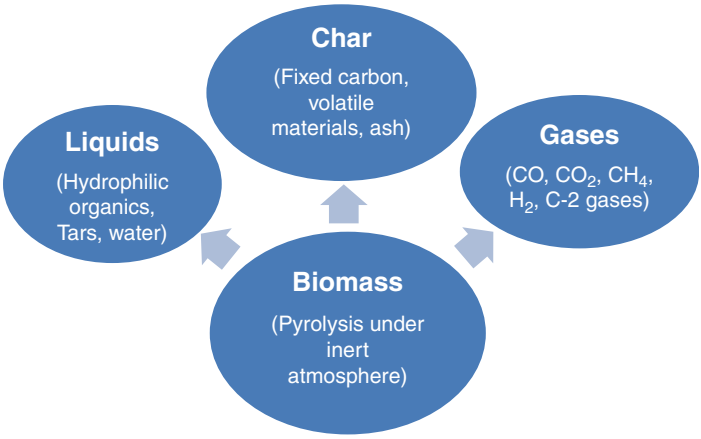

Fig. 2 Major products formed in biomass pyrolysis

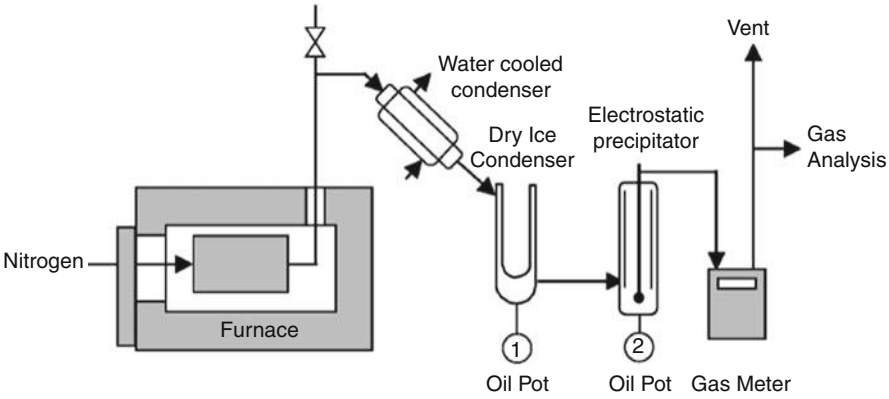

Fig. 3 Schematic representation of slow pyrolysis setup (Bridgwater et al. 2007) (Copyright © 2014 Interscience Enterprises Ltd)

to liquid and gas products formed. In the past, slow pyrolysis of biomass using pits and mounds or kilns was common practice. Bridgwater et al. (2007) demonstrated product yields and characteristics in slow pyrolysis of eucalyptus mallee, and the experimental setup reported in this study is shown in Fig. 3 (Bridgwater et al. 2007).

Fast Pyrolysis

Fast pyrolysis involves high heating rates and short vapor residence times. The pyrolysis reaction temperature applied in this process is usually around 500 °C. Fast pyrolysis requires feedstocks with smaller particle size (<2 mm) and a setup that is capable of removing vapors quickly from the presence of the hot solids. Fluid beds, stirred or moving beds, and vacuum pyrolysis system designs have been used for this application. Commercial processes using fast pyrolysis method have been reviewed and reported (Bridgwater et al. 1999; Bridgwater and Peacocke 2000). In fast pyrolysis the biomass heating rate is very rapid (>300 °C/min) and used specifically to obtain high yields of single-phase bio-oil. A fast pyrolysis experimental setup reported by Bridgwater et al. (2007) is shown in Fig. 4. Since the fast pyrolysis process yields higher concentrations of volatiles, its value for soil applications is limited. Fast pyrolysis produces 50–85 % of bio-oil, 5–25 % of solid char, and 10–20 % of gases, depending on the nature of feedstock and operating conditions.

Other Techniques

Methods such as intermediate pyrolysis, flash pyrolysis, hydrothermal carbonization, and gasification have also been reported. Intermediate pyrolysis was used in electronic waste disposal feedstock (Hornung 2013). The performance of this

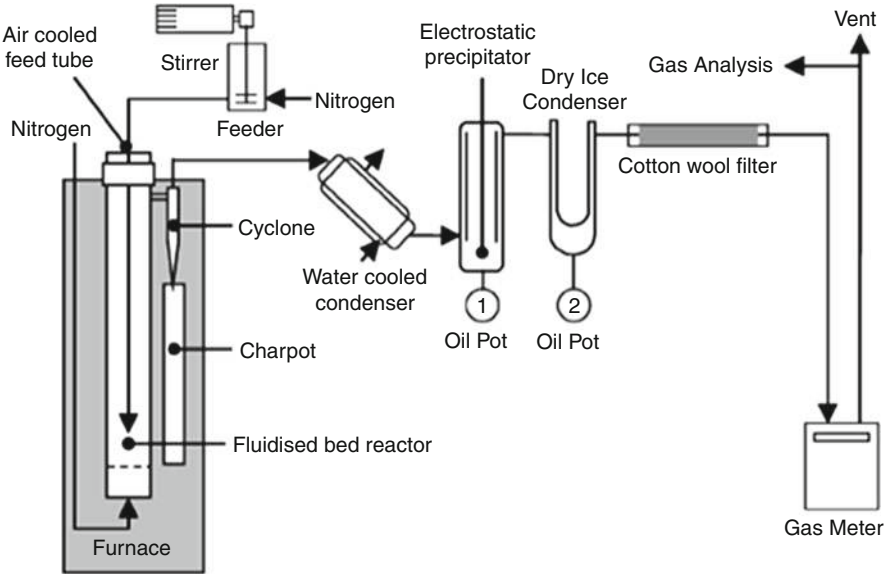

Fig. 4 Schematic representation of fast pyrolysis setup (Bridgwater et al. 2007) (Copyright © 2014 Interscience Enterprises Ltd)

method is very similar to slow pyrolysis and there is not much literature available. Flash pyrolysis methods are similar to fast pyrolysis but required higher temperatures and shorter residence times (Demirbas and Arin 2002). However, hydrothermal carbonization is used in the conversion of biomass into carbon-rich solids in water at high temperatures and pressure (Kruse et al. 2013). Since water is used in hydrothermal carbonization process, there is no need to dry feedstock prior to carbonization and it is a useful method for liquid biomass conversion. The gasification method involves partial combustion of biomass in a gas flow containing a controlled level of oxygen at high temperatures ranging from 500 °C to 800 °C. The main product in this process is syngas.

During pyrolysis, the heat transfer rate is one of the important parameters for determining the product yield and properties. According to IEA (2007), biochar product yields in slow and fast pyrolysis are 35 % and 12 %, respectively (IEA 2007). Depending on the pyrolytic conditions such as temperature, heating rate, vapor residence time, and biomass feedstock composition, the physiochemical properties and quality of biochar vary widely (Enders et al. 2012; Ronsse et al. 2013). Masiello (2004) explained that at low temperature, biochar chemical composition is closer to the original feedstock, while high temperature biochar is closer to graphite (Masiello 2004). Biochar produced at low temperature has high volatile matter and lower fixed carbon and ash contents than its high temperature counterpart (Bourke et al. 2007). Earlier studies have demonstrated that biochar with high volatile organic content contributed to nitrogen immobilization and microbial

activity reduction which negatively affected plant growth (Deenik et al. 2010; Spokas et al. 2012). Thus, it is clear that improving the yield of biochar for carbon sequestration and agricultural purposes has been associated with slow pyrolysis in which production gas and liquid co-products will be reduced (Angın 2013; Crombie et al. 2013; Demiral and Ayan 2011; Demirbas 2004; Hossain et al. 2011; Manya 2012; Mašek et al. 2013; Ronsse et al. 2013). Prior to use, a key step involves the evaluation of biochar characteristics that are responsible for its quality and efficacy for the intended application. The details of various biochar characterization methods have been summarized.

Biochar Characterization

The physicochemical properties and composition of the feed biomass are a function of the content of cellulose, hemicellulose, lignin, and extractives. Once the biochar is produced, determining key characteristics using relevant analytical techniques enable the understanding of the potential of the biochar product for proposed applications. Especially the temperature used in the pyrolysis process has shown an impact on both biochar production distribution and the nature of biochar (Kim et al. 2010; Méndez et al. 2013). When the pyrolysis temperature is higher, less biochar is generated and the microstructure develops more effectively. If the temperature is too high, the loss of carbon and other functional group elements on the surface is excessive. The chemical composition, pH, surface charge, and thermal stability of biochar, as well as the heavy metal fate in the biochar body, are also functions of pyrolysis temperature. The information obtained by physicochemical characterization of biochar may help understand the environmental and agronomic functions and facilitates production of desired biochar which offers specified benefits. Properties such as bulk density, elemental composition (ultimate analysis), pH, proximate analysis, and surface properties will help in assessing the biochar quality (Okimori et al. 2003). The details of analytical methods used to characterize biochar properties have been summarized.

Bulk Density

Since the solid density of biochar is directly related to its mechanical strength, it can be used to estimate the biochar's relative ability to withstand wear and tear during soil applications. Generally, the biochar has a higher density than the biomass feedstock from which it was derived. Bulk density is defined as weight per unit volume of material and expressed in kilograms per cubic meter (kg/m^3). Bulk density of biochar is measured by adding a known amount of mass into a container of known volume. Generally, biochar bulk density is around 0.2–0.5 g/cm^3 (Brewer et al. 2014; Özçimen and Karaosmanoğlu 2004).

Elemental Composition

Elemental analysis is generally performed by combusting biochar under excess oxygen using an Elemental Analyzer (EA). This analysis includes quantitative estimation of carbon, hydrogen, nitrogen, sulfur, and oxygen. Also, elemental ratios of C:O, O:H, and C:H are reported as reliable methods to measure the extent of pyrolysis of biochar (Cheng et al. 2008; Kuzyakov et al. 2009). Chan and Xu (2009) reported that during pyrolysis, biomass carbonizes to yield biochar which is highly recalcitrant in nature and has a potential impact on soil health and productivity (Chan and Xu 2009). Thus, quantification of elemental components and their ratios of biochar samples are very important to assess their quality as they may influence soil properties.

pH

Measuring pH is crucial to choose the right char for soil applications depending on the soil nature. The simplest way to measure pH is to make a char and water slurry and use a standard laboratory pH meter. Biochar pH is known to be neutral to basic.

Functional Group Analysis

Qualitatively, Fourier transform infrared spectroscopy (FTIR) is frequently used to detect functional groups in biochar samples. The information is helpful in comparing biochar samples produced under different conditions. Some of the selective stretching group frequencies of biochar samples in IR spectra include O-H (3,400 cm^{-1}), aliphatic C-H (3,000–2,860 cm^{-1}), aromatic C-H (3,060 cm^{-1}), and the carbonyl (C = O) (1,700 cm^{-1}) functionalities.

Proximate Analysis

Proximate analysis of biochar includes parameters like volatile organic compounds (VOCs), moisture content, ash content, and fixed carbon. Biochar VOCs are formed during pyrolysis by breakdown or rearrangement of chemical structures present in biomass feedstock. Biochar VOCs have greater impact on plant and microbial responses to biochar amendments because they are known to inhibit/stimulate microbial and plant processes (Baldwin et al. 2006; Klinke et al. 2004). Analyzing VOC content in biochar prior to soil amendment may avoid adverse agronomic effects. Analytical methods such as pyrolysis-gas chromatography/mass spectrometry (pyr-GC/MS) methods have been developed for VOC analysis in biochar samples (Clough et al. 2010; Galipo et al. 1998; Spokas et al. 2011). Thermogravimetric analysis (TGA) has been used routinely to determine the moisture content,

volatiles, percentage of fixed carbon, and ash content in biochar samples (Garcia et al. 2013; Kim et al. 2010; Kim and Agblevor 2007; Ottaway 1982; Slaghuis and Raijmakers 2004).

Surface Property Characterization

The surface area characteristic is expressed in the extent of porosity of the biochar which in turn depends on the cell structure of the starting materials. The best-known and most commonly used method for evaluating specific surface areas of biochar materials is the Brunauer-Emmett-Teller (BET) nitrogen physisorption method. For example, if feedstock has larger pore sizes, it can yield biochar with larger surface area resulting in greater nutrient retention properties. These larger pores can also enhance microbial activity (Warnock et al. 2007). In addition, scanning electron microscopy (SEM) has been used for studying the morphology of biochar materials. SEM analysis helps in obtaining details about pore structure and their distribution among the biochar produced under different pyrolysis conditions and from different biomass sources (Fang et al. 2013; Özçimen and Karaosmanoğlu 2004; Shaaban et al. 2013). Figure 5 shows SEM images of biochar produced from wood sources (Fig. 5a), sugarcane bagasse (Fig. 5b), and goat droppings (Fig. 5c) and pyrolyzed at 550 °C. Different physical microstructural property is represented in these images. The macroporous structures in wood derived biochar are arranged in an array of parallel domains, whereas that for the sugarcane bagasse is expressed in a radial distribution. Biochar from goat dropping may only be microporous.

Other analytical instruments used to determine biochar properties include X–ray photoelectron spectroscopy (XPS), energy dispersive X-ray spectroscopy (EDX), near-edge X-ray absorption fine structure (NEXAFS) spectroscopy, nuclear magnetic resonance (NMR) spectroscopy, gas chromatography/mass spectrometry (GC/MS), and total organic carbon (TOC) analyzer (Chintala et al. 2012; Fernandes and Brooks 2003; Keiluweit et al. 2010; Lee et al. 2010; Moon et al. 2013; Srinivasan and Sarmah 2014). Studies on characterization of biochar properties have been respired in the literature (Abdel-Fattah et al. 2014 ; Ahmad et al. 2014; Brewer et al. 2014; Chia et al. 2014; Hmid et al. 2014; Jindo et al. 2012; Liu et al. 2014; Mimmo et al. 2014; Novak et al. 2009; Pujol et al. 2013; Rajkovich et al. 2012; Shaaban et al. 2013; Stanger et al. 2013; Zhao et al. 2013b). Overall, detailed characterization of biochar samples provides valuable information useful in understanding the environmental and agronomic efficacy of biochar samples in depth.

Biochar Benefits: Carbon Sequestration

For the past few decades, CO_2 emissions in the atmosphere have been increasing significantly each year. It has been estimated that each year approximately 2 Gt of carbon is set free as CO_2 in response to deforestation and degradation of soils.

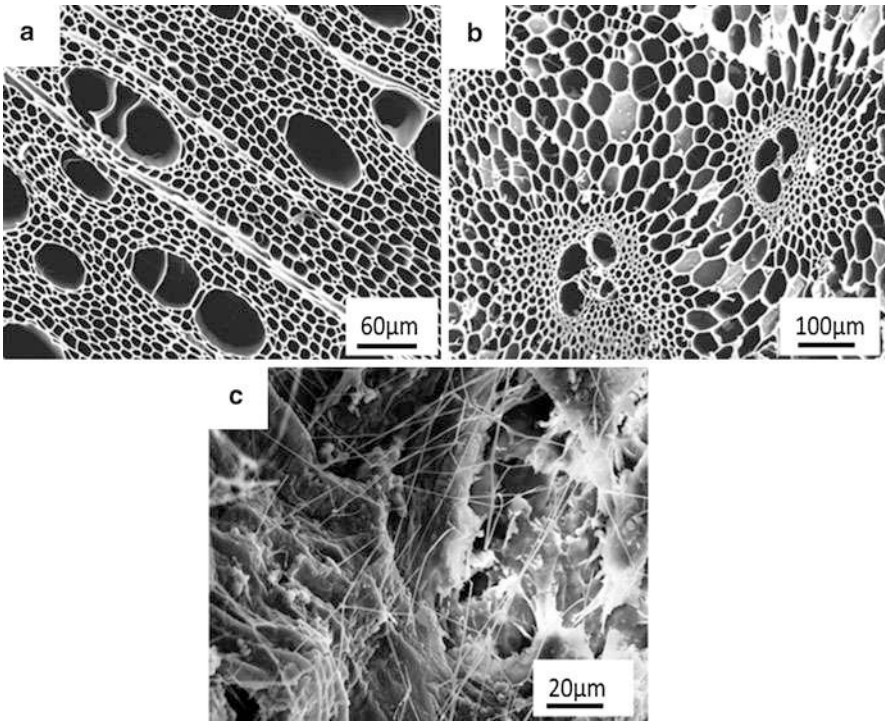

Fig. 5 Scanning electron microscope (SEM) images showing macroporosity of a wood-derived (**a**), sugarcane bagasse (**b**), and goat dropping (**c**) biochar produced by slow pyrolysis: The biochar samples were gold coated and imaged with beam energy of 20 kV on a Zeiss EVO 50VP SEM

The US Department of Energy (USDOE) has estimated that by 2020 the global, annual net production of CO_2 will be 33.8 billion metric tons (USDOE 2010). Energy sources, fires, deforestation, and soil degradation activities have been contributing to increasing the levels of CO_2 emissions into the atmosphere. Since CO_2 is the foremost greenhouse gas (GHG), its enrichment in the atmosphere triggers an increase in atmospheric temperature and ultimately results in global climate change. Researchers have been looking for potential strategies to mitigate climate change by either reducing greenhouse gas emissions or by carbon sequestration, e.g., in aboveground soils. In the past, the Intergovernmental Panel on Climate Change (IPCC) has listed several climate change mitigation options: (1) carbon capture and storage, (2) energy efficiency, (3) switch to low-carbon fuels, (4) nuclear power, (5) renewable energy, (6) enhancement of biological sinks, and (7) reduction of non-CO_2 greenhouse gas emissions (IPCC 2005). Among these options enhancing biological sinks and carbon capture and storage can balance CO_2 in the atmosphere. But again carbon capture and storage concept is associated with high energy consumption generating additional emissions associated with carbon capture. However, the other mitigation approaches are only

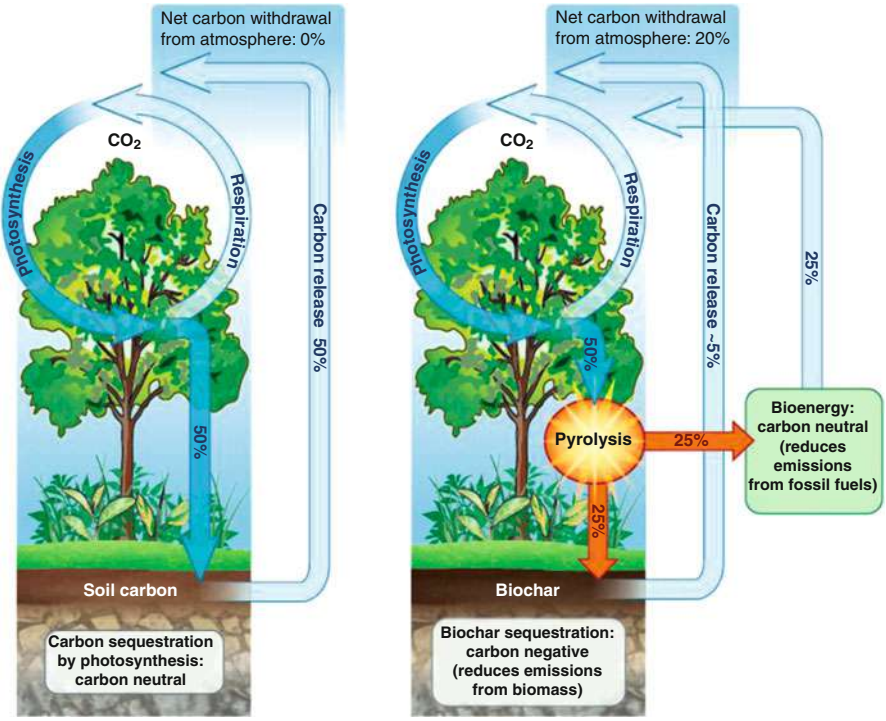

Fig. 6 Illustration of normal and biochar-based carbon cycles (Lehmann 2007) (Copyright © 2007 Nature Publishing Group)

preventive or controlling measures. The carbon cycle function in natural and biochar-based scenarios is shown in Fig. 6. In the case of normal cycle, plants absorb atmospheric carbon dioxide as part of the biological carbon cycle but they are inadequate to handle huge amounts of carbon dioxide released in the atmosphere. So the net carbon withdrawal by the natural carbon cycle from the atmosphere is zero. In addition, plants decay and this biomass releases captured carbon dioxide into the atmosphere. If this biomass is converted into biochar and used to amend soil, the net carbon withdrawal from the atmosphere is 20 % as shown in Fig. 6. Additionally, biochar-based carbon cycle can reduce emissions by 12–84 % and offers the opportunity to convert bio-energy into a carbon-negative strategy (Lehmann 2007).

During the biomass pyrolysis, bio-oil, biochar, and syngas are the three main products. These products can influence the global carbon cycle in the following ways. All the main products obtained during pyrolysis can be used as energy sources which can reduce fossil energy use. In general, biomass decomposition can release a significant amount of carbon dioxide into the atmosphere. By pyrolyzing the biomass, the biochar with enriched stable carbon is produced and will remove carbon

dioxide from the atmosphere that would otherwise be released into the atmosphere through bacterial decomposition in the soil. This biochar added into soil becomes a carbon sink and long-term carbon storage.

Biochar carbon sequestration is fundamentally different from other forms of carbon sequestration. It refers to the capture and subsequent storage of carbon to prevent it from being released into the atmosphere (Duku et al. 2011). The primary effect of biochar production on greenhouse gas fluxes is the avoidance of emissions that would have occurred had the biomass been left to decompose. For example, biochar from herbaceous and woody feedstock sources is found to have a carbon content of 60.5–66.7 % and 74.5–80 %, respectively. One can assume from these figures that for every ton of biochar applied to the soil, 0.61–0.80 t of carbon (equivalent to 2.2–2.93 t of CO_2) can be sequestered (Galinato et al. 2011). Using the highest carbon content of the wood-based biochar (i.e., 80 %) and the CO_2 offset price range of $1 to $31/MT CO_2 (West and McBride 2005), the approximate value of biochar carbon sequestration is $2.93–$90.83/MT biochar. Biochar carbon sequestration might avoid difficulties such as accurate monitoring of soil carbon due to spatial and temporal variation which are the main barriers to inclusion of agricultural soil management in emissions trading. Using the turnover rate and the quantity of carbon has been suggested as a method to be used in assessment of the carbon sequestration potential and that could be done independently from biochar use as soil amendment or other non-fuel purposes.

Biochar Benefits: Soil Amendment

Since biochar is produced from waste biomass such as crop residues, manures, timber and forestry residues, and green waste, its use as a soil amendment has been suggested as a sustainable approach in achieving soil fertility and enhanced crop productivity along with other environmental benefits (Chan et al. 2007). In the past, highly fertile carbon-rich terra preta soils in Central Amazonia are widely cited as evidence that charcoal addition to soils brings benefits to the soils (Lehmann 2003). Due to the increasing recognition for the potential of the terra preta as a model for modern agriculture, the use of biomass-derived biochar has raised a lot of research and development interests (Lehmann 2003; Lehmann et al. 2009). Biochar soil amendment becomes a practice to improve soil fertility and crop productivity while maintaining high levels of soil carbon (Ibrahim et al. 2013; Lehmann et al. 2011). Biomass-derived biochar has been proposed as a potential strategy to enhance soil fertility and crop productivity that can boost food security. Studies have shown that the application of biochar to soil enhances soil fertility by increasing the soil cation-exchange and water retention capacities as well as microbial activity, thereby improving agricultural productivity (Lehmann 2007; Lehmann and Rondon 2006).

Enhanced Soil Fertility and Crop Productivity

Effect of Biochar pH and Surface Properties on Nutrient Availability and Cation-Exchange Capacity (CEC)

Once biochar was amended into soil, it exists as soil aggregates rather than free organic matter, thus making up the overall structure of the soil (Liang et al. 2008). According to Sohi, the soil texture and chemistry can be modified based on biochar's pH and surface properties (Sohi 2012). Also, the chemically active biochar surface properties change soil nutrient dynamics and can act as a catalyst for soil functions. A statistical meta-analysis undertaken by Jeffery et al. (2011) to evaluate the relationship between the application of biochar and crop productivity showed an overall small, but statistically significant benefit of biochar application to soils on crop productivity. Even though the grand mean increase is 10 %, the mean results for each analysis performed within the meta-analysis covered a wide range (from −28 % to 39 %) with the greatest (positive) effects with regard to soil analyses being observed in acidic (14 %) and neutral pH soils (13 %) and in soils with a coarse (10 %) or medium texture (13 %). This observation suggests that two of the main mechanisms for yield increase may be a liming effect and an improved water holding capacity of the soil, along with improved crop nutrient availability (Jeffery et al. 2011). Generally, biochar pH values are neutral to basic ranging from pH 6.2 to 9.6 (Chan and Xu 2009). Effects of biochar on soil chemistry appear to arise from modification of soil pH. In the case of acidic soil, there is a reduction in cation-exchange capacity (CEC) and nutrient availability observed with lower pH values. In addition to the nature of the feedstock, a significant importance to biochar properties is the temperature of production. The production temperature influences properties such as the biochar surface chemical characteristics (pH), bulk surface area, and carbon content. Although it has been argued that other factors such as soil type, soil chemistry, organic matter content, and climate may be of greater importance to the agricultural impact of biochar incorporation, the importance of production temperature cannot be overlooked (Mukome et al. 2013). Typically, there is little or no cation-exchange capacity of soil organic matter at very low pH, but this increases with higher pH, and biochar is no exception. However, the point at which the CEC (cation-exchange capacity) of biochar is zero (point of zero charge, pzc) is dependent on the production temperature. It is seen from Fig. 7 that both pH and surface area of biochar appear to increase with production temperature, as carbon yield decreases and so the optimum temperature is probably within the range of 450–550 °C.

CEC is a measure of the surface charge in a soil or a biochar and refers to the ability of a soil/biochar to hold onto nutrients. The benefits for soil work both ways as it will absorb nutrients and prevent leaching yet release the nutrients when required by plants. The level of CEC of biochar gives an indication of the abundance of negatively charged sites on the biochar which can retain exchangeable cations that are essential plant macronutrients, e.g., NH_4^+ and Ca^{2+} (Carrier et al. 2012). For example, Lehmann (2003) demonstrated that biochar reduced leaching of NH_4^+, maintaining it in the surface soil where it is available for plant uptake. The production of a partially oxygenated biochar that possesses enhanced cation-exchanging

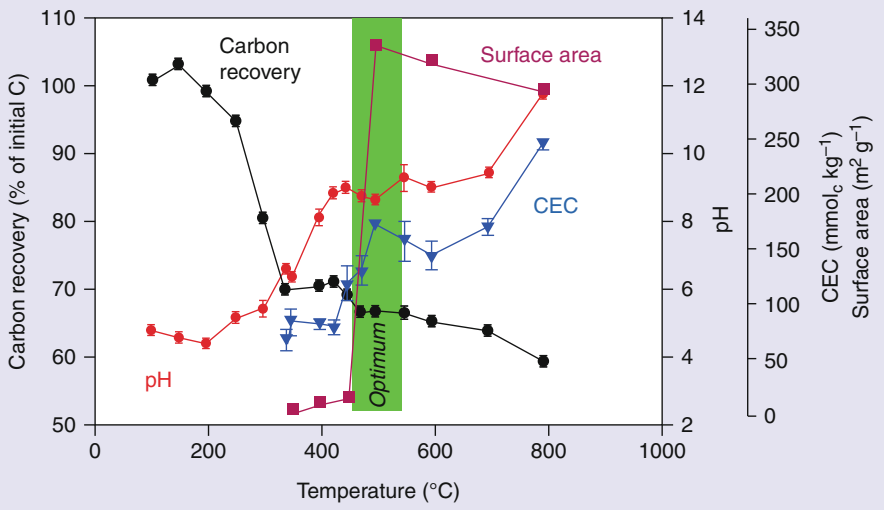

Fig. 7 The impact of temperature on biochar properties. Temperature effects on carbon recovery, cation-exchange capacity (measured at pH 7), pH, and surface area are shown here (Lehmann 2007) (Copyright © 2007 Ecological Society of America)

property by reaction of the biochar source with oxygenating compounds such that the biochar homogeneously acquires oxygen-containing cation-exchanging groups has been reported with oxygenated biochar possessing CEC of at least 140 mmol/kg (Lee et al. 2011, 2013). This concept is based on the experimental finding that the O:C atomic ratio in biochar material correlates with its cation-exchange capacity. Along with aging, the CEC capability increases as evidenced in the terra preta soils of the Amazon (Glaser et al. 2002). Charges on the high surface area can increase cation-exchange capacity (CEC), thereby increasing a soil's ability to retain and supply nutrients. It is well known that both organic and mineral fractions of soil contribute to cation-exchange capacity. The cation-exchange capacity controls the flush of ammonium ions after fertilizer application and mineralization of soil organic matter. This mineralization of organic matter helps in mitigating loss of nitrate leaching. Ash content, phosphorus, potassium and other trace elements present in biochar may impact on crop growth (Steiner et al. 2007).

It is important to note that even though the CEC of biochar is hampered at the pzc, the biochar surface is still available for sorption interactions with other chemical species through hydrogen bonding. For example, the hydrophobic surface of wood-derived biochar has been demonstrated to enhance perchlorate adsorption via H-bonding to oxygen containing groups on the biochar surface (Fang et al. 2013). The principle is illustrated in the schematic in Fig. 8. The totally hydrophilic aliphatic biomass surface (which is unreceptive to ClO_4^- anion) when subjected to pyrolysis and transformed into biochar acquires an aromatic hydrophobic nature. The newly created hydrophobic surface interacts through H-bonding with the ClO_4^- anion. Fang et al. (2013) suggested that it is possible to tune the sorption properties

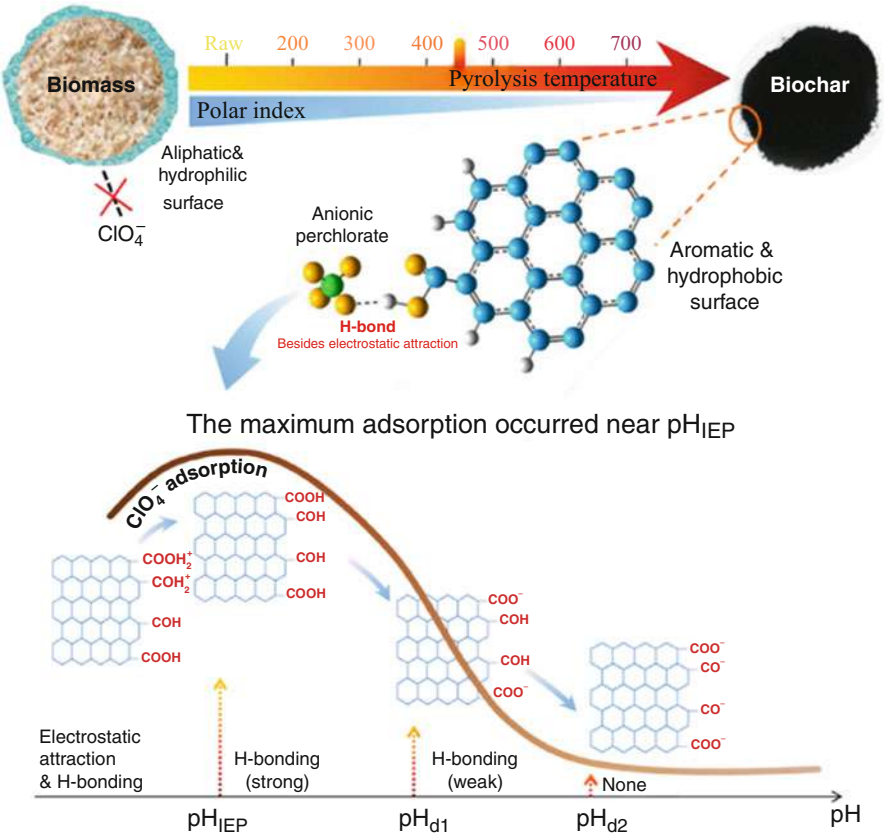

Fig. 8 The schematic of pH-dependent perchlorate (ClO_4^-) adsorption mechanisms onto high temperature biochar with different structural properties and surface functional groups. The maximum adsorption occurred at the point of zero surface charge (Fang et al. 2013) (Copyright © 2013 American Chemical Society. IEP = isoelectric point; d1 =; d2 =)

of biochar by changing the solution pH and concluded that the maximum adsorption interaction occurs at the point of zero charge. The surface area of biochar has a significant impact on the magnitude of interactions between biochar and the soil environment. The surface properties of biochar derived from biomass is crucial in understanding water retention, nutrient retention, sorption capability, and microbial activity of biochar (Day et al. 2005; Fernandes and Brooks 2003; Yu et al. 2006).

Habitat for Microbial Activity

Biochar addition to soil has been shown to increase microbial activity as well as microbial efficiency. In fact, enhanced microbial activity influences the nutrient availability, moisture retention, and cation-exchange capacity (CEC) and is associated with plant growth. Due to porous nature, biochar has been shown to improve soil microorganism abundance and cause effects on nutrient cycle and soil structure

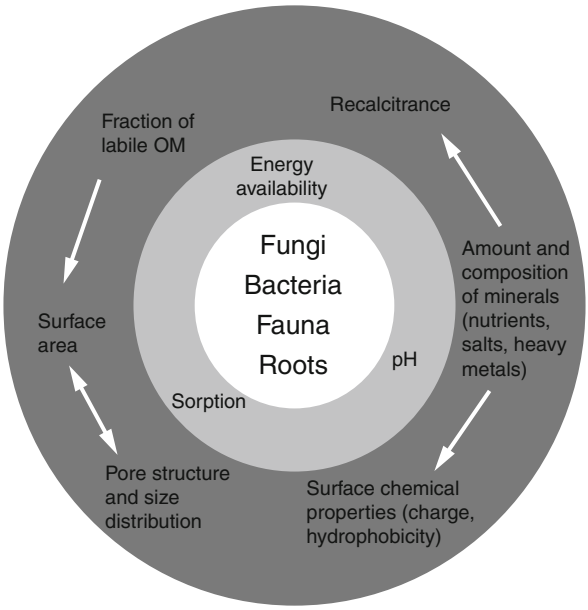

Fig. 9 A schematic overview of correlation between biochar properties and soil microbial community: outer circle represents biochar properties; intermediate circle denotes soil process which influences the microbial community, whereas inner circle shows a qualitative estimation of the strength of the connection. White arrows indicate influence between biochar properties (Lehmann et al. 2011) (Copyright © 2011 Elsevier Ltd. OM =)

that leads to soil growth (Grossman et al. 2010; O'Neill et al. 2009; Pietikäinen et al. 2000; Rutigliano et al. 2014). This scenario has been evidenced further in terra preta soils of the Amazonian Basin (Atkinson et al. 2010). Various biochar properties that influence the soil microbial community and relation between biochar properties and soil microbial community have been documented (Lehmann et al. 2011). The proposed correlation between biochar properties and soil microbial community reported by Lehmann et al. 2011 is illustrated in Fig. 9. Substantial research evidence documenting stimulation of indigenous arbuscular mycorrhizal fungi by biochar has positive impact on plant growth due to increase in nutrient availability, moisture retention, and cation-exchange capacity (Rondon et al. 2007; Warnock et al. 2007). Biochar has demonstrated its function as soil conditioner by making nutrients available to plants and improving soil structure. The surface area and pore structure properties of biochar can increase soil water holding capacity, and the micro-pore spaces with positively charged surfaces can improve soil water retention and in turn reduce nutrient loss through leaching (Lehmann and Joseph 2009; Verheijen et al. 2010). In addition to the chemical stabilization of nutrients, modification of the physical structure of the bulk soil may result in biochar not simply increasing the capacity of soil to retain water, but also nutrients in soil solution. CEC of biochar may be due to leaching of hydrophobic compounds from biochar or by increasing carboxylation of carbon through abiotic oxidation (Cheng et al. 2006).

Mobility and Bioavailability of Heavy Metals

Growing human activities and industrial revolution have resulted in the concentration of metal such as cadmium (Cd), copper (Cu), and lead (Pb) in contaminated

soils. These heavy metals may have negative consequences on agricultural productivity and human health. Thus, in contaminated soils, heavy metals such as Cd, Cu, and Pb and their mobility and bioavailability are of agricultural and environmental concern. Biochar soil amendment has been considered to be an alternative remediation method to not only promote plant growth but also reduce the mobility of metals in contaminated soil (Beesley et al. 2010, 2014; Houben et al. 2013; Uchimiya et al. 2011b). Several studies have demonstrated that biochar soil amendment was successful in retaining these heavy metals in contaminated soils (Clemente et al. 2010; Tang et al. 2013; Uchimiya et al. 2010, 2011a). The presence of various functional groups and the highly porous nature of biochar have demonstrated it to be very effective in the adsorption of heavy metals. The pH of biochar also plays an important role in controlling the mobility of heavy metals. Studies have explained that an increase in pH and CEC affects the metal immobilization process (Beesley et al. 2011; Uchimiya et al. 2011a). Therefore, biochar has been considered a potential amendment for promoting the establishment of a plant cover and phytostabilization strategies on contaminated soils (Beesley et al. 2011).

Pesticide Sorption

Biochar is considered as a universal sorbent. Compared to natural soil, biochar-amended soil has greater sorption ability due to its large surface area and charge density (Liang et al. 2006). Application of biochar as sorbent is a cost-effective approach and has shown strong affinity for organic contaminants (Yang and Sheng 2003; Yu et al. 2010). The usage of pesticides in agricultural practice poses a potential risk of groundwater pollution. These environmental contaminants have been monitored in groundwater. Based on solubility and dissipation behavior in soil, these contaminants may represent elevated risk of leaching. This leaching process is affected by sorption and desorption behaviors in soil. Biochar works as a super sorbent and decreases the leaching potential of these contaminants in soils which further helps to mitigate groundwater contamination (Ahmad et al. 2014; Guo et al. 2006; Loganathan et al. 2009). The mechanism for the sorption characteristic of biochar has been proposed by Ahmad et al. (2014) and the details have been illustrated in Fig. 10.

The large surface area (1,000 m^2/g), micro-, meso-, and macro-porosity, diverse surface and bulk properties of biochar has imparted to it different sorption properties of biochar (Downie et al. 2009). It is unsurprising that the presence of biochar in soil plays an influential role in the sorption properties of soil. The application of biochar to the sorption or removal of organic and inorganic pollutants has been tested using four theoretical isotherm models, namely, Langmuir, Freundlich, Dubinin-Radushkevich, and Temkin models (Zhang et al. 2011). The Langmuir model is described by the following equation:

$$\frac{C_e}{q_e} = \frac{1}{Q_0 K_L} + \left(\frac{1}{Q_0}\right) C_e \tag{1}$$

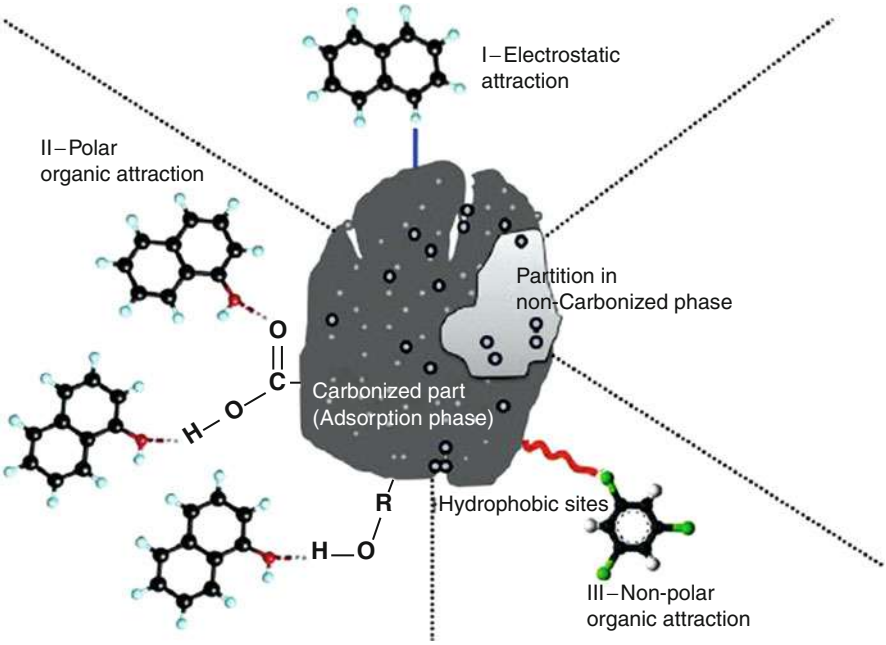

Fig. 10 Biochar interaction with organic contaminants: Electrostatic attraction between biochar and organic contaminant (I), polar organic contaminant (II), and non-polar organic contaminant (III). (Ahmad et al. 2014) (Copyright © 2014 Elsevier Ltd)

where q_e and C_e are, respectively, the amount adsorbed per gram of adsorbent (mg/g) and the solute concentration in solution (mg/l) at equilibrium and Q_0 and K_L are constants related to the maximum adsorption capacity (mg/g) and the intensity of adsorption(l/mg), respectively. An essential characteristic of the Langmuir isotherm is explained in terms of the dimensionless separation factor (R_L) defined by the equation

$$R_L = \frac{1}{1 + K_L C_i} \tag{2}$$

where C_i is the initial concentration.

The Freundlich's model is described by the equation

$$In\, q_e = In\, K_F + \left(\frac{1}{n}\right) In\, C_e \tag{3}$$

where K_F (mg/g) is the adsorption capacity of the adsorbent and n gives an indication of how favorable the adsorption process is.

The Dublin-Radushkevich equation has a linear representation of the form

$$In\ q_e = In\ Q_0 - K_{DR}\ \varepsilon^2 \tag{4}$$

where K_{DR} (mol^2/K^2) is a constant related to the mean adsorption energy and ε is the Polanyi potential which can be calculated from the equation

$$\varepsilon = RT\ In\left(1 + \frac{1}{C_e}\right) \tag{5}$$

A plot of In q_e versus ε^2 gives K_{DR} as the slope and Q_0 and the intercept.

The Temkin equation is also given in a linear form as

$$q_e = B_T\ InK_T + B_T\ InC_e \tag{6}$$

where $B_T = RT/b_T$, the constant b_T is related to the heat of adsorption, and K_T is the equilibrium binding constant corresponding to the maximum binding energy.

The Langmuir and Freundlich models have been most commonly used to describe adsorption isotherms. These adsorption isotherms describe the relation between the adsorbate loading on the adsorbent (Q_e) and the liquid-phase concentration of the adsorbate (C_e) at equilibrium conditions. The Langmuir model corresponds to the homogeneous monolayer adsorption, whereas the Freundlich model defines the adsorption onto adsorbents with heterogeneous surface (Yang et al. 2014). Additionally, the dynamics of an adsorption process in terms of the order and the rate constants has been evaluated using the pseudo-second-order kinetic equation given as

$$\frac{t}{Q_t} = \frac{1}{K_2 Q_{\max}^2} + \frac{1}{Q_{\max}} t \tag{7}$$

$$Q_t = K_w\ t^{1/2} + I\ (\text{Weber} - \text{Morris model}) \tag{8}$$

where $Q_{\max}$ and Q_t are the adsorption capacities (mg/g) at the equilibrium and at time t, respectively; K_2 and K_w are the constants of pseudo-second-order and the Weber-Morris model, respectively; and I is the intercept (Yang et al. 2013, 2014). The units of K_2 and K_w are g/(mg. min) and (mg/g).$min^{-1(½)}$, respectively.

Altering Nitrous Oxide (N_2O) Emissions

Global nitrous oxide (N_2O) emissions mainly originate from soil due to the extensive use of nitrogen (N) fertilizers in agriculture. N_2O is one of the potent greenhouse gases (GHG) released into the atmosphere from both natural (about 60 %) and anthropogenic sources (approximately 40 %), and its atmospheric concentration in 2013 was about 325.9 parts per billion. Its estimated impact on climate is 298 times greater than equal emissions of carbon dioxide, over a period of 100 years. Biochar

addition to soils reduces nitrous oxide (N_2O) emissions by slowing down the nitrogen cycle, possibly as results of an increase in the carbon/nitrogen ratio (Ussiri et al. 2009). Further, crop productivity enhancement is possible with biochar amendment with no or minimal fertilizers, which helps in mitigating other greenhouse gas emissions from soil and on indirect emissions. Irrigation costs can be reduced by biochar amendment.

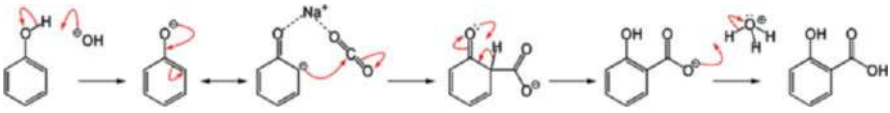
Emerging Applications in Power Generation

Scientific Background

With the goals of developing novel CO_2 capture and utilization technologies, a recent study by Chen et al. (2014) used biochar as a substrate in their study of CO_2 reactions with carbonaceous materials at temperatures below 100 °C. Their study synthesized scientific observations and principles from disparate fields: chemically and photochemically induced CO_2 fixation on carbon, acoustic physics and chemistry, structural characteristics of biochar, and solvent-induced swelling of carbonaceous materials. Each of these strands will be described below. The relevant hypotheses, tests of these hypotheses, and technological implications are discussed in later sections.

Chemically and Photochemically Induced CO_2 Fixation on Carbon

At the outset of their efforts, Chen et al. (2014) sought new CO_2 fixation processes, such as the Kolbe-Schmitt reaction R1 below (Kolbe 1860; Schmitt 1885; Lindsey and Jeskey 1957) that could represent the initial steps for viable CO_2 utilization and capture.



(*R*1)

The reverse reaction of R1, i.e., the desorption of CO_2, has a desorption energy of 24–29 kJ per mole of CO_2 (Dewar et al. 1988; Bonneau-Gubelmann et al. 1996) which is within the range for the CO_2 desorption by amines that has been considered the most viable means of CO_2 capture and desorption. The hydroxyl groups can also be functionalized by amine through a linker such as sulfonic acid. Since the synthesis procedure is designed mainly for CO_2 capture (Brunelli et al. 2012) but not directly for CO_2 utilization or reuse, no detailed discussion is given here.

While reaction R1 might be considered for CO_2 capture, the resultant product is expected to have a lower heating value than the reactant phenol, so the reaction cannot be considered as a major CO_2 recycle route for fuel production. On the other

hand, photochemical or photocatalytic CO_2 fixation, recently reviewed by Kumar et al. (2012) and by Izumi (2013), could add heating value through reductive photocarboxylation, in which the aromatic structures are also reduced by the addition of hydrogen. This was first accomplished by Tazuke et al. (1975, 1986) by Hg-lamp irradiation of a solution of an aromatic hydrocarbon and CO_2 in the presence of an electron donor (*N*,*N*-dimethylaniline, DMA) and a hydrogen atom donor (dimethylformamide, DMF). Instead of using a liquid solvent, Chateauneuf et al. (2002) used supercritical CO_2 in their reductive photocarboxylations. The reaction equilibrium favors carboxylated product under high CO_2 pressure. Nearly complete conversion of anthracene was observed at 35 °C and 2,000 psi, with DMA as the electron donor and 2-propanol as the hydrogen atom donor. About 57 % of the product was dihydrocarboxylic acid. This carboxylation reaction can be stated as

$$\begin{aligned} \mathrm{PAH} + \mathrm{h}\nu \rightarrow \mathrm{PAH}^{*} + \mathrm{DMA} \rightarrow \mathrm{PAH}^{\bullet -} + \mathrm{CO_2} \\ \rightarrow \mathrm{PAH}^{\bullet} - \mathrm{CO_2}^{-} + \mathrm{iPrOH} \rightarrow \mathrm{H-PAH-CO_2}^{-} \end{aligned} \qquad \text{(R2)}$$

The key to the remarkably high conversion of anthracene rests on the role of the electron donor in forming the reaction intermediate $PAH^{\bullet -}$, a charged free radical, by electron transfer to the photochemically excited PAH*.

The thermal carboxylation of phenolic PAHs R1 and reductive photochemical carboxylation R2 of PAHs promoted the authors' interests in fixing CO_2 on naturally available carbonaceous materials. These CO_2 fixation reactions could serve as a major step for CO_2 capture and CO_2 utilization. Due to the reductive nature of the photochemical R2, the resultant product should have higher heating value than the reactant PAH, and thus the CO_2 is recycled to an energy source in a cradle-to-cradle carbon cycle. The process would be most attractive if the carbonaceous material were a renewable biomass, as will be described below.

Sonochemical and Sonophysical Effects

Acoustic cavitation consists of at least three distinct, successive stages: nucleation, bubble growth, and implosive collapse (Ince et al. 2001). During the collapse stage, the energy released is so extreme that trapped gases undergo molecular fragmentation, which is the underlying phenomenon in homogeneous sonochemistry. This collapse is accompanied by the emission of light, or sonoluminescence (SL) (Suslick and Flannigan 2008). Spectroscopic analyses of SL reveal that the temperature and pressure can reach 20,000 K and several thousand bar, respectively (Suslick and Flannigan 2008). Water splits during the bubble-collapse stage, and the formation of oxygen, hydroxyl, and peroxyl radicals is attractive for oxidizing organic waste in water and for the oxidative desulfurization of fuels (Mason 1990). Strongly reducing protons also form during water splitting.

Sonication has been widely adopted to enhance mixing and reduce mass transfer limitations in liquid/solid interactions. Ultrasound is also capable of leaching fine minerals such as K, Na, S, Cl, P, Mg, Ca, Fe, and Al, from porous carbonaceous materials (Ahmed et al. 2004). As a result of mineral leaching, the internal surface

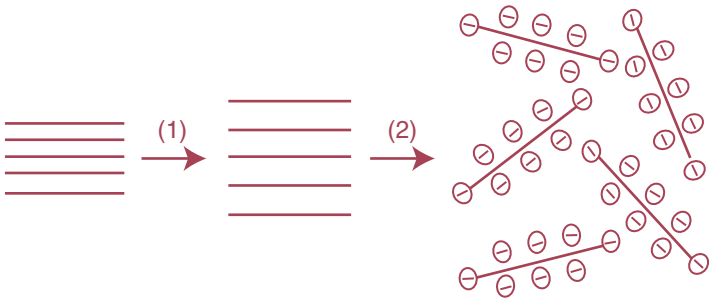


Fig. 11 Graphite can be oxidized to graphite oxide (Step 1), which can be exfoliated into single-layer platelets of graphene oxide (GO) by ultrasound (Step 2)

area of carbon increases, which, in turn, creates higher heating value and higher rates of fluid-surface reactions such as gasification, thus improving the efficiency of the carbon fuel.

Graphite can be oxidized to graphite oxide, producing intercalated hydroxyl and epoxide groups and a disrupted sp^2-bonded carbon network. Stankovich et al. (2006) demonstrated that graphite oxide in phenyl isocyanate is completely exfoliated by ultrasound (150 W) for 1 h, producing single-layer graphene oxide (GO); see Fig. 11. GO platelets are expected to be more reactive than graphitic oxide clusters due to the higher contact area in GO, a feature that will be discussed below. The interests in conducting ultrasound treatment on biochar (see below) were to induce positive benefits on the heating value of the biochar by inducing exfoliation of its graphite oxide, along with mineral removal and water splitting.

Structural Characteristics of Biochar

Chen et al. (2014) chose biochar (Fig. 12) for their ultrasonic and photocatalytic treatments for several structural reasons.

First, biomass-derived (Hammes and Schmidt 2009) and coal-derived (Franklin 1951) chars and petroleum coke (Yen et al. 1961) contain stacks of graphite oxide clusters with reactive carbon edges which could serve as binding sites for CO_2. Ultrasound-exfoliated GO will be even more reactive than the raw char. Second, biochar is more porous than coal-derived char and petroleum coke and is expected to have a higher rate of fluid/solid reactions. Third, the acidic ions of dissolved CO_2 in water can enhance the dissolution of metal ions in the biochar. Fourth, TiO_2 in char is a known semiconductor; it could serve as an electron donor in photocatalytic reductive fixation of aromatics and CO_2, while H_2O can serve as the desired hydrogen donor. Biochar is thus an attractive, renewable carbonaceous material to investigate the treatments proposed.

Solvent-Induced Swelling of Carbonaceous Materials

It has been demonstrated that coal, biomass, and coal-derived chars can be swelled by solvents, including CO_2 and H_2O, after breakage of the cross-links in their macromolecular structure (Gathitu et al. 2009; Mirzaeian and Hall 2006, 2007).

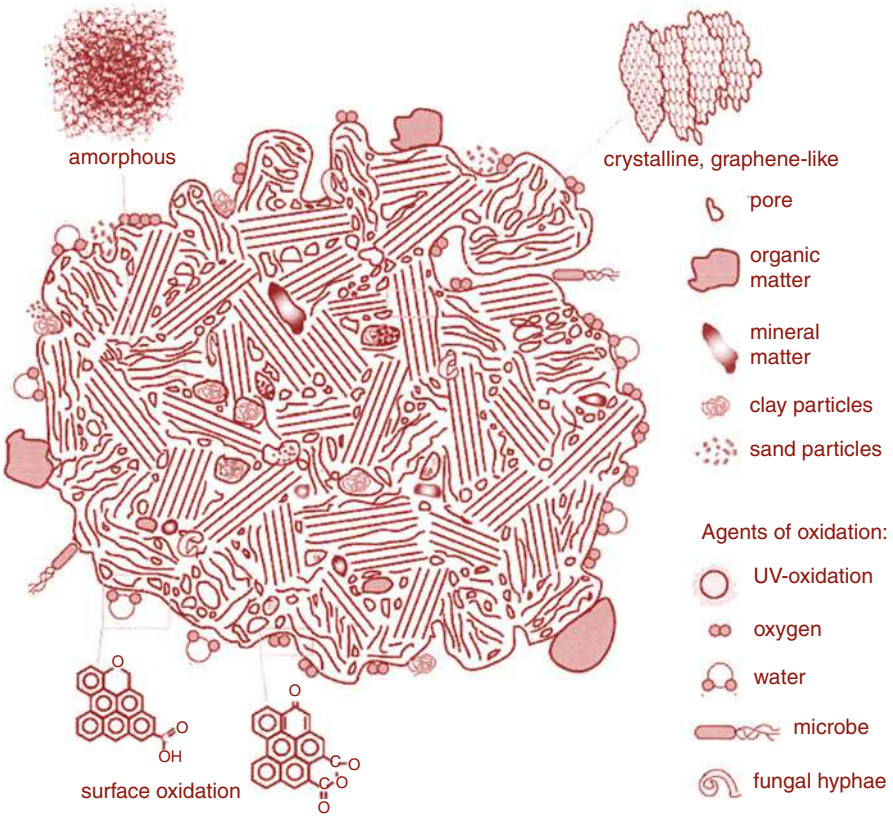

Fig. 12 Graphite oxide clusters form the backbone of the biochar structure (Hammes and Schmidt 2009)

Hydrogen bonds, especially those contributed by hydroxyl and carboxyl groups, have been considered by many as the major cross-links between aromatic clusters (Larsen and Gurevich 1996). The swelled carbonaceous materials have higher porosity and, therefore, higher gas/solid reactivity in processes such as gasification (Wall et al. 2002), which suggests the potential benefits of treating carbon with CO_2 and H_2O (see Fig. 13).

Tested Hypotheses and Technological Implications

Hypotheses

Consideration of the acoustic and photochemical interactions of CO_2 with PAHs as discussed above led Chen et al. (2014) to a set of hypotheses. To start with, they hypothesized that in a single reactor of biochar with CO_2 and H_2O, ultrasound would simultaneously induce the following synergistic chemical and physical processes:

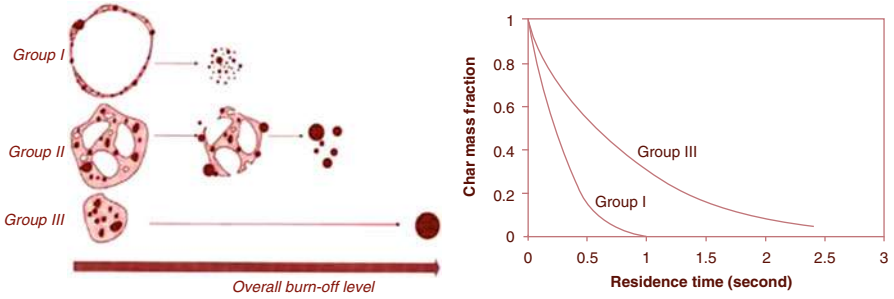

Fig. 13 Porous carbons (Group I particles) possess a higher gasification rate than non-porous carbons (Group III particles) (Wall et al. 2002) (Copyright © 2002 Elsevier Science Ltd)

graphite oxide exfoliation, water splitting, leaching of minerals, carboxylation, hydrogenation, and swelling. As a result, the treated biochar would have a higher heating value, higher reaction rates, and fewer operational and maintenance problems in the subsequent power-generation processes. Moreover, any CO_2 fixed reductively on biochar could be recycled in power/heat generation, thus creating a cradle-to-cradle carbon cycle.

Secondly, Chen et al. (2014) hypothesized that in a single contactor of biochar with CO_2 and H_2O and suitable donors, solar irradiation would induce the following synergistic chemical and physical processes simultaneously: carboxylation, hydrogenation, water splitting, and swelling. As a result, the treated biochar would have a higher heating value and higher reaction rates.

Results of Hypothesis Testing

Ultrasonic and photocatalytic treatments of a sorghum-derived biochar with CO_2 and H_2O at 60 °C resulted in the following observations (Chen et al. 2014):

- Remarkable increases in heating value (HV) for both treatments: 50 % increase for ultrasonic treatment and 20 % increase for photochemical treatment
- Large increases in internal surface area (up to 16-fold) for both types of treatment
- Significant leaching of minerals (60–98 % of Si, K, and Na) that are detrimental to power generation but beneficial to soil after they are captured in the leachate (water)
- Significant hydrogenation, calculated as 9 % additional hydrogen after ultrasonic treatment and 24 % additional hydrogen after photochemical treatment
- Carbon fixation, calculated as 13 % additional carbon after ultrasonic treatment and 16 % additional carbon after a simultaneous photochemical and ultrasonic treatment
- No significant change in oxygen content of the biochar

Further, Fourier transform infrared (FTIR) spectroscopy suggests that carboxylation occurs during photochemical treatments (Chen et al. 2014). The increase in internal surface area (by N_2-BET) during ultrasound treatment is lower than that

from photochemical treatment, suggesting the possibilities of surrendering mesopore volume by exfoliated GO platelets during ultrasound treatment. The increases in heating value result from the combined processes of carbon fixation, mineral removal, and, in the photochemical treatment, hydrogenation. The observed increases in carbon and hydrogen content are attributable, in part, to carboxylation, water splitting, and hydrogenation; H_2O and CO_2 are the only H and C sources in the treatments. These observations are consistent with their hypotheses, although much work remains to optimize the conditions and elucidate the responsible mechanisms.

Implications for Sustainable Technologies

The results discussed above suggest new paradigms for the following technologies:

- Ultrasonic pretreatment of biochar (or other selected carbon feedstock) prior to gasification for simultaneously increasing thermal efficiency, decreasing CO_2 emissions, and reducing operational issues
- Photochemical pretreatment of biochar (or other selected carbon feedstock) prior to gasification, for increasing hydrogen content
- CO_2 capture by functionalized nanographene oxide (GO), phenolic compounds, and char-derived polycyclic compounds that have not been the focus of a systematic CO_2 capture study

Figure 14 illustrates the major streams and variables in a pretreatment process, ultrasonic or photochemical, before the char is fed into a gasifier and combustor.

Power generation with a pretreatment unit offers several sustainable benefits since it is expected to:

- Have higher thermal efficiency due to the 20–50 % higher heating value of the char
- Have a higher power-generation rate due to the more porous nature (16×) of the char

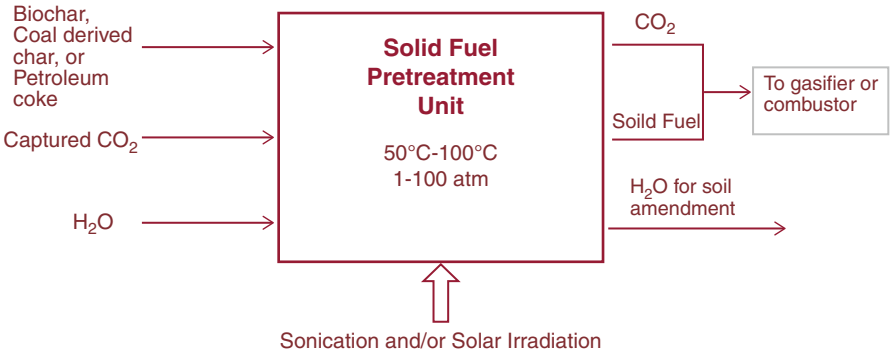

Fig. 14 Streams and variables of a pretreatment process

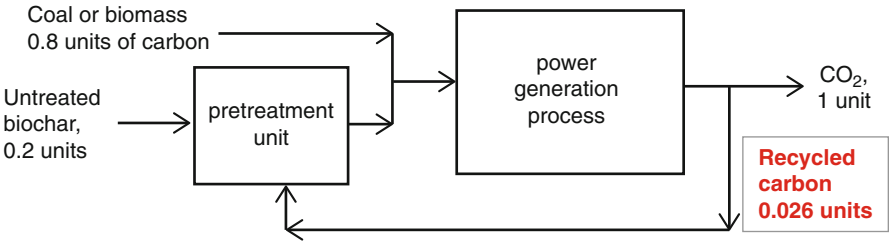

Fig. 15 The ultrasound-treatment unit recycles 2.6 % carbon in the feed, thus creating a cradle-to-cradle carbon cycle

- Exhibit fewer operational and maintenance issues such as fouling and slagging due to the removal of detrimental minerals K, Na, and Si (60–98 %)
- Offer a new CO_2 capture and utilization route since carbon in biochar picks up CO_2 in treatment
- Offer a waste (biochar) utilization route
- Return the soil nutrients, K and Na, in the leachate back into the soil

The benefits of such treatment on thermal efficiency and CO_2 recycling are not merely incremental. Assuming char's heating value increases by 50 % and 20 % of such increase is used by the pretreatment process, the energy output from char combustion will be 1.40 times that of the untreated char. For a co-generation power plant that uses char as only 20 % of its fuel source, with the rest from coal or biomass (see Fig. 15), the overall energy output will increase to 28 % (20 % × 1.40), resulting in a net gain of 8 % in the total output. This would be considered a significant improvement for power plants.

A carbon balance has been conducted for a co-gasification process where 20 % of carbon in the feed comes from biochar based on the 13 % increase in biochar's carbon content during treatment. Figure 15 illustrates the impact of introducing an ultrasonic biochar pretreatment unit on CO_2 emissions prior to biochar's injection into a gasifier. It suggests that the pretreatment unit renders it possible to recycle about 2.6 % of burned carbon fixed in the char. In a co-generation process shown in Fig. 15, the treatment results in 13 % carbon fixation on char and, therefore, 2.6 % carbon recycle – creating a cradle-to-cradle carbon cycle. The scale of this CO_2 uptake is noteworthy. The anthropogenic production of CO_2 is so high that the current total CO_2 utilization does not account for even 1 % of overall CO_2 emissions, and a single technology capable of using 1 % of its CO_2 emissions can be considered a major contribution (Styring et al. 2012).

The efficiency of ultrasound energy output was estimated by using a short treatment time of 3 min, which results in a 19 % increase in heating value (see Fig. 16). The energy consumed by the sonicator during the 3-min treatment was 0.65 kcal/g, which is less than the increase in heating value of the biochar, 0.91 kcal/g, during the 3-min treatment (from 4.83 to 5.74 kcal/g). Although the energy gain (the difference between these two quantities) seems to be limited, it is expected that a

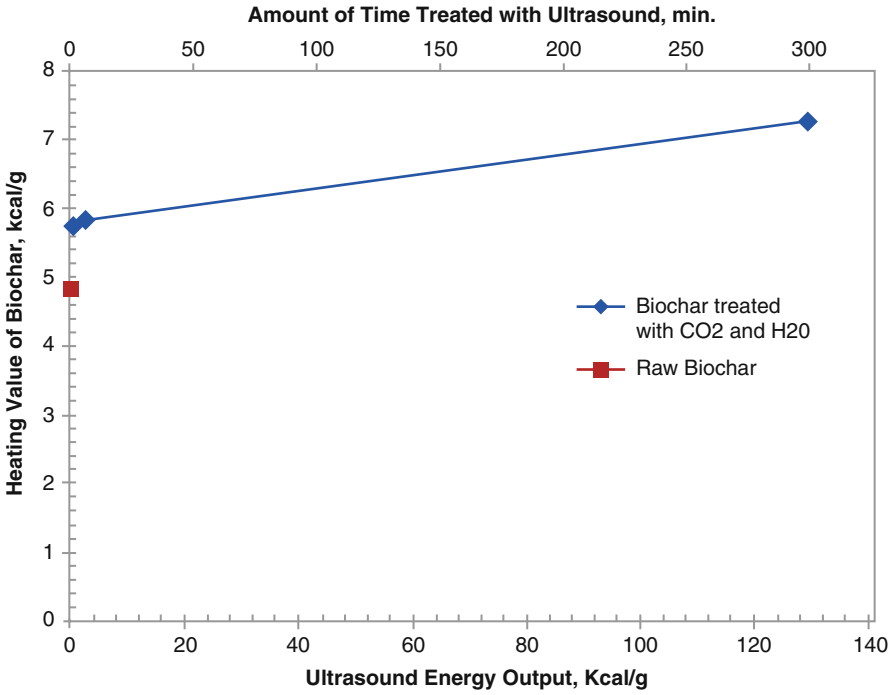

Fig. 16 Ultrasound power increases biochar's heating value. Biochar was treated with (CO_2 + H_2O) and 90-W ultrasound transducer (Chen et al. 2014) (© 2014 American Institute of Chemical Engineers)

majority of the ultrasound energy was dissipated in its surroundings through several modes in the initial apparatus, in which cavitation consumes only a small fraction of the energy. Ultrasound treatment induces energy gain mainly through the loss of mineral content and increases in hydrogen and carbon contents as a result of the treatment. These synergistic physical and chemical processes are believed to be the results of carboxylation, water splitting, hydrogenation, graphite oxide exfoliation, leaching, swelling, etc.

In practice, ultrasonic energy can be used much more efficiently by directly inserting a high-power ultrasonic horn into the solution in the treatment reactor. Thus, the test data indeed support the potential benefits in energy efficiency and the economics of installing a biochar pretreatment reactor prior to gasification or combustion. The pretreatment concept is technically viable. For instance, Mahamuni and Adewuyi (2010) reviewed the costs of various commercial advanced oxidation processes (AOPs) involving similar ultrasound devices for waste-water treatment, containing ideas for further reducing the costs for advanced ultrasound-treatment processes. Pretreatment is also viable because CO_2, H_2O, and residual heat are usually readily available in power plants.

Medical Applications

Biochar has many technological applications even though it is usually considered a by-product in biofuel production. As discussed above, biochar has been adopted in soil amendment and remediation of organic and inorganic contaminants in soil and water. Interests in biochar have intensified in the last decade mainly due to biochar's stability in sequestrating carbon in soil and its use for soil amendments. More recently, Nguyen and Pignatello (2013) evaluated biochar's ability in recovery and containment of marine oil spills. The study of ultrasonic and photochemical interactions of biochar with CO_2 and water (Chen et al. 2014) has provided foundations to explore novel technologies for CO_2 utilization and CO_2 capture.

On a separate front, biochar's medical applications have been scrutinized. We include only a short discussion for completeness since it is not directly related to mitigating climate change. Interestingly, most of these applications were developed with bamboo biochars in China, Japan, and Taiwan where bamboo is widespread. As stated by Zhong et al. (2010), bamboo can be harvested more than 20 times than trees on the same area. It can be harvested annually and regenerated without replanting. It sequestrates up to 12 t of CO_2 per hectare and generates 30 % more oxygen than trees during its growth.

Most of the medical applications of bamboo biochars are based on their abilities to generate far-infrared (FIR) radiations and negative ions (Lou et al. 2007). Bamboo biochar has 15.3–24.1 cmol/kg cation-exchange capacity. Bamboo biochar adsorbs nitrate-nitrogen more effectively than activated carbon (Mizuta et al. 2004). The negative ions generated by bamboo biochar remove the odors and refresh air.

Bamboo char has high electrical conductivity; chemically modified bamboo biochar has been used for developing lithium-sulfur batteries (Gu et al. 2015). Bamboo charcoal can generate a good amount of negatively charged ions that have the property of giving electrons to nearby matters, while charcoal adsorbs positive ions. Bamboo char dissipates electromagnetic (EM) waves emitted by devices such as television, personal computers, cell phones and microwave over, etc., by bouncing them, and the released EM waves can be absorbed by bamboo char due to its high electrical conductivity. The absorbed energy is then dissipated as far-infrared (FIR) emissions. Teraoka et al. (2004) reported that FIR emitted by bamboo biochar at wave lengths between 4 and 16 μm inhibits the growth of Henrietta Lacks (HeLa) cervical cancer cells in vitro at 37 °C. At ambient temperatures, ~25 °C, FIR inhibits tumor growth in mice (Nagasawa et al. 1999; Udagawa et al. 2000; Hamada et al. 2003). Ishibashi et al. (2008) found that the FIR-induced inhibitions of proliferations of cancer cells are controlled by basal expression level of heat shock protein 70A. Moreover, whole-body FIR irradiation at wave length between 7 and 12 μm is believed to improve human health and sleep by keeping the body warm, enhancing the blood circulation, and reducing blood pressure (Honda and Inoue 1988; Inoue and Kabaya 1989; Wang et al. 2006). A number of bamboo char-based food, beauty care, textile, sleepwear and health support products are commercially available.

Conclusions

Pyrolysis process converts biomass organic matter to biochar and increases the recalcitrance of carbon which becomes more resistant to chemical and/or biological decay. Due to its recalcitrant nature, biochar has long-term stability and its soil amendment utilization has been proposed as a way to store carbon in the soil for longer periods than if biomass was left to decay. The physical and chemical properties of biochar support soil health by altering the pH in acidic soils, increasing water retention capacity, and enhancing nutrient availability and microbial activity. Since biochar has high sorption capacity, its agricultural soil amendment will be helpful in reducing leaching of pesticides and pollutants in soil. Much more research is required to establish characterization methods and best management practices for biochar applications in various fields that can help to understand the mechanisms underlying biochar applications for soil amendment and environmental applications. In conclusion, based on the extensive research evidence, it is clear that biochar is indeed a viable soil amendment option for agricultural and environmental purposes worldwide.

Abstract

Electricity is perhaps the most versatile energy carrier in modern economies, and it is therefore fundamentally linked to human and economic development. Electricity growth has outpaced that of any other fuel, leading to ever-increasing shares in the overall mix. This trend is expected to continue throughout the following decades, with large – especially rural – segments of the world population in developing countries climbing the "energy ladder" and becoming connected to power grids (UNDP, World energy assessment: 2004 update. United Nations Development Programme, New York, 2004). Electricity therefore deserves particular attention with regard to its contribution to global greenhouse gas emissions, which is reflected in the ongoing development of low-carbon technologies for power generation. The main purpose of this chapter is to provide a bridge between detailed technical reports and broad resource and economic assessments on wind power. The following aspects of wind energy are covered: the global potential of the wind resource, technical principles of wind energy converters, capacity and load characteristics, life-cycle characteristics, current scale of deployment, contribution to global electricity supply, cost of electricity output, and future technical challenges. Wind power is the second-strongest-growing of renewable electricity technologies, with recent annual growth rates of about 34 %. The technology is mature and simple, and decades of experience exist in a few countries. Due to strong economies of scale, wind turbines have grown to several megawatts per device, and wind farms have now been deployed offshore. The wind energy industry is still small but competitive: 120 GW of installed wind power contributes only about 1.5 % or 260 TWh to global electricity generation at average capacity factors of around 25 % and levelized costs between 3 and 7 US¢/kWh, including additional costs brought about by the variability of the wind resource. The technical potential of wind is larger than current global electricity consumption, but the main barrier to widespread wind power deployment is wind variability, which poses limits to grid integration at penetration rates above 20 %. Life-cycle emissions for wind power alone are among the lowest for all technologies; however, in order to compare wind energy in a systems view, one needs to consider its low capacity credit: adding emissions from fossil-fuel balancing and peaking reserves that are required to maintain overall systems reliability places wind power at about 65 g/kWh. Wind power's contribution to twenty-first-century emission abatement is potentially large at 450–500 Gt CO_2.

Introduction

Electricity[1] is perhaps the most versatile energy carrier in modern economies, and it is therefore fundamentally linked to human and economic development. Electricity growth has outpaced that of any other fuel, leading to ever-increasing shares in the

[1]Responsible for the section on technical principles of wind energy converters

overall mix. This trend is expected to continue throughout the following decades, with large – especially rural – segments of the population in developing countries climbing the "energy ladder" and becoming connected to power grids (UNDP 2004). Electricity therefore deserves particular attention with regard to its contribution to global greenhouse gas emissions, which is reflected in the ongoing development of low-carbon technologies for power generation.

Parts of this chapter are based on a report on the status of electricity-generating technologies (Lenzen and Badcock 2009; Lenzen 2010). That report was commissioned with the objective of providing an up-to-date snapshot of multiple criteria related to electricity generation, but not with the objective to provide a tool or a basis for multi-criteria decision analysis.

Why the need for a new assessment of the state of wind energy, or for that matter, electricity-generating technologies? This work does not aim to replace milestone reports such as the Energy Technology Perspectives (IEA 2008a) or the World Energy Assessment (UNDP 2004). Its main focus is twofold: (a) to provide more technical information than is usually found in global assessments on critical technical aspects, such as variability of wind power, and (b) to capture the most recent findings from the international literature.

The chapter unfolds by presenting an up-to-date summary reviews on the following aspects of wind energy:

1. Global potential of resource
2. Technical principles of wind energy converters
3. Capacity and load characteristics
4. Life-cycle characteristics
5. Current scale of deployment
6. Contribution to global electricity supply
7. Cost of electricity output
8. Future directions

The chapter concludes with a summary.

Global Potential of Resource

In 2008, the global capacity of wind energy converters was 121 GW, generating about 260 TWh of electricity or about 1.5 % of global electricity production (WWEA 2008). Most of the capacity (Fig. 1) is installed in the USA (25 GW) and in the EU (about 65 GW), followed by China (12 GW) and India (10 GW).

Wind energy deployment has been increasing rapidly throughout the past decade, recording growth rates of around 30 % since 1996 (Fig. 2). More than half of the 2008 additions occurred in the USA and in China (Fig. 3), with the USA overtaking Germany as the leader in installed wind capacity.

Measurements from numerous surface and balloon-launch monitoring stations suggest that the global technical potential from onshore wind energy exceeds current

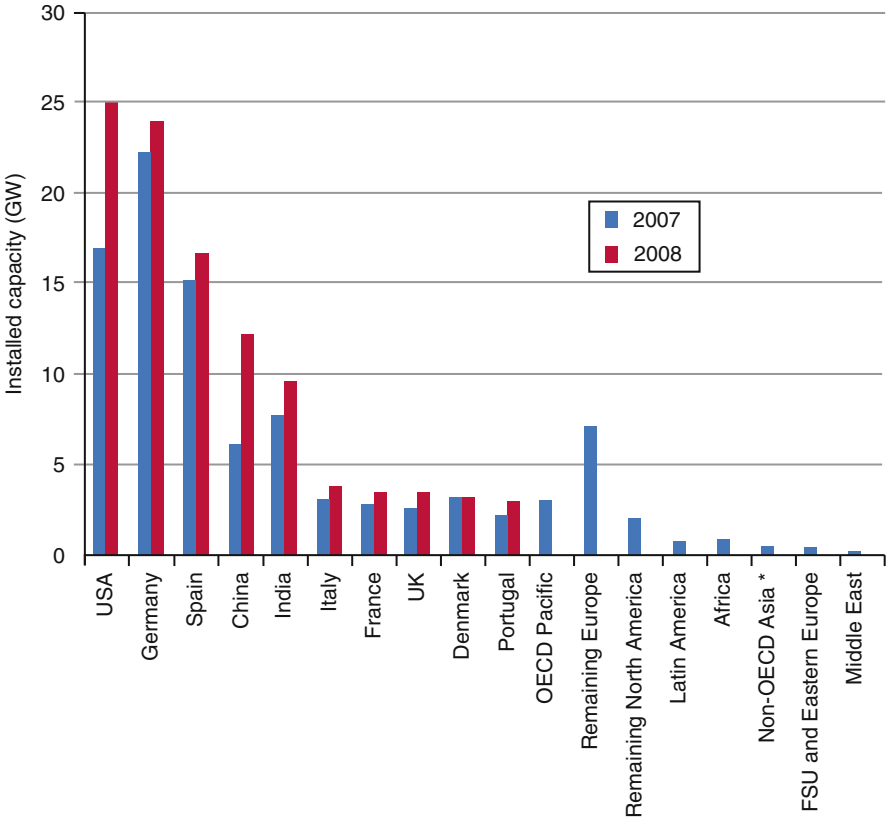

Fig. 1 Installed wind power capacity by region (Compiled from WWEA (2008), GWEC (2008)) (*Asia excludes China and India)

world electricity demand. Using global grid-cell data, Hoogwijk et al. (2004) undertake a detailed assessment of:

1. The theoretical potential (the energy content of global wind).
2. The geographical potential of onshore wind. Hoogwijk et al. assessment excludes land areas with wind speeds below 4 m/s (if the cutoff point had been 6 m/s, areas with current wind turbine installations would have been excluded). It also excludes areas unavailable for turbine installation, such as nature reserves and areas with other functions, and urban areas and high altitudes above 2,000 m with low air density. For further details, Table 1 in Hoogwijk et al. (2004) provides suitability factors, which shows the percentage of a land area available for wind turbine installation.
3. The technical potential (extrapolating wind data to hub height, considering wake effects and realistic power densities in MW/km^2, applying average capacity factors, subtracting downtime).

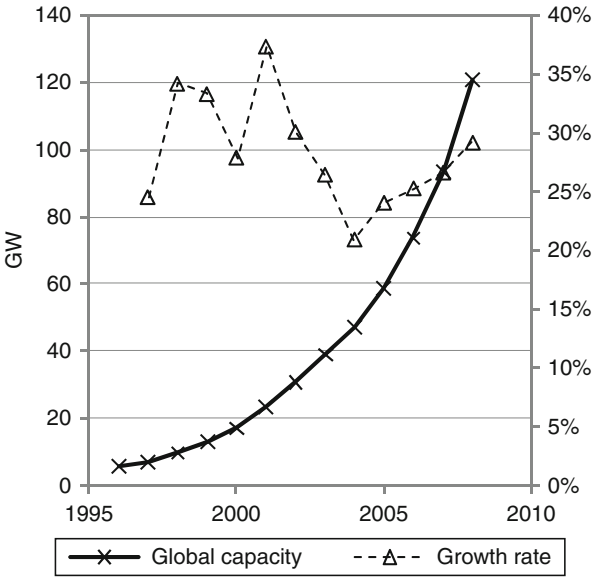

Fig. 2 Historical development of installed wind power capacity and annual growth rates (Compiled from WWEA (2008), GWEC (2008))

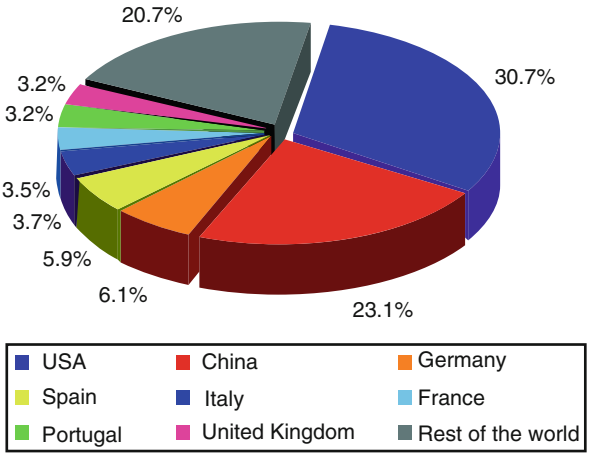

Fig. 3 Regional shares of added capacity in 2008 (After WWEA (2008))

4. The economic potential, given the cost of alternative sources (calculating rated turbine power optimized for grid-cell wind conditions, regressing capital cost and turbine output as a function of rated power and an economies-of-scale factor).

While the theoretical onshore potential exceeds humankind's energy consumption by a few 100-fold, Hoogwijk et al. (2004) estimate the technical potential to be about 100 PWh/year and the economic potential at cost below 7 US¢/kWh to be about 20 PWh/year, both of which still exceed current global electricity consumption. This is consistent with previous studies (Archer and Jacobson (2005) and

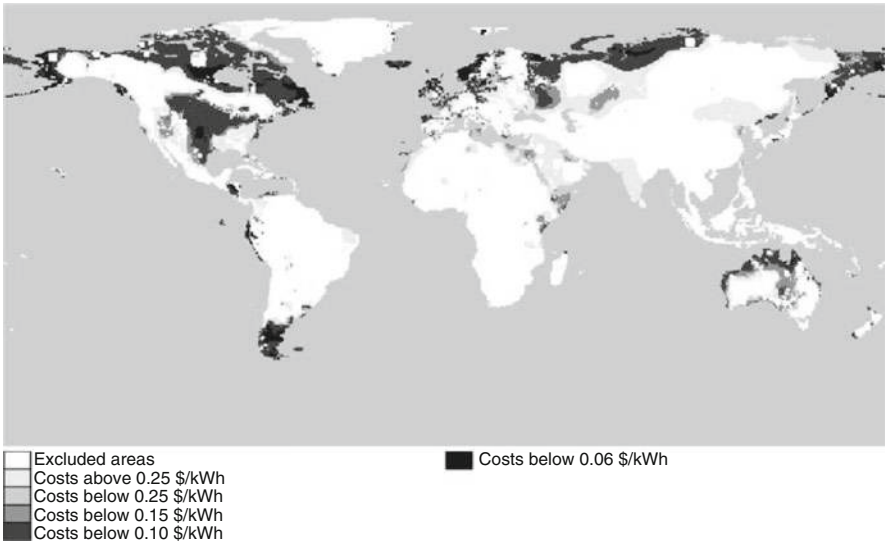

Fig. 4 The economic potential of onshore wind power (After Hoogwijk et al. (2004))

references listed by Hoogwijk et al. (2004) in their Sect. 7.2). However, most of the economic onshore potential – 15 PWh/year – is concentrated in a few remote regions (Fig. 4), namely, the north of Canada (8 PWh/year), Patagonia (4 PWh/year), Siberia (2 PWh/year), and the coastal regions of Australia (1 PWh/year). Only about 5 PWh/year overlaps with regions of significant electricity consumption, the Central USA (3 PWh/year), Western Europe (1 PWh/year), and Central America (1 PWh/year). Relatively small potential is found in Africa, South Asia, and Southeast Asia. The regional technical potentials given by Hoogwijk et al. (2004) are confirmed in studies on the USA (US Department of Energy et al. 2008), India (Carolin Mabel and Fernandez 2008), and China (Changliang and Zhanfeng 2009). Hoogwijk et al. (2004) do not include any grid integration, transmission, and distribution issues in their assessment, which is instead dealt within their later publication (Hoogwijk et al. 2007). The resolution of their global assessment is also such that it cannot account for specific circumstances at the small-region geographical level. In India, for example, the technical potential is further limited by transmission capacity of the grid (Carolin Mabel and Fernandez 2008).

Offshore potential is estimated to be even higher (see Kempton et al. (2007)), but reliable wind data are often lacking (Hoogwijk et al. 2004). Offshore wind power is currently seen as more expensive than onshore wind but at higher penetration rates in the longer term could offer more benefits than onshore because of its more level output and its proximity to large coastal cities (Snyder and Kaiser 2009).

The later assessment of wind by Hoogwijk et al. (2007) takes into account a whole range of effects occurring with increasing penetration, such as output smoothing and increasing interconnection, depletion of the wind resource, requirements of

reliability backup and short-term spinning reserves, and increasingly discarded excess wind energy.

The potential of wind power is hence not limited by the resource potential but instead by how much can be integrated into existing power supply systems without causing major supply and demand imbalances and at acceptable costs (Holttinen 2008). At a given penetration rate, wind power's mitigation potential would depend on future electricity demand. Assuming steady increases in turbine size (from 1.5 MW in 2007 to 2 MW in 2030) and capacity factor (from 25 % in 2007 to 30 % in 2030), the GWEC (2008) projects a moderate growth scenario to lead to 1,400 GW capacity in 2030 (generating 3,500 TWh) and 1,800 GW in 2050 (4,800 TWh). Assuming a 2030 demand of 30 PWh, this scenario is equivalent to an average penetration rate of just over 11 % (compare GWEC (2008, p. 40)). 2050 annual CO_2 mitigation would then amount to about 4.4 Gt CO_2/year. Extrapolating this trend linearly to 2,100 yields a crude estimate of 350 Gt CO_2 total mitigation potential. In addition, the GWEC (2008) reference scenario yields about 1.7 Gt CO_2/year in 2050, or 150 Gt CO_2 until 2100, and the advanced scenario yields about 8.2 Gt CO_2/year in 2050, or 650 Gt CO_2 until 2100. These scenarios are consistent with estimates by the GWEC (2008, pp. 38, 45–46). A long-term global penetration rate of around 20 % is perhaps realistic (compare estimates of 15–20 % in Resch et al. (2008)) given that (a) large economic potential is not available in all world regions and (b) current research indicates substantial difficulties of integrating wind at penetration rates higher than 20 % (Hoogwijk et al. 2007). This corresponds to a total mitigation potential of about 450–500 Gt CO_2. For comparison, Hoogwijk et al. (2007) arrive at potentially avoided CO_2 emissions of 1 Gt CO_2/year, just in OECD Europe and the USA, at carbon prices of around US $30–50/t CO_2. This figure is in the ballpark of the estimate given above.

Technical Principles of Wind Energy Converters

This section discusses modern wind energy conversion systems. However, before setting forth the different types of wind turbines along with their design principles and characteristics, a reminder of the origin of winds, followed by a brief overview of the historical development of wind-powered devices, will first unfold.

Wind power is actually a form of solar power as winds result from solar radiation. Sunbeams entering the atmosphere heat the Earth's surface but not evenly across the surface and over time. Indeed, the equator receives more energy from the sun than the poles and dry land surfaces absorb, retain, and release heat at different rates than the oceans. Consequently, air masses surrounding the Earth's surface warm and cool at different rates. Since hot air masses are lighter than cold ones, they rise and reduce the atmospheric pressure below them drawing in cooler air masses. This creates a global atmospheric convection system that gives birth to winds. Since these air masses are in motion, they have kinetic energy. Wind energy converters capture this kinetic energy and then convert it into a useful form of energy such as electricity or mechanical power.

Sailboats and sailing ships have been using the power of the wind for at least the last 3,000 years. However, the first recorded use of (vertical-axis) windmills to operate irrigational and agricultural projects was in the seventh century BC in the Afghan highlands. The most ancient historical documents pertaining to horizontal-axis windmill technology date from about 1,000 AD and were found in the regions of Persia, Tibet, and China. From there, the technology spread westward to Europe where it was later, at the beginning of the twelfth century, extensively used to grind flour (Ackermann and Söder 2002).

Another seven centuries or so will pass before the first windmill designed for electricity production is built in Scotland in 1887 by Professor James Blyth. Set up in his holiday cottage, his 10-m-high wind turbine charged accumulators engineered by the Frenchman Camille Alphonse Faure to power the lighting of the cottage, thus making it the first residential area in the world to have electricity supplied by wind power (Shackleton 2009). A precursor of modern horizontal-axis wind generators was developed in Yalta, USSR, in 1931. This 100 kW generator mounted atop a 30-m tower was reported to have a capacity factor of 32 %, quite close to current wind machines (Wyatt 1986).

On the eve of the twenty-first century, rising concerns over energy security of supply and global warming paved the way to an expansion of interest in all available forms of renewable energy in general and in wind power in particular. Like this, and boosted in addition by readily available wind resources and economies of scale, worldwide grid-connected wind capacity doubled approximately every 3 years during the 1990s. After the 2003 surge in oil prices due to the geopolitical situation in the Middle East, interest in commercial wind power further expanded.

Modern Wind Energy Conversion Systems

Wind power is the conversion of the kinetic energy of winds into another form of energy, either mechanical or electricity. If the useful form of energy is mechanical (to, for instance, pump water or grind stones), the converter is generally referred to as a windmill. In contrast, if the useful form of energy is electricity, the converter is called a wind turbine or a wind energy converter. In the following section, focus will be on the latter technology, that is, to harness the kinetic energy of wind to produce electricity.

Before examining modern wind energy conversion systems, it is important to bear in mind that only a given fraction of the (kinetic) energy of wind can effectively be harnessed. If all the energy was to be extracted by a wind turbine, the air mass would come to a stop in the intercepting rotor area jamming the cross-sectional area for the following air masses. The theoretical limit of the kinetic energy of the wind that can be harnessed by a hypothetical ideal wind energy extraction machine (referred to as Betz's law and derived by combining the fundamental laws of conservation of mass and energy) is 16/27 (59.3 %).

Wind energy conversion systems can either depend on aerodynamic drag (force acting in a direction opposite to the oncoming flow velocity) or on aerodynamic lift.

Most of modern wind turbines are based on the aerodynamic lift. The resulting force stemming from the blades intercepting the air flow has two components: a (drag force) component in the direction of the flow and a (lift force) component perpendicular to the drag. The lift force is a multiple of the drag force and consequently the main driving power of the rotor, by means of which it produces the necessary driving torque.

The orientation of the spin axis of wind turbines based on aerodynamic lift (lift-type wind turbine) can be either vertical or horizontal. However, horizontal-axis machines are more commonly used for large-scale industrial applications (AWEA 2009).

Horizontal-Axis Wind Turbines

Horizontal-axis wind turbines (HAWTs) consist of a tower atop of which a nacelle containing the rotor, the generator, and an optional gearbox is mounted.

There exist diverse mechanisms to position the nacelle into or out of the wind. Small turbines are pointed by a wind vane, while large ones most of the time use a wind sensor coupled with a servomotor to electrically yaw (align) the nacelle toward or away from the wind depending on the signal sent by the wind sensor.

Since the power in the wind is a cube of the wind speed, the converted mechanical power must always be controlled at high wind speed. This power output control can be achieved by stall control (the blade position remains unchanged but natural turbulences occurring behind the blades in high wind speed reduce the aerodynamic forces and thus the power output), pitch control (the blade angle of attack is reduced at higher wind speed and so are consequently the aerodynamic forces and the power output), or a combination of the two, active stall regulation (the blade angle of attack is fine-tuned to create stall along the blade).

If the wind speed rises above the cutout wind speed threshold (usually varying between 20 and 30 m/s), the turbine is shut off and the rotor is turned out of the wind to avoid potential damage to the primary turbine structure. In so doing, a substantial quantity of energy is wittingly lost. However, equipment capital costs required to strengthen the primary structure to resist wind speeds over the cutout wind speed threshold will likely be larger than the value of the lost energy that could have had otherwise been harvested over the lifetime of the wind turbine.

The number of blades of a horizontal-axis wind turbine depends on its purpose. Turbines designed with two or three blades are usually more suited for electricity generation, while turbines designed with 20 or more blades are generally more suited for mechanical operations (e.g., water pumping).

While most generators are designed to run in the range of 1,200–1,800 rpm (revolutions per minute), large wind turbine rotors most of the time operate at speeds between 10 and 60 rpm. To convert the slow rotational speed of the blades to the higher speeds necessary to drive the electrical generators, gearboxes are therefore used on a majority of large turbines. However, direct mechanical connection (direct drive) can also be achieved with generators designed to run at very low rpm. Such

generators usually consist of many poles (the required rpm of a generator depends on the number of pole pairs) and are very large (large diameter to accommodate the large number of poles) in comparison to generators attached to gearboxes (NREL 2001).

A fixed-speed turbine technology imposes the rotational rate of the turbine to that of the electric grid, whereas a variable-speed turbine technology allows the speed of the rotor to be proportional to the wind speed. In so doing, the former technology forgoes a substantial amount of wind potential, while the latter, in contrast, considerably improves the aerodynamic efficiency in high wind and allows to run at lower speeds so that, everything else being kept equal, a variable-speed technology collects more energy than its fixed-speed counterpart. However, this enhanced energy capture that comes at a high price because of the expensive embedded power electronics and control systems can be economically counterbalanced by fixed-speed wind turbines.

Drawbacks of HAWTs are that the tall towers and blades, up to 90 m long, are difficult to transport and to erect, necessitating tall and expensive cranes and skilled operators. In addition, their imposing structures make them pointedly visible across large areas, disrupting sceneries and landscapes, sometimes leading to local opposition.

In spite of turbulence issues, downwind HAWTs have also been engineered. First, because no additional mechanism for maintaining them aligned with the wind are necessary and second because in high winds, blades can bend, which decreases their swept area and subsequently their wind resistance. However, since turbulences ultimately lead to fatigue failures, horizontal-axis wind turbines are almost exclusively upwind machines.

Vertical-Axis Wind Turbines (VAWT)

The main advantage of this disposition, especially at sites where the wind direction is highly patchy, is that the turbine does not need to be pointed into the wind to be effective. In addition, the generating machinery and gearbox can be placed at ground level, easing maintenance and lowering material requirement.

However, drawbacks are that the driving torque of the rotor varies more noticeably within each turn, the static torque is rather low, and the rotor has to be started up by using the generator as a motor (Sesto and Casale 1998). In addition, it is difficult to erect vertical-axis turbines atop towers. Consequently they are most of the time erected close to the foundations upon which they rest (ground or building rooftop, for instance). It entails that, for a given installed capacity, less wind energy can be harnessed as wind blows slower at lower altitude. In addition, air masses flowing close to the ground are turbulent, potentially producing vibration, and subsequently noise and bearing wear, increasing the maintenance and/or shortening the equipment lifetime (Golding 1997). In contrast, the wind always strikes at a consistent angle the face of a horizontal-axis blade whatever the position in the rotation ensuring a consistent lateral wind loading during a revolution, reducing

vibration and audible noise. Moreover, as opposed to HAWTs, blades, which are fixed to the shaft, cannot be adjusted (pitched), so that power output can be controlled only by aerodynamic stall.

Characteristics of a Wind Turbine

A wind turbine installation is made up of subsystems to harness the energy from the wind (rotor), to point the turbine into the wind (yaw mechanism), and to convert the mechanical rotation into electrical power (generator), as well as subsystems to start, stop, and control the turbine. Horizontal-axis medium to large size grid-connected wind turbines (>100 kW) currently occupy the biggest market share and are expected to principally account for wind deployment in the near future (Ackermann and Söder 2002). This section therefore specifically focuses on their designs that can be divided into three parts (NREL 2006):

- A tower on top of which the nacelle is mounted
- The rotor that includes blades
- The generator that includes an electrical generator, control electronics, and most of the time a gearbox

The Tower

The tower is an important part of a wind turbine primarily because it supports the nacelle and the rotor. The tubular steel tower design is the most widespread technological choice, even though there exist other alternatives like lattice towers or concrete towers. Towers are conical, with their diameter decreasing toward the nacelle, to enhance their strength on the one hand and reduce their material intensity on the other.

In areas with a high surface drag, it is better to erect tall towers since the wind blows faster farther away from the ground. More specifically, wind speed follows in daytime the wind profile power law, which foresees that wind speed rises proportionally to the seventh root of altitude (Peterson and Hennessey 1978). Consequently, doubling the altitude of a turbine theoretically increases the expected wind speeds by 10 % and the expected power by 34 %. However, to avoid buckling, increasing the tower height generally entails enlarging the diameter of the tower as well.

Rotor: Blade Design and Count

Turbine blades, sometimes slightly tilted up, are positioned significantly ahead of the tower and made rigid to prevent them from being shoved into the tower by high winds. Most modern large-scale wind turbine rotor blades are therefore made of

glass fiber-reinforced plastics (e.g., epoxy), which, besides, allows for low rotational inertia and quick accelerations, should gusts of wind occur (variable-speed turbines). In contrast, previous generations of (fixed-speed) wind turbines whose rotational speed is imposed by the AC frequency of the power lines are manufactured with heavier steel blades and therefore higher inertia (Sahin 2004).

The determination of the number of blades depends on the purpose of the wind turbine as aforementioned. Wind turbines for electricity generation usually use either two or three blades even though two-bladed designs are more the exception than the norm for large-scale grid-connected horizontal-axis wind turbines.

The rotor moment of inertia of a three-bladed wind turbine is simpler to comprehend than that of a two-bladed one. In addition, three-bladed wind turbines are often better accepted for their visual aesthetics and are responsible for lower audible noise than their two-bladed counterparts (Thresher and Dodge 1998). Furthermore, during the yawing (alignment) of the nacelle in or out of the wind, a cyclic load is exercised on the root end of every blade and whose magnitude is function of the blade position. Three-bladed turbines see their cyclic load symmetrically balanced when combined at the turbine drivetrain shaft, contributing to smoother maneuvers during yawing.

On the flip side, two-bladed wind turbines, when equipped with a pivoting teetered hub, can also nearly filter out the cyclic loads into the turbine driveshaft and system during yawing. Moreover, the tower top weight is lighter and so consequently is the whole supporting structure, lowering associated costs. In addition, two-bladed turbines can have a higher rotational speed than their three-bladed counterparts. Indeed, the degree of rigidity necessary to avoid hindrance with the tower imposes a lower limit on the thinness of the blades and subsequently (a lower limit) on their mass. However, this is only true for upwind machines as bending of blades enhances tower clearance for downwind ones. Likewise, cheaper gearbox and generator costs can be achieved with two-bladed turbines as faster rotational speeds reduce peak torques in the turbine drivetrain. Lastly, the fewer the number of blades the higher the system reliability is, chiefly through the dynamic loading of the rotor into the tower and turbine drivetrain systems.

Electrical Generator

The energy captured by the blades is subsequently passed onto the generator via a transmission system consisting of a rotor shaft with bearings, brakes, an optional gearbox, as well as a generator.

Whereas the power generation industry resorts almost integrally to synchronous generators because of their variable reactive power production (voltage control), most wind turbines generate electricity through (six-pole induction) asynchronous generators that are directly connected with the electricity grid. However, some designs also use directly driven synchronous generators (Ackermann and Söder 2002).

Electrical generators produce AC (alternating current) power by definition. While the previous generations of (fixed-speed) wind turbines spin at a constant speed governed by the frequency of the grid they are connected onto, new (variable-speed)

ones most of the time rotate at the speed that produces electricity most efficiently being given the actual wind conditions. This can be achieved either using direct AC-to-AC frequency converters (cycloconverters) or using DC current link converters (AC to DC to AC). Although variable-speed turbines require costly power electronics that in addition generate supplementary power loss, a substantially larger fraction of the wind energy can be harnessed by the rotor (NREL 2001).

Control Electronics

Wind conditions being highly variable across sites and over time, a wind turbine is designed to operate over a large range of wind speeds (usually between 12 and 16 m/s). Therefore, to avoid any potential damage to the primary turbine structure during operation in strong winds while ensuring an optimal aerodynamic efficiency of the rotor in light ones, the rotational speed and torque of the rotor must permanently be monitored and controlled. There are several approaches to successfully achieve this (power output) control.

Stall Regulation

This technique requires the rotor to spin at a constant speed (independent of the wind speed). When a wind stream is intercepted in the rotor area, it creates natural turbulences right behind the blades. This is called the stall effect. As a result, aerodynamic forces (induced drag or drag associated with lift) are reduced and so subsequently is the power output of the rotor (Ackermann and Söder 2002).

If the stall effect is a complicated dynamic process to comprehend, stalling is an easy power output control to practically implement as the faster the wind blows, the larger the stall effect is (passive regulation). However, stalling increases the (ordinary) drag by increasing the cross section of the blade facing the wind.

Pitch Control

Pitching the angle of attack of the blades into (respectively out of) the wind increases (respectively reduces) the aerodynamic forces and subsequently the power output of the rotor. One of the main technical challenges associated with designing pitch-controlled wind turbines is getting the blades to furl (to swing out of the wind) swiftly enough in case of a gust of wind. Seemingly, these systems must be able to adjust the pitch of the blades by a fraction of a degree at a time, depending on the wind speed, to control the power output.

The pitching system in medium and large size grid-connected wind turbines is usually based on a hydraulic system, controlled by a computer system. To prevent an eventual hydraulic power failure to furl the blades, pitch regulation systems are also spring-loaded.

By permanently fine-tuning at an optimum angle the rotor blades (even in low-wind conditions), pitch-controlled turbines achieve a better yield at low-wind sites than stall-regulated turbines. In addition, the thrust exercised by the rotor on both the tower and the foundation being significantly lower for pitch-controlled turbines than their stall-regulated counterparts, the primary structure of the former is less material intensive and likely incur lower costs. Moreover, stall-regulated (fixed-pitch) turbines must be shut down when the cutout wind speed threshold is reached, whereas pitch-controlled ones can progressively evolve toward a spinning mode as the rotor operates in a no-load mode at the maximum pitch angle (fully furled turbine).

On the flip side, once the stall effect becomes effective (in high wind conditions), the power oscillations occurring on stall-regulated turbines and stemming from the wind oscillations are smaller than those occurring on pitch-controlled turbines in a corresponding regulated mode (Ackermann and Söder 2002).

Active Stall Regulation

This regulation system is a combination between and a culmination of pitch and stall approaches. It is a combination because, to optimize the aerodynamic efficiency of the rotor and to ensure a torque large enough to create a turning force in light winds, the rotor blades are pitched like in a pitch-controlled wind turbine, whereas after the rated capacity is reached, they are pitched in the opposite direction (than that of a pitch-controlled turbine) in order to increase their angle of attack and install them into a deeper stall.

It is a culmination because active stall regulation achieves a power output control smoother than the jerky one associated with pitch-controlled turbines while still preserving at the same time the advantage of pitch-controlled turbines over stall-regulated ones to turn the blades parallel to the airflow (the so-called low-load feathering position) and subsequently reducing the thrust on the turbine structure (Ackermann and Söder 2002).

Wind Farms

Groups of turbines are often combined into wind farms whose installed capacity can range from a few to several 100 MW. The largest wind farm for commercial production of electric power, situated in Texas, USA, combines 421 turbines into a 735 MW plant. Such turbines are usually three bladed and have high tip speeds (the ratio between the rotational speed of the tip of a blade and the actual velocity of the wind) of 300 km/h. Their supporting structures tower from 60 to 90 m above ground, while their associated blades range from 20 to 40 m in length. Wind plants have short construction lead times, even compared to those of transmission infrastructure.

Trends

Variable-speed turbines with pitch control using either direct driven synchronous ring generator or double-fed asynchronous generators are likely to become the norm, not the exception. However, cost of energy is and will remain the key driving force of wind energy growth. Therefore, if variable-speed turbines are to become a sound economic winner, additional costs incurred by power electronics required by most variable-speed designs must clearly be counterbalanced by the enhanced energy capture.

Capacity and Load Characteristics

Wind energy converters are dependent on the wind, and hence turbine output varies over time, across all timescales ranging from seconds to up to years. Measuring, modeling, and understanding this variability are crucial for site selection and also for integration of wind power into electricity grids.

In 2008, the global capacity of wind energy converters was 121 GW, generating about 260 TWh of electricity (WWEA 2008). This yields a capacity factor of about 24.5 % (Fig. 5).

Plant outages are not as problematic with wind power as they are with fossil, nuclear, or large hydro, because numerous wind plants are usually distributed over a wide geographical area (Archer and Jacobson 2007). Such decentralization in a power supply system reduces the requirements for contingency reserve, since this type of reserve is mostly tied to the largest potential source of failure, which is the largest single generator in the system (Holttinen et al. 2008). Output from wind farms can be expected to be smoother than that of a single turbine, but smoothing effects on larger scales may not be so significant and may also vary between regions. While smoothing effects are discernible when comparing single turbines with wind farms and regions (Fig. 6, and also a similar figure for the UK in Oswald et al. (2008)), combining regions as such may not necessarily lead to much additional smoothing because of strong correlations in the wind regime over large distances (Fig. 7). Østergaard (2008) artificially combines the wind output of West and East Denmark (which are not connected into a common grid) and obtains only small averaging effects. Oswald et al. (2008) uses weather maps to demonstrate the correlation and variability of wind regimes across a large area combining Ireland, the UK, and Germany (Fig. 7). His findings (confirmed for Germany in Weigt (2008, Sect. 3.1 and Fig. 4)) cast doubt on the effectiveness of a trans-channel "supergrid" in smoothing out variations in wind load. Holttinen et al. (2009) present a detailed account of variability across geographical and temporal scales. Archer and Jacobson (2003) present wind speed data for a single site, and three and eight sites in Kansas, USA, and show how the frequency of low-wind events decreases as the number of included sites increases.

However, wind generators cannot – without storage – react to changes in demand because unlike hydropower they cannot follow a fluctuating demand (Fig. 8). Therefore, in the absence of supply matched end uses, they require a flexible electricity grid

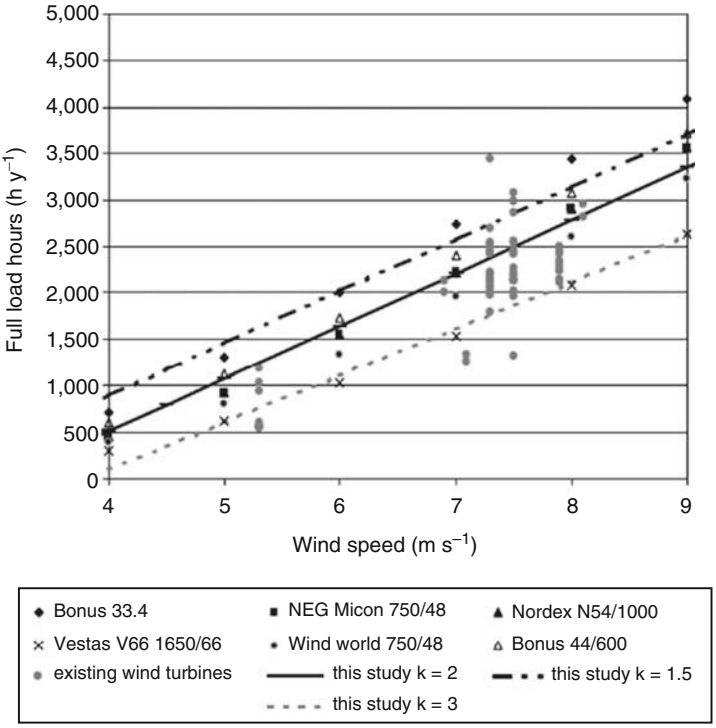

Fig. 5 Average capacity factor as a function of wind speed. Most turbines operate in a range between 2,000 and 3,000 full load hours, which is equivalent to capacity factors between 23 % and 34 % (After Hoogwijk et al. (2004); *k* is the Weibull wind speed distribution parameter). For wind farms at certain windy sites, average capacity factors of up to 45 % are reported (Archer and Jacobson 2007)

with a sufficient portion of technologies that can react quickly to demand changes, such as hydropower or natural-gas-fired plants (GWEC 2008; Söder 2004).

The *average capacity* factor of 24.5 % given above does not reflect the circumstance that electricity system planners must meet demand whenever it occurs and not on average. Where a technology is assessed with regard to its ability to supply peak load, the *capacity credit* describes the fraction of average capacity that is reliably available during peak demand. Capacity credit is also referred to in the literature as *demand capacity* (Pavlak 2008), *capacity value* (Milligan and Porter 2008), or *moderation factor* (Lund 2005). The difference between the average capacity and capacity credit is proportional to the time when wind power cannot meet (peak) demand because of a lack of wind. For example, provided a filled reservoir, the capacity credit of hydropower is virtually equal to its average capacity, but this is not the case for wind power because of its variability and uncertainty. Some generators assign zero capacity credit to wind; however, this is unrealistic (Diesendorf 2007). Wind can achieve up to 40 % capacity credit when penetration is low and times of

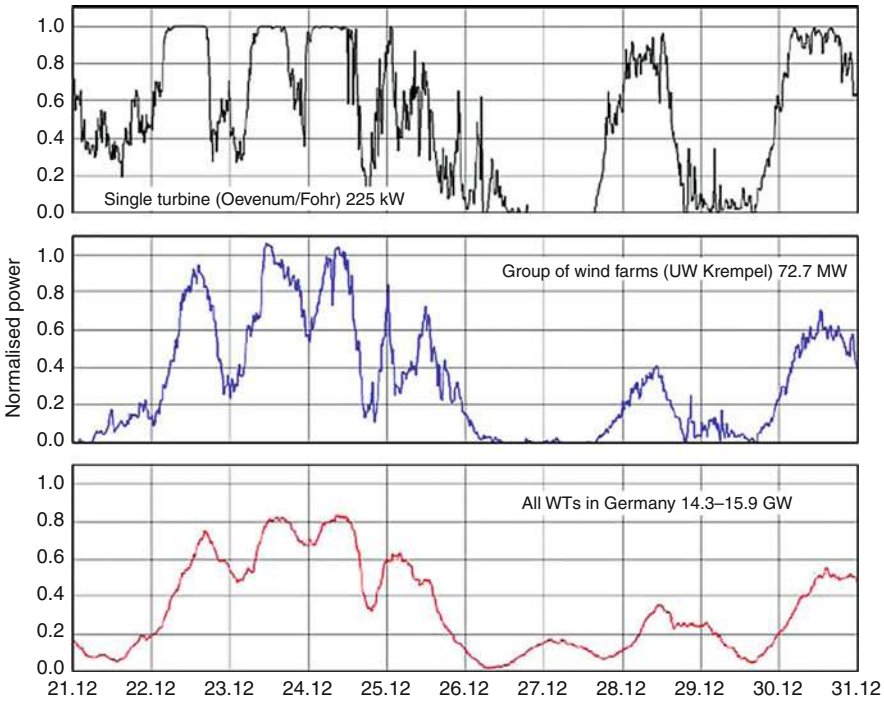

Fig. 6 Normalized power output from a single wind turbine (*top*), and group of turbines (*middle*), and all turbines in Germany (*bottom*; after Focken and Lange)

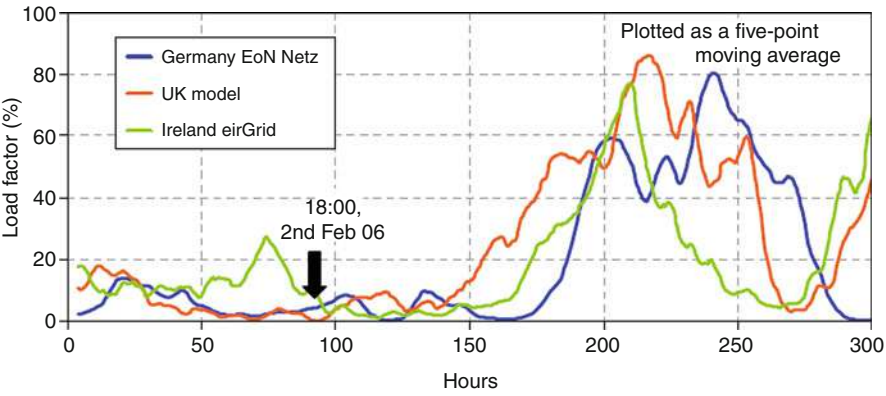

Fig. 7 Variability and correlation of wind loads across Ireland, the UK, and Germany (After Oswald et al. (2008)). On February 2, the electricity demand in Britain reached its peak for 2006

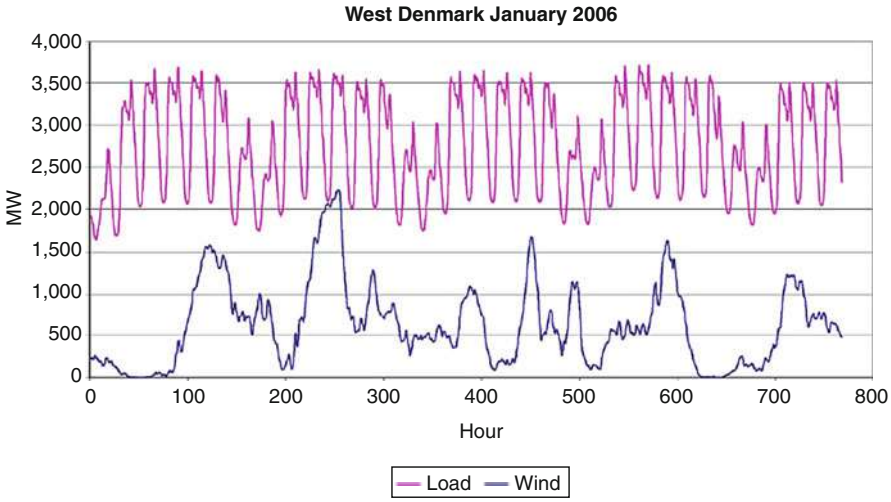

Fig. 8 Wind power output and load in West Denmark (After Söder et al. (2007), © 2007 IEEE)

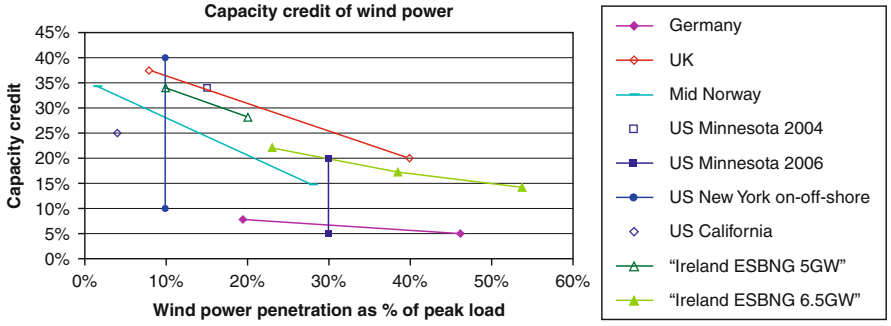

Fig. 9 Capacity credit of wind power as a function of wind penetration (After Holttinen et al. (2009)). Note that as penetration approaches 20 %, the capacity credit starts to fall consistently below wind power's average capacity factor. The results from Mid-Norway show that geographical dispersion improves capacity credit. Decreasing capacity credits have been confirmed theoretically, for example, by Martin and Diesendorf (1980)

ample wind coincide with times of high demand (Holttinen et al. 2009). In general, however, the higher the penetration of wind power in a system, and the more uncorrelated wind output with demand load, the lower its capacity credit (see Fig. 11 in Strbac et al. (2007) and Fig. 9).

Capacity credit is usually measured by applying probability calculus to hourly data on load, generation capacity, ramp rates, and planned or forced outages and applying merit orders in which technologies that avoid fuel costs are recruited first (Milligan and Porter 2008). The *loss-of-load probability* $\mathrm{LOLP}_i = \mathrm{Prob}(\sum_j C_j < L_i)$, with C_j being the capacity of generator j in the grid and L_i the load at hour i, is the probability that a supply system is not able to meet demand in hour i. Integrating

LOLP overall operating hours results in the*loss-of-load expectation* LOLE $= \sum_i$ LOLP$_i$, which is expressed in units of hours/year, or days/10 years, and provides a measure of system reliability. A common system LOLE target is 1 day/10 years, in which case the system has to import capacity from elsewhere. This corresponds to a $1 - 1/(10 \times 365) = 99.97$ % probability that the system will be able to meet demand without having to import capacity.

A power supply system is usually made up of a technology mix. A measure that allows characterizing the incremental contribution of any one component to the reliability of the system is the *effective load-carrying capability*ELCC, which is the new firm (i.e., zero-variance) load that can be added to the system including the incremental capacity increase, without deteriorating the system's reliability. Adding a new generator G as well as a hypothetical firm load ELCC to a system, hourly LOLP becomes LOLP$_i$ = Prob($\sum_j C_j + G < L_i +$ ELCC). ELCC is a hypothetical firm (i.e., zero-variance) load that can be added to a system as a result of the addition of a non-firm (i.e., variable) capacity G that would not change the system's LOLE. ELCC is hence calculated by solving $\sum_i$ Prob($\sum_j C_j < L_i$) = $\sum_i$ Prob($\sum_j C_j + G < L_i +$ ELCC).

ELCC depends critically on the ability of a generator to meet demand at top-ranking LOLP hours, which, in the case of wind, is determined by the correlation of wind output with top-ranking LOLP hours. *Capacity credit* is the ratio of ELCC and rated capacity. Defined as such, capacity credit values are around or lower than the average capacity (Fig. 9). However, capacity credit has at times been measured as the ratio of ELCC and average power (Martin and Diesendorf 1980), in which case it varies between 0 % and 100 %. As a result, where grid operators are required to meet demand at usual loss-of-load expectations, reserve load-carrying capacity or storage has to be secured (Pavlak 2008, Fig. 10).

Similarly, operators also strive to avoid having to curtail surplus wind power at times of high wind, raising different management issues again (Holttinen 2008). Geographical dispersion of wind turbines can help to reduce variability as well as increase predictability of output (Holttinen et al. 2008). Even during a rapidly passing storm front, power from dispersed capacity will take a few hours to change (Söder et al. 2007). Depending on the characteristics of the power system, that is, composition and diversity of technologies, demand management, size, demand profile, and degree of interconnection, low capacity credit poses barriers to the degree of integration of wind energy. In general, the more flexible, load-following capacity there is in the existing grid, the higher the potential penetration of wind power. However, operators run either the risk of not meeting demand by committing too much cheap slow-start capacity or the risk of overrunning cost by committing too much expensive fast-start capacity (DeCarolis and Keith 2006).

Grid integration issues have largely been studied theoretically, except for some European regions. For example, while Denmark receives on average more than 20 % of its electricity from wind, it sometimes receives much higher percentages and sometimes very little, in which case Denmark exports or imports electricity from the European grid and thus relies on other generation technology for load balancing (Pavlak 2008; Østergaard 2003), in particular Norwegian, Swedish, and Finnish hydro reservoirs and idle peaking plants in Denmark (Sovacool et al. 2008).

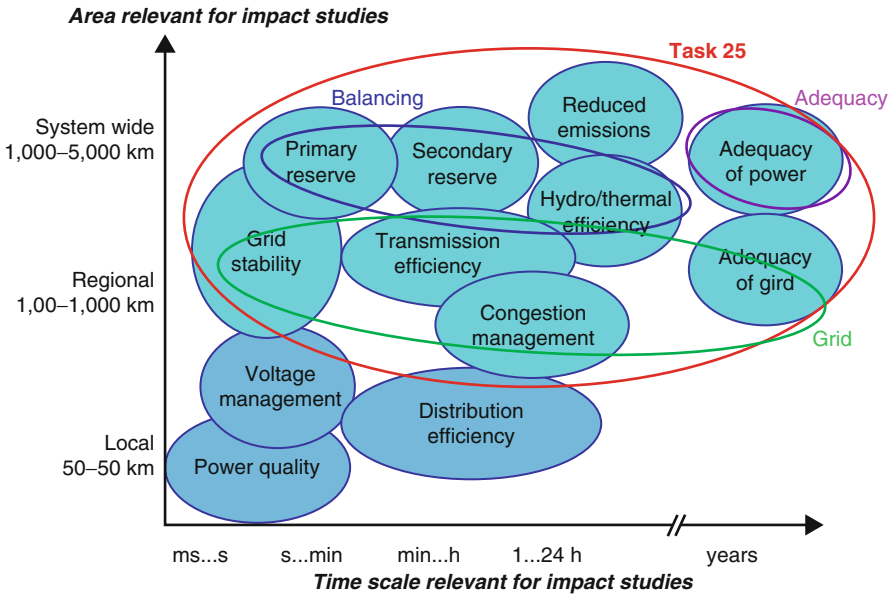

Fig. 10 Typology of grid impacts of wind power across temporal and spatial scales (After Holttinen et al. (2009)). *Balancing* reserves deal with short-term variability in the order of up to 24 h. *Adequacy* in peak-load situations (i.e., low LOLE) has to be secured long term and requires load-carrying reserves to compensate for shortfalls in capacity credit

For higher degrees of integration, the management and/or export of excess wind loads become(s) an issue (DeCarolis and Keith 2006). Söder et al. (2007) report results from four regional systems with high wind penetration, among which two are connected to a larger outside system, and two are not. Management of wind power variability involves the requirement for flexible interconnection capacity and the ability to curtail wind power production, respectively. Hoogwijk et al. (2007) (Fig. 9) find that – subject to supply and load correlation – the amount of electricity that has to be discarded grows strongly for penetrations in excess of 20–30 %. Lund (2005) investigates a scenario for expansion of wind power to cover 50 % of Danish demand and concludes that supply–demand balancing problems would become severe. Similarly, penetration of less than 20 % can lead to instabilities if a grid is not well interconnected with other grids, such as in the case of Spain (Hoogwijk et al. 2007).

Life-Cycle Characteristics

Lenzen and Munksgaard (2002) review and analyze a large body of literature on the life cycle of wind energy converters, comparing bottom-up component analyses with top-down input–output analyses. In their multiple regressions, these authors take into account not only technical features such as scale, vintage year, and load factor but also scope and methodology of the analysis (Fig. 11).

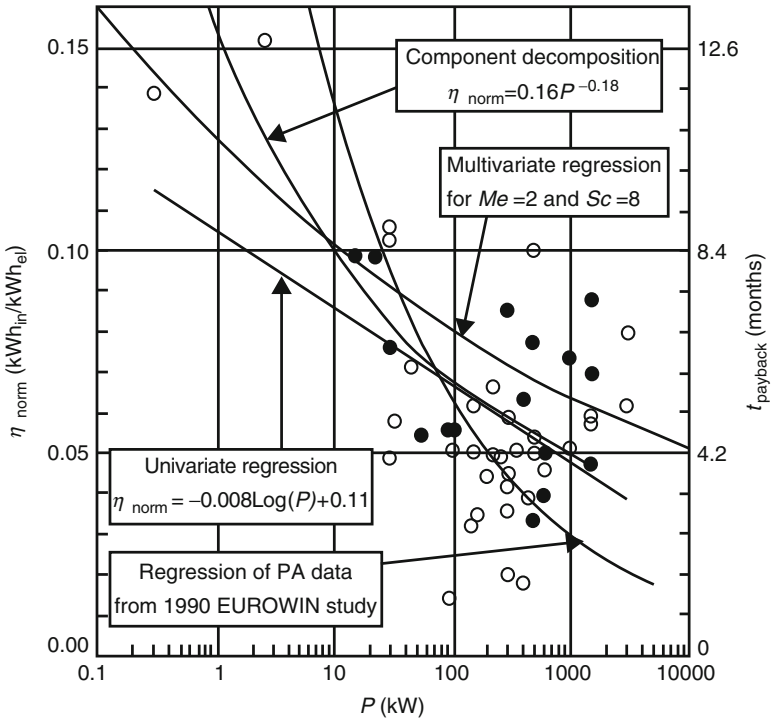

Fig. 11 Cumulative energy requirements of wind energy converters as a function of rated power (After Lenzen and Munksgaard (2002)). The multivariate regression line takes into account different scopes and methodologies adopted in case studies. 0.05 kWh_{th}/kWh_{el} is found to be realistic for modern large turbines

A more recent study by Wagner and Pick (2004) confirms the energy payback times between 3 and 7 months, which – assuming a turbine lifetime of 20 years – corresponds to cumulative energy requirements between 0.035 and 0.075 kWh_{th}/kWh_{el}. The cumulative energy requirement η is related to the energy payback time, that is, the time it takes the wind turbine (lifetime T) to generate the primary-energy equivalent of its energy requirement, via $t_{payback} = \eta \cdot T \cdot \varepsilon_{fossil}$. ε_{fossil} is the conversion efficiency (assumed to be 35 %) of conventional power plants that are to be displaced by wind turbines.

Lenzen and Munksgaard (2002) found greenhouse gas intensities for the larger, modern turbines to be about 10 g/kWh_{el}, ranging among the lowest values for all electricity generation technologies. Lenzen and Wachsmann (2004) found large variations of specific life-cycle emissions of wind turbines between countries where turbine components were produced.

Roth et al. (2005) and Pehnt et al. (2008) take the reduced capacity credit of wind into account in their systems LCA and conclude that CO_2 emissions arising from the need of additional reserves add between 35 and 75 g CO_2/kWh, thus outweighing CO_2 emissions from the turbine life cycle. However, these values depend strongly on the technology mix of the overall power system.

Noise and impacts on birds are likely to be small from wind farms, compared to other impacts (GWEC 2008). Snyder and Kaiser (2009) provide a detailed account of possible ecological impacts from offshore wind farms.

The mitigation potential of wind in a power system represents an optimization problem, because the higher the penetration of wind power, the higher the emission reductions, and also the higher the variability cost.

Current Scale of Deployment

Due to large economies of scale, the scale of single wind energy converters has been increasing steadily (Fig. 12), featuring taller towers and larger rotors. Larger turbines with ratings above 3.5 MW are usually dedicated to offshore power generation, while onshore installations are usually rated between 1.5 and 3 MW (GWEC 2008). In early 2009, the French manufacturer Areva deployed 5 MW turbines for operation 45 km offshore of the German North Sea island of Borkum (Jha 2009). Five-megawatt turbines are also installed at the Beatrice site (40 m depth) off the Moray Firth east of Scotland (http://www.repower.de/index.php?id=369). In 2007, the average size of operating turbines was 1.5 MW.

Contribution to Global Electricity Supply

In 2008, the global capacity of wind energy converters was 121 GW, generating about 260 TWh of electricity or about 1.5 % of global electricity production (WWEA 2008). Most of the capacity (Fig. 1) is installed in the USA (25 GW, 1 % of electricity generation) and in the EU (about 65 GW, 3.7 %), followed by China

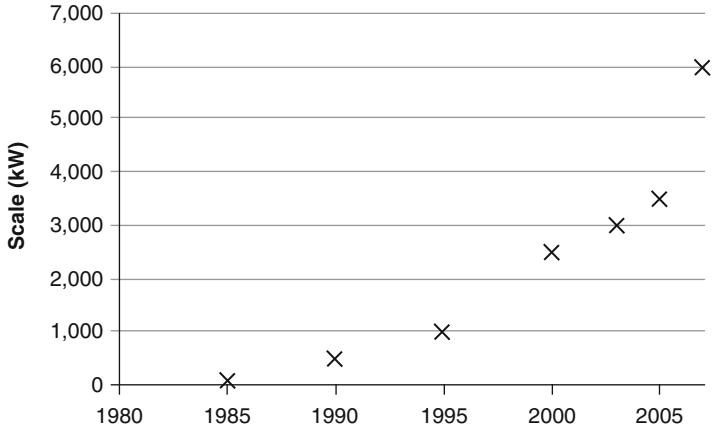

Fig. 12 Maximum scale of wind energy converters over time (Compiled after Hoogwijk et al. (2004), GWEC (2008), Joselin Herbert et al. (2007))

(12 GW) and India (10 GW). However, regional shares of wind power can be much higher in some countries: Denmark (21 %), Spain (12 %), Portugal (9 %), Ireland (8 %), and Germany (7 %). However, it is worth noting that Denmark at times receives much higher percentages of its electricity from wind and sometimes very little, in which case Denmark exports or imports electricity from the European grid and thus relies on other generation technology for load balancing (Pavlak 2008; Sovacool et al. 2008).

Wind energy deployment has been increasing rapidly throughout the past decade, recording growth rates of around 30 % since 1996 (Fig. 2). More than half of the 2008 additions occurred in the USA and in China (Fig. 3), with the USA overtaking Germany as the leader in installed wind capacity (WWEA 2008). In the USA, wind power has represented 40 % of 2007 national capacity growth (Bolinger and Wiser 2009).

Most of the wind generation is onshore; only about 1.1 GW is presently installed offshore, mainly located in Denmark (420 MW), the UK (300 MW), Sweden (135 MW), and the Netherlands (130 MW) (IEA 2008b, www.ieawind.org/Annex_XXIII.html). A further 8 GW were planned in early 2009 (Jha 2009).

Cost of Electricity Output

Capital costs make up about 80 % of total wind energy cost, with the remainder for operation and maintenance, since the wind turbine does not require any fuel input. Blanco (2008) presents a detailed breakdown of these costs; in onshore installations, the turbine covers 70 % of capital cost, with the remainder for grid connection, civil works, taxes, permits, etc. Within the turbine, the tower and blades make up for half of the costs. Electricity costs vary with site conditions: assuming a 20-year plant life, 5–10 % discount rate, and 23 % average capacity factor, Blanco (2008) states a levelized cost range for electricity from European 2 MW wind turbines between 6.5 and 13 US¢/kWh. Welch and Venkateswaran (2008) and Snyder and Kaiser (2009) report US cost estimate between 3 and 5 US¢/kWh and DeCarolis and Keith (2006) between 4 and 6 US¢/kWh.

Levelized electricity cost is the constant (discounted to present values) real wholesale price of electricity that recoups owners' and investors' capital costs, operating costs, fuel costs, income taxes, and associated cash flow constraints. They exclude costs for transmission and distribution. Levelized cost may differ from sales prices, because of profits or losses. The figures reported here are averages over plant types and vintages and over locations with varying resource endowments and demand profiles. Actual cost for particular plants may be different from the cost given here. Levelized electricity costs are strongly determined by the competitive landscape, in particular the extent and nature of regulation, subsidization and taxation, primary fuel (coal, gas, uranium) prices, and future carbon pricing. While under government regulation operators are able to transfer costs and risk to consumers and taxpayers, this is not the case in deregulated electricity markets, where high interest rates lead to investors favoring less capital-intensive and therefore less

risk-prone power options. Electricity cost figures reported here refer to the financial and regulatory environment at the time of publication of the various references.

Civil works and especially the foundations are much more expensive in offshore installations, where they represent 20 % of capital cost, leading to higher levelized cost of 9–16 US¢/kWh. This is confirmed in an estimate of 10 US¢/kWh by Snyder and Kaiser (2009). However, technological learning can bring these costs down in the future (IEA 2008b; Smit et al. 2007).

Wind energy costs have increased during the past 3 years, mainly driven by supply tightness and price hikes of raw materials (IEA 2008b), which is difficult to control by government fiscal policy. Bolinger and Wiser (2009) provide a detailed analysis of most recent upward cost trends. Yet, the analysis of learning curves for the industry suggests that levelized costs will come down through increased efficiency, by about 10 % for every doubling of capacity (Blanco (2008); compare Fig. 14 in UNDP (2004)). As with other nonfossil electricity generation technologies, wind plant operators expect the competitive landscape to change in favor of wind power, once carbon is adequately priced (GWEC 2008; DeCarolis and Keith 2006). In the future, wind energy is also expected to benefit more from not being affected by fuel price volatility.

However, depending on the penetration of a power system with variable wind energy, additional indirect costs arise for maintaining LOLE, because wind energy will not be able to meet demand at its average capacity factor but at a generally reduced rate depending on its capacity credit (DeCarolis and Keith 2006). In addition, the presence of wind power in a power supply system introduces short-term variability and uncertainty and therefore requires balancing reserve scheduling and unit commitment. Grid operators need to meet peak demand to certain statistical reliability standards even when wind output falls relative to load. During these periods, which range from minutes to hours, electricity markets need to recruit demand-following units (such as gas, hydro, or storage), which at times of sufficient wind remain idle, so that costs arise essentially for two redundant systems (Pavlak 2008; Benitez et al. 2008) and for inefficient fuel use during frequent ramping (see p. 903 in Hoogwijk et al. (2007), Benitez et al. (2008), Smith et al. (2007)). Both adequacy and balancing cost (compare Fig. 10) are sometimes referred to as intermittency cost; however, in this chapter the term variability cost is used because strictly speaking wind energy is variable and not intermittent (Diesendorf 2007). Thus, wind energy reduces dependence on fuel inputs but does not eliminate the dependence on short-term balancing capacity and long-term reliable load-carrying capacity.

The impact of wind power on the power supply system is critically dependent on the technology mix in the remainder of the system, because the more flexible and load-following existing technologies, the less peak reserves are needed. It is also dependent on time characteristics of system procedures (frequency and duration of forecasts, etc.) and local market rules (Holttinen 2008). In general, the higher the wind penetration, the higher the variability in the supply system, and the more long-term reserve and short-term balancing capacity has to be committed (Fig. 13) on short-term balancing only. The corresponding cost increases are only partly offset by

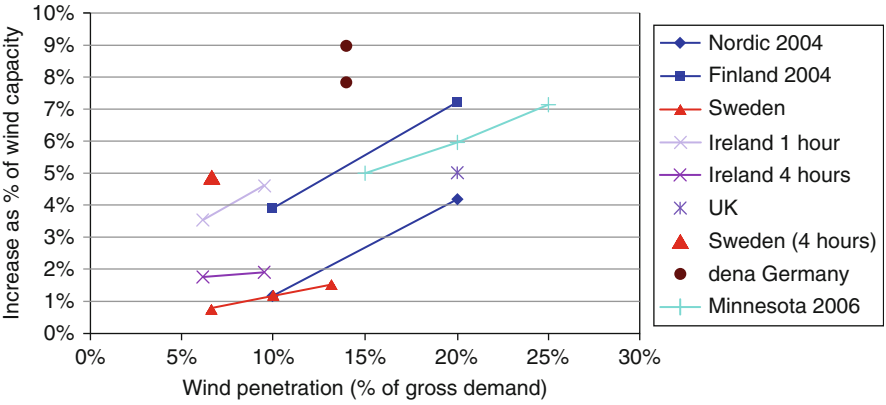

Fig. 13 Increase in short-term balancing requirement as a percentage of wind power as a function of wind penetration (After Holttinen et al. (2009))

a smoothing out of wind variability when many turbines are dispersed and interconnected over a wide geographical area (Hirst and Hild 2004), but they are more than offset by reduced fuel and operating cost. In specific applications, the cost of additional wind power also depends on the relative locations of turbines, load, and existing transmission lines and on whether sufficient load-carrying reserve exists in the grid or has to be built.

As expected, variability costs scatter significantly depending on a large array of parameters. They cannot be derived from capacity credit estimates, since these do not contain any information about to what extent cheap base load and expensive peak load are being displaced by wind (Martin and Diesendorf 1982). Variability costs are difficult to disentangle from overall cost in real-world grids (DeCarolis and Keith 2006), so that they have largely been estimated for theoretical settings, using statistical models for resource and load fluctuations and least-cost-optimizing generation and reserve scheduling under given output limits, startup and shutdown cost, ramp-rate restrictions, planned outages, fuel cost, and day-ahead forecasts (Holttinen et al. 2008; Hirst and Hild 2004). They have been quoted between 0.2 and 0.4 US¢/kWh for existing installations (Snyder and Kaiser 2009; GWEC 2008) and also higher at 1–1.8 US¢/kWh (DeCarolis and Keith 2006; Benitez et al. 2008; Ilex and Strbac 2002) for larger degrees of wind penetration. In a more up-to-date survey, Holttinen (2008), Strbac et al. (2007), and Smith et al. (2007) report on recent findings about increases in balancing requirements due to the presence of wind, ranging widely between 0.05 and 0.5 US¢/kWh (Fig. 14). Hence, at penetrations of up to 20 %, variability cost can be expected to be about equal or less than 10 % of generation cost.

Hoogwijk et al. (2007) (see Fig. 15) run numerical experiments at large-scale penetration rates of up to 45 % and find that beyond 30 % penetration the cost incurred by discarded excess electricity becomes comparable to base cost (6 US¢/kWh).

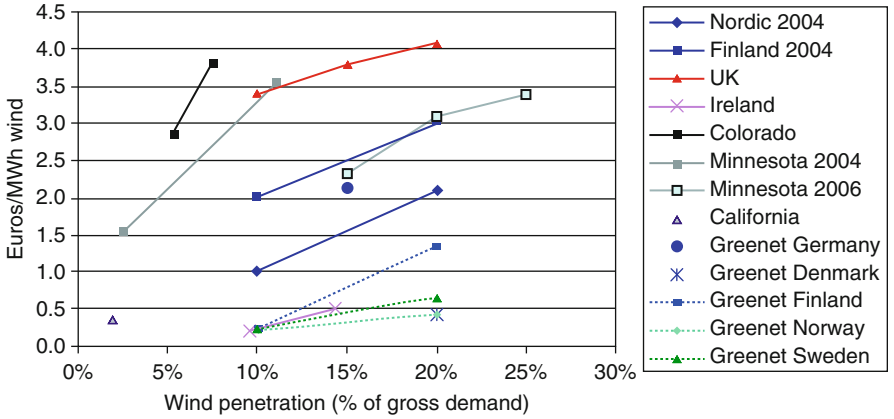

Fig. 14 Increase in balancing requirements per kWh of wind power as a function of wind penetration (After Holttinen et al. (2009))

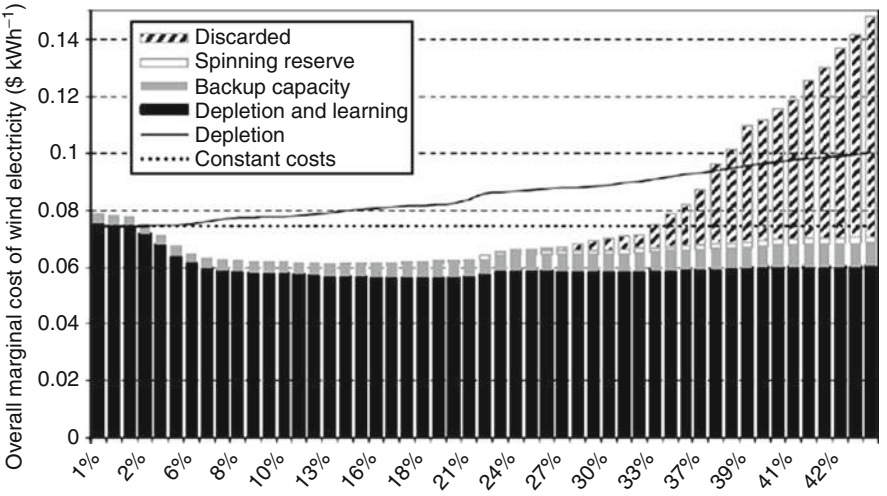

Fig. 15 Marginal cost of wind electricity at varying degrees of penetration (After Hoogwijk et al. (2007))

The market for wind turbine manufacturing is diverse and competitive, with manufacturers spread across many countries. However, large corporations are entering the market, sometimes assimilating smaller entities (GWEC 2008). During the recent wind market boom, and the shift to larger turbines, the industry faced a number of supply chain bottlenecks related to gearboxes and large bearings (Blanco 2008), leading to waiting times for turbines of up to 30 months (Sovacool et al. 2008).

Future Directions

Wind energy faces a number of technical future challenges. The variable and distributed nature of wind energy requires specific grid infrastructure in order to ensure grid stability, congestion management, and transmission efficiency. Significant investment in grid infrastructure has to occur in order to allow for substantial global penetration of wind energy (GWEC 2008). One of the most significant challenges is hence the integration of wind power into a large grid and the theoretical modeling of power system behavior at high penetration rates of wind. Recent efforts are also aimed at improving short-term forecasting of wind, which is still less accurate than forecasting of load (Holttinen et al. 2009). With increasing interconnection and geographical dispersion, forecasting errors are expected to decrease (see Fig. 16).

Some researchers suggest directing wind power to where it can be most competitive or where its variability does not create problems. Some industrial applications and also combined heat and power plants can – within limits – adjust their demand to supply (Østergaard 2003). Dedicated load-leveling applications such as desalination, aluminum smelting, space and water heating, or chargeable hybrid vehicle fleet can deal with hourly variations in wind power since they only require a certain amount of energy over a period of many hours (Kempton et al. 2007; Pavlak 2008). For example, large-scale vehicle-to-grid technologies can significantly reduce excess wind power at large wind penetration and replace a significant fraction of regulating capacity, but as Lund and Kempton (2008) show in a study for Denmark, electric vehicles would not nearly eliminate excess power and CO_2 emissions, even if they had long-range battery storage.

Tavner (2008) and Smith et al. (2007) list improvements in resource, turbine and systems modeling and forecasting, capital cost reduction, lifetime extension, transmission upgrading, and system integration as the main future research challenges for wind power. Joselin Herbert et al. (2007) review past developments and present

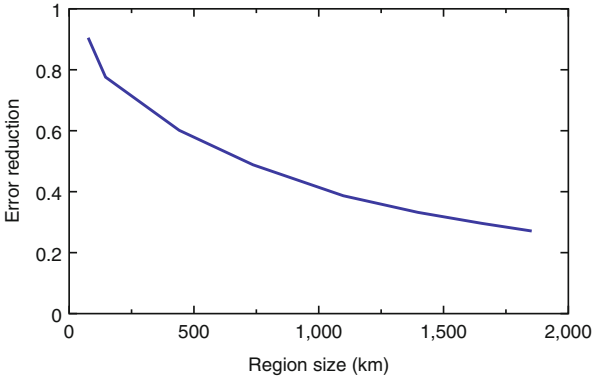

Fig. 16 Measured forecast error as a function of spatial range of interconnection (After Rohrig). The error reduction plotted on the y-axis is the ratio of the root-mean-square error (*RMSE*) of prediction at a regional scale and the single-site prediction RMSE

research needs for wind technologies, such as for resource assessment, site selection, turbine aerodynamics, wake effects, and turbine reliability. Offshore wind deployment faces technical challenges in the form of extreme wind conditions that exceed tolerances of current onshore turbines (Snyder and Kaiser 2009; Smit et al. 2007). The IEA Wind Offshore subgroup's tasks include research on ecological issues and deepwater installation. In order to reduce offshore wind costs, turbine concepts, submerged structures and cabling, and remote operation and maintenance will need to undergo further research (Blanco 2008). Many of the above issues are approached through theoretical modeling, be it turbine structure, system control and balancing, wind conditions, or reliability (Tavner 2008). Surprisingly, offshore wind power generation shares many of large hydropower and nuclear power's challenges regarding public opinion. Firestone and Kempton (2007) report a case study where the majority of survey respondents opposed offshore wind power development for environmental reasons and that many of the beliefs were "stunningly at odds" with the scientific literature. Perceived landscape changes also feature in a survey by Zoellner et al. (2008), but economic considerations more strongly influenced acceptance.

Summary

Wind energy deployment has witnessed a rapid increase throughout the past decade, with annual growth rates around 30 %, generating now about 1.5 % of global electricity. The technology is mature and simple, and decades of experience exist in a few countries. Due to strong economies of scale, wind turbines have grown to several megawatts per device, and wind farms have now been deployed offshore. In recent years, wind power has become competitive without subsidies, in markets without carbon pricing. The global technical potential of wind exceeds current global electricity consumption; however, taking into account the temporal mismatch and geographical dispersion of wind energy and demand loads and requirements for supply–load balance and grid stability, the maximum economic potential appears to be in the order of 20 % of electricity consumption. At such rates of wind energy penetration, and without storage and supply matched demand, the integration of wind power into electricity grids and long-distance transmission begins to present significant challenges for system reliability and loss-of-load expectation. The main issue for future deep penetrations of wind on a global scale is hence how wind plants can be integrated across very large geographical scales and with other variable power sources. For example, there are popular proposals for integrating parts of North African solar power for output smoothing of large wind supply in Europe. Some commentators remark that these proposals may be difficult to implement because of political and supply security issues; others are more optimistic. Finally, the life-cycle greenhouse gas emissions from wind power are some of the lowest among all electricity-generating technologies, but depending on the remainder of the power supply system, emissions arise because of the use of conventional technologies for supply–demand balancing.

Wave Power: Climate Change Mitigation and Adaptation

Gregorio Iglesias and Javier Abanades

Contents

Abstract

Wave energy has a great potential in many coastal areas thanks to a number of advantages: the abundant resource, with the highest energy density of all renewables, leading to higher availability factors than, e.g., wind or solar energy, and the low environmental and particularly visual impact, not least in the case of

DOI 10.1007/978-3-319-14409-2_81

offshore floating wave energy converters (WECs). In addition, a novel advantage will be investigated in this work: the possibility of a synergetic use for carbon-free energy production and coastal protection. All in all, these advantages make wave energy a promising alternative to conventional energy sources. In this chapter the fundamentals of the wave resource and its characterization are outlined. The technologies for wave energy conversion are classified according to three criteria, the most representative WECs are presented, and the technological challenges discussed. Next, the environmental impacts of wave energy extraction are analyzed, with a focus on the reduction of coastal erosion.

If there are two main strategies to cope with climate change, mitigation and adaptation, wave farms participate on both. Indeed, wave energy contributes to mitigating climate change by two means, one acting on the cause, the other on the effect: (i) by bringing down carbon emissions (cause) through its production of renewable energy and (ii) by reducing coastal erosion (effect). Given that one of the causes of climate change is precisely coastal erosion – through sea-level rise and increased storminess – the contribution of wave farms to its mitigation is indeed welcome. As for adaptation, wave farms – which typically consist of floating WECs – adapt naturally to sea-level rise; this is a major advantage relative to conventional coastal defense schemes, based on fixed structures (seawalls, detached breakwaters, groynes, etc.)

Introduction

The adverse effects brought about by the world's reliance on fossil fuels are well known: (i) greenhouse gas emissions that exacerbate climate change, (ii) diminished reserves of carbon fuels, and (iii) geopolitical wrangling over the control of the oil and gas reserves, which has led to many conflicts and all-out wars in the last decades. In addition, the variability in oil and gas prices has a deleterious effect on the global economy. These arguments, and the international treaties and protocols signed to foster the efforts against climate change, call for the development of renewable energy sources.

Among renewable energies, the potential for development of marine renewable energy[1] (MRE) is widely recognized (Bahaj 2011; Iglesias and Carballo 2009), so much so that it is poised to become a fundamental pillar in the EU energy policy (cf. SET-Plan European Commission 2007). The MRE industry has a target for 2050 of 188 and 460 GW of installed capacity for ocean energy (wave and tidal) and offshore wind, respectively (EU-OEA 2010; Jeffrey and Sedgwick 2011; Moccia et al. 2011). The figures for 2020 are 3.6 and 40 GW for ocean and offshore wind energy, respectively (EWEA et al. 2012). In view of these values, it is obvious

[1]Marine renewable energies include both ocean energy and offshore wind energy. Ocean energy comprises essentially wave and tidal energy, but also Ocean Thermal Energy Conversion (OTEC) and salinity gradient energy.

that a relevant breakthrough is necessary for these targets to be attained. In the case of wave energy, single WECs will not be able to supply the amounts of energy that are required; therefore, arrays of devices, also known as wave farms, are to be deployed. As indicated above, these wave farms can serve not only to generate carbon-free energy and thus meet the previous targets but also to protect coastal sections experiencing erosion, flooding, or both.

Different types of waves exist in the ocean: (1) wind-generated waves, (2) tsunamis (seismic disturbance waves), and (3) tidal waves. In the following the terms "wave energy" or "wave power" are used to denote the energy and power of wind waves, respectively. Winds are caused by the differential heating of the Earth's atmosphere by the Sun, which in turn gives rise to waves through a complex energy transfer. In the transformation of solar energy into wind and, subsequently, wave energy, a concentration process occurs which augments power density. Thus, whereas the power density supplied by the Sun is of the order of 1.70×10^2 Wm^{-2}, the average wind power density is approx. 5.80×10^2 Wm^{-2} at a latitude of 15 °N or 15 °S, and the average wave power density is approx. 8.42×10^3 Wm^{-2}. It follows that wave energy can be considered a concentrated form of solar energy.

Wave energy presents a number of advantages relative to other renewables: the abundance and high density of the resource in many coastal areas, leading to high availability values (approx. 90 % vs. 30 % in the case of wind or solar energy), and, importantly, the low environmental and, in particular, visual impact of wave energy converters. On the downside, the cost of wave energy is often alluded to, and the levelized cost of energy (LCOE) of wave energy has been the object of recent studies, e.g., Astariz and Iglesias (2015). In this respect it is important to mention that the externalities of wave energy are often neglected in the analysis; these enhance economic viability of wave energy and should be accounted for – not least in public policy making (Astariz and Iglesias 2014). Moreover, the economies of scale that will occur once the rhythm of WEC production increases will contribute to lowering the costs of wave energy, much as in the case of offshore wind or, more generally, any nascent technology, from automobiles to computers.

The structure of this chapter is as follows. The fundamentals of the wave resource are summarized in section "Fundamentals of the Wave Energy Resource." For this resource to form the basis of a fully fledged renewable and thus contribute significantly to the energy mix, it is necessary to work along three lines: (i) the spatial and temporal variability of the resource must be assessed, the areas with potential determined, and their potential quantified (section "Wave Resource Characterization"); (ii) the existing technologies must be developed into reliable and efficient WECs (section "Wave Energy Conversion"); and (iii) the environmental effects of wave energy extraction must be investigated and in particular the effectiveness of wave farms as coastal protection means (section "Wave Farms"). On these grounds, future directions for wave energy are outlined (section "Future Directions") and conclusions drawn (section "Conclusions") as to the effectiveness of wave power to combat climate change, with a focus on the mitigation of its

effects on the double front of its roots (greenhouse gas emissions) and its consequences (sea-level rise and increased storminess).

Fundamentals of the Wave Energy Resource

In the following ocean waves and the wave resource are presented (section "Waves and the Wave Resource"), followed by a brief summary of their mathematical treatment, with references for the reader interested in further details (section "Mathematical Aspects of Ocean Waves").

Waves and the Wave Resource

The process of wind wave generation, whereby energy is transferred from the wind to the sea surface, is controlled by the wind speed under a quadratic relationship – meaning that, although stricto sensu any wind is capable of generating waves, in practice it is only the strong (storm) winds that generate wave fields of relevant power for energy conversion. This occurs primarily in the high seas, far from the coast. The waves thus generated travel over thousands of miles of open ocean in an extraordinarily efficient process of energy transmission – with very small energy losses – until they eventually reach a coastline. In approaching the shoreline, waves leave deep water, propagating over intermediate and, subsequently, shallow water. Whereas waves in deep water do not interact with the seabed, in intermediate water they start interacting ("feeling") the seabed, and this interaction intensifies as water depths decrease, consisting of two fundamental processes, refraction and shoaling, which modify wave properties.

Ultimately, waves reach the shoreline, where they are extinguished, their energy being in part dissipated through breaking and in part reflected back. In areas sheltered by natural or man-made structures (headlands or breakwaters and groynes, respectively), another process is to be added to the former: diffraction. As a result of these nearshore processes, wave patterns in intermediate and shallow water are generally more complex than offshore – all the more so where the bottom contours are irregular. Indeed, an uneven bathymetry typically leads to wave energy concentrations in certain areas (Fig. 1) – the so-called nearshore hotspots (Iglesias and Carballo 2010a) – and areas where the resource is comparatively very weak (e.g., bays). The typical spatial extent of nearshore hotspots is $O(10^2–10^3$ m), and therefore a detailed study (usually involving numerical modeling) must be carried out to determine the optimum locations for a wave farm (Carballo and Iglesias 2012; Veigas et al. 2014).

The complexity of the wave energy resource stems not only from its spatial variability but also from its temporal fluctuations, which occur at different time scales (Carballo et al. 2015). At the shortest (wave) time scale, an individual wave is generally different from the next, only some seconds later; at longer time scales (monthly, seasonal), the wave resource will typically differ markedly, with values

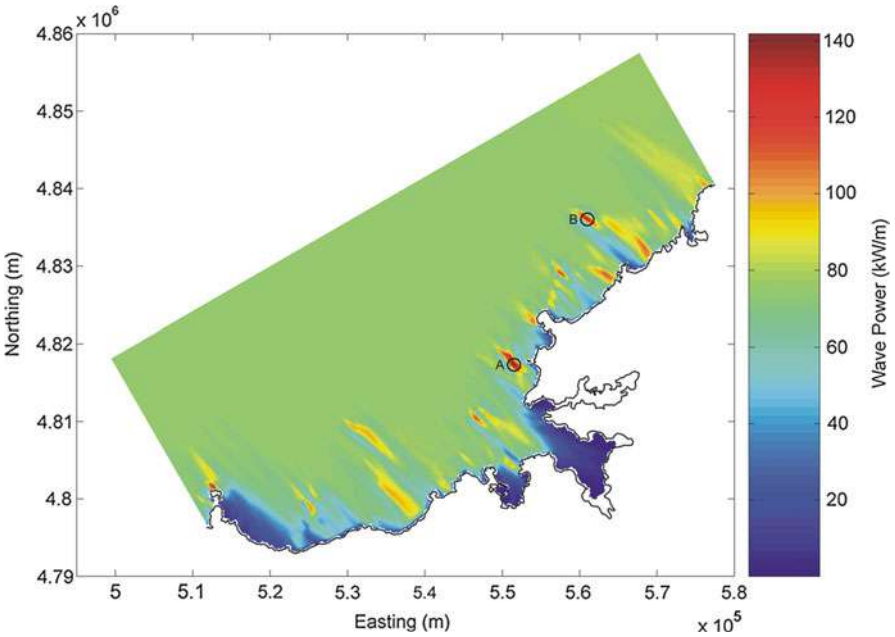

Fig. 1 Nearshore hot spots off the coast of NW Spain (Iglesias and Carballo 2009)

in winter bearing little resemblance to those in summer (Fig. 2); at even longer time scales (hyperannual), oscillations (Iglesias and Abanades 2014) such as ENSO (El Niño-Southern Oscillation) or NAO (North Atlantic Oscillation) must be taken into account.

In view of the variability of the wave resource – spatial and temporal – a fundamental requirement for its exploitation is a detailed assessment of this variability in the areas or regions of interest. The variability of the wave climate has long been investigated for other purposes, including navigation, port and coastal engineering, offshore engineering, and naval architecture – incidentally, fields in which wave energy is a source of concern (of loading, in technical terms) rather than a benefit. For this reason, the outcome of previous work, albeit informative, is often insufficient for purposes of assessing the wave resource, and an ad hoc characterization of the wave resource is necessary.

The areas with realistic potential for the development of wave energy present average power values above 20 kWm^{-1} and tend to be located in the mean and high latitudes owing to the global atmospheric circulation. Furthermore, the seasonal variability of the wave resource is typically lower in the Southern Hemisphere than in the Northern. On this basis, many coastal areas of South America, Africa, and Australia would be particularly attractive for wave energy exploitation – with the downside of their distance to the energy consumption centers.

The characterization of the wave resource has been undertaken recently in a number of areas with potential (Fig. 3) for the development of wave energy areas

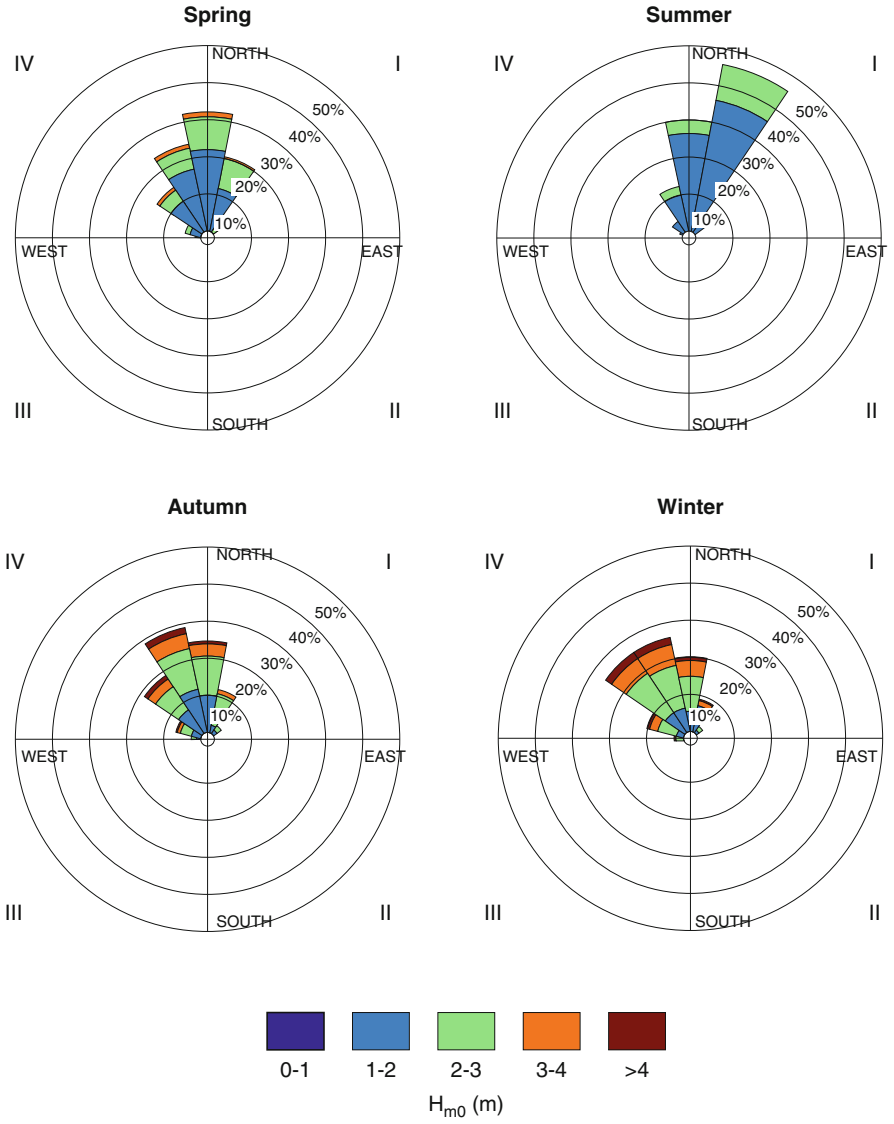

Fig. 2 Seasonal wave height roses at La Isla Bonita in the Island of La Palma (Iglesias and Carballo 2010b) (H_{m0}, significant wave height)

(Bernhoff et al. 2006; Defne et al. 2009; Folley and Whittaker 2009; Gonçalves et al. 2014; Iglesias and Carballo 2009, 2010a, c, 2011; Lenee-Bluhm et al. 2011; Pontes et al. 1998; Rusu and Guedes Soares 2012; Stopa et al. 2011; Thorpe 2001; Vicinanza et al. 2013). However, much work remains to be done in the small-scale characterization of the nearshore variability of the wave resource in the areas of interest.

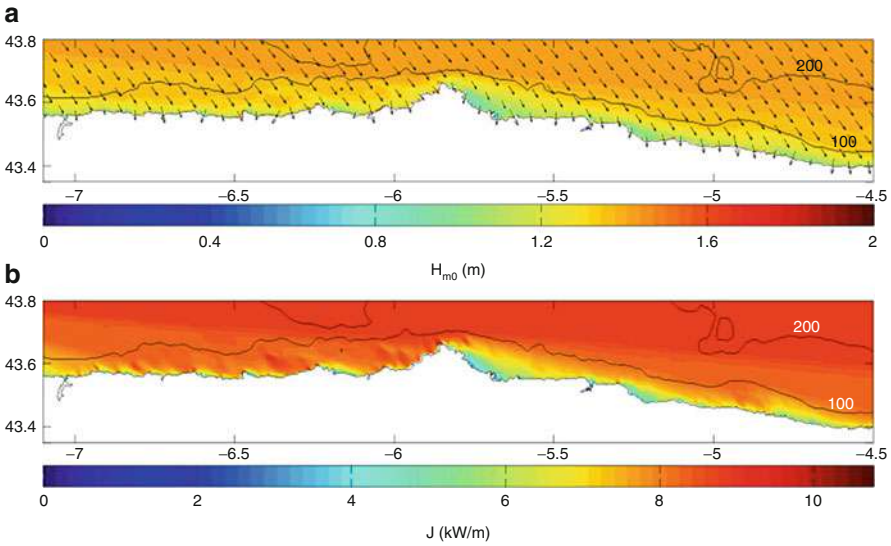

Fig. 3 Wave patterns: significant wave height and direction (**a**) and wave power (**b**) in the North Coast of Spain for the following deepwater wave conditions on 13/04/2009 at 03:00 UTC: significant wave height, 1.5 m; energy period, 10.0 s; mean wave direction, 315° (Iglesias and Carballo 2010c)

This characterization is typically carried out through numerical models, ideally calibrated and validated with wave data from wave buoys or other sources (Iglesias and Carballo 2009, 2010c; Iglesias et al. 2009). The following section summarizes the main principles of the characterization of the wave resource. For additional details the interested reader is referred to Carballo and Iglesias (2012).

Mathematical Aspects of Ocean Waves

Ocean waves consist of a superposition of a very large number of individual sinusoidal (harmonic) waves, each with its own amplitude, frequency, and direction. This superposition is expressed mathematically as a Fourier series, which can represent any sea state (Holthuijsen 2007). The Fourier series, a time domain concept, has its counterpart in the frequency domain in the wave energy density spectrum, usually referred to for brevity as the wave spectrum, which quantifies the distribution of wave energy over the different frequencies. Often, the directional information is contained in the spectrum, which is then a directional spectrum.

On the basis of the directional wave energy spectrum, it is possible to compute the wave parameters of interest, some of which are presented below for convenience; further details on irregular wave theory may be found in Holthuijsen (2007).

If the directional wave energy density is denoted by $S(f, \theta)$, with f the wave frequency, the spectral moments may be defined as

$$m_n = \int_0^{2\pi}\int_0^{\infty} f^n S(f,\theta)df\,d\theta, n = 0,1,2\ldots \tag{1}$$

The significant wave height is then given by

$$H_s = 4m_0^{1/2} \tag{2}$$

and the peak wave period may be computed as the inverse of the frequency at the spectral peak (f_p),

$$T_p = \left(f_p\right)^{-1} \tag{3}$$

Wave power, or wave energy flux, is given by

$$P = \rho g \int_0^{2\pi}\int_0^{\infty} c_g(f,h)S(f,\theta)df\,d\theta \tag{4}$$

where ρ is the seawater density, g is the gravitational acceleration, and c_g is the group celerity, i.e., the velocity at which wave energy propagates, which is a function of the wave frequency and water depth (Eq. 19). Seawater density depends on salinity and temperature, which vary in time and space; an average value was taken for this work, $\rho = 1025$ kg/m^3.

Equation 6 yields the wave power per unit width of wave front; if a certain wave energy converter (WEC) captures the energy of a width b of wave front, the corresponding power is

$$P_{WEC} = Pb \tag{5}$$

Naturally the actual power output will depend on the converter efficiency. The mean wave direction may be obtained from the directional wave energy spectrum through

$$\theta_m = \arctan \frac{\int_0^{2\pi}\int_0^{\infty} S(f,\theta)\sin\theta\,df\,d\theta}{\int_0^{2\pi}\int_0^{\infty} S(f,\theta)\cos\theta\,df\,d\theta} \tag{6}$$

In many cases, the detailed shape of the spectrum is unknown, and only some of the characteristic wave parameters are given. In this case, the wave power, also known as wave energy flux, can be computed from the following approximation:

$$J = \frac{\rho g^2}{64\pi} T_{m01} H_s^2 \tag{7}$$

where ρ is the water density, g is the acceleration due to gravity, H_s is the significant wave height (m), and T_{m01} (s^{-1}) the wave energy period:

$$T_{m01} = \frac{m_0}{m_1} \tag{8}$$

Wave Resource Characterization

The characterization of the wave resource is usually carried out by means of numerical wave models, which are introduced in section "Wave Models." The main points for their practical application to characterize the wave resource are explained in section "Methodology."

Wave Models

In characterizing the wave resource, it is necessary to assess not only the average values of wave power or the total annual resource but also the variability of the resource in terms of sea states or, in other words, the characteristics of the waves (significant wave height, peak period, mean direction, etc., or even more accurately, the directional wave spectrum) behind the resource.

This characterization is customarily carried out with numerical models of coastal wave propagation (e.g., SWAN, Simulating WAves Nearshore). There are many types of models, each type solving a specific equation that applies to certain conditions. A review of existing wave models is outside the scope of this chapter, and the interested reader is referred to Folley et al. (2012). A brief summary is presented in the following.

Coastal wave models can be classified into phase-resolving and phase-averaged (spectral) wave models. In turn, each of these categories comprises many models, solving different equations or variants of equations. Many phase-resolving models are based on Berkhoff's *mild-slope equation* (Berkhoff 1974), in its fully fledged (elliptical) version or in its parabolic and hyperbolic incarnations. Alternatively phase-resolving models may be based on Boussinesq's equation, e.g., Johnson (1997), which is adept at modeling nonlinear energy transfer in shallow water and has been recently extended to intermediate water depths. As for phase-averaged models, usually referred to as spectral models, they typically solve the spectral wave action balance equation (Hasselmann 1971; Holthuijsen et al. 1989; Longuet-Higgins and Stewart 1961) and are often the preferred choice in characterizing the wave resource, for their ability to model wave generation and propagation over large domains efficiently.

Spectral models solve the spectral wave action balance equation without a priori assumptions on the shape of the wave spectrum. The wave field is described by the two-dimensional wave action density spectrum, $N(\omega,\theta)$, where ω is the angular wave frequency and θ is the wave direction. The wave action density spectrum is used in lieu of the energy density spectrum, for action density is conserved in the presence of currents whereas energy density is not; in any case, the wave energy spectrum may be computed from the wave action spectrum.

The spectral wave action balance equation reads

$$\frac{\partial N}{\partial t}+\frac{\partial(c_x N)}{\partial x}+\frac{\partial\left(c_y N\right)}{\partial y}+\frac{\partial(c_\omega N)}{\partial \omega}+\frac{\partial(c_\theta N)}{\partial \theta}=\frac{F}{\omega} \tag{9}$$

The first term on the left-hand side represents the local rate of change of wave action density in time; the second and third terms stand for the propagation of wave action over geographical space, with propagation velocities c_x and c_y in the x and y directions, respectively; the fourth term quantifies the shifting of the relative frequency due to variations in depths and currents, with propagation velocity c_ω in the ω direction; finally, the fifth term represents the effects of refraction induced either by depth variations or by currents, with propagation velocity c_θ in the θ direction. The expressions of the above propagation velocities are derived from linear wave theory. As for the right-hand side of Eq. 9, F is the source term representing the effects of generation, dissipation, and nonlinear wave-wave interactions.

Wave power is then computed as

$$J_x=\int_0^{2\pi}\int_0^{360}\rho g c_x E(\sigma,\theta)d\sigma d\theta \tag{10}$$

$$J_y=\int_0^{2\pi}\int_0^{360}\rho g c_y E(\sigma,\theta)d\sigma d\theta \tag{11}$$

where $E(\sigma, \theta)$ is the directional spectral density, which specifies how the energy is distributed over frequencies (σ) and directions (θ). The wave power magnitude is then calculated as

$$J=\left(J_x^2+J_y^2\right)^{\frac{1}{2}} \tag{12}$$

Methodology

In practice, the detailed characterization of the resource for the purposes of wave energy exploitation is of interest in nearshore areas, for it is in these areas that wave farms can be deployed. Indeed, the water depths and lengths of submarine

connections (cables) quickly place a practical limit on the distances to the coastline at which it is economically feasible to build a wave farm. Thus, it is the nearshore resource that is of practical interest.

First, the offshore wave resource must be properly characterized as a prerequisite, for offshore wave conditions are required to prescribe the boundary conditions. The characterization of the offshore wave resource can be carried out using: (i) deepwater wave buoy data, where available; (ii) numerical models that account for wave generation and propagation in deep water (e.g., WAVEWATCH III); (iii) remote sensing (satellite, HF-RADAR, etc.); (iv) hindcast datasets; or a combination of the above.

The primary factors that produce the spatial distribution of the wave resource in the nearshore are the deepwater wave resource and the bathymetry. The typical source of bathymetric data is nautical charts. In some areas, however, it may be advisable to complement existing charts with ad hoc surveys, in particular of the area of interest. Therefore, the second consideration in characterizing the nearshore resource is that the bathymetry file must have a good spatial resolution in the area of interest, ideally $O(10^1$ m), for the model to be able to calculate wave propagation accurately. Nevertheless, this fine spatial resolution is not necessary throughout the computational domain, and medium and even coarse resolutions – which are normally available from off-the-shelf nautical charts – can be acceptable from deep water to the area of interest, depending on the level of accuracy required (Fig. 4).

Third, the geometry of the computational grid should be chosen based on the geometry of the coastline and the area of interest. Cartesian, curvilinear, or combined grids may be used (Fig. 5) (Carballo and Iglesias 2012; Iglesias and Carballo 2009). It is important to bear in mind that numerical disturbances often arise at the boundaries, so these must be set far enough from the study area for model results not to be polluted.

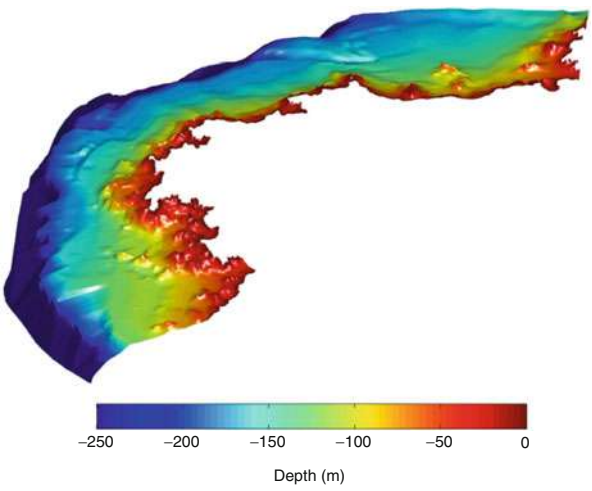

Fig. 4 Perspective view of the bathymetry used for the characterization of the nearshore wave resource (Iglesias and Carballo 2009)

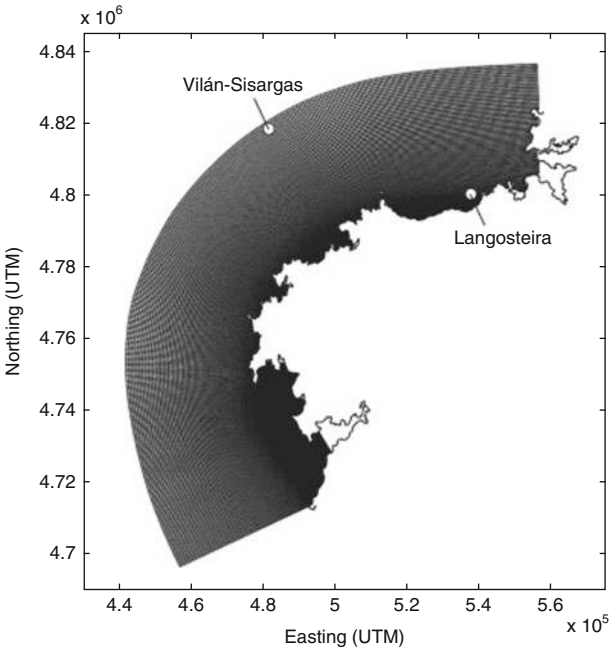

Fig. 5 Curvilinear grid for the characterization of the nearshore wave resource (Iglesias and Carballo 2009)

Fourth, the computational grid must have sufficient resolution, not least in the study area, which usually encompasses the lee of the wave farm up to the shoreline and the wave farm itself. The optimum resolution may be established through a sensitivity analysis, in which the grid is progressively refined until no significant differences can be detected in the results. A fine grid in the area of interest is often nested into a coarser grid with a view to limiting the computational cost of the model. Alternatively, a variable size mesh can be adopted, with increasing resolution toward the area of interest.

Last, but not least, the numerical model ought to be calibrated and validated. The model should ideally be driven with offshore data from wave buoys and calibrated and validated by comparing numerical results with observations from coastal wave buoys located within the computational domain. Time series of relevant wave parameters can be used to compare the model results with the coastal wave buoy data, and statistical indicators (e.g., R^2, RMSE, NMSE) can be applied to quantify the goodness of fit. It is well known that goodness of fit can decrease significantly under storm conditions. Furthermore, wave buoys are in the habit of failing in heavy storms; consequently, storm values are typically underrepresented in the dataset, which may lead to biased (and not conservative) assessments of goodness of fit.

Wave Energy Conversion

Wave energy conversion is a relatively young technology, and intensive research efforts have been devoted over the last years to the development of WECs (Carballo and Iglesias 2012). These technologies were reviewed by a number of authors (Clément et al. 2002; Drew et al. 2009; Falcão 2010; Falnes 2007; Iglesias et al. 2010; McCormick 1981; Thorpe 1999). At present no single technology can be deemed to be the definitive technology. A number of crucial aspects – from the energy performance to survivability under storm conditions – require further investigation. In addition to the existing technologies, new patents continue to appear. This interest in the sector is driven by the fact that the global wave resource is vast and more than sufficient to set wave energy on a par with other renewables such as hydropower or wind energy.

Historical Perspective

Although research and development of wave energy conversion did not gain momentum until 1973, with the world economy under the effects of the first oil crisis, the potential of wind waves for energy generation has long been acknowledged. Indeed, the first attempt to harness the wave resource dates back to the eighteenth century: the Girard brothers' patent registered in France in 1799. There is little information on the device in question, but it is known that in the late eighteenth century, it was tentatively applied in England to elevate seawater and subsequently using the energy thus stored as potential energy. This was followed by the tests carried out in Algeria by the French engineer M. Fursenot in the first decades of the nineteenth century with a device that captured wave oscillation and transformed it into energy by means of cams and gears.

Historically buoyant systems oscillating on the free surface feature prominently in the development of wave energy conversion, as in the case of the mechanism invented by P. Wright and patented in March of 1898 under the name "Wave Motor." In the following year, a new development came out, the Ocean Grove; based on an intake plate which, united to the shafts of a series of pumps, raised water to a group of elevated tanks, this WEC was designed so as to facilitate the subsequent use of the potential energy of the stored water. A device with a similar concept was in operation at the Oceanographic Museum of Monaco for 10 years, pumping seawater to the aquarium using wave energy. This WEC was ultimately destroyed by wave action.

The French scientist Montgolfier developed a "compliant flap" and installed it in a pilot plant in the Black Sea in 1917. With a nominal power of 10 kW, it was based on the dynamic pressures exerted by the movement of water particles. Its operating principle was very simple: a flexible sheet was placed perpendicular to the direction of wave propagation, thereby absorbing wave energy.

However, major efforts to convert wave power into energy did not begin in earnest until the oil crisis of 1973. A great deal of concepts for wave energy

conversion were put forward, many of which were patented; however, only a few progressed to the testing stages, and even fewer managed to actually produce energy. These first-generation converters laid the foundations for the current technologies.

It was also in the context of the oil crisis in the 1970s that studies aimed at a better understanding of wave mechanics were undertaken, often in connection with oil platforms. In the same decade research was carried out on cavity resonance devices, including the work by Yoshio Masuda at the Japan Marine Science and Technology Center and by R. M. Ricafranca at the RMR Research and Engineering Services in the Philippines. Working separately, they created the first two commercial WECs, belonging to the category that would later be called OWCs, or Oscillating Wave Columns.

The operating principle of OWCs is the oscillation of a water column inside a chamber connected with the ocean through an opening below the surface. The oscillating water column acts like a piston for the air in the upper part of the chamber, alternately compressing and decompressing it. The upper part of the chamber is connected with the exterior through a conduit in which the power take-off (PTO) system is installed – a bidirectional air turbine connected to a generator. When the water column rises, the air is compressed and expelled from the chamber, thereby driving the PTO. In the next half cycle, when the water column falls, the air pressure in the chamber decreases and air is absorbed from outside, also driving the PTO.

A British project carried out by the National Engineering Laboratory (Glasgow) capitalized on the knowledge acquired in the preceding years to improve on Masuda's WEC. However, this work did not progress beyond the prototype phase. Instead, Masuda was able to develop his device, a floating OWC named "Kaimai," into operation. Mounted on a barge and with a rated power of 1.3 MW, Kaimai was deployed off the coast of Japan.

In those years no less than £13 M were allocated for development and research in the field of marine energies by the British government. Stephen Salter, an engineer with the University of Edinburgh, presented the so-called Salter Duck in the 1980s. Rocking under wave action, its elements pumped a hydraulic fluid which in turn drove a generator. The project eventually stalled due to high operating costs (estimated). A recent reexamination of this WEC produced cost figures ten times lower than those initially estimated.

Also in the UK (in Southampton) Christopher Cockerell worked in the development of a WEC based on the relative movement of plates connected by hinged joints. Waves cause a relative movement between the plates, which pumps a high-pressure hydraulic fluid that drives a turbine connected to a generator. In 1974 the company Wave Power Limited was founded in order to commercialize the work and patents held by Cockerell's research group. The first of these devices was huge, measuring 50 m wide and 100 m long. Experiments with unidirectional waves and plates of different lengths were undertaken to determine the optimum configuration; when the prototypes were subjected to real operating conditions, they proved to be rather inefficient.

In Oxford Robert Russell, director of the Hydraulics Research Station at Wallingford, designed a device that would operate in shallow waters. The system, called the HRS Rectifier, was an anchored structure that breached through the surface of the water, with sluice gates closing off two tanks.

Although these WECs did not pass the experimental phase or, when they did, were not deemed efficient enough to warrant further development, they did form the knowledge basis upon which many of today's devices are built.

Classification of WECs

Wave energy converters can be classified according to different criteria: (i) installation site, (ii) dimensions relative to the wave length, and (iii) principle of operation. The latter is arguably the most usual and will be developed in more detail.

Classification According to the Installation Site

Three types of WECs can be distinguished according to this criterion:

(i) Onshore WECs, located entirely on land.
(ii) Onshore-offshore WECs, which capture wave energy in the nearshore and transform it into electricity in an onshore facility.
(iii) Offshore WECs, which are deployed in the sea. This group may be further divided according to whether the WECs are floating or resting on the seabed.

Classification According to the Dimensions Relative to Wave Length

This criterion distinguishes between two types of WECs: point absorbers and line absorbers. The dimensions of point absorbers are at least one order of magnitude smaller than the wave length, whereas the predominant dimension of line absorbers is of the same order of magnitude as the wave length. Line absorbers can be orientated transversally or longitudinally to the incoming wave direction.

Classification According to the Principle of Operation

There are three categories within this classification:

(i) Overtopping devices, based on waves overtopping a barrier, and the overtopping flow rate being stored at a reservoir and subsequently used to drive a turbine
(ii) Wave-activated bodies, which capture wave energy through the heaving motion of a floater
(iii) Oscillating Water Columns (OWCs), which – as indicated above – use a water column as a piston to create an air flow which in turn drives a turbine-generator group

Based on the principle of energy capture, they can be classified into: OWC, oscillating bodies, and overtopping devices. A short description of the three types is provided below.

WEC Technologies

Having put forward different criteria on which WEC technologies can be classified, in this section the state of the art is reviewed through notable WECs. The first criterion of classification (installation site) is followed to systematize the review.

Onshore WECs

As explained above, this group encompasses WECs that have both the energy capture and electricity generation systems onshore. Also known as first-generation devices, their technology is the most mature within the field. Indeed, some WECs in this category have already been in operation for a number of years. They are characterized by their relatively simple and inexpensive maintenance, a result of both their good accessibility as onshore devices and the fact that they are less exposed to the harsh marine environment than the other categories. Another substantial advantage is the absence of a submarine cable – unlike offshore devices. As a disadvantage, the wave resource that onshore WECs can exploit is smaller due to bottom friction and depth-induced wave breaking. A further disadvantage is the occupation of land and the corresponding environmental impact on the coastline, which can be more or less significant depending on the type of shoreline and the actual design of the device.

Within the onshore category, the oscillating water column (OWC) is the most advanced technology. The water column is housed in a semi-submerged concrete or (less commonly) steel chamber connected to the sea by an underwater opening. The lower part of the chamber is flooded with seawater, and its upper part contains air. The oscillation of the water inside the chamber (the "water column") induced by the waves outside causes the alternate compression and decompression of the air above, which is used to drive a bidirectional air turbine coupled to an electrical generator. There are currently several OWCs in operation (Falcão 2000; Torre-Enciso et al. 2009), e.g., Mutriku (Fig. 6 – Spain) or Pico (Acores, Portugal).

Civil works are the most important chapter in the cost of an OWC plant. In order to minimize this cost, OWCs have been installed on breakwaters, using the breakwater caissons to accommodate the chamber and its incumbent mechanical and electrical parts. Moreover, installation on a breakwater reduces not only the construction cost of the OWC itself, but also that of its road access and electricity connection. Maintenance costs are also reduced due to the easy access. Examples of OWCs installed on breakwaters are Sakata (Japan) and Mutriku (Spain), the latter with 16 chambers, each connected to a Wells turbine with a nominal power of 0.75 MW. Another project, finally not carried out, was envisaged at the recently built jetty at the Foz do Douro (Porto, Portugal). At present there are plans to install

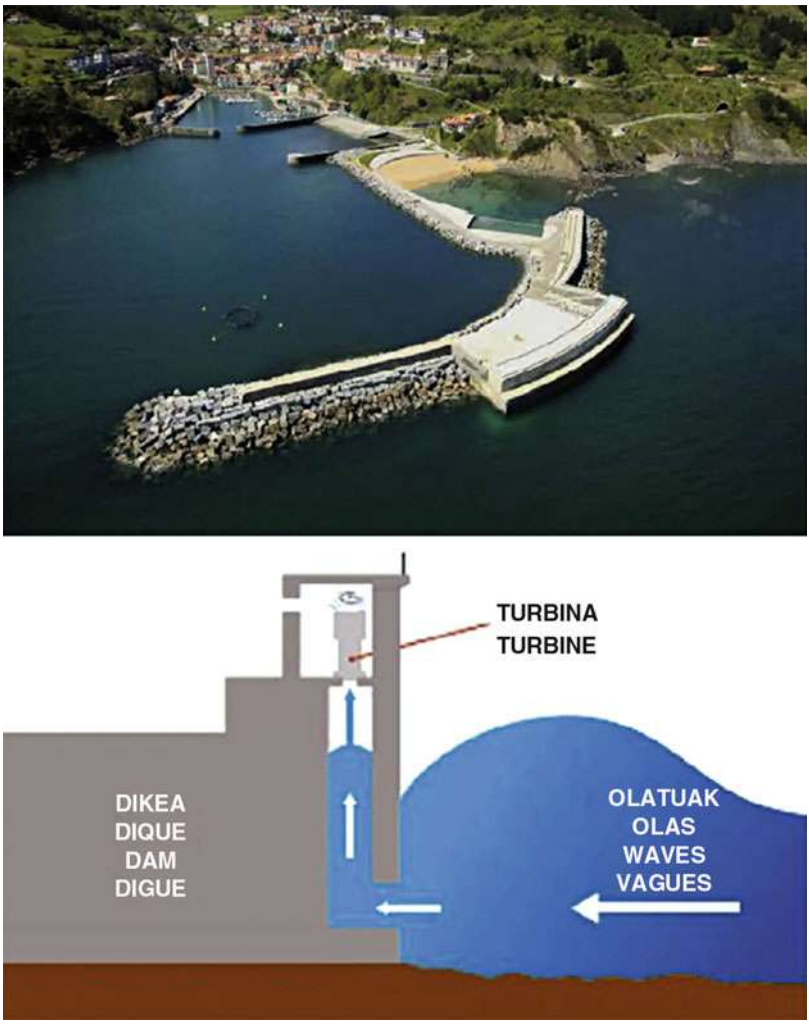

Fig. 6 Mutriku breakwater-mounted OWC (*top*) and schematic of the system (*bottom*) (Courtesy of EVE (2014))

the so-called U-OWC (Arena et al. 2013), an OWC with a U-shaped chamber, in the caisson breakwater of Civitavecchia (Italy).

Another group within this category consists of WECs whose principle of operation is wave overtopping, e.g., the Tapchan (Mehlum 1986) and the Seawave Slot-Cone Generator (Vicinanza and Frigaard 2008; Vicinanza et al. 2008). The former consists of a funneled-shape channel concentrating waves and directing their run-up toward an elevated reservoir. The difference in elevation between the water in this reservoir and the sea surface is used to drive the PTO. The volume of the reservoir can be large enough to store energy as potential energy, so that it is

only transformed into electricity when the demand arises. On the minus side, its disadvantages are related to the installation site, first, the very extension of the littoral area that it occupies; second, the environmental impact; third, the need for a relatively deep nearshore area for waves to reach the shoreline (and the entrance to the channel) without breaking and thus losing their energy; and, finally, the requirement of a microtidal range at the installation site (under 1 m), or else the efficiency would be considerably reduced. Tapchan was installed in Toftestallen, Øygarden (near Bergen, Norway), in 1985 and subsequently decommissioned.

In the Seawave Slot-Cone Generator, wave run-up over a sloping ramp (in principle on a rubble-mound breakwater) is captured through horizontal slots at three different levels, each connected with a reservoir. The outlets of the three reservoirs are connected to a multistage turbine, itself coupled with either an electrical generator or a hydrogen generation system.

The capture system of WaveStar (Denmark) consists of a number of hemispheric floaters, each connected to a hydraulic pump. The floaters are accommodated on a platform supported by two steel piles and oriented so that they are aligned perpendicular to the prevailing wave direction. Although the WaveStar platform is not strictly speaking on the shoreline, it was connected when installed to the shoreline by a catwalk; on these grounds, WaveStar is classified here as an onshore WEC. A 1:10 model installed at sea was recently tested (Kramer et al. 2011; Marquis et al. 2010).

Onshore-Offshore WECs

Onshore-offshore WECs can be regarded as a variant of onshore WECs in that the electricity generation occurs onshore; the difference with purely onshore WECs is that the capture system is in the sea.

This concept attempts to combine the advantages of onshore and offshore systems. The greater resource and smaller environmental impact of offshore WECs are achieved (to a certain extent), and the easier access and cheaper maintenance of onshore WECs are also attained (in part).

Oyster (Cameron et al. 2010) is one of the better known examples within this category. Its structure, with floating elements, is hinged at a base on the seabed and made to oscillate by waves. The oscillation around its vertical (rest) position drives a seawater piston that pumps water through a high-pressure flow line to an onshore hydroelectric power conversion plant. In order to minimize the cost of the line and bring friction losses down, the point absorber should not be far from the onshore part of the installation, which places a limit on the water depth at which the wave energy capture system can be installed – a downside shared by all the WECs in this category. Moreover, the nearshore installation of the capture system is not without a non-negligible environmental impact, including, not least, a visual impact.

The CETO III point absorber (Fig. 7), an evolution of the CETO I, consists of a number of submerged spheres that move back and forth with the waves (Mann 2011). These spheres are connected to pumps which drive high-pressure water to the onshore PTO, consisting of a Pelton turbine and an electrical generator.

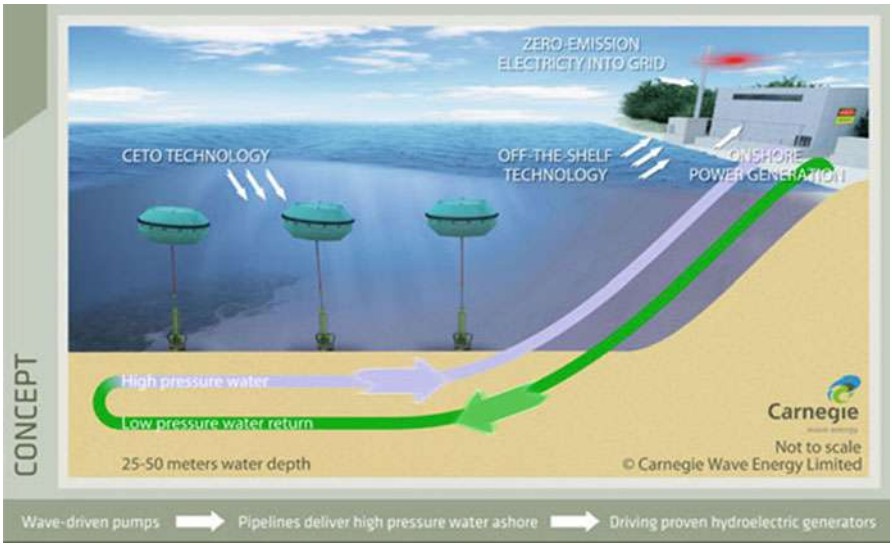

Fig. 7 Examples of onshore-offshore converters: the CETO wave energy converter (Courtesy of Carnegie Wave Energy)

Alternatively, the pumped water could be used to obtain freshwater using inverse osmosis.

Seadog is a point absorber device consisting of a floatation element that moves up and down inside a chamber with the passage of waves. This motion is used to propel a pump which pressurizes seawater; the high-pressure water is driven to the onshore installation, where it is used to power a turbine-generator module or a desalination plant. Several Seadog devices can be connected in parallel or in series. A water reservoir is part of the onshore facility, so the energy can be stored as potential energy and the generation of electricity can be accommodated to the demand – much as in the Tapchan.

Waveberg is a line absorber device consisting of a series of interconnected floaters. The joints between the floaters are activated with the passing waves, and their motion is used to propel piston-type pumps that drive high-pressure water to the shoreline part of the system, consisting of a turbine-generator group. The recommended water depth for the capture system is of the order of 50 m.

Finally, the wave-powered diaphragm pump is a point absorber system that exploits the oscillating movement generated by waves. At present it is an idea that has not yet been put into practice. The base of this device is a box-shaped concrete structure, full of rocks, designed to maintain the WEC stable on the ocean floor. The upper part of this base is an octagonal structure of steel housing 16 cylindrical columns. Within each one of these is a pump, separated from the other 15 through the use of used tires with cylindrical separators. All of these pumps are, in turn, housed in a large cylinder suspended in a raft measuring 32 m in diameter, which provides the buoyancy necessary to lift it when wave crests pass.

To transport the water from the capture system to the onshore generation system, piping is used to which the 16 pumps are connected using nonreturn valves. Once the fluid has been transferred onshore, it can be made to descend through a conventional hydraulic turbine connected to an electrical generator, or it may be stored in a reservoir for use when required. As in the case of Waveberg, the wave-powered diaphragm pump is designed to work at depths of approximately 50 m.

Offshore WECs

Offshore WECs are possibly the most prolific branch of wave energy conversion technology and can be classified into floating and fixed devices.

Floating Devices

The following WEC designs, Wave Dragon and WaveCat (Fig. 8), are based on wave overtopping (Fernandez et al. 2012; Iglesias et al. 2008; Kofoed et al. 2006; Tedd and Kofoed 2009). Overtopped water is collected in one or several reservoirs above the sea level. The water in these reservoirs is driven back to sea through one or several Kaplan turbines, much as in a conventional hydropower scheme. In the case of Wave Dragon, overtopping occurs at a ramp perpendicular to the direction of the incoming waves. In order to capture a wave front length larger than the ramp itself, two deflectors protrude from the ramp sides; they focus the waves toward the ramp, thereby enhancing wave height. Overtopping water is collected in a reservoir above the sea level; the difference in elevation between the water in the reservoir and the outside (sea) water is used to propel an ultra-low head Kaplan turbine. Freeboard and draft are varied according to the wave conditions. Wave Dragon is one of the heaviest WECs, with a structure around 30,000 t. This requires a substantial mooring system.

The WaveCat differs from the Wave Dragon in its structure and in the way overtopping occurs. Like a catamaran – from which it takes its name – WaveCat consists of two hulls. Unlike a catamaran, however, the hulls are convergent rather than parallel, so that from above they form a wedge. With a single-point mooring system (e.g., CALM, catenary anchor leg mooring), WaveCat swings so that it is always orientated in the direction of the incoming waves, which propagate into the wedge. As a wave crest advances between the two hulls, the wave height is enhanced by the tapering channel until, eventually, the inner hull sides are overtopped. Unlike Wave Dragon, in which the overtopping wave crest impinges normally on a ramp, in the case of WaveCat the overtopping crest impinges obliquely on the hull side. Overtopping water is collected in three reservoirs on each hull, at different levels – all above the mean sea level. The difference in elevation with respect to the exterior (sea) level is used to drive a turbine for each reservoir as the water is let out back to sea. Freeboard and draft, as well as the wedge angle, can be varied according to the sea state.

The advantages are threefold. First, overtopping occurs along the hull sides, so the WEC motions do not significantly affect the overtopping volumes but merely shift the point along the hull where overtopping starts. Second, the oblique overtopping signifies that the wave loads on the structure are considerably lower

Fig. 8 Overtopping wave energy converters: Wave Dragon (*top*) and WaveCat (*bottom*) (Courtesy of Wave Dragon AS (2005) and the COAST Research Group at Plymouth University and Fernandez et al. (2012))

than in the case of normally incident waves. Last, but not least, the wedge between the hulls can be closed so WaveCat becomes a conventional (monohull) ship – a useful survivability strategy. Maintenance costs are expected to be low, similar to those of a ship, and the fact that it can be towed to a dry dock in its closed configuration (monohull) and repaired using the same installations is an added advantage.

Pelamis (Fig. 9) belongs to another category of onshore WECs (wave-activated bodies). It is a semi-submerged device composed of four cylindrical sections held together by Cardan joints. As waves pass, the cylinders are displaced up and down by the buoyancy force, thereby activating the joints. These are equipped with a hydraulic system that takes advantage of the joint motions to pressurize an oleo

Fig. 9 Examples of oscillating body converters: Pelamis II (*left*) and PowerBuoy (*right*) (Courtesy of Pelamis Wave Power (2014) and Ocean Power Technologies Inc (2014))

hydraulic fluid. This pressure is used to propel a turbine-generator module. Pelamis is conceived for deployment at intermediate water depths, at distances from the coastline between 5 and 10 km. For complex repair operations, the Pelamis must be towed to a nearby port (Henderson 2006).

Another device that oscillates perpendicularly to the wave front is the Anaconda (Chaplin et al. 2007), which consists of a submerged flexible tube made of plastic materials and filled with seawater at low pressure; the tentative dimensions of the system are 5 m (diameter) and 150 m (length). It is moored at a single point so that it swings when the wave direction changes; thus, it is always head to sea. The tube is filled with seawater under low pressure. As a wave passes along the tube, a pressure bulge is excited and then moves down the tube in front of the crest, continuously capturing energy from the wave. At the stern is a turbine, which is driven by the flow resulting from the periodical pressure bulges. The turbine is coupled to an electrical generator. Among its advantages is its null visual impact (for it is submerged).

The next group of devices within the offshore category is composed of floatation elements oscillating on the sea surface. Among these is WET EnGEN, a point absorber consisting of a floating element that moves up and down along a steel mast with the passage of wave crests. The mast is inclined at an angle of 45° relative to the quiescent sea surface and swivels freely around its base with the purpose of being aligned to the wave direction. As the float moves up and down with the sea surface, it pulls on a cable housed within the mast, which conveys the energy to a rotational generator installed within the foundation.

The Aegir Dynamo WEC is another point absorber with an internal cylinder and an external, floating ring. The cylinder is anchored by means of cables or chains to deadmen laying on the seabed so that it remains practically stationary. The external, floating ring moves vertically with the sea surface. The cylinder houses a rotational generator that is driven continuously by the alternating motion of the external ring through a transmission system that transforms the ring's vertical motion into rotational motion.

Another subgroup within the offshore category is floating platform WECs, which have in common two main characteristics: they float and all their essential systems are above sea level – the mooring excepted. A representative of this subgroup is FO3, which takes advantage of the motion of the sea surface under waves by means of buoys mounted in rows and connected to the platform. The buoys drive pumps that pressurize an oleo hydraulic fluid, which in turn drives an electrical generator.

Finally, another line of development in floating offshore WECs is floating OWC devices (López and Iglesias 2014; López et al. 2014), e.g., Oceanlinx MK1 and Sperboy. The principle of operation of the OWC itself is the same as for onshore OWCs.

The Oceanlinx MK1 has a large rectangular chamber housed in a substantial structure. The turbine is designed so as to increase the energy efficiency of the device taking into account the prevailing wave frequency. Soft start systems powered by the electricity network are also included for the turbine to gain velocity faster.

The Sperboy is a vertical cylinder with hollow walls for flotation; within the cylinder is the chamber, connected to the sea through the cylinder bottom, which is open. While the lower part of the chamber is inundated, its upper part is filled with air, as in all OWCs. On the top of the device are four horizontal ducts through which air leaves and enters the chamber, driven by the alternating ascent and descent of the water surface within the chamber. The alternating air flow propels four Wells turbines (one in each duct), which in turn drive electrical generators.

The MAWEC converter, developed by Leancon, has a number of features in common with OWCs but also some differences – among which, the fact that the flow driving the turbine is recirculated. The device in plain view has a V shape. Each arm of the "V" has the transverse section of an inverted channel. The upper section is connected to two rows of vertical pipes, each with 30 pipes. The principle of operation is based on the fact that the length of the device is greater than the average wave length. When a wave reaches the end of the channel, it creates high- and low-pressure zones situated in front and behind the wave crests, respectively. The high pressure in front of the wave crest drives air flow through the corresponding tubes to a turbine, which drives a generator. The circuit is closed when the air expelled by the turbine is absorbed by the tubes under low pressure behind the wave crest. Valves are fitted to the ends of the low-pressure tubes to ensure that the flow occurs always in the same direction, i.e., the tubes are closed when they are in front of the wave crest. This conception allows for conventional turbines to be used rather than the far more expensive Wells turbines typical of OWCs.

Submerged Devices

Submerged offshore WECs are less common than floating ones, the reason being that underwater components add a new level of complexity. Designs are mostly at an early stage of development, and some of the most developed eventually failed.

The Archimedes Wave Swing WEC (Fig. 10) is composed of two cylinders measuring 9.5 m in diameter (de Sousa Prado et al. 2006; Valério et al. 2007).

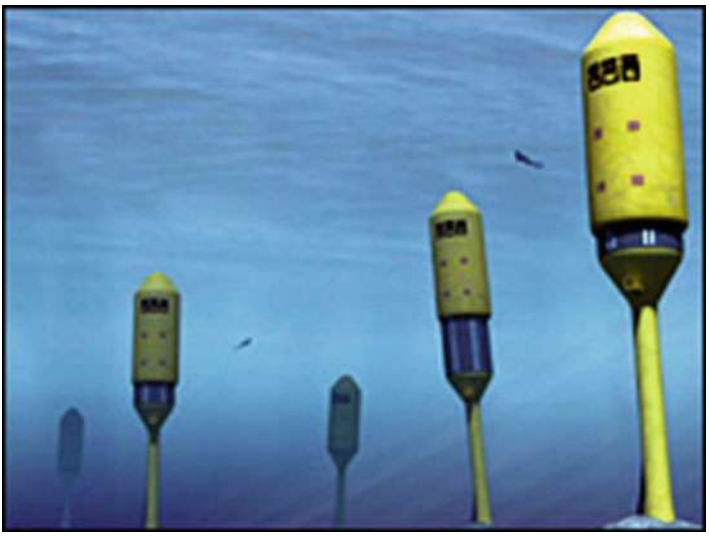

Fig. 10 Archimedes wave swing (Picture courtesy of AWS Ocean Energy (2015))

One of the cylinders is anchored to the seabed by means of a concrete structure. The other is located outside the first, at a higher elevation and full of air. When the crest of the wave passes over, the airbag is compressed, pressing the float downward. Conversely, when the trough of the wave passes over, the air expands, and the cylinder rises again. Magnets located in the upper cylinder generate electricity when they move relative to the coil inside the lower cylinder. This device cannot be seen on the surface of the sea, for it is located at a depth of 6 m – which reduces its visual impact. It does not have any hydraulic fluids, so there will be no leaks leading to contamination. On the other hand, the maintenance of this device is relatively complex, as all the equipment is underwater. However, this is advantageous in terms of survivability under storms. The device must be refloated in order to perform maintenance work. The manufacture of this WEC is of intermediate difficulty, given that it is a very large structure which requires significant resources in order to transport it to its anchoring site.

The Stellenbosch Wave Energy Converter is one of the first ideas for wave energy conversion, which did not materialize. The device's collector is installed on the seabed, forming a "V," and the power take-off is located at the tip of the V. It can be classed in the group of point absorbers. A bag of air is placed in a cavity at the top of the structure. As the crest of the wave passes over, the trapped air is compressed, thereby opening the high-pressure valves and allowing the air to flow toward a series of high-pressure pipes. When the trough of the wave passes, the pressure inside the bag drops and the low-pressure valves open. This yields a continual, one-way flow of air. In order to exploit this flow, on the converter is placed a one-way turbine between the low- and high-pressure collection tubes. The environmental impact of this device would be classified as intermediate, given that

it is a large apparatus occupying a large amount of space on the seabed. Nevertheless, it has no moving parts and does not interfere with marine life.

The wave rotor device represents a class of WECs that exploit the movement of the water as waves pass to drive a series of turbines. It employs two types of turbines: Darrieus and Wells. The rotors are used to generate electricity from upward and downward currents. The device is based on the same principle as wind turbines, which may also be installed on top of the WEC, taking advantage of the structure necessary for the wave energy converter. These systems can be quite efficient, as they feature no intermediate phases of energy transfer. The environmental impact of this type of device is intermediate, due to its visual impact and the existence of moving parts. Maintenance is relatively simple, but the fact that most of their components are underwater does complicate servicing. This type of device is constructed of familiar materials that are widely known but subjected to particular stresses. This converter is currently in a computational model and partial-scale design phase.

Finally, the BioWAVE device moves in the same way as a seaweed when a wave passes over it. This swaying motion is converted into electricity through the use of a specially developed generator called the O-Drive^{TM}, which is found at the point of articulation on the bottom of the device. If a storm approaches, the device protects itself by lying down on the seabed. Its environmental impact is thought to be minimal, as it has no high-speed parts which could harm marine life, and the anchoring system will also have only a slight impact. The maintenance difficulty of this device will be intermediate, as this type of apparatus has all its important mechanisms underwater. The manufacture of this converter is of intermediate complexity. Although the mast is easy to manufacture, the production of the energy absorption point is fraught with more difficulties.

Wave Farms for Coastal Protection

Introduction

A very significant proportion of the world's population (44 %) live within 150 km of the coast, and eight of the ten major cities are located on the coast (Oceans 2011), transforming the littoral into an extended hub for socioeconomic activity. This creates a substantial pressure on the coastal environment, with demands of use arising from fishing and aquaculture to residential, transport, industrial, or recreational purposes. This pressure is exerted on the single most sensitive, dynamic environment on the planet – the littoral. The resulting complex picture is further compounded by climate change, which can affect the coast chiefly through two main effects: sea-level rise and increased storminess.

In view of the large population of coastal areas throughout the world, it follows that climate change is likely to have one of its main impacts – in terms of socioeconomic consequences – through its effects on the coast. For example, in the case of the UK (Fig. 1), a significant portion of the coastline (17 %) is threatened by erosion; in the case of England and Wales, erosion rates exceed 10 cm per year

along approximately 28 % of the coastline (~1040 km) (EUROSION 2004). These figures are set to increase as a result of sea-level rise and increased storminess due to climate change, e.g., Pugh (2004), Chini et al. (2010), and Wadey et al. (2014) (Fig. 11).

It is hard to overstate the economic and environmental consequences of coastal erosion and flooding: loss or damage to property and infrastructure, disruption to the transport chain, losses through decreased revenues in the tourist and recreational sectors, etc. – hence, the importance of coastal defense. Almost half of the coastline (44 %) of England and Wales is protected by structures or artificial beaches (Huthnance and Mieszkowska 2010), and substantial investment (over £3.2 billion from April 2010 to March 2015) is undertaken by the Department for Environment, Food & Rural Affairs (DEFRA) in flood and coastal erosion risk management (DEFRA 2015).

The conventional approach to defending the coast against flooding and erosion involves coastal structures – this is the so-called "hard engineering" approach. The downsides of this approach are well known, not least its visual impact (armored coastlines) and, in the context of transition coasts, the inability of structures to adapt to sea-level rise. Indeed, there have been recently many cases of coastal structures failing to cope with the increased pressures of climate change (Castelle et al. 2015; Kendon and McCarthy 2015; Senechal et al. 2015; Sibley et al. 2015; Slingo et al. 2014; Spencer et al. 2015). A case in point is the failure of the Dawlish seawall (Devon, England) in the winter 2013/2014 – the stormiest period of the past 60 years, compounded by the highest sea-level of the past 100 years (Haigh et al. 2015) – which led to the destruction under massive overtopping of a critical section of railway and consequently the disruption to the rail link between SW England and the rest of the country for 3 months (Fig. 1). Other examples include the failure of the La Coruna seawall (Spain), the collapse of the Aberystwyth seawall (Wales), and the dramatic erosion affecting many beaches throughout

Fig. 11 Coastal infrastructure and property at risk

Fig. 12 Consequences of increased storminess in Soulac-sur-Mer (France) after winter 2013/2014

Europe, from Spain (e.g., Aviles, Barreiros) to France (e.g., Truc Vert, Biscarrosse) to the UK (e.g., Chesil, Perranporth, Isle of Man), which in some cases resulted in the demolition of buildings due to the great volumes of erosion that affected the foundations, such as in Soulac-sur-Mer (France – Fig. 12).

These examples of failures of coastal structures – due to either structural collapse or excessive overtopping – expose the dramatic consequences of the inadequacy of many of the existing structures in the current transition scenario. The conventional approach to solving this problem entails upgrading the existing structures or building new ones, in both cases at a large cost. The downsides of this approach are related to the difficulty of fixed coastal structures in dealing with the transition conditions, notably sea-level rise, and more generally to the environmental, and particularly visual, impact of these structures on the littoral.

The advent of marine renewable energy, particularly wave energy, posits wave farms as an alternative to coastal defense that presents numerous advantages, not least in the current transition environment. Wave farms, or arrays of wave energy converters (WECs), extract energy from the waves. Recent research has proven that nearshore wave farms lead to not only milder wave climates in their lee (Carballo and Iglesias 2013; Iglesias and Carballo 2014; Millar et al. 2007; Palha et al. 2010; Reeve et al. 2011; Rusu and Guedes Soares 2013; Vidal et al. 2007) but, importantly, reduced beach erosion under storm and post-storm conditions (Abanades et al. 2014a, b, 2015a, b; Mendoza et al. 2014; Zanuttigh and Angelelli 2013), which amounts to effective coastal protection – much as that provided by a conventional coastal structure. However, nearshore wave farms present three main advantages relative to coastal structures. First, by providing renewable, carbon-free energy, wave farms contribute to decarbonizing the energy supply and thereby combating the man-made causes of climate change. Second, the environmental impact of wave farms on the littoral – the single most sensitive

environment in the planet – is considerably lower than that of coastal structures. Last, but not least, wave farms consisting of floating WECs (e.g., WaveCat, Wave Dragon, DEXA) adapt naturally to sea-level rise and therefore can cope well with the main impact on the littoral of climate change. Thus, rather than resorting to the conventional approach (more structures) to fix obsolete, underperforming structures, deploying wave farms to generate carbon-free energy as their main purpose and, in synergy with it, defend the coastline against erosion and flooding is a new alternative that warrants consideration. Incidentally, their application to coastal defense would enhance their economic viability through the savings achieved in conventional defense schemes.

This alternative to conventional coastal defense schemes (based on structures such as groynes, detached breakwaters, etc.) is in fact a new paradigm to mitigating climate change and confronting two global challenges: the environmental repercussions of the current energy model and the risks to properties and infrastructure posed by coastal erosion. As explained, these two challenges are connected, for climate change is set to exacerbate coastal erosion through its effects of sea-level rise and increased storminess.

The effects of wave farms on coastal processes and, in particular, their effectiveness for coastal protection are investigated through a case study: Perranporth, a beach in Cornwall (SW England) that has experienced significant erosion over the last years, not least during the harsh winter 2013/2014. Indeed, the Shoreline Management Plan has identified the area as subject to significant erosion risk, and a number of options are being assessed to confront this challenge (CISCAG 2011).

The case study is analyzed through a suite of state-of-the-art process-based models, combined for the first time for this purpose – a third-generation spectral wave model and a coastal processes model. The evolution of the beach with and without the nearshore wave farm is studied in different scenarios, involving wave farms deployed at different locations and distances from the shoreline, plus the baseline scenario (without the farm). The response of the coastal system is analyzed at different time scales, from the short (days) to the medium (months) term, with the long-term study as future work. A set of ad hoc indicators is defined to quantify the effects of wave energy absorption by the farm on coastal processes and, in consequence, the degree of protection afforded by the wave farm in the different scenarios.

Case Study: Perranporth Beach (UK)

The effectiveness of wave farms in mitigating dune erosion on the beach was analyzed by means of a case study: Perranporth Beach (Fig. 13). The selection of this case study is motivated by two reasons: (i) the erosion experienced by the beach over the last years, particularly under the cluster of heavy storms (Fig. 14) of February 2014 (CISCAG 2011), and (ii) the interest of the area for wave energy development, as shown, e.g., by the nearby

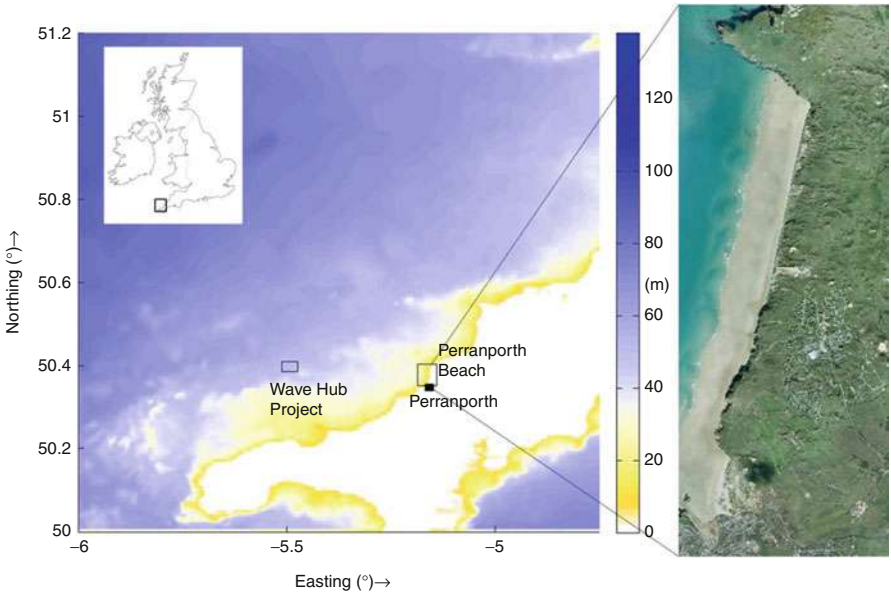

Fig. 13 Location of Perranporth Beach and the Wave Hub in SW England (*left*; water depths in m) and aerial photo of the beach (*right*; courtesy of Coastal Channel Observatory)

Fig. 14 Damages at Perranporth Beach after storms in winter 2013/14. Courtesy of West Briton

Wave Hub – a grid-connected offshore facility for WEC testing (Gonzalez-Santamaria et al. 2013; Reeve et al. 2011).

For this work wave buoy data were used alongside hindcast (numerical modeling) data. Half-hourly data were obtained from the directional wave buoy off Perranporth, in approximately 10 m of water, operated by the Coastal Channel Observatory. The analysis of these data reflects the exposure of the area to heavy swells generated by the long Atlantic fetch, as well as to locally generated wind seas. The average significant wave height (H_s), peak period (T_p), and peak direction (θ_p) in the period covered by the wave buoy data (2006–2012) were 1.79 m, 10.36 s, and 280°, respectively.

Hindcast data were obtained from WaveWatch III, a third-generation offshore wave model that is run on global and regional (nested) grids, the latter with a resolution of 0.5° (Tolman 2002). These values were prescribed at the outer boundaries of the wave model.

In addition to these large-scale hindcast wave data, three-hourly wind data obtained from the Global Forecast System (GFS) weather model were used to drive the wave model. The mean wind speed at a height of 10 m above the sea surface was $u_{10} = 9.5\ \mathrm{ms}^{-1}$ during the study period; the strongest winds, from the NW, had u_{10} values over $20\ \mathrm{ms}^{-1}$.

SW England is subjected to a semidiurnal tidal regime and a large tidal range (macrotidal), with a mean spring value of 6.3 m at Perranporth. The tide was accounted for in the modeling, with constituents obtained from the TPXO 7.2 global database (Egbert et al. 1994).

A 4 km long beach with a nearly flat intertidal area ($\tan \beta = 0.015$–0.025), Perranporth (Austin et al. 2010; Masselink et al. 2005) has medium sand size ($D_{50} = 0.27$–0.29 mm). The bathymetry (Fig. 15), kindly provided by the Coastal Channel Observatory, showed elevation values between −20 and 25 m relative to the local chart datum (LCD). A submarine bar is present between −5 and −10 m and has a bearing on behavior of the beach; under energetic waves and increased offshore sediment transport, it grows at the expense of the intertidal beach face. Overall, profile changes at Perranporth affect primarily the lower intertidal and subtidal active regions (Scott et al. 2011). In addition to the aforementioned submarine bar, Perranporth is characterized by a well-developed dune system.

Suite of Process-Based Numerical Models

Wave Propagation Model

Wave propagation is calculated with a third-generation numerical model, SWAN (Simulating WAves Nearshore), described in section "Wave models." This model was successfully applied in a number of works (Abanades et al. 2014b; Carballo and Iglesias 2013; Iglesias and Carballo 2014; Millar et al. 2007; Palha et al. 2010; Smith et al. 2012) to model wave farm effects on nearshore wave conditions.

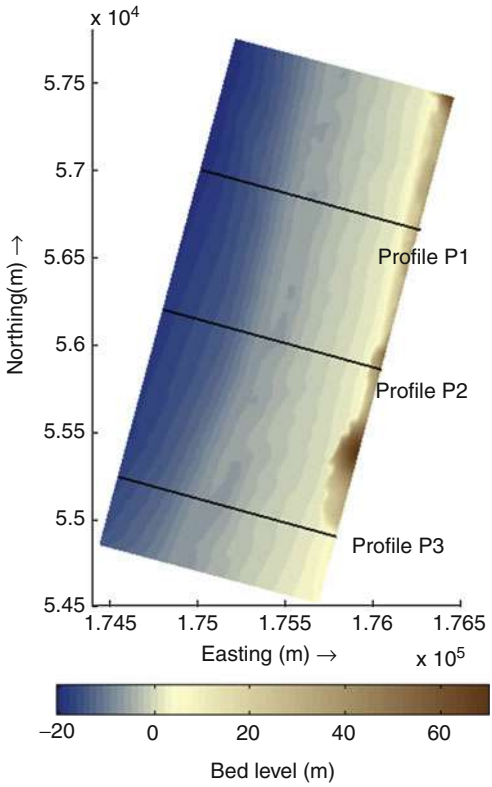

Fig. 15 Computer-modeled bathymetry at Perranporth Beach, including profiles P1, P2, and P3 (Water depth in m)

Two computational grids (Fig. 16) were used to obtain a high-resolution results in the area of interest without compromising computational efficiency, as follows: (i) a large-scale grid covering approx. 100 × 50 km with a resolution of 400 × 200 m and (ii) a small-scale (nested) grid focused on Perranporth Beach, covering an area of approx. 15 × 15 km with a resolution of 20 × 20 m. Thanks to the fine resolution of the nested grid, the individual WECs in the farm could be demarcated and their individual wakes modeled with accuracy – a prerequisite to establishing the wave farm effects on the beach profile (Carballo and Iglesias 2013). The offshore and nearshore bathymetric information – obtained from the UK data center Digimap and the Coastal Channel Observatory, respectively – was interpolated onto these grids (Fig. 17).

Based on the review of WEC technologies (section "WEC Technologies"), WaveCat, a floating overtopping WEC for offshore deployment, was selected. The wave farm considered consisted of 11 WaveCat WECs arranged in two rows (Fig. 18) – the same layout as in Carballo and Iglesias (2013), with a distance between devices of 90 m (equal to the distance between the twin bows of a single WaveCat WEC). Wave-WEC interaction was characterized on the basis of ad hoc laboratory tests (Fig. 18) reported by Fernandez et al. (2012).

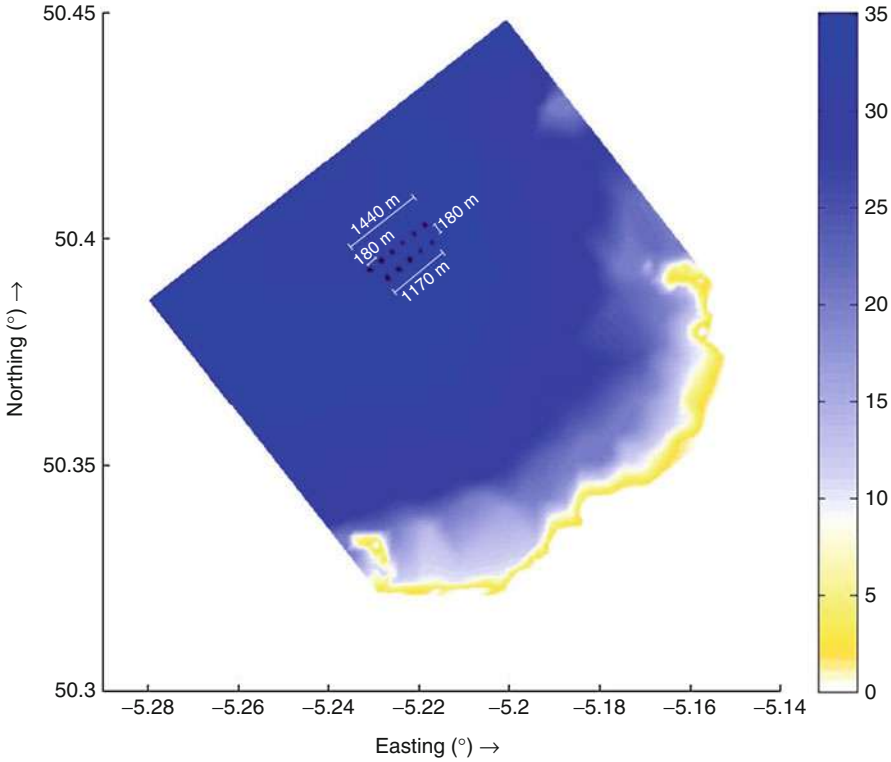

Fig. 17 The array of WECs, or *wave farm*, off Perranporth (water depths in m)

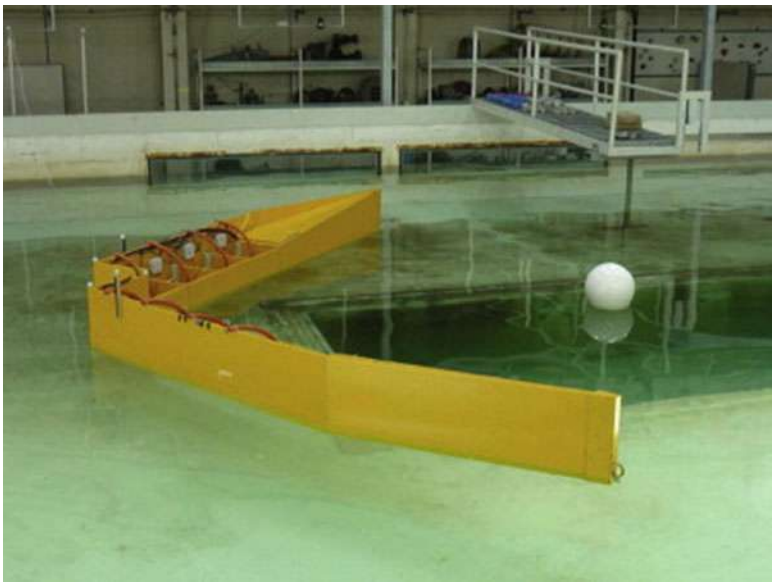

Fig. 18 Physical model tests of WaveCat (Carballo and Iglesias 2013)

Coastal Processes Model

A two-dimensional model for wave propagation, long waves and mean flow, sediment transport, and morphological changes of the nearshore area, beaches, dunes, and back barrier during storms, XBeach solves the time-dependent short wave action balance, the roller energy equations, the nonlinear shallow water equations of mass and momentum, sediment transport formulations, and bed update on the scale of wave groups concurrently. A full description of XBeach can be found in Roelvink et al. (2006) or Roelvink et al. (2009).

The input conditions for XBeach, the coastal processes model were obtained from the output of the SWAN wave propagation model. Sediment transport is modeled with the following depth-averaged advection-diffusion equation (Galappatti and Vreugdenhil 1985):

$$\frac{\partial(hC)}{\partial t}+\frac{\partial(hCu^E)}{\partial x}+\frac{\partial}{\partial x}\left(D_s h\frac{\partial C}{\partial x}\right)+\frac{\partial(hCv^E)}{\partial y}+\frac{\partial}{\partial y}\left(D_s h\frac{\partial C}{\partial y}\right)=\frac{hC_{eq}-hC}{T_s} \tag{14}$$

where C represents the depth-averaged sediment concentration, which varies on the wave-group time scale, D_s is the sediment diffusion coefficient, the terms u^E and v^E represent the Eulerian flow velocities, T_s is the sediment concentration adaptation time scale that depends on the local water depth and the sediment fall velocity, and C_{eq} is the equilibrium concentration, thus representing the source

term in the sediment transport equation. The sediment transport formula defined by Van Thiel de Vries (2009) was used to determine the sediment equilibrium concentration.

For this case study, the model was applied in one and two dimensions horizontal, 1DH (x,z) and 2DH (x, y, z), respectively. In the 1DH case the evolution of two profiles (Profiles P_1 and P_2 in Fig. 15) was investigated. In the 2DH case the entire Perranporth Beach was studied, with a computational grid that extended 1250 m across shore and 3600 m alongshore with a resolution of 6.25 and 18 m, respectively. In both cases the model was driven by spectral parameters obtained from the nearshore wave propagation model, the root-mean-square wave height, H_{rms}; mean absolute wave period, T_{m01}; mean wave direction, θ_{m}; and directional spreading coefficient, s; these were used to construct time series of wave amplitudes, including wave groups – of relevance in beach behavior under erosive conditions (Baldock et al. 2011).

Impact Factors

A set of ad hoc impact indicators recently developed were used to analyze impacts of the wave farm on the beach morphodynamics. Three impact indicators developed by Abanades et al. (2014a) were applied to the results of the coastal processes model (XBeach): (i) bed level impact (*BLI*), (ii) beach face eroded area (*FEA*), and (iii) nondimensional erosion reduction (*NER*).

The bed level impact (*BLI*), with units of m in the S. I., represents the change in bed level caused by the wave farm, calculated as

$$BLI(x,y) = \zeta_f(x,y) - \zeta_b(x,y) \tag{16}$$

where $\zeta_f(x, y)$ and $\zeta_b(x, y)$ are the seabed level in the presence or absence of the farm, respectively, at a generic point of the beach. The y-axis is aligned with the general coastline orientation, and the x-axis is positive away from the sea. $BLI > 0$ or $BLI < 0$ signify that the wave farm leads to a higher or lower seabed level relative to the baseline (no farm) scenario, respectively.

The beach face eroded area (*FEA*), with units of m^2 in the S. I., is a profile function that quantifies the storm-induced erosion in the beach face. Unlike the preceding parameter, which compared the farm and baseline (no farm) scenarios, the *FEA* index is defined separately for both scenarios, baseline (FEA_b) and wave farm (FEA_f):

$$FEA_b(y) = \int_{x_1}^{x_{\max}} [\zeta_0(x,y) - \zeta_b(x,y)]\,dx, \tag{17}$$

$$FEA_f(y) = \int_{x_1}^{x_{\max}} [\zeta_0(x,y) - \zeta_f(x,y)]\,dx, \tag{18}$$

where $\zeta_0(x, y)$ is the initial bed level at the point of coordinates (x, y), and x_1 and x_{max} are the values of the x-coordinate at the seaward end of the beach face and landward end of the profile, respectively.

A second profile function is the nondimensional erosion reduction (*NER*), given by

$$NER(y) = 1 - (x_{max} - x_1)^{-1} \int_{x_1}^{x_{max}} [\zeta_0(x,y) - \zeta_f(x,y)][\zeta_0(x,y) - \zeta_b(x,y)]^{-1} dx, \quad (19)$$

which quantifies the change in the eroded area of a generic profile (y) caused by the wave farm as a fraction of the total eroded area of the same profile. $NER > 0$ and $NER < 0$ signify a reduction or increase in the eroded area.

Medium-Term Impacts

Based on the wave buoy data from November 2007 to October 2008, the wave propagation model was validated. An excellent agreement between model results and wave buoy observations was achieved (Fig. 19), with a coefficient of correlation (R) and root-mean-square error of 0.97 and 0.38 m, respectively.

Upon validation, the numerical model was applied to compare the wave patterns with and without the wave farm, and to establish the wave conditions that were to be the input to the coastal processes model. The effects of the wave farm on the nearshore wave patterns are clear, for instance, in Fig. 20, corresponding to a storm peak. The significant wave height goes down by over 30 % in the direct wakes of the WECs – a reduction that is less marked on the beach itself, as a result of wave energy diffracted from the sides of the farm into its lee. This reduction of wave height is particularly apparent in the northern section of the beach owing to the deepwater wave direction (approx. WNW).

As explained, wave power on the beach was reduced by the presence of the farm. To quantify the effects of this reduction, the profiles P1 and P2 were followed from November 2007 to April 2008. The coastal processes model was forced with the spectra generated by the wave propagation model run with and without the wave farm.

In the presence of the wave farm (Fig. 21), the evolution of the profiles from the initial conditions to 3 months into the simulation is characterized by erosion concentrated on the beach face – the section exposed to wave uprush – with the eroded sediment depositing on lower sections.

In Fig. 22 the comparison between the farm and no farm scenarios is presented for profile P2. The energy extracted by the farm leads to a substantial reduction (approx. 3 m) in the erosion of the dune, which displaces the landward extreme of the eroded area more than 10 m toward the sea. This displacement can be of particular relevance in cases such as Soulac-sur-Mer (Fig. 12), where some

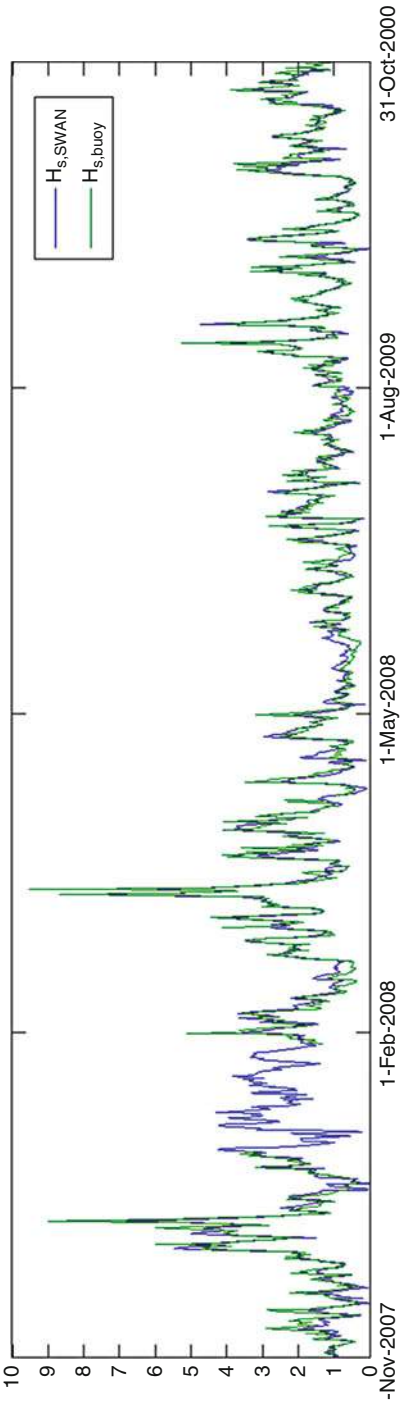

Fig. 19 Time series of modeled ($H_{s,\ SWAN}$) vs. observed ($H_{s,\ buoy}$) significant wave height

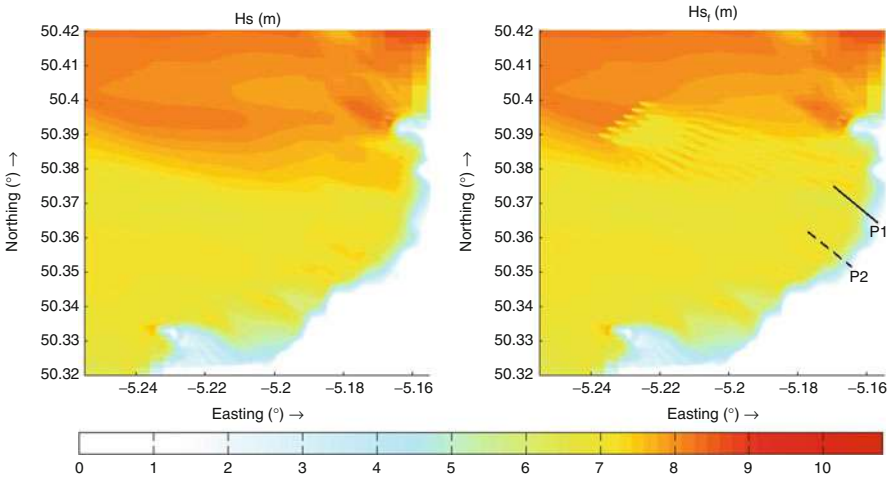

Fig. 20 Significant wave height in the no farm or baseline scenario (*Hs*, *left*) and in farm scenario (*Hsf*, *right*) at the storm peak on 10 Mar 2008, 18:00 UTC (deepwater wave conditions: $H_{s0} =$ 10.01 m, $T_p = 15.12$ s, $\theta_p = 296.38°$). Profiles P1 and P2 are delineated for reference

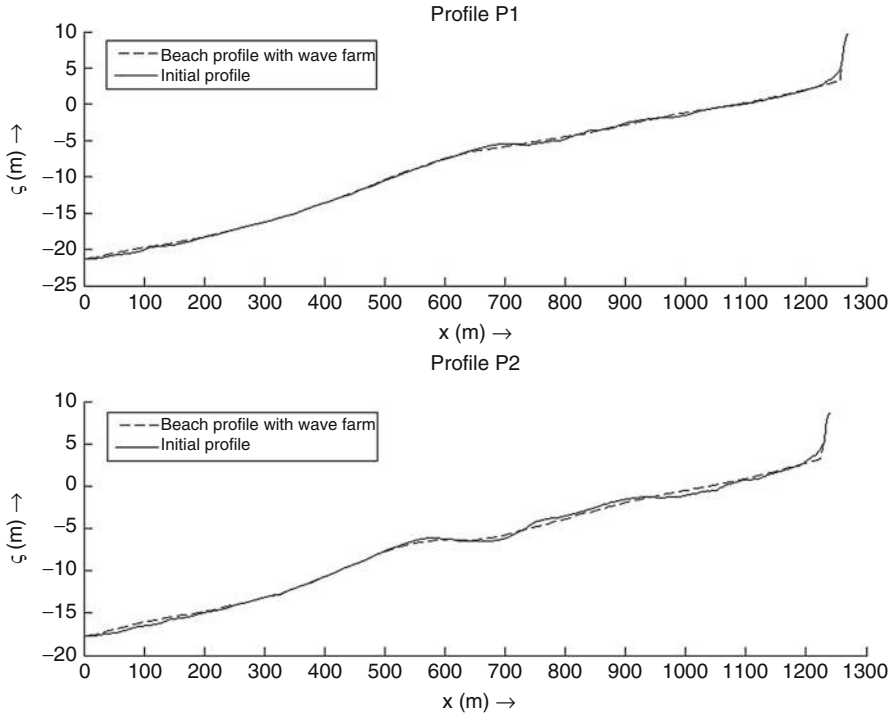

Fig. 21 Bed level at Profiles P1 and P2: initial (1 Nov 2007, 0000 UTC) and after 3 months, in the presence of the wave farm (22 Jan 2008, 15:47 UTC)

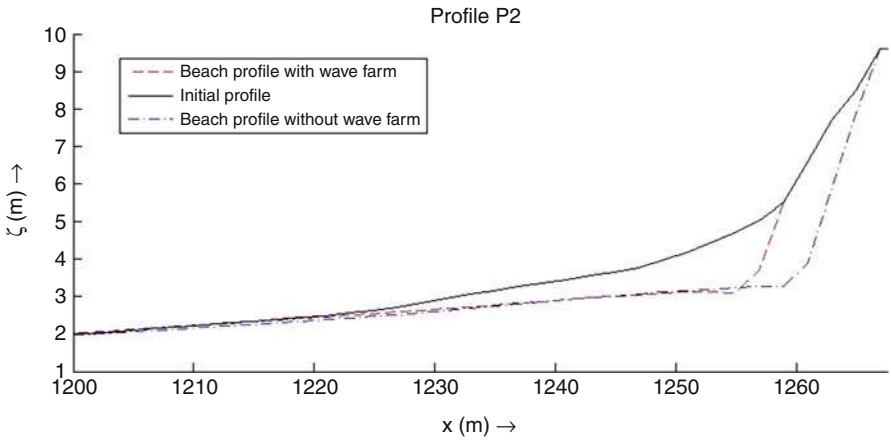

Fig. 22 Beach face level at Profile P2: initial (1 Nov 2007, 0000 UTC) and after 3 months with and without the wave farm (22 Jan 2008, 15:47 UTC)

buildings were at risk due to storm-induced erosion at the toe of the foundations. Had a wave farm been deployed off that section of the coast, the demolition of many a building would be avoided.

The impact of the wave farm on the beach profile was analyzed through the parameters defined in section "Suite of Process-Based Numerical Models." The *BLI* parameter along Profiles P1 and P2 (Fig. 23) was analysed for three different points

Table 1 *FEA* and *NER* factors for Profiles P1 and P2 at different points in time: 1 month (*M1*), 3 months (*M3*), and 6 months (*M6*) after the beginning of the study period

	M1			*M3*			*M6*

in time: 1 month (*M1*), 3 months (*M3*), and 6 months (*M6*) into the study period. A significant reduction of the erosion on the beach face and the submarine bar ($x \sim 600$ m) is apparent. Given that the bar is an essential element of the beach response to storms, its reinforcement thanks to the wave farm clearly increases the resilience of the system. This effect strengthens over time, as *BLI* values soar over the submarine bar.

The *BLI* values for both profiles were similarly non-negligible on the beach face, indicating that the wave farm reduces the erosion also in this section of the profile. To quantify these effects, the *FEA* and *NER* indicators were computed (Table 1). Comparing the two profiles, the effectiveness of the wave farm is more apparent in the northern section of the beach (Profile P1). The comparison between the FEA_b and FEA_f values and the nondimensional values of *NER* reflect the effectiveness of the wave farm in reducing storm-induced erosion and in maintaining this reduction over the medium term (M6 values, after 6 months). The relatively smaller reduction in proportional terms (*NER*) after 6 months is due to the fact that the later part of this period is not particularly stormy (March and April) – with fewer storms and less erosion, the reduction in storm-induced erosion is quantitatively smaller. Nevertheless, *NER* values after 6 months are still relevant.

The results in Table 1 showed a significant reduction of the erosion along profiles P1 and P2, which may indicate some degree of coastal protection owing to the presence of the wave farm nearshore. However, these results must be corroborated by means of a 3D study of the beach – and this is the main aim of the following section.

Short-Term Impacts

Having studied the medium-term effects of the wave farm on the beach profile, this section focuses on the response of the system in the short term during the storm, from 5 December 2007 0000 UTC to 10 December 2007 0600 UTC. The mean values of significant wave height, peak period, and peak direction were $H_s = 4.2$ m, $T_p = 12.1$ s, and $\theta_p = 295°$, respectively.

Based on the results of the wave propagation model, the coastal processes model was applied to determine how the modification of the nearshore wave conditions

affected the coastal processes and, consequently, the beach morphology. As in the previous section, the impact was quantified by means of the indicators defined in section "Suite of Process-Based Numerical Models."

The reduction of the erosion was particularly apparent on the dune, with values of *BLI* over than 4 m (Fig. 24) – the outcome of wave energy extraction by the wave farm. Similarly, the submarine bar experienced reduced erosion, particularly in water depths between 5 and 10 m and in the middle area of the beach, where the *BLI* parameter reached 0.5 m. The material that was eroded from the dune deposited primarily on lower sections of the profile, between the bar and the dune, leading to negative values of *BLI*, of the order of –0.5 m.

The beach face eroded area (*FEA*) values confirmed the effect of the wave farm in reducing erosion (Fig. 25). The most drastic erosion occurred in the southernmost end of the beach ($y \sim 0$ m) and in its northern section, the reason being that the former is not backed by the dune system, and the latter is exposed to larger waves. As regards the mid-south area of the beach, the *NER* factor presented a large variability in the section 500 m $< y <$1500 m, owing to the small values of baseline erosion (small values of the denominator in the expression of *NER*). The wave farm proved to be more effective in countering erosion in the northern area of the beach, in the direct lee of the WECs. The nondimensional erosion reduction (*NER*) confirmed this effectiveness, with values over 30 % along more than 1000 m of beach (Fig. 26).

Future Directions

At this point wave energy is generally considered as an expensive form of renewable. This is due, in part, to the early stage of development of the technology and, in part, to the difficulties posed by the harsh marine environment. In any case, for wave energy to truly take off, its costs must decrease substantially.

Over time it may be expected that, as the technologies develop, a proper chain of production for wave energy components is established, and manufacturing of WECs assumes an industrial scale, economies of scale will ensue which will lead to cost reductions. The process whereby the development of an incipient technology, improvements by practice, and economies of scale lead to savings is exemplified by the so-called learning curve. The greatest opportunities for cost reduction in wave energy as a stand-alone energy source at present are related to the installation and construction processes (Astariz and Iglesias 2015) and the optimization of WEC design.

In addition to the previous options, two "strategic" approaches for reducing the cost are (i) using wave farms for coastal defense in synergy with their main function of generating carbon-free energy (section "Wave Farms") and (ii) combining wave energy with other forms of marine renewable – notably, offshore wind (Astariz et al. 2015a, b, c; Perez Collazo et al. 2014; Stoutenburg et al. 2010).

The application of wave farms to coastal protection was investigated in section "Wave Farms." Its advantages are twofold: enhanced economic viability through

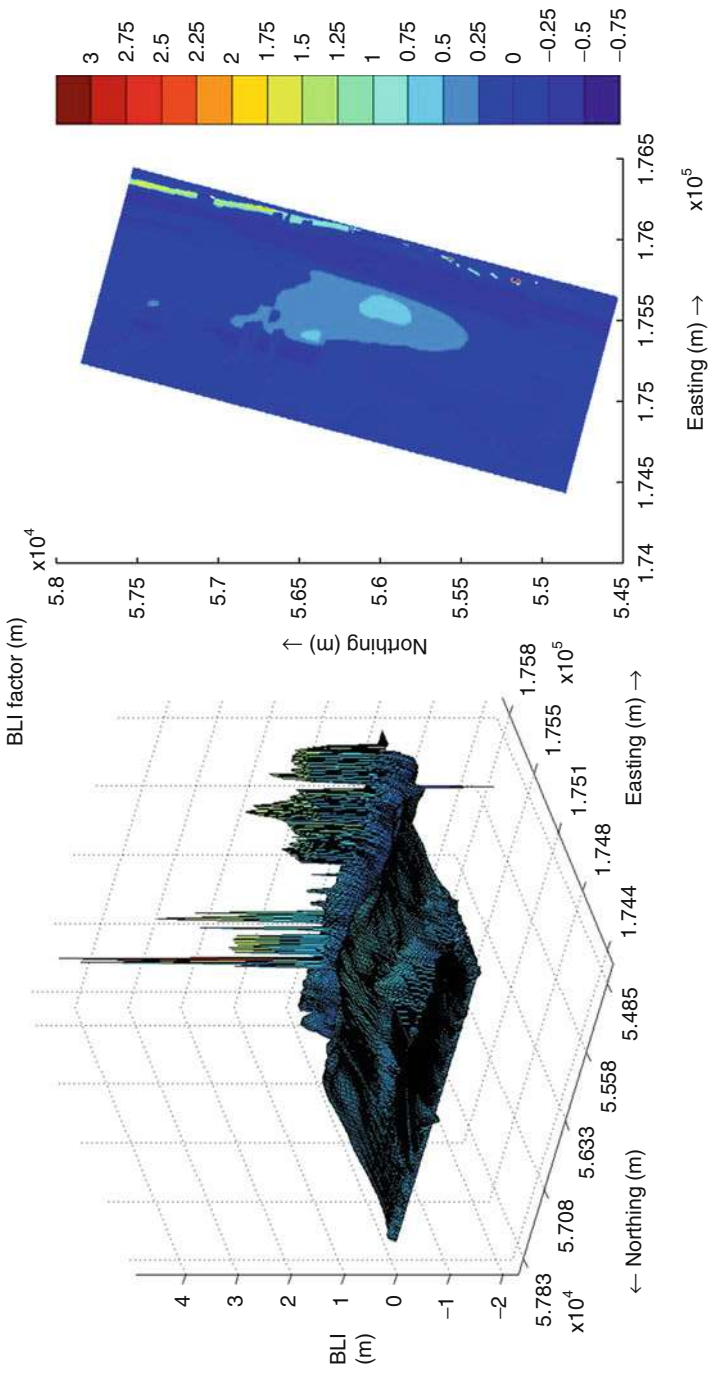

Fig. 24 Bed level impact (*BLI*) at the end of the study period

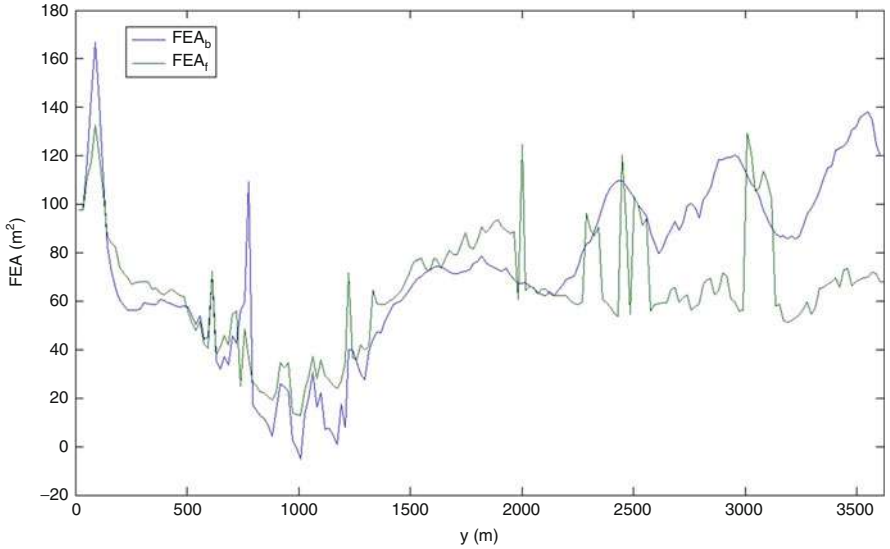

Fig. 25 Beach face eroded area in the baseline (FEA_b) and wave farm (FEA_f) scenarios at the end of the study period

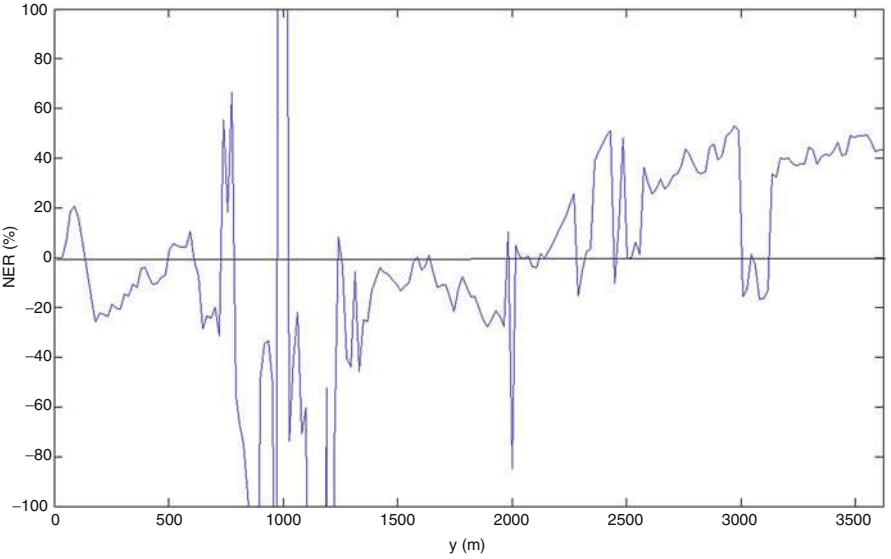

Fig. 26 Nondimensional erosion reduction (*NER*) on the beach face at the end of the study period

savings in conventional defense schemes and adaptability to effects of climate change such as sea-level rise (unlike conventional coastal defense schemes based on structures). So far the effectiveness of wave farms for coastal protection has been established in the short and medium term. The multidecadal response of the coastal

system must be studied in order to establish their long-term efficiency. In addition, further research is necessary to accurately predict the savings that could ensue.

Combined wave-offshore wind energy brings down costs through shared electrical infrastructure (cables, substation, grid connection), foundations and substructures (hybrid systems) or moorings, and maintenance (crews, boats, and other equipment). These items represent a substantial portion of the total cost, and therefore sharing them with an offshore wind farm would be effective in improving the economic viability of wave energy. Additional advantages of combined offshore wind and wave energy are (i) optimized use of the scarce marine space, with an enhanced energy yield per unit area; (ii) smoother power output; and (iii) a less energetic wave climate within the offshore wind farm, which will reduce the loads on foundations and, importantly, increase the weather windows for maintenance, which will in turn reduce downtime (Astariz et al. 2015b; Pérez-Collazo et al. 2015).

Research into these two avenues for reducing costs – the synergetic application of wave farms to coastal protection and combined wave-offshore wind farms – is currently under way by means of numerical modeling, laboratory work, and fieldwork. Laboratory and field data are necessary to improve the understanding of wave-WEC interaction, hence of the effects of wave farms on their environment, not least on the littoral. They constitute the means for calibrating and validating numerical models, which are instrumental in optimizing WEC design and modeling wave propagation through the wave farm and coastal processes in its lee.

Conclusions

In this chapter a review of wave energy was presented, from the wave resource to the technologies to harness it to its application to coastal defense or in combination with offshore wind. As regards the wave resource (section "Wave Resource Characterization"), its fundamentals were explained, and the procedure to characterize its temporal and spatial variability by means of numerical modeling and field data was outlined. This characterization is essential in: (i) selecting optimum wave farm locations; (ii) predicting the energy output of a wave farm; (iii) assessing its downtime, which may be due to extreme sea states, insufficient wave height, or maintenance (scheduled or unscheduled, after breakdowns); and (iv) determining the installation and maintenance costs. In sum, the characterization of the wave resource is fundamental to analyzing the viability of a wave energy project and to selecting the wave energy conversion technology that is most appropriate to a given site.

The different technologies for wave energy conversion (section "Wave Energy Conversion") were classified according to three criteria: installation site, dimensions relative to wave length, and principle of operation. Next, representative WECs of each category were briefly reviewed. Nowadays no single technology can be said to have gained overall acceptance, and it remains to be seen which concept will prevail. What is certain at present is that the two factors that are most

likely to influence the outcome of this natural selection process are economic viability and reliability, both of which depend on the performance (energy efficiency, i.e., capture width ratio) and survivability.

Wave farms were shown to be an efficient method to protect the coast in the short and medium term (section "Wave Farms") – with research into their long-term efficiency included into the future research lines (section "Future Directions"). In this regard, their advantages relative to conventional coastal protection means (based on structures: detached breakwaters, groynes, etc.) in terms of adaptation to sea-level rise and low environmental (particularly visual) impact are noteworthy. Promising quantitative results were obtained in the study case, with reductions over 50 % in storm-induced erosion.

The objectives of greenhouse gas reduction established by the Kyoto protocol and other treaties can only be attained by means of a very substantial increase in the proportion of renewables in the energy mix. This can only be possible through the expansion of consolidated renewables (e.g., offshore and onshore wind, solar, hydropower) and the development of nascent renewables (e.g., wave, tidal). In the case of wave energy, this development is taking place, with intensive research into a number of technologies, and new opportunities through combinations with other renewables (offshore wind) and the synergetic application to coastal protection. This chapter showed that wave energy is emerging as a promising renewable capable of tackling climate change on the double front of its causes (through reduced carbon emissions) and effects, particularly on the coast (erosion).

Contents

Abstract

While most renewable energies are, directly or indirectly, derived from the sun, geothermal energy originates in the interior of the earth. Geothermal energy is the most stable of the renewable energies because it can be utilized constantly, regardless of weather or season. Geothermal energy can be used not only for power generation but also for direct heat application. The development of geothermal power generation entered a phase of rapid growth in 2005, and its total installed capacity worldwide reached 10.7 GW_e in 2010. The capacity of 10.7 GW_e appears small when compared with solar and wind power generation; however, the high-capacity factor of geothermal power plants, which is 0.7–0.9, provides several times greater electricity from the same installed capacity than

photovoltaic and wind plants. Direct heat application can be used almost anywhere on land. Geothermal resources are classified into two categories: hydrothermal convection resources and thermal conduction resources. Today's geothermal power capacity is mainly hydrothermal-based and unevenly distributed in volcanic countries. As a borehole is drilled into deeper formations, formation temperature becomes higher but permeability becomes lower. Hydrothermal convection resources have a limit depth. Rock's brittle-plastic transition gives a bottom depth to permeability, and it is the absolute limit depth for the hydrothermal convection resources. Enhanced or engineered geothermal systems (EGS), in which fractures are artificially created in less-permeable rocks and heat is extracted by artificially circulating water through the fractures, are still at a demonstration stage, but they will extend geothermal power generation to thermal conduction resources and to depths even deeper than the brittle-plastic transition. Assessment of worldwide geothermal resource potential is still under study. However, an estimate shows that potential is 312 GW_e for hydrothermal resources for electric power generation to a depth of 4 km, 1,500 GW_e for EGS resources to a depth of 10 km, and 4,400 GW_{th} for direct geothermal use resources. Were 70 % of hydrothermal resources, 20 % of EGS resources, and 20 % of direct-use resources to be developed by 2050, it could reduce carbon dioxide emission by 3.17 Gton/year, which is 11 % of the present worldwide emission.

Introduction

While most kinds of renewable energy available are, directly or indirectly, derived from the sun, geothermal energy originates in the interior of the earth. This makes geothermal energy distinct from other kinds of renewable energy, giving its use merits as well as demerits.

Geothermal energy is the most stable energy among a variety of renewable energies. The capacity factor, a ratio of working time of the facility, of geothermal power plants is as high as those of thermal power plants, qualifying geothermal power generation as a base load electricity source. Geothermal energy can be supplied constantly from the earth's interior regardless of time of the day or night, weather, or season.

Assessment of the resource potentials of most kinds of renewable energy, such as the wind velocity and solar radiant energy, is not very difficult because they can be directly observed. Assessment of geothermal resource potential is not as easy, however, because geothermal resources are stored in the earth's crust. This makes the initial investment risk for geothermal energy developments higher.

For many years, geothermal energy development was only undertaken in volcanic countries such as Italy, New Zealand, Japan, the USA, the Philippines, Iceland, and Indonesia. More recently, however, less volcanic countries, such as Germany, Australia, France, and Switzerland, have begun enthusiastically developing geothermal power plants under a new concept of the enhanced or engineered geothermal

system (EGS). Innovation in geothermal energy utilization technology currently aims at a goal that every country can use geothermal energy.

Heat in the Earth's Interior

Enormous heat is stored in the earth's interior. The simplified thermal structure of the earth's interior is illustrated in Fig. 1. The deepest hole ever drilled was the SG-3 well in Kola Peninsula, Russia, that reached a depth of 12,262 m in 1989

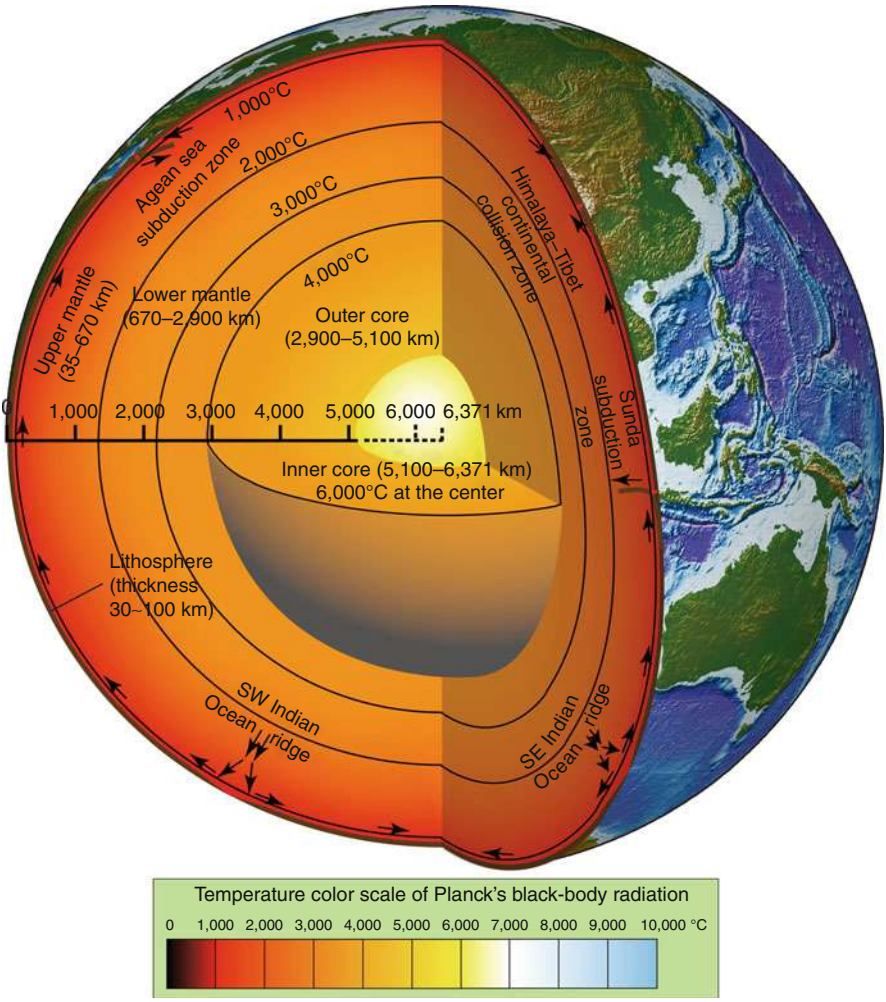

Fig. 1 Simplified thermal structure of the earth's interior (Topographic data are taken from Lindquist et al. (2004) and drawing is made with GMT by Wessel and Smith (1998))

(Fuchs et al. 1990). The hole reached only 0.2 % of the radius of the earth, suggesting that direct temperature measurement of the earth's interior would be difficult. The temperature of the earth's interior is estimated from the transmissibility and velocity of seismic waves, high-temperature and high-pressure experiments for mineral phase changes, a model calculation of temperature increases by the adiabatic compression of mineral phases, a model calculation of electric conductivity of mineral phases, and many other methods. All of these are indirect estimates and inevitably yield a large opportunity for error. The temperature at the center of the earth is commonly estimated to be 6,000 °C, but that may easily yield an error ±1,000 °C (Fig. 1).

Seismological observation delineates that the outer core of the earth consists mainly of molten state iron and nickel, and the mantle of the earth consists of solid state peridotite (ultramafic rocks mostly composed of olivine, Ca-poor pyroxene, and Ca-rich pyroxene). When the melting point temperatures of these are considered at the given pressure, the core-mantle boundary is estimated to be about 4,000 °C (Kanamori 1978). The abrupt change of the velocity of seismic waves at a depth of 670 km in the lower and upper mantle boundary is ascribed to the phase changes from γ phase of spinel to perovskite + magnesiowüstite at 1,600 °C (Tajika 1996). The thickness of the lithosphere, a rigid plate, is less than 30 km near the axis of ocean ridges and increases to 100 km away from the ridge. Low-velocity zones of the seismic waves or asthenosphere underlie the rigid plate at a depth between 70 and 250 km. This zone is partially fused and probably reaches 1,000 °C because of the wet solidus temperature of peridotite. Therefore, only a thin veneer of the earth's surface is less than 1,000 °C, and the 93 % volume of the earth's interior exceeds 1,000 °C (Fig. 1). Thus, the earth is some sort of a thermal engine.

The derivation of the heat is mainly attributed to the accretion heat from bombardment of unsorted micro-planet materials and the heat from gravitational differentiation and compression in the initial stage of the earth's formation history some 4.6 billion years ago (Takahashi 1996). The earth is gradually losing the initial heat with time. Nevertheless, abundant heat is still stored in the earth's interior, 4.6 billion years after its incipiency. The thermal life of the earth is prolonged by the additional heat generation in radioactive decay. Based on the past 4.6 billion years, the earth's heat will be probably preserved for another 4.6 billion years. Thus, the earth is some sort of a semipermanent thermal engine.

Quantity of Thermal Energy Supplied from the Earth's Interior

The earth's interior constantly supplies heat to the surface. This heat transportation phenomenon is called "terrestrial heat flow." Terrestrial heat flow can be measured in wells at a depth from 0.3 to 3 km on shore, where the solar radiant heat does not reach. Terrestrial heat flow can be measured in shallower wells on the ocean floor because of no disturbance by solar radiant heat. Terrestrial heat flow is calculated from the observed thermal gradient multiplied by the thermal conductivity of the constituent rocks. An average terrestrial heat flow is 65 ± 1.6 mW/m^2 onshore and 101 ± 2.2 mW/m^2 offshore (Tajika 1996). The value of the terrestrial heat flow

observed on shore consists of not only heat flow from the earth's interior but also heat flow from radioactive decay of elements such as uranium, thorium, and potassium predominantly concentrated in the continental crust. About half of the terrestrial heat-flow value on shore may be derived from radioactive decay. The value of the terrestrial heat flow observed offshore has a negative correlation with the geological age of the ocean floor. The younger ocean floor tends to yield the higher terrestrial heat flow (Tajika 1996).

Including both continental and oceanic regions, a global average terrestrial heat flow is $87 \pm 2.0\ \mathrm{mW/m^2}$. This value $2.1 \times 10^{-6}\ \mathrm{cal/cm^2 \cdot s}$ ($87\ \mathrm{mW/m^2}$) multiplied by the entire global area is converted to the annual value, yielding an annual global terrestrial heat-flow energy $E_{hf} = 1.3 \times 10^{21}$ J/year or 3.2×10^{20} cal/year (Mizutani and Watanabe 1978). This heat-flow energy causes a variety of the earth's internal dynamics, such as mantle convection, plate tectonics, earthquakes, and magma generation. Thermal energy of lava flow and volcanic ash that erupted from global volcanoes is estimated to be $E_e = 3 \times 10^{19}$ J/year or 7×10^{18} cal/year (Mizutani and Watanabe 1978). This energy is one or two orders of magnitude lower than the terrestrial heat-flow energy that causes it. Many active volcanoes form high-level magma chambers that heat up ground water to discharge fumaroles (natural vents of steam and volcanic gas) and hot springs. The discharge energy of fumaroles and hot springs on the earth is estimated to be $E_w = 2 \times 10^{18}$ J/year or 5×10^{17} cal/year (Mizutani and Watanabe 1978). This energy is also one magnitude lower than the volcanic eruption energy that causes it.

The earth seems to be an almost semipermanent thermal engine, where abundant terrestrial heat flow is always being lost from the earth's surface. Therefore, artificial utilization of the terrestrial heat flow does not seriously affect the dynamic equilibrium of the earth. This is a concept of the environment-friendly geothermal energy utilization.

Direct Use of Geothermal Energy

Since the early history of human beings, hot springs and steaming grounds were utilized for a variety of purposes such as bathing, cooking, balneology, and healing. Direct use of geothermal energy thus has a long history over the last few millenniums. The direct use of geothermal energy is currently extended to the hot-water supply, swimming pools, space heating, snow melting, drying foods or materials, condensing sugar, greenhouse cultivation, and fish cultivation. Geothermal heat pumps for heating and cooling of buildings and houses are rapidly spreading in the world. Methods of direct use of geothermal energies are briefly described here.

Bathing is one of the most traditional direct uses of geothermal energy. For example, as of March 2010, there are 27,825 hot-spring sources in Japan (Ministry of the Environment and Japan 2011), most of which were developed by drillings for bathing in hot-spring resort hotels. In China, since the China Western Development policy was launched in 2000, many hot springs were developed by 3,000-m class deep drillings to the porous Ordovician limestone strata (Zheng 2004).

In New Zealand, the Maori people have traditionally cooked foods in steaming grounds in Rotorua and Taupo. Large-scale flower cultivation greenhouses heated by hot springs are found in Monte Amiata, Italy. Shrimp cultivation by hot water from the geothermal power plant is famous in Wairakei, New Zealand. In Iceland, approximately 90 % of residences are heated by hot water from geothermal power plants and hot-spring wells. Thus, Iceland has become an almost energy-independent nation.

Use of geothermal heat pumps, a direct use of geothermal energies, has increased rapidly because they do not require any geothermal anomaly areas and can be utilized almost everywhere on land. The equivalent number of the 12 kW units (typical of US and Western European homes) reached 2.94 million in 2010, over double the number of units in 2005 (Lund et al. 2010). Temperature is constant underground. This can be experienced in limestone caves, which feel warm in winter and cool in summer. Only the atmospheric temperature changes from day to night and due to seasonal variation of solar radiant energy. Solar radiant energy reaches the shallower part of the ground, to a depth of 10, 20, or 30 m, depending on the rock species of strata, but does not reach the deeper formations. Therefore, heat can be wasted through a well as shallow as 50 or 100 m underground by a heat pump in summer and can be extracted in winter. Geothermal heat pumps resemble air conditioners (air-sourced heat pumps), but air conditioners waste heat to the atmosphere in summer, causing the heat island phenomenon. Increasing use of geothermal heat pumps for heating and cooling of buildings and houses will effectively mitigate the global warming and the heat island phenomena.

Geothermal Power Generation

Geothermal power generation has a relatively short history, beginning only in the last century. Geothermal power-generation experiments were successfully initiated at Larderello in Tuscany, Italy, in 1904 (Dickson and Fanelli 2004). Since then, a variety of methods of geothermal power generation have been developed. These methods are briefly described here.

Geothermal power generation is classified into two categories: steam flash power generation from high-temperature hydrothermal resources of 150–370 °C and binary cycle power generation from low-temperature hydrothermal resources of 50–200 °C (Fig. 2). In the 1970s, geothermal fluids less than 150 °C could not have been economically utilized for electric power generation. The only available method of geothermal power generation in those days was conventional-type steam flash power generation, which uses the conventional steam turbine directly rotated by the natural steam from the geothermal production wells (Fig. 3). Even if the subsurface natural fluid is a liquid state under the high-pressure geothermal reservoirs at a depth, a pressure release by the drill hole makes the fluid boil and the steam ascends to the surface automatically. This phenomenon is called “borehole flash” and requires the temperature of water to be at least 150 °C (Fig. 3). Therefore, the temperature threshold of 150 °C used to be important. This situation changed with the development of binary cycle power-generation technology in the 1980s. The binary cycle

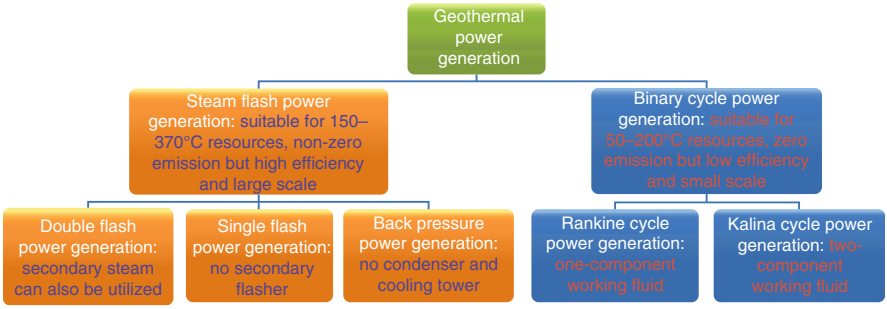

Fig. 2 Classification of geothermal power generation

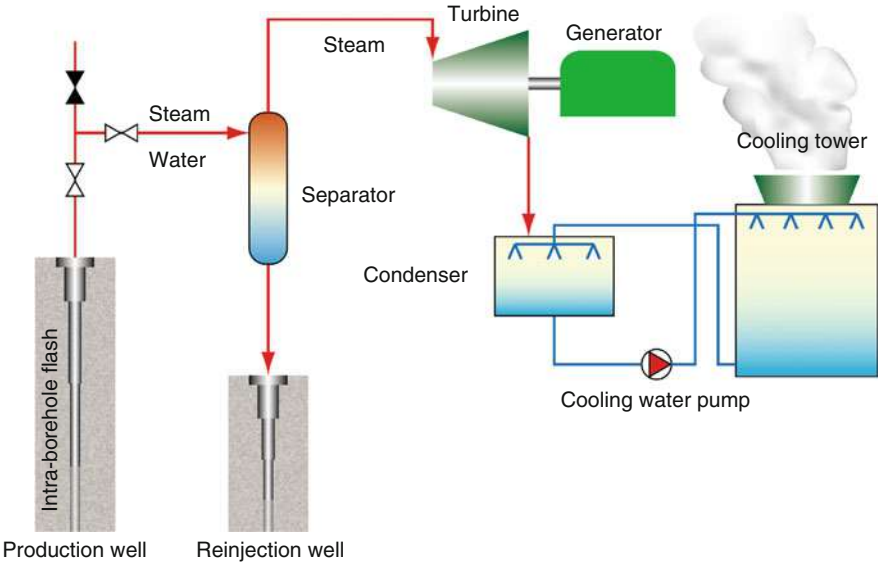

Fig. 3 Illustration of a plant of the single flash geothermal power generation (Modified from Dickson and Fanelli (2004))

power-generation method uses a secondary working fluid, such as pentane or ammonia, that has a low boiling-point temperature (Fig. 4). When the temperature of subsurface water is around 150 °C or lower, the water is not easy to flash. Then, subsurface hot water is pumped up from the production wells. The subsurface water is only used as a heat source for the secondary working fluid. Today, binary cycle power-generation technology enables use of moderate- (150–90 °C) to low-temperature (<90 °C) geothermal fluids (Fig. 4).

The most common type of binary cycle power generation is Rankine cycle power generation, which uses one-component working fluid with the fixed boiling-point temperature under a constant pressure. When a hydrocarbon is used for the working

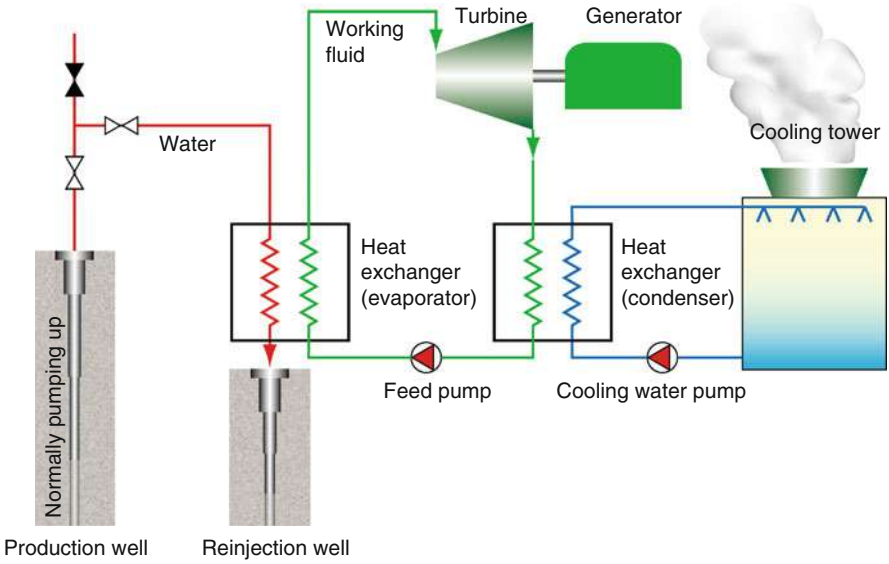

Fig. 4 Illustration of a plant of the binary cycle geothermal power generation (Modified from Dickson and Fanelli (2004))

fluid, such as pentane and butane, the system is called an organic Rankine cycle (ORC). In 1980, Aleksandr I. Kalina invented a binary cycle power-generation system that uses a two-component working fluid of ammonia and water. This system is called Kalina cycle power generation. The boiling-point temperature is continuously changed with the ratio of two components under a constant pressure so that the thermal efficiency is higher than that of the Rankine cycle. The original Kalina cycle is specific to binary cycle power generation with the ammonia-water working fluid, but it seems more useful to extend it to binary cycle power generation with a two-component working fluid (Fig. 2).

The most efficient existing cycle of thermal engines converting a given amount of thermal energy into work is expressed by the Carnot cycle. The Carnot cycle is a particular thermodynamic cycle proposed by Nicolas Léonard Sadi Carnot in 1824, and this theorem contributed to establish the second law of thermodynamics. The most efficient cycle of thermal engines is expressed as follows:

$$\eta = \frac{Q_H - Q_L}{Q_H} \tag{1}$$

where η is the efficiency of the thermal engine, Q_H is the thermal energy given from the high-temperature heat source to the working fluid, and Q_L is the thermal energy wasted from the working fluid to the low-temperature heat source. Any excellent thermal engine cannot exceed the idealistic efficiency expressed by Eq. 1. Equation 1 indicates that the temperature difference between high- and low-temperature heat

sources is critically important for the efficiency of thermal engines regardless of any species of materials of working fluid. It can be easily estimated from Eq. 1 that the ideal thermal efficiency of high-temperature steam flash power generation might be close to 0.5 but that of the low-temperature binary cycle power generation might be close to 0.2. In addition, low-temperature binary cycle power generation has large amounts of energy loss in the heat exchangers so that the available thermal efficiency is normally close to half of the ideal efficiency, as low as 0.1.

From the environmental point of view, steam flash power generation releases small amounts of natural steam from the cooling tower that contains small amounts of carbon dioxide. Hence, subsurface hot water in binary cycle power generation is only used as heat sources for the working fluid, and it can be totally recharged into shallower crust by reinjection wells. Zero-emission operation by a closed-loop system is possible in binary cycle power generation. Therefore, binary cycle power generation is more environmentally friendly, even if the thermal efficiency is low. When high-temperature hydrothermal fluid is unusually high in carbon dioxide, water binary cycle power generation, where relatively pure water is used as the secondary working fluid, is a possible option for zero-emission operation instead of the conventional steam flash power generation.

Category of Geothermal Resource Base

The assessment of a geothermal resource requires economic feasibility criteria, the same as other resources. Geothermal resources are one of the "invisible" resources stored in the earth's interior. Therefore, the confirmation of geothermal resources requires geological assurance processes such as exploration, drilling, and production tests. Based on factors of economical feasibility and geological assurance, geothermal resources are defined on a so-called McKelvy diagram, as shown in Fig. 5 (Muffler and Cataldi 1978).

In 1978, an economically feasible depth for geothermal power developments was considered to be about 3 km (Brook et al. 1979). There were not any geothermal wells deeper than 3 km at that time. Today, deep wells, at depths of 3.58 km at Unterhaching, Germany; 4.42 km at Cooper Basin, Australia; and 5 km at Soultz, France, are commonly utilized for geothermal power generation (Kaieda 2009). Likewise, the extent of geothermal resources is rapidly enlarging with time and technological innovation (Fig. 5).

The geothermal resource base, including future geothermal resources, is considered here (Fig. 5). A geothermal resource base is classified into three categories by the kind of the heat transportation medium: hydrothermal convection system, thermal conduction system, and high-level magma system (Fig. 6). The hydrothermal convection system is, in a narrow sense, a traditional geothermal resource. Conventional geothermal power generation includes steam flash-type power generation and binary cycle power generation using hydrothermal convection resources. The thermal conduction system is a next-generation geothermal resource and is economically marginal at this time. The high-level magma system is a remote future geothermal

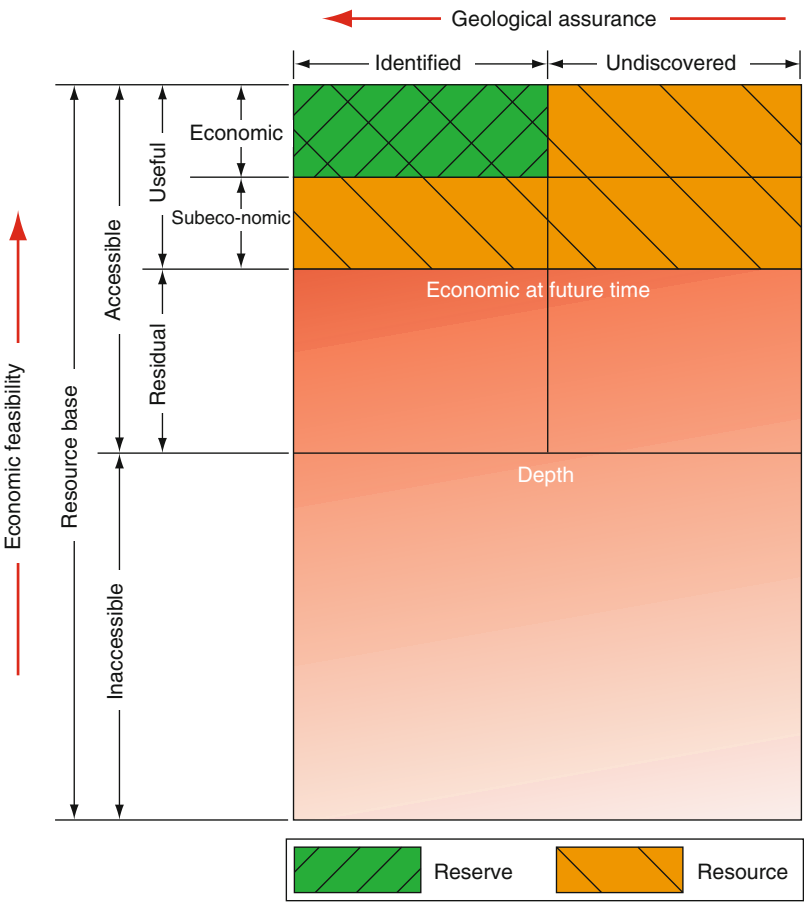

Fig. 5 Definition of geothermal resources on the so-called McKelvy diagram (Muffler and Cataldi 1978)

resource. However, the high-level magma systems have already played an important role of sub-volcanic heat sources to form hydrothermal convection systems.

Three representative thermal gradients are shown in Fig. 3, where their curvatures arise from the heat generation of radioactive decay mostly generated in the upper granitic crust. The geothermal gradient labeled "Continent" shows an average trend about 30 °C/km on the continental regions, "Volcanic zone" shows the higher trend about 40 °C/km on active volcanic zone, and "Older continent" shows the lower trend about 18 °C/km on the coldest region. In any geothermal gradient regions, if a hole is drilled deeper and deeper, the formation temperature can be higher and higher. Therefore, the greater depth is promising, with more abundant geothermal energy in terms of the temperature regime.

However, the permeability of crustal rocks is known to rapidly decrease with increasing depth of the crust (Fig. 6; Manning and Ingebritsen 1999). Permeability is

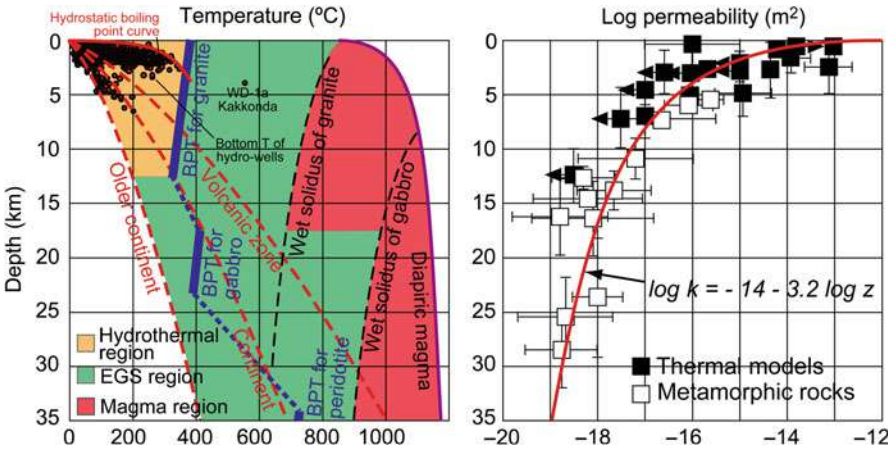

Fig. 6 Temperature (*left*) and permeability (*right*) with a depth of earth's crust. In the *left* diagram, *red dots* show 6,522 bottom hole temperatures from Japanese wells (Muraoka et al. 2007) and BPT indicates the brittle-plastic transition. The *right* diagram is redrawn from Manning and Ingebritsen (1999)

hydrological flow efficiency of water or water-dominated fluids in crustal rocks. This parameter depends not only on the porosity of rocks but also on the density of fractures of the macroscopic rock strata. The depth dependency of permeability indicates that the velocity of hydrothermal convection dramatically decreases with increasing depth of crust. Therefore, hydrothermal reservoirs become rarer with increasing depth of the crust. This is a continuous model on the permeability-depth relationship. There is another constraint on the permeability-depth relationship: the concept of the brittle-plastic transition. All rocks will lose permeability at the depth of the brittle-plastic transition below which all fractures and pores will be closed by the viscous behavior of rocks (Fournier 1991). Schematic models of the brittle-plastic transitions on upper granitic crust, lower gabbroic crust, and upper peridotite mantle are shown in Fig. 6. The WD-1a well drilled to the depth of 3,729 m in Kakkonda, northeastern Japan, penetrated the brittle-plastic transition at a depth of 3,100 m (Muraoka et al. 1998). The brittle-plastic transition on the upper peridotite mantle may coincide with the bottom of the lithosphere. This is a discontinuous model on the permeability-depth relationship. The continuous model (Manning and Ingebritsen 1999) and discontinuous model (Fournier 1991; Muraoka et al. 1998) on the permeability-depth relationship are probably compatible with each other. When the crust is observed statistically, the continuous model will be valid. When the crust is observed in some specific locality, the discontinuous model is obtained.

Based on both continuous and discontinuous models, the permeability-depth relationships suggest that all hydrothermal convection resources have a limit depth. As a borehole is drilled into deeper formations, the formation temperature becomes higher but permeability becomes lower. Therefore, hydrothermal convection resources have a limited depth. Particularly, the brittle-plastic transition of rock property gives a bottom depth to permeability and it gives the absolute limit depth

for the hydrothermal convection resources. As a result, the region of the hydrothermal system is confined to the low-temperature and shallow region, as schematically shown in Fig. 6.

Enhanced or engineered geothermal systems (EGS), in which fractures are artificially created in less-permeable rocks and heat is extracted by artificially circulating water through the fractures, are still at a demonstration stage. However, they will extend geothermal power generation to the thermal conduction region to a broad depth range even greater than the brittle-plastic transition and to a broad temperature range even higher than the brittle-plastic transition (Fig. 6). Even if the given depth is a plastic region, artificial circulation of water makes the local domain brittle and attains artificial fracturing. Therefore, the EGS technology will open the next generation of geothermal power generation that can be applied anywhere on land (Tester et al. 2006).

Sub-solidus Magma Penetrated by Well WD-1a in Kakkonda, Japan

The exploration well WD-1a was drilled to a depth of 3,729 m in the Kakkonda geothermal field, northeast Japan, using efficient borehole cooling techniques in July 1995 (Fig. 7; Muraoka et al. 1998; Muraoka 2005). The well penetrated an

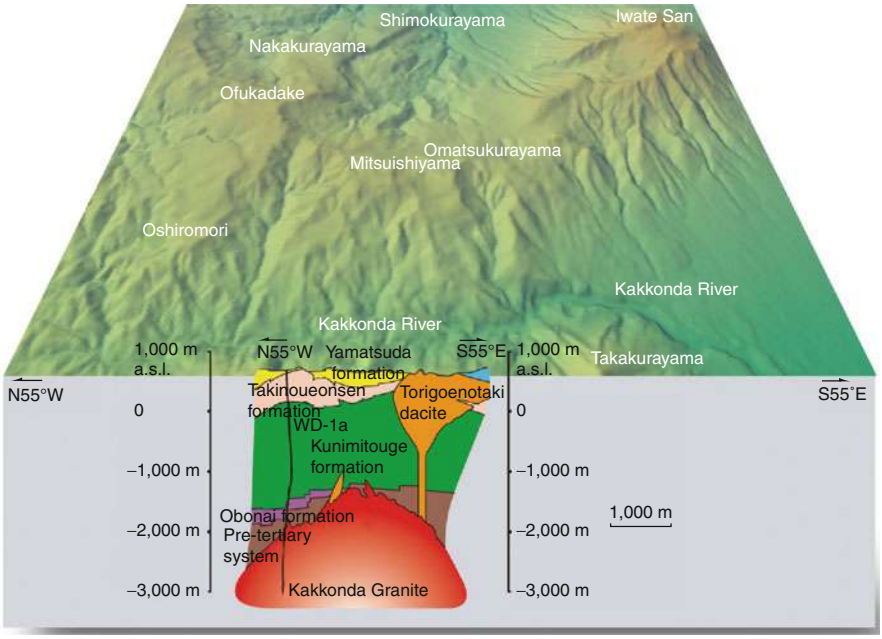

Fig. 7 The Kakkonda geothermal field, Iwate Prefecture, Japan, and the well WD-1a (Muraoka et al. 1998; Muraoka 2005)

entire shallow hydrothermal convection zone, an entire contact metamorphic aureole, and part of a young granitic intrusion called the Kakkonda Granite. The recovered temperature of the well indicates a boiling-point-controlled profile up to 380 °C to a depth of 3,100 m, and a conduction-controlled profile with a very high gradient from 3,100 m to the bottom of the hole, where the temperature is 500 °C (Fig. 8; Muraoka et al. 1998; Muraoka 2005). The well WD-1a may be the first geothermal well that encountered 500 °C, which exceeds the conventional hydrostatic boiling-point curve (Fig. 6). An inflection point of the temperature-depth profile at 3,100 m and about 380 °C reflects the brittle-plastic boundary (Fig. 8). The brittle-plastic boundary constrains the maximum depth of fracture formation, and the fracture distribution constrains the maximum depth of hydrothermal convection.

The theory of lithosphere strength can be applied to the well WD-1a. The theory consists of Byerlee's law in a brittle region and a power law creep equation in a plastic region (Fig. 9). The Byerlee's law in a brittle region is expressed by the following equation (Brace and Kohlstedt 1980):

$$\begin{aligned} \overline{\sigma}_1 &\cong 5\overline{\sigma}_3, \quad \overline{\sigma}_3 < 110\,\text{MPa} \\ \overline{\sigma}_1 &\cong 3.1\overline{\sigma}_3 + 210, \quad \overline{\sigma}_3 > 110\,\text{MPa} \end{aligned} \tag{2}$$

where

- σ_1 = the maximum principal stress
- σ_3 = the minimum principal stress

Figure 9 is only constrained by the upper equation. The power law creep is expressed by the following equation (Brace and Kohlstedt 1980):

$$\dot{\epsilon} = A(\sigma_1 - \sigma_3)^{\mathrm{n}} \mathrm{e}^{\left(\frac{-\mathrm{H}}{\mathrm{RT}}\right)} \tag{3}$$

where

- $\dot{\epsilon}$ = strain rate, s^{-1}
- A = material constant specified to the rock or mineral species
- n = stress exponent
- H = activation enthalpy, J mol^{-1}
- R = gas constant, J K-1 mol^{-1}
- T = temperature, K

Most of these parameters are reasonably determined on the well WD-1a. The strain rate $\dot{\epsilon}$ is given to be 10^{-12} s^{-1} because of the active compressive tectonic region (Fournier 1991). Taking the data from quartz diorite close to the Kakkonda Granite, the stress exponent n is given to be 2.4, and activation enthalpy H is given to be 219 kJ mol^{-1}. The temperature T is given by the temperature profile of the well WD-1a in Fig. 8. The material constant A varies from 10^{-19} to 10^{49} according to the

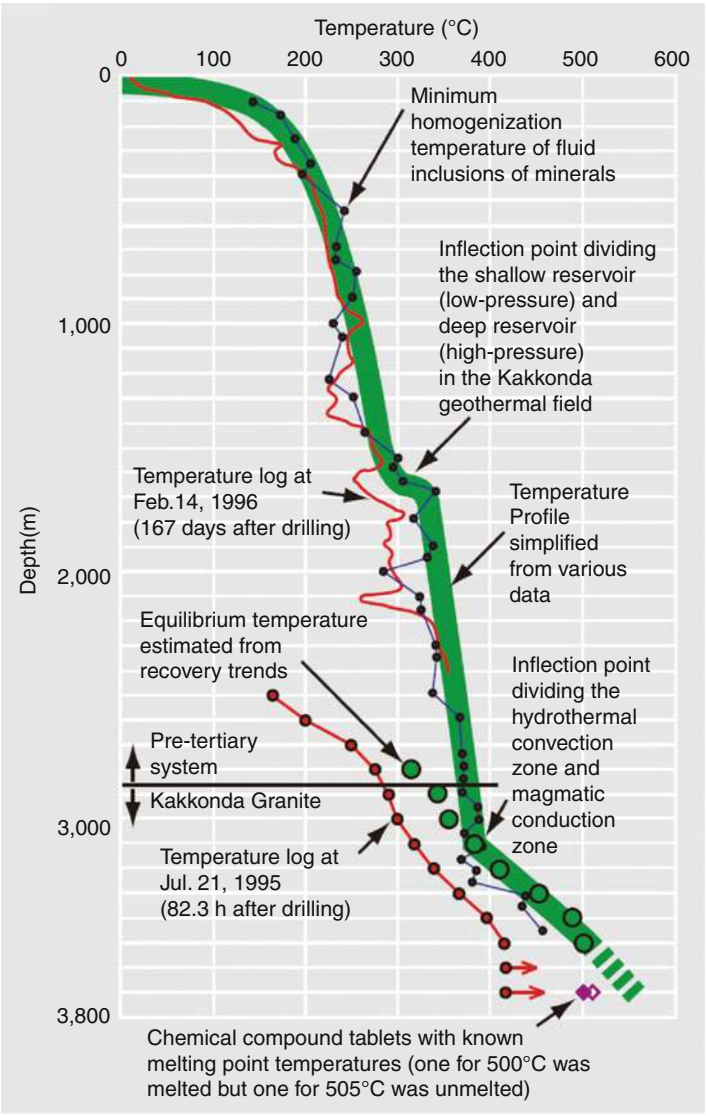

Fig. 8 Temperature profile of the well WD-1a in the Kakkonda geothermal field, Japan (Muraoka et al. 1998; Muraoka 2005)

given material, and only this parameter cannot be reasonably determined. However, the inflection point of the strength curve by the temperature inflection in the plastic region should coincide with the depth of 3.1 km, restricting the material constant A to be $10^{-0.85}$. Then, the strength curve on the plastic field is drawn as shown in Fig. 9 (Muraoka et al. 1999).

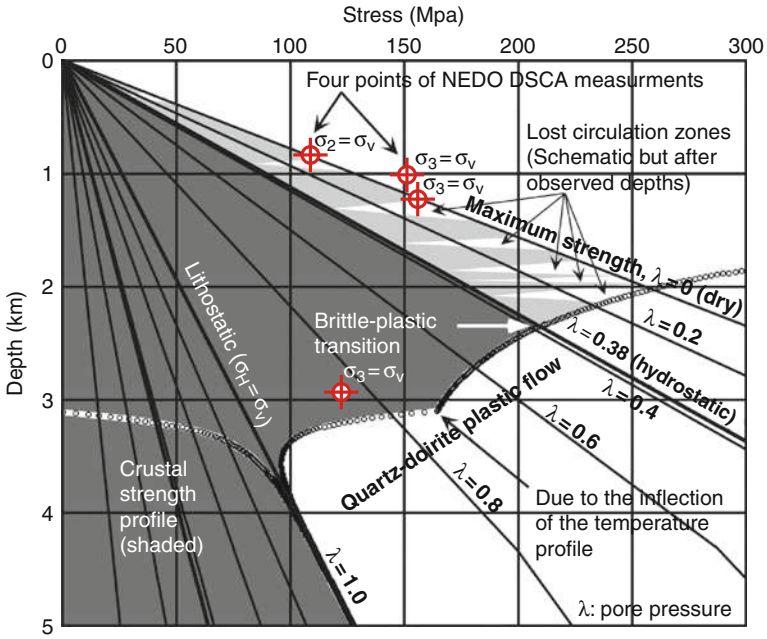

Fig. 9 Crustal strength-depth relation along the well WD-1a in the Kakkonda geothermal field, Japan (Muraoka et al. 1999)

The four points of stress ratio measurements of the differential strain curve analysis (DSCA) on the core samples (New Energy and Industrial Technology Development Organization 1996) are well explained by the model of the strength profile drawn by the Byerlee's law and the power law creep equation as shown in Fig. 9. Particularly, closure of σ_1 value to σ_3 at the deepest DSCA stress ratio measurement indicates that the dramatic strength weakening occurred as being accommodated by the plastic field as shown in Fig. 9. Three points of DSCA stress ratio measurements in the brittle field are close to the dry line ($\lambda = 0$). This is also reasonable because the sampling of cores could have been only performed from impermeable zones with no lost circulation. These observations strongly support that the well WD-1a actually penetrated the brittle-plastic transition (Muraoka et al. 1998; Muraoka 2005).

The brittle-plastic transition may primarily be expected in the temperature inflection point at the depth of 3,100 m and the temperature 380 °C (Muraoka et al. 1998). However, the graphical representation makes it clear that the brittle-plastic transition in a strict sense probably lies at a shallower depth, like 2,400 m, where the maximum strength is attained at 360 °C (Fig. 9). A zone of very high concentration of low-angle fractures is observed in the depth interval from 1,770 to 2,860 m (Fig. 10; Muraoka and Ohtani 2000). This fracture zone likely reflects the maximum strength zone of the bottom of the brittle layer because this zone may play a role of the dehydration front and dehydration-induced weakening front (Muraoka and Ohtani 2000).

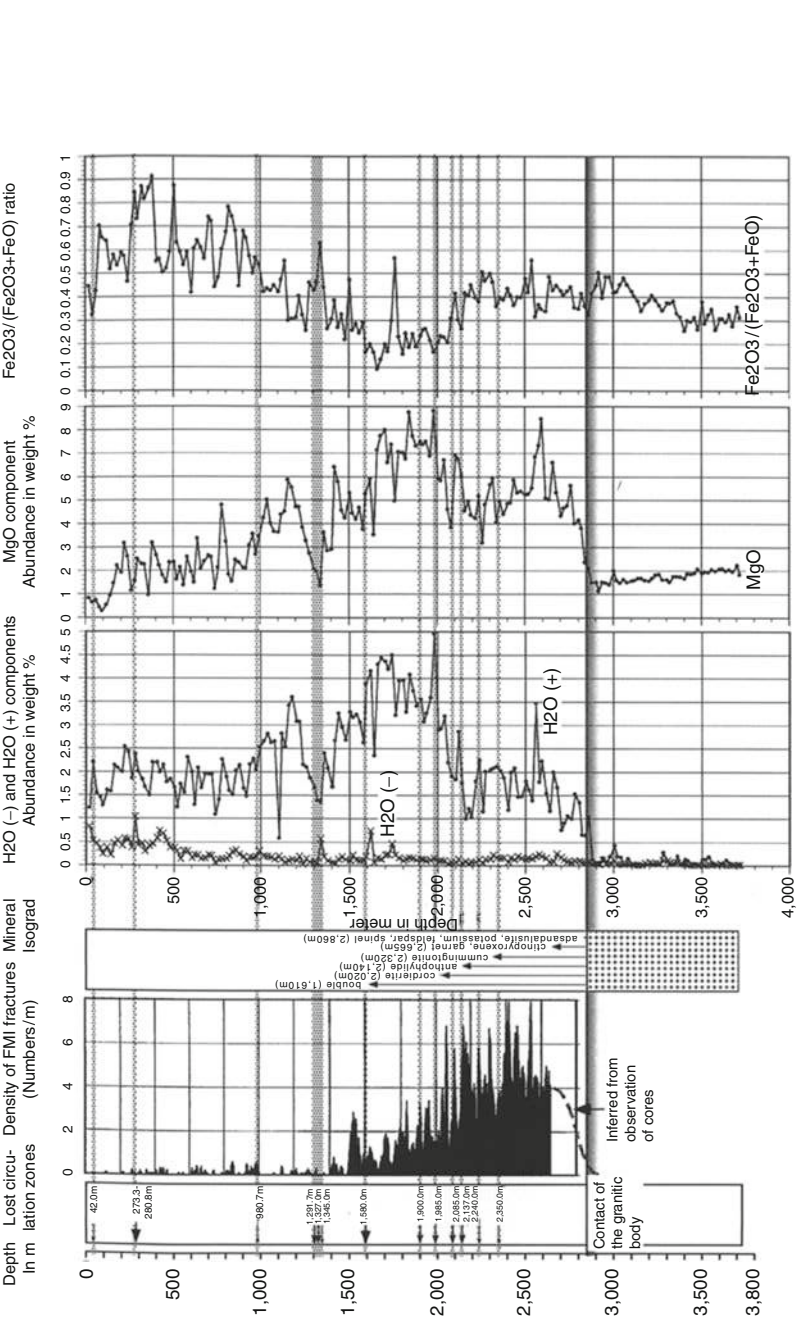

Fig. 10 Chemistry of cutting samples from the contact metamorphic aureole of the Kakkonda Granite and high concentration of low-angle fractures (Muraoka and Ohtani 2000)

Distribution of Geothermal Resources in the World

High-temperature hydrothermal resources (>150 °C) are unevenly distributed in the world. Figure 11 shows global topography, global bathymetry (topography of ocean floors), plate boundaries, active volcanoes (Siebert and Simkin 2002), and representative geothermal power plants. High-temperature hydrothermal resources that are hot enough for the steam flash-type power generation are associated with active volcanic zones so that most of the geothermal power plants are developed in active volcanic zones. This is because sub-volcanic magma chambers or their sub-solidus equivalents (hot intrusive bodies) are serving for geothermal heat sources for the high-temperature hydrothermal reservoirs. Actually, young plutonic bodies are often penetrated by geothermal wells not only in the Kakkonda geothermal field, Japan, as described in the preceding section, but also in other geothermal fields such as The Geysers, in California, USA; Tongonan and Palinpinon, in the Philippines; and Mutnovsky, in Russia (Muraoka 1993).

Active volcanic zones are associated with two types of plate boundaries: spreading and convergent. A typical spreading plate boundary is mid-ocean ridges. In Fig. 11, mid-ocean ridges are not represented as volcanoes, but they are the largest volcanoes on the earth that are lineally continued. Their geothermal development has been difficult so far because of the high cost of submarine exploitations. As a result, most of the geothermal power plants are built in the volcanic zones of the convergent plate boundaries. One exception is the Great Rift Valley in the eastern Africa, where spreading plate boundaries appear on shore. The other exception is the Salton Sea and Cerro Prieto geothermal fields in the western North America, where spreading plate boundaries or their transform faults appear on shore. The last exception is Iceland, which is situated on the mid-Atlantic ridge where the ridge appears above sea level because of the strong volcanic activity in the hot spot.

Most of geothermal power plants are developed in the volcanic zones of subduction zones. Particularly, the largest subduction zones are found in the circum-Pacific regions. Although the first geothermal power generation was accomplished in Italy in 1904, the largest geothermal power country is currently the USA, the second is the Philippines, and the third is Indonesia. All of these are situated along the circum-Pacific regions. Geothermal electricity plays a very important role in Central America, where 10 % or higher ratios of electricity are supplied from geothermal power generation in many countries. It seems curious that very few geothermal power plants have been developed in South America, in spite of the huge geothermal potential in the Andes. The Copahue geothermal power plant used to operate in Argentina, but it has been terminated. No geothermal power plant is currently operating in South America. In other words, South America has reserved a large potential for geothermal power development in the near future.

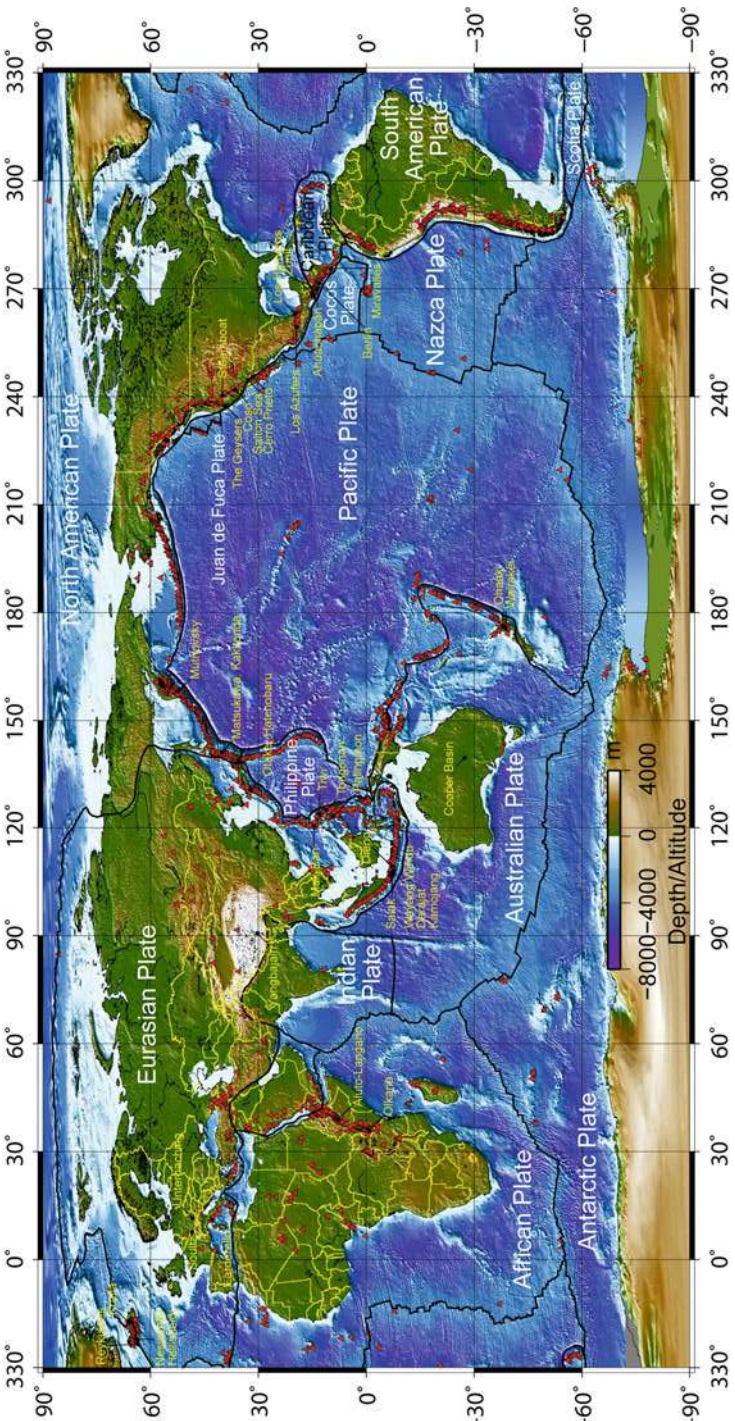

Fig. 11 Global topography, global bathymetry, plate boundaries, active volcanoes, and representative geothermal power plants (Topographic data are taken from Lindquist et al. (2004), drawing is made with GMT by Wessel and Smith (1998), and active volcanoes are taken from Siebert and Simkin (2002))

Global Geothermal Resource Potentials

Assessment of global geothermal resource potentials is hard to accomplish because subsurface exploration data with uniform accuracy are seldom available on a global scale. However, a rough estimate is possible by analogical reasoning. Hydrothermal power resources, EGS power resources, and direct-use resources are estimated here by analogical reasoning.

Stefansson (Stefansson 2005) estimated world geothermal assessment based on well-known data on active volcanoes (Siebert and Simkin 2002). Hydrothermal resources high enough in the temperature for the steam flash-type power generation are normally associated with active volcanoes, and therefore, his method is an excellent analogical reasoning by use of well-known data. Although the size of the active volcano varies from the 100-km-long Toba caldera in Indonesia to 0.6-km-long maars (explosion of volcanic craters without remarkable tuff rings in its surroundings) such as Megata in Japan, these size differences might cancel one another by using statistical data. Here, modification is made from the original paper because some data have been updated. Table 1 and Fig. 12 show a relationship between the numbers of active volcanoes and assessed hydrothermal power resources in eight representative countries modified from the original paper (Stefansson 2005). A number of active volcanoes are taken from the catalog (Siebert and Simkin 2002), where submarine volcanoes are excluded. Assessed hydrothermal power potentials are taken from each reference described in Table 1. A regression equation is obtained between numbers of active volcanoes and estimated hydrothermal power resources in eight representative countries:

Table 1 Number of active volcanoes and estimated geothermal potential for electrical generation in eight representative countries. The number of active volcanoes is taken from Siebert and Simkin (2002) where submarine volcanoes are excluded

Country	Number of active volcanoes	Assessed hydrothermal power potentials (MW)	References
USA	163	39,090	William et al. (2008)
Indonesia	137	27,140	Darma et al. (2010)
Japan	93	23,470	Muraoka et al. (2008)
Philippines	46	6,000	Wright (1999)
Mexico	39	6,000	Mulas de Pozo et al. (1985)
Iceland	27	5,800	Palmason et al. (1985)
New Zealand	12	3,650	Lawless (2002)
Italy	12	1,500	Buonasorte et al. (2007)

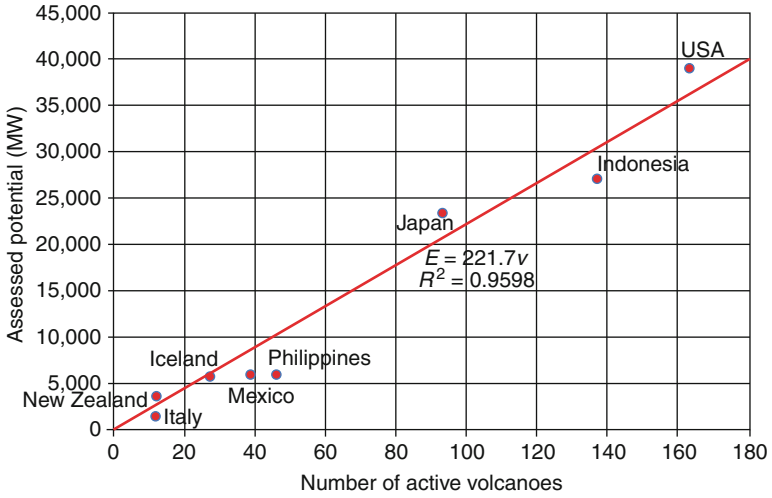

Fig. 12 Correlation between the number of active volcanoes and estimated geothermal potential in eight representative countries slightly modified from Stefansson (2005). The number of active volcanoes is taken from Siebert and Simkin (2002), where submarine volcanoes are excluded

$$E = 221.7\,\nu \tag{4}$$

where

- E = hydrothermal resource potential for geothermal power generation (MW_e)
- ν = a number of active volcanoes without submarine volcanoes

The maximum exploitation depth of Eq. 4 is not strictly defined in the different assessment condition in each country, but it is roughly assumed to be a depth of 4 km. Equation 4 is useful to estimate hydrothermal resource potentials when the subsurface exploration data are not fully available. If a number of global active volcanoes, 1,406 excluding submarine volcanoes, are input into this equation, about 312 GW_e are obtained as a hydrothermal resource potential for geothermal power generation in the world.

Only a few countries estimated the EGS resources. The EGS resources are, however, almost proportional to the width of the given area. Therefore, an estimate in the USA (Tester et al. 2006) can be used as teacher data, and it can be extrapolated to the world according to the area ratio. Tester et al. (2006) estimated EGS resources to be at least 100 GW_e in the USA for the exploitation to a depth of 10 km. The widths of the land area of the world and the USA are 148,890,000 km^2 and 9,826,635 km^2, respectively. Then, 1,500 GW_e was obtained as a global EGS resource potential.

Assessment of direct-use resources is far more difficult to attain because of the variety of uses: baths, swimming pools, snow melting, hot-water supply, space heating, greenhouses, and drying foods. Therefore, it needs some simplification.

Stefansson (2005) estimated hydrothermal resources lower than 130 °C for direct use to be 4,400 GW_{th} based on the resource frequency distribution like a power function.

This seems an excellent estimate, because the number is almost 10 % of the annual global terrestrial heat-flow energy. As described in the earlier section, an annual global terrestrial heat-flow energy $E_{hf} = 1.3 \times 10^{21}$ J/year, and 10 % is 1.3×10^{20} J/year, which is equivalent to 4,120 GW_{th}. Therefore, the estimate for direct-use resources of 4,400 GW_{th} seems reasonable.

Present State of Geothermal Development in the World

The present state of geothermal development in the world is briefly described for geothermal power generation (Bertani 2010) and on direct use (Lund et al. 2010). The installed capacity of geothermal power generation in the world is 10,715 MW_e as of 2010, and the growth rate during the last 5 years was the second greatest, after the early 1980s, as shown in Fig. 13. The produced electricity during the year 2010 was 67,246 GWh (Bertani 2010). The capacity factor, a ratio of working time of the facility, of geothermal power plants is 0.72 throughout the world. This capacity factor is amazingly high compared with not only other renewable electricity sources but also thermal or nuclear power sources. The five largest geothermal power-generation countries – the USA, the Philippines, Indonesia, Mexico, and Italy – account for about 75 % of the world geothermal power capacity (Table 2).

The installed geothermal energy facilities for direct utilization at the end of 2009 were 50,583 MW_{th}, and the thermal energy used was 438,071 TJ/year (121,696 GWh/year) as shown in Fig. 14 (Lund et al. 2010). Again, the growth rate during the last 5 years was rapid compared to the past. The capacity factor of direct use was 0.27 at the end of 2009, and it was decreasing with passing time. This is because

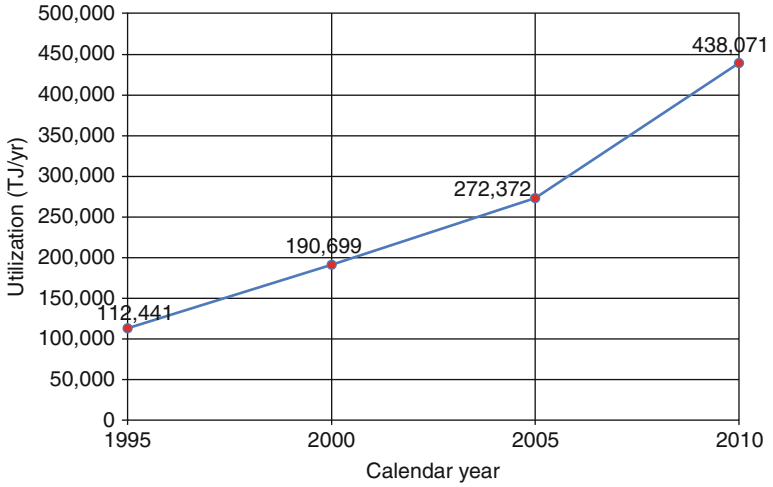

Fig. 14 Growing direct geothermal use in the world (Lund et al. 2010)

geothermal heat pumps are rapidly spreading among a variety of direct utilization methods, and the capacity factor of geothermal heat pumps is normally less than 0.2. Almost all countries are utilizing geothermal heat directly (Table 3). Countries in colder regions tend to use more geothermal heat.

Geothermal Cascade Utilization Technology

To date, geothermal resources tend to be used for a single utilization purpose, and the spent resources have been wasted into reinjection wells or rivers, in the case of low-temperature direct use. However, a more efficient utilization is repeated consumption of energy such as a cascade from the high-temperature resources to the low-temperature resources as shown in Fig. 15. This can be called geothermal cascade utilization.

A typical example is seen in Iceland, where voluminous hot water spent in geothermal power plants is transported by pipelines, more than 25 km long, to a tank on the hill of Reykjavik City. Then, the hot water is distributed to each residence for space heating. This is a typical example of the geothermal cascade utilization.

More efficient cascade utilization is possible with steam flash-type power generation, binary cycle power generation, space heating, and snow melting in descending order as shown in Fig. 15. Cascade utilization makes geothermal resources several times more efficient. However, for the development of the geothermal cascade utilization, heat exchange technology and scale-inhibition technology are critically important.

Table 3 Direct geothermal utilization in the world (Lund et al. 2010)

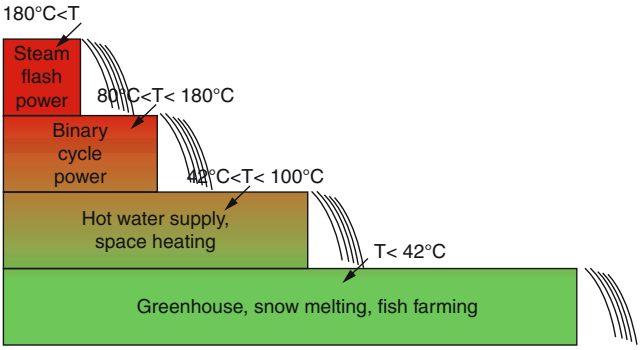

Fig. 15 A concept of the cascade utilization of geothermal energy

Mitigation of Global Warming by Geothermal Development

If 70 % of hydrothermal power resources and 20 % of EGS resources are developed by 2050, these capacities would be 218 GW_e and 300 GW_e, respectively, and their total installed capacity would be 518 GW_e. When the capacity factor is assumed to be 0.72 and the unit reduction of carbon dioxide emission by the replacement from the oil thermal power to geothermal power is assumed to be 817 g-CO_2/kWh (Mongillo 2005), it could reduce carbon dioxide emission by 2.67 Gton/year.

If 20 % of direct-use geothermal resources are developed by 2050, its installed capacity would be 880 GW_{th}. When the capacity factor is assumed to be 0.27 and the reduction unit of carbon dioxide emission by the replacement from the oil fuels to geothermal energy is assumed to be 409 g-CO_2/kWh (Mongillo 2005), it could reduce carbon dioxide emission by 0.50 Gton/year. Both geothermal electricity and direct use could reduce carbon dioxide emission by 3.17 Gton/year, which is 11 % of the present worldwide emission.

Future Directions

Available geothermal energy could commonly increase with increasing depth of drill holes in any geothermal gradient regions. The deepest hole ever drilled was the SG-3 well in Kola Peninsula, Russia, that reached a depth of 12,262 m, only 0.2 % of a radius of the earth (Fuchs et al. 1990). There still remain voluminous unexploited crust and upper mantle, and new technology will open a variety of techniques to utilize the enormous heat in the earth's interior. Many researchers thought that only volcanic countries enabled geothermal power generation in the 1970s. However, today, less volcanic countries such as Germany, Australia, France, and Switzerland are leading the EGS technology development for geothermal power generation. A 1.5-MW_e pilot power plant for the EGS has been operating in Soultz, France, since

June 2008. Geothermal utilization technology thus may achieve the goal of the EGS, where every country can use geothermal energy.

Abstract

Climate change is regarded as the most severe challenge for the human being. The view on accelerating hydropower development and ensuring adequate water storage infrastructure to mitigate and adapt climate change has been widely accepted by the international community. Based on the challenge induced by climate change and the advantages on energy consumption and GHGs emission, the current development status, this chapter describes the importance and significance on development hydropower and ensuring adequate water storage facility for world sustainable development, mitigating, and adapting climate change. And it also points out the path on developing water and energy in a reliable, cheap, and environment-friendly way.

Introduction

The world is changing. Population growth and economic development turn to be the prime driving power that stimulates the ever-increasing demand for resources and energy, while the environment and resources are the biggest bottleneck that restricts human development today. Global climate change is the most outstanding expression of this constraint. As proven by physical, political, and economic studies with respect to climate change, the issue of global climate change is one of the largest, most extensive, and most profound challenges ever experienced by man up to now, and also one of the most important factors relating to future socioeconomic development of the world and reconstitution of the global political and economic pattern.

Necessary action is needed to be taken in adapting global climate change. On the one hand, the adjustment of the structure of energy supply should be actively pushed forward, as to change the leading role of hydrocarbon energy in the structure and reduce greenhouse gas emissions; on the other hand, security measures against the consequence of global climate change should be adopted, to enlarge the stock and improve the regulation capacity. To store water is actually to store energy.

The international community has realized that the lack of adequate water storage facilities will weaken man's response to changes and directly hinder the fulfillment of development objectives in the years to come. Thus, hydropower development to ensure adequate water storage facilities is important for dealing with climate change and solving the problem of energy.

Overview of Global Hydropower and Dam Development

Overview of Hydropower Development in the World

As the most technically mature and reliable source of renewable energy, hydropower plays an important role in the global supply of energy. Global hydropower theoretical reserve is 39,097 TWh/year with a technical availability about 14,653 TWh/year and an economic availability about 8,728 TWh/year. Except Antarctica, hydropower distributes everywhere in the world (Table 1, Fig. 1).

In 2007, there was an installed capacity of 848,400 MW and an output of 2,045,000 GWh/year on the globe, taking up about 20 % of power supply. The degree of hydropower development reached 35 % if based on the output as percentage of the economic availability, with 11 % in Africa, 25 % in Asia, 45 % in Oceania, 71 % in Europe, 65 % in North America, and 40 % in South America, respectively (Table 1).

The global total volume of water resources is about 55 trillion m^3. Due to the uneven distribution in time and space, the total availability is about 9 trillion m^3 only. According to the definition given by the International Commission on Large Dams, more than 50,000 large dams (higher than 15 m or 5–15 m, storage capacity larger than 3 million m^3) have been built in the world up to date. These dams control about 3.5 trillion m^3 water resources, about 38 % of the total volume available on the globe, and play an important role in comprehensive water utilization and management. Many dams in the world serve the function of power generation. For instance, 44 out of the reservoirs with a storage capacity over 25 billion m^3 on the globe serve the function of power generation, including 16 for the sole objective of power generation. These 44 reservoirs provide a total storage capacity of 2.5 trillion m^3 (about 37 % of the world total) and an annual output over 500 TWh/year, taking up about 18 % of the world hydropower generation. In 2007, out of the 370 dams higher than 60 m under construction in the world, 217 were designed for the primary or only function of power generation.

According to the statistical data of 2008, there were 16 countries depending upon hydropower for over 90 % energy supply, for example, Norway and Albania, 49 for over 50 %, including Brazil, Canada, Switzerland, and Sweden; and 57 for over 40 %, including most South American countries. The average degree of hydropower development in developed countries was higher than 60 %, up to 90 % in France, and ever over 90 % in Italy (Table 2).

Table 1 Profile of global hydropower development

	Theoretical reserve (GWh/year)	Technical availability (GWh/year)	Economic availability (GWh/year)	Installed capacity (MW)	Hydropower output (GWh/year)	Degree of development (%)
Africa	2,590,234	1,303,246	848,434	21,486	94,124	11
Asia	19,701,583	7,654,565	4,487,377	329,737	1,107,622	25
Oceania	633,384	195,987	88,644	13,470	40,259	45
Europe	2,900,767	1,120,541	752,348	178,814	530,999	71
North America	7,574,535	1,763,478	1,014,910	167,042	664,244	65
South America	5,696,000	2,615,299	1,536,197	137,908	607,577	40
Total	39,096,600	14,653,115	8,727,911	848,456	3,044,825	35

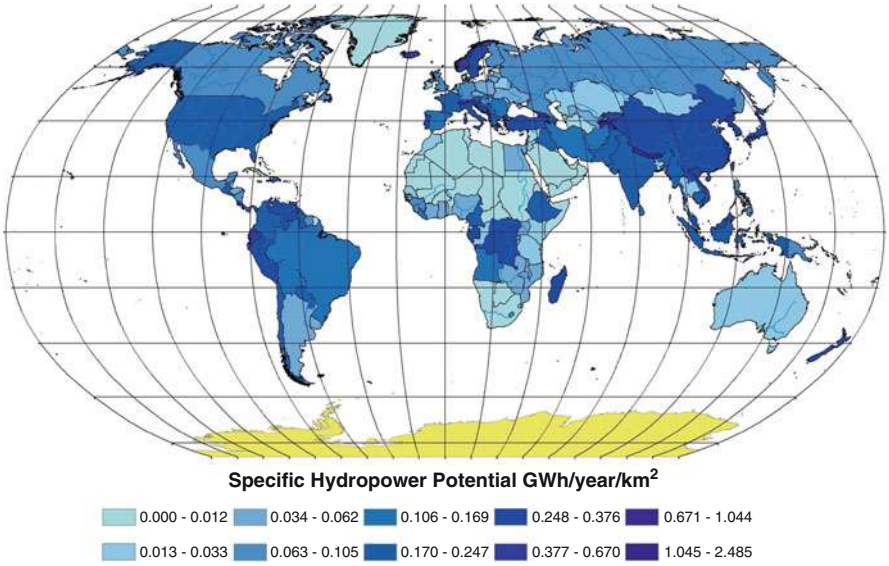

Fig. 1 Global hydro power density (GWh/year/km^2)

The 50,000 large dams in operation are distributed geographically as follows: 59.7 % in Asia, 21.1 % in North America, 12.6 % in Europe, 3.3 % in Africa, 2.0 % in South America, and 1.3 % in Australia.

There were 5,443 dams higher than 30 m in China in 2009 and 4,685 in 2003, taking up 38 % of the world total base on the data of 2003, the largest number of all countries. With regard to the number of built and ongoing dams higher than 30 m in 2003, the following countries were in the second to the seventh places, respectively: USA with 1,533; Japan with 1,075; Spain with 517; India with 504; Turkey with 376; and Italy with 322. By the function of reservoirs, statistics from the International Commission on Large Dams indicated that among 33,105 registered dams single-purpose dam accounts for 72 % and the rest of 28 % is for multipurpose. For single purpose dams, the distribution for each purpose lead to the following results: 48.6 % for irrigation, 17.4 % for hydropower, 12.7 % for water supply, 10 % for flood control, 5.3 % for recreation, 0.6 % for navigation and fish farming, and 5.45 for others. For multipurpose dams, the distribution for majority purpose lead to the following results: 24.6 % for irrigation, 18.7 % for hydropower, 16.3 % for water supply, 18 % for flood control, 12.2 % for recreation, 6.4 % for navigation and fish farming, and 3.8 % for others.

In order to have a better understanding of dam construction in the world, dams and reservoirs are tabulated below by number, height, storage capacity, and power output. With minor change over the recent years, the data are based on the statistical report published by the International Commission on Large Dams and the typical data produced by Chinese National Committee on Large Dams in 2005 (Tables 3, 4, 5, and 6).

Table 2 Hydropower development by countries in 2008

Country	Economic availability (TWh/year)	Hydropower output (TWh/year)	Percentage in economic availability (%)	Hydropower installed capacity (MW)	Total installed capacity (MW)	Storage capacity (10^9 m^3)
China	1,753	565.5	22.9	172,600	792,730	692.4
United States	376	270.0	71.8	78,200	687,000	1,350
Canada	536	350.0	65.3	72,660	114,950	650
Brazil	763.5	331.7	43.4	83,752	88,620	568
Russia	852	170.0	20.0	47,000	224,240	793
India	442	121.7	27.5	37,000	112,060	213
Japan	114.3	92.5	80.9	22,000	268,280	20.4
France	72	64.6	89.7	25,200	111,200	7.5
Norway	205.1	121.8	59.4	29,040	27,890	62
Italy	54	51.3	95.0	17,460	98,626	13
Spain	37	23.3	63.0	18,450	62,300	45.5

Overview of Hydropower and Dam Development by Continents

Europe

In the early 1920s, most of the large dams in Europe were built in UK (220 in total). At the end of 2006, more than 5,280 large dams were registered in Europe, with the first numbers in Spain (1,188), France, and UK, over 500, respectively.

Table 5 First 10 built and ongoing reservoirs

No	Name of dam	Storage capacity (10^8 m^3)	Objective	Country
1	Kariba	1,806	H	Zimbabwe/ Zambia
2	Bratsk	1,690	HNS	Russia
3	High Aswan Dam	1,620	IHC	Egypt
4	Akosombo	1,500	H	Ghana

10	Bratsk	1964	4,500	22,500	Russia

UC under construction

The first objective of dams in Europe is power generation, which is followed by irrigation and water supply. In the European countries, the usage (and importance) of reservoirs varies considerably, particularly in the aspect of hydropower generation. This variation reflects the difference in topography, rainfall, and government policy. Many reservoirs designed for hydropower purposes are often located in mountainous areas and north European countries, obviously different from those for irrigation and water supply. The latter are relatively small in scale, generally in lowland countries and south European countries. About a quarter of the dams in Europe are designed for multipurpose operation. In several countries, hydropower contributes more than a half to the national power supply, for example, 97 % in Albania, 70.1 % in Iceland, 70 % in Latvija, and even up to 99 % in Norway.

In 1960, dam construction and hydropower development reached the climax in many parts of Europe. However, the focus today is to maintain and repair existing dams as required by new acts and regulations. In 2006, the installed capacity of hydropower stations under construction in Europe was about 4,733.2 MW, which was distributed in 20 countries, including Germany, Greece, Iceland, Italy, Macedonia, Portugal, Slovenia, and Ukraine.

Asia

Asia has being reached the climax of hydropower development. Most of the under constructed large dams higher than 60 m are distributed in Asia, 276 in total. The International Commission on Large Dams listed a total number of 35,070 large dams in Asia in 2006. Most of the dams in Asia are built for the purpose of irrigation, and then power generation, flood control, and water supply. At present, the first objective of dams in Asia varies from one country to another, including irrigation in India and Turkey, flood control, irrigation, and power generation (including pumped storage stations) in China, flood control and pumped storage in Japan, and irrigation and power generation in Iran. There are nine Asian countries where hydropower takes over 50 % of the national power supply. As shown by statistical data of the International Commission on Large Dams, this percentage is 14 % in China (based on the power output in 2007), 17.1 % in India (2007), 18 % in Russia, and 25.4 % in Turkey.

Generally, China, India, Turkey, Japan, and Iran are most vigorous in dam construction. The climax of dam construction in Asia appeared in the period of 1970–1980, with more than 200 dams built each year. In 2006, the installed capacity in progress was larger than 189,010 MW, mostly in China, and also in India, Iran, and Russia.

India has a large population, but the water availability per capita is about 1,829 m^3/year only, less than 30 % of the world average, representing water shortage. The number of dams in operation in India is 4,083, with a total installed capacity of 213 billion m^3. The dams in India are 90 % earth and rock fill ones, including 2,600 higher than 15 m. The national installed capacity of hydropower is 37,000 MW. Tehri Dam, the highest rock-fill dam, 260.6 m, has been completed.

Russia saddles the European and Asian continents, sharing long borders with China. There is a total annual mean precipitation of about 9.348 trillion m^3 and runoff of 4.262 trillion m^3, representing very rich water resources. At present, there are 101 dams in operation in the country, including 58 rock fill and 43 concrete ones, with a total storage capacity as large as 793 billion m^3 and an installed capacity about 47,000 MW. There are 85 hydropower stations with an installed capacity over 10 MW. In addition, about 7,000 MW is under construction. The planned installed capacity is about 12,000 MW. Bureya Dam, a concrete gravity dam with a height of 140 m and a storage capacity of 3.5 billion m^3, is the highest dam under construction.

North America and Central America

According to statistical data of the International Commission on Large Dams, there were 8,252 large dams in North America and Central America in 2006, including

some 6,510 in the USA. 4 countries out of 15 in the region, the hydropower generation is over 50 % of national power supply. They are Canada, Costa Rica, Haiti, and Panama. The hydropower output of Canada is the largest in North America, the third place in the world, and that of the USA is in the fourth place. The sum of these two countries takes up more than one-fifth of the world total. Flood control, power generation, irrigation, water supply, and recreation are the primary objectives of the large dams in the USA.

After the Second World War, the number of dams built and put into operation boosted in this part. In the USA, the number of dams put out of operation exceeds the number of dams newly registered and constructed each year.

The large dams under construction in Central America provide an installed capacity of about 3,047.1 MW (including Mexico). By the end of 2006, Mexico had built 668 large dams, with an annual output of 25,000 GWh. The installed capacity in progress is about 2,250 MW.

South America

In 2006, there existed 799 large dams in South America, including almost half of them in Brazil (387 in total). The first objective is power generation and flood control. Now, there are many high dams under construction in South America, mostly in Brazil, Venezuela, and Ecuador, with a total installed capacity of 11,327 MW distributed in nine countries. Proposed projects will provide another installed capacity of 62,956 MW.

Brazil is most active in hydropower development, which accounts for 76.6 % of the national power output. Other countries keen on hydropower development include Paraguay (99.99 %), Columbia (78 %), Peru (65 %), Venezuela (73.3 %), French Guiana (60 %), Chile (43.5 %), and Ecuador (43.5 %).

In 2007, there was a total installed capacity of about 11,327 MW under construction in 13 South American countries.

Africa

Africa is less capable in developing and regulating water resources. As suggested by the statistical data of the International Commission on Large Dams, there were 1,815 built large dams in Africa, including over 80 % in South Africa (1,166), Zimbabwe (250), and Morocco (120). In 2006, more than 20 African countries were developing hydropower resources, but the number of dams higher than 60 m was not large, only 13. There was a total installed capacity of 7,489 MW in progress in 17 countries in 2007, including 3 countries with an installed capacity larger than 1,000 MW, namely, Ethiopia (1,277 MW), Guinea (1,291 MW), and Sudan (1,300 MW). In the arid and semiarid north and south parts of Africa, dams are built mainly for irrigation. In the middle and other humid parts, the first objective is power generation.

The “Southern Africa Power Pool” has done something in investing in future power infrastructures here. In Africa, the percentage of hydropower in 22 countries takes up more than 50 % of the national power supply, and even more than 90 % in 5 countries including Zambia, Mozambique, and Namibia.

Oceania

There are altogether 621 large dams here, mostly in Australia (541) and New Zealand (67). Dams are first for the objective of water supply, but also for power generation and irrigation as well. There are three countries where hydropower constitutes over 50 % of the national power supply, namely, Fiji (50 %), New Zealand (60 %), and Papua New Guinea (65 %).

In Australia and New Zealand, the climax of dam construction was witnessed in 1980 (about 10 dams on the average each year). In 1990, the speed was slowed down. Now, there is only one 60 m high dam under construction in Australia, where the focus is shifted to small hydropower and water supply facilities.

Small Hydropower (SHP) Development

Small Hydropower

Under favorable circumstances, small hydropower (SHP) represents one of the cheapest methods of electricity generation. Of all the renewable energy sources, small hydro (large as well) represents the highest density of resource. For a long time, small hydro has been generally overshadowed and confused with large hydropower (LHP). The focus over the years in many developing countries (for instance, in some countries of Africa, Asia, and Latin America) has been large-scale hydropower schemes. SHP has attracted relatively little attention from entrepreneurs, equity investors, and project financiers in recent years in emerging economies with the exception of some of them. However, given the current global context, the cost competitiveness of the technology and the size of the remaining resource, investment analysts believe that small hydro has the potential to enjoy rapid expansion, particularly in emerging economies. Economically viable and proven small-scale hydropower technologies have been commercially developed and are available for generating both electrical and mechanical power for rural industrialization and development. In continents like Africa and Asia, small hydropower development is an adequate measure for electrification in rural areas.

In industrialized countries (e.g., European Union), SHP development followed a very specific way (Pelikan 2005):

- Phase 1: decentralized energy demand by industry (up to 1940/1950)
- Phase 2: economic-driven decrease until 1970
- Phase 3: energy crisis and boom until 1990
- Phase 4: decrease driven by environmental concerns up to present

Thousands of small hydroelectric plants were abandoned in Europe and North America during the period from the 1950s to the early 1980s. In 1990s, small hydropower plants virtually ceased to exist in the Former Soviet Union and Central and Eastern Europe.

However, in the EU, there is a good hope that the last phase will change its trend due to a recently enacted legally binding targets for increasing renewable energy use by 20 % by 2020. Actually, in some European countries (for instance, Balkan region/South Eastern Europe), there is ongoing boom of constructing new SHP plants.

Similarly, small hydropower development is actually booming in the USA. Driven by federal incentives, the market continues to grow and SHP is now recognized as one of the most cost effective and environmentally friendly forms of renewable power. Similar trends can also be seen in other countries, in particular in Brazil, Canada, and China.

SHP Versus Large Hydropower (LHP)

Major attributes of small (SHP) and large hydropower (LHP) are given in Table 7. It is important to realize that SHP is not simply a reduced version of a large hydropower plant. Specific equipment is needed to meet the fundamental requirements of simplicity, high-energy output, environmental measures, and maximum reliability.

A comparison of data from Fig. 2 representing small and large hydropower utilization, shows that in all continents, with the exception of Europe, small hydro has big untapped resources that may be utilized in the future, with Europe having realized close to 50 % of its potential.

Classification of Small Hydropower Plants

A common classification of hydropower plants according to installed power capacity is shown in Fig. 3.

Hydropower plants are often subdivided into “large” hydro (LHP) that usually involve dams, and small hydro (SHP), involving mini, micro, and pico schemes that are normally run-of-river systems and have little or no water storage capacity.

There is currently no agreement in the international community as to the definition of small hydropower. The upper limit is generally regarded to be 10 MW in capacity that suggests still minimal negative impact on environment. However, small hydro in the USA can refer to projects between 1 and 30 MW, in Canada between 1 and 50 MW, while in China it is as high as 50 MW (Table 8).

This classification can be supplemented by hydraulic head, operational mode (run-of-river, pondage/reservoir type), applicable turbine technology, etc.

Small hydro systems can either be connected to the grid and provide power to the grid or they can be used for independent and stand-alone applications in isolated remote areas. Micro, Mini, and even small hydro plants may provide power only to an isolated community or a single home.

Pico-Micro hydroschemes are generally stand-alone systems, that is, are not connected to the electricity grid. They are used for domestic electricity applications such as lighting, TV/radio, and battery-charging. It is becoming a mature technology which should now be considered as part of the menu of alternatives to grid extension,

Table 7 Major attributes of small (SHP) and large (LHP) hydropower

Positive			Negative		
	SHP	LHP		SHP	LHP
Emissions-free, with virtually no CO_2, NO_x, SO_x, hydrocarbons, or particulates	+	+	Frequently involves impoundment of large amounts of water with loss of habitat due to land inundation. Freshwater reservoirs might emit GHGs emissions.	–	+
Proven and reliable technology, indigenous resource, resistant to inflation	+	+	Altering river flows and natural flooding cycles, sedimentation/silting	–/+	+
Renewable resource with high conversion efficiency to electricity (90+%)	+	+	Variable output – dependent on rainfall and snowfall	+	+/–
Dispatchable with storage capability	–	+	Impacts on river flows, water quality, aquatic ecology, including fish migration and oxygen depletion	–/+	+
Usable for base load, peaking, improves grid stability	–/+	+	Social impacts of displacing indigenous people	–	+
Attractive energy pay-back ratio, low operating and maintenance costs	+	+	Health impacts in developing countries	–	+
Long lifetime – 50+ years typical, up to 100 years	+	+	High initial capital costs	+	+
Technology suitable for rural electrification notably in developing countries, output is consumed near the source	+	–/+	Long lead time in construction of mega-sized projects	–	+
Promotes multipurpose uses (irrigation, navigation, flood defense, recreation)	+	+	Structural dam failure risks	–/+	+

diesel generators, solar PV systems, and other energy systems presently being used in rural areas, especially developing countries. In comparison to these options, pico-hydro can be installed at a lower cost for the same energy output and in the markets where it has become established, subsidies have not been required.

Current Status of SHP

Overview of SHP Development of the World

As indicated in Table 9, global installed SHP capacity in 2008 was 53.7 GW representing TWh/year generation in electricity. Roughly 10 % of global economically feasible SHP potential has been exploited up to now. The biggest exploitation rate is observed in Europe – 46 %, whereas African continent have a long way to go – less than 2 %.

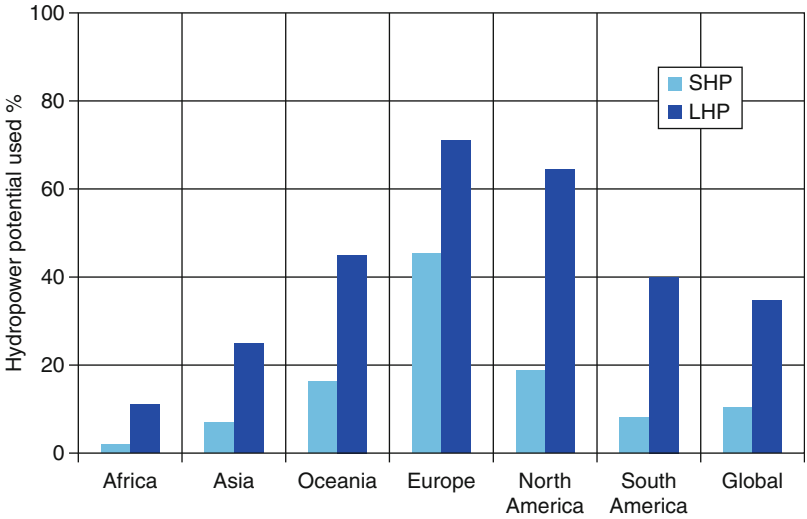

Fig. 2 Proportion of the small and large hydropower currently used to the economically feasible potential in each region

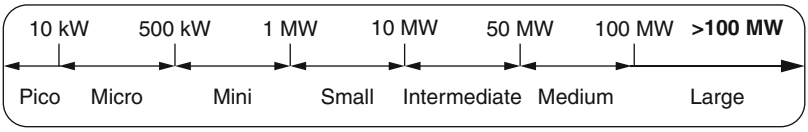

Fig. 3 Common classification of various hydropower schemes according to installed power capacity

Russia is attributed to Asian continent.

Economically feasible potential is subject to considerable fluctuations (due to economic competitiveness among power options, the status of energy, and environmental legislation). This issue is more problematic in emerging economies where data on SHP are scarce.

Global small hydro contribution to the gross electricity mix is insignificant – around 1 % and it is of a similar scale to the other renewable energy sources. Despite this, it should not be neglected though, because there is an even much larger market potential in Asia, South America, and Africa. SHP share to the global hydropower generation is more than 6 %. It is quite clear that SHP is the second largest renewable energy source after large hydropower in all contents. But in Europe electricity generation from wind energy is currently surpassing SHP.

There are, of course, many ways to look at global SHP players. Table 10 shows the 10 top countries with the highest share of SHP installed capacity and electricity generation, with China on top.

Small hydropower sector is represented according to country's SHP plant size limit.

Table 8 SHP definition and classification in selected countries

Continent/organization	Major attributes of classification
Africa	Guinea, Kenya, Nigeria, South Africa (<10 MW), Lesotho (<15 MW), Madagascar (<20 MW), Mozambique (<25 MW)
Asia	Nepal, Philippines (<10 MW), India (<25 MW), Russia (<30 MW)
	China (<50 MW). According to the scale of installed capacity, it can be divided into four grades: 0.5–5 MW, 5–10 MW, 10–25 MW, and 25–50 MW. It also can be divided into three types: run-of-river SHP, adjustable SHP, and irrigation SHP
Europe, ESHA (European Small Hydro Association), the European Commission and the UNIPEDE (International Union of Producers and Distributors of Electricity)	The European Union has no uniform classification criteria for SHP. As a rule, the installed power capacity is the main classification criterion (units up to 10 MW). However, this limit is set at 3 MW in Italy, 8 MW in France, and 5 MW in the UK, 2 MW in Latvia
	For the statistical purposes there is a common division between two groups of hydro schemes: less than 1 MW and between 1 and 10 MW
North and Central America	Small hydropower limit is often high
	In Canada, there are three categories recognized under small hydro: Micro hydro (less than 100 kW); Mini hydro (100 kW–1 MW) and Small hydro (1–50 MW)
	In the USA small hydro refers to hydropower potential $\geq$1 MW and $\leq$30 MW, and low power refers to hydropower potential <1 MW
	Mexico: small (1< P <30 MW)
South America	This continent is mostly dominated by large SHP capacity limit, more often up to 30 MW
	Brazil small hydropower sector is represented by two distinct classes: Mini hydropower plants (P $\leq$1 MW) and small hydropower plant (1 MW < P $\leq$30 MW) and Argentina (<30 MW), Chile, Columbia, Peru (<20 MW), Bolivia (<10 MW)
Australia and New Zealand	In Australia small hydro is divided into three categories: micro (less than 100 kW), mini (100 kW to <1 MW) and small (1 MW to <10 MW)
	New Zealand: 20 MW
UNIDO (United Nations Industrial Development Organization)	Micro <100 kW; Mini 101–2,000 kW; Small 2–10 MW
IN-SHP (International Network on Small Hydropower), International Small-hydro Atlas	Micro <100 kW; Mini 101–500 kW; Small 0.5–10 MW
	Small Hydro: 50 kW < P <10 MW installed capacity

Table 9 Profile of small hydropower (installed capacity <10 MW/site) development by continents

Continent	Economically feasible (realizable) SHP potential (TWh/year)	Installed capacity (MW)	SHP generation (TWh)	Degree of development (%)	SHP contribution in total hydropower electricity generation (%)	% of global SHP installed capacity
Africa	135	776	2.5	1.9	2.69	1.4
Asia	1,198	23,752	82.4	6.9	7.44	44.3

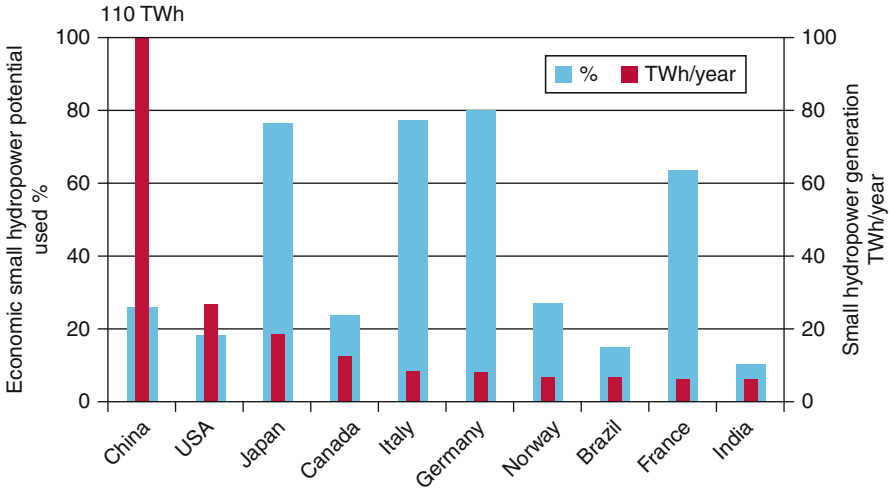

Fig. 4 Economic small hydropower potential that is currently utilized in selected countries (% and TWh/year)

Not surprisingly, countries with large mass and river drainage basins, including China, the USA, India, Canada, Brazil, and Japan, with the exception of hydro-rich country Russia, appear on the list. Another measure would be to look at SHP contribution to their overall electric energy generation. In this case, Norway (5 %), China (3.7 %), Italy (2.9 %), and Canada (2.1 %) are on the top.

In the cases of Japan, Italy, and Germany, for example, nearly 80 % of the economically viable small hydro resources have already been tapped, whereas large countries such as China, Canada, the USA, Brazil, and India having huge SHP potential have a long way to go (Fig. 4).

Overview of SHP Development by Continents

Africa

The African Continent is endowed with enormous hydropower potential that needs to be harnessed. The focus over the years in many African countries has been large-scale hydropower schemes. Recent studies have shown that electricity generation through small hydropower is gaining market share owing to its short gestation period, low investment, and least environmental impacts (Hydropower resource assessment of Africa. In: Ministerial conference on water for agriculture and energy in Africa: the challenges of climate change et al. 2008).

The current level of utilization of SHP potential is very low in the continent with regard with other continents. Total installed capacity of these plants exceeds 770 MW with power generation of 135 TWh/year in the continent. Small hydro is not popular in the individual countries either: in the majority of them, total installed capacity of SHP plants rarely exceeds a few dozen megawatts.

However, the assessed SHP economically feasible potential in a larger number of countries is quite high: Congo Democratic Republic, 33.7 TWh/year; Madagascar, 18 TWh/year; Angola, 15 TWh/year; Ethiopia, 16.2 TWh/year; Guinea, 12 TWh/year; and Cameroon, 11.5 TWh/year.

Europe

More than 24,000 SHP plants (units up to 10 MW) with total installed capacity of 16 GW and annual production of nearly 55 TWh/year operate in Europe. (Small hydropower sector of the European part of Russia is shortly represented under Asia continent.)

In the European Union (EU), the potential for medium and large-scale hydropower projects is already exploited to a high degree (some 80 %), small hydropower projects become the subject of increased development. In 2006, there were nearly 21,000 SHP plants with total installed capacity of 13 GW and total electricity generation of 41,000 GWh in the EU (ESHA and SERO 2008). More than 80 % is concentrated in the following six countries: Austria, France, Germany, Italy, Spain, and Sweden. In addition, Switzerland and Norway have a high SHP capacity followed Bulgaria, the Czech Republic, Poland, and Romania.

About 1.2 % of the total electricity generated as well as 9 % of all renewable energy in EU came from SHP. On average, a statistic SHP plant in the EU had a capacity of 0.6 MW and produced about 2.0 GWh in 2006.

Oceania

The continent's installed capacity of SHP is 280 MW with power generation of 1.1 TWh/year, against an estimated potential of 6.8 TWh/year. SHP hydro schemes are popular in New Zealand (P = 108 MW; E = 509 GWh/year), Australia (P = 70 MW; E = 255 GWh/year), and French Polynesia (P = 47 MW; E = 164 GWh/year). Small hydro plants are not developed in the remaining countries.

Asia

In China, small hydropower refers to such SHP project whose installed capacity is not more than 50 MW.

There are abundant and widely distributed SHP resources in China; SHP supplies some 30 % of the renewable energy electricity in China and constitutes the main electricity supplier in nearly half of the territory, one-third of the counties, and one quarter of the total population in China (Zhou et al. 2009). In 2004, China's total installed capacity of SHP is 34.66 GW and its generation is 97.79 TWh, the highest one in the world. The number of SHP stations operating in the country exceeds 45,000. There are abundant SHP resources in China, and the potential installed capacity is 128 GW (or 422.4 TWh/year) in technology, ranking first in the world.

Japan is the second largest after China with regard to the total installed capacity of small hydro schemes (P = 3,509 MW, E = 18.8 TWh/year). Nearly 80 % of the economically feasible potential has been harnessed so far.

Russia has the second highest level of mean annual river runoff in the world, after Brazil. The bulk of the stream flow is concentrated in the eastern part of the country.

The European part of Russia accounts for less than 25 % of the country's water resources (IEA 2003). The economic potential of small-scale hydropower can be estimated at 493 TWh/year, including more than 100 TWh/year in the European part of country. Before 1980s, some 7,000 small hydropower plants with a total capacity of 1,500 MW operated in the country, but later on due to commissioning of large power plants almost all of them were abandoned. Currently, there are plans to refurbish and develop some 3,000 MW in small-scale hydropower capacity.

India's total SHP capacity amounts to 2,046 MW (power generation 6.2 TWh/year).

Micro-hydro installations are especially widespread in Asia, where there is a significant resource potential for further development (Vietnam, Nepal, Korea DPR, Sri Lanka, Thailand, and Laos).

South America

Nearly 950 small hydropower plants with total installed capacity of 2,055 MW and annual power production of 8.9 TWh/year operate in the continent. Only a minor part of the economically feasible potential has been tapped so far (some 8 %).

In the past, Brazil favored large hydropower schemes, largely ignoring small hydropower (less than 30 MW). But as most of the economically feasible large dams have already been built, the attention is now shifting to small-scale hydropower, particularly in rural areas. Actually there is biggest number of hydro plants 570, with total installed capacity of 1,429 MW and electricity generation of 6.7 TWh/year. Brazil is followed by Peru and Argentina (installed capacity 237 and 92 MW, and electricity generation 1.0 and 0.34 TWh/year, respectively).

North and Central America

There are currently about 1,100 MW of installed small hydro capacity with power production of 41 TWh/year in the region. Some 19 % of economically feasible potential has been developed so far.

The USA is the first with regard number of plants in operation (2,050), installed capacity (7,087 MW), and electricity production (26.7 TWh/year). Canada is the second largest SHP producer in the region having an installed capacity of 3,400 MW and generating 12.8 TWh/year. The remaining countries' SHP capacities are significantly smaller: Mexico – 109 MW and 480 GWh/year, Costa Rica – 77 MW and 306 GWh/year, Honduras – 60 MW and 276 GWh/year.

Central America has outstanding potential for hydropower development. Costa Rica, Nicaragua, Guatemala, Panama, and Honduras are especially active in developing SHP plants.

SHP Prospects and Future Potential

Long-term challenges for small hydropower development are the following:

- Capture the low-head, run-of-river hydro resource in a sustainable manner using new technology
- Fish passage and fish friendly turbines
- Minimal water impoundment
- Minimal impacts on aquatic ecology
- No sediment buildup or depletion beyond normal levels

It is difficult to make forecast of global small hydropower due to the many uncertainties. Analysis of currently published studies, reports, papers, and information existing in available data bases shows there are no reliable SHP future development figures and scenarios. By contrast with large hydropower, where comprehensive and reliable data bases are available, statistics of small hydro are very scarce, incomplete, or event incompatible with different data providers. This is true even for developed countries; the figures of small hydropower economic or technical potential are seldom available.

At the time the World Energy Council (WEC) (2004) estimated that, under current policies, installed capacity of small hydro would increase to 51 GW by 2020, with the largest increase coming in China. Under the WEC's favorable case scenario, installed capacity increases to about 75 GW by 2020. All regions of the world are experiencing significant increases in small hydro capacity, with China again showing the largest increase (Small Hydropower Fact Sheet 1999).

Projections made by Zhou et al. (Zhou et al. 2009) show that in China by 2015, the installed capacity of SHP will be 63 GW (49.4 % of the total potential), 79 GW (61.5 %) by 2020, and 103 GW by 2030. SHP in the European Union will expand also impressively. Following BAU (Business As Usual – is based on projections of future emission if no action is taken) scenario, SHP installed capacity (<10 MW/site) will increase from 13 GW up to 16 GW by 2020. If optimal conditions for developing SHP (barriers are not an obstacle, the support system are well designed for SHP, etc.) are established, then the total installed capacity could reach 20 GW.

A recent study of estimation of small hydropower resources in the USA has shown that 41 states distributed around the country have sufficient potential to increase their generation by at least 50 % (US Department of Energy 2006). This means, that SHP installed capacity could be increased from the current 7.1 GW to more than 10 GW.

Relationship Between Hydropower and Water Storage Development and Socioeconomic Development

Hydropower Enables Multipurpose Utilization of Water and Hydroenergy Resources

Water represents fundamental natural resources, strategic economic resources, and a key environmental element. Subsequent to population growth, economic development, and urbanization, the water demand of human being is increasing at the speed

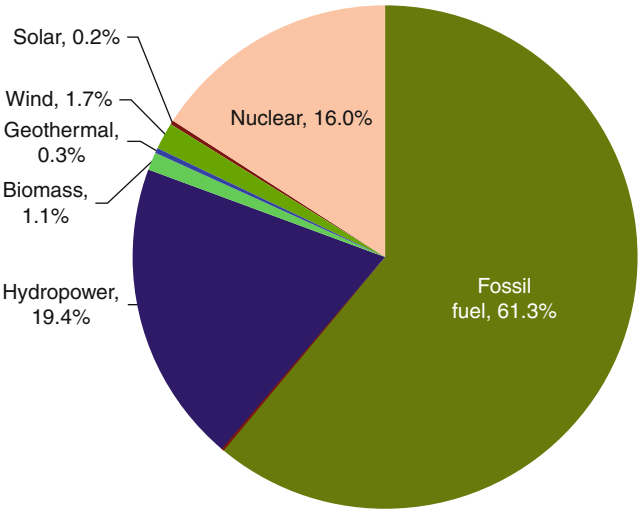

Fig. 5 Power generation by type

of 64 billion m^3/year. It is estimated that 47 % of the total population on the globe will live in places with a desperate water shortage (UNESCO 2009). Global climate change has caused profound evolution of water circles and water resources, obviously expressed by the increased variation of rainfall and water resources in time and space, significant change of hydrological process, and frequent occurrence of extreme weather events. All these have aggravated the imbalance between water supply and demand in water-deficit areas, increased the degree of difficulty in water resources development and utilization, and caused more difficulties in disaster alleviation and relief.

During the past century, multipurpose dams and reservoirs have provided an opportunity for drought protection, flood mitigation, water provision for rural and urban need, navigation, recreation, as well as energy. Moreover, its comprehensive advantage on water and energy utilization is popped out gradually with successive occurrence on energy crisis, water crisis, food crisis, and climate change.

Water storage is energy storage. It has played an important role in modern power systems. Currently, hydropower generation accounts for approximate 20 % of world electricity (EIA 2008), which is the second dominating power after fossil fuel (Fig. 5).

Large water storage facilities built for hydropower development are generally used for multiple purposes, such as flood control, water supply, navigation, power generation, irrigation, environmental protection, and recreation. Many of them act as the engine to increase the regional capability of integrated and well-coordinated development and become the landmark of countries where they are located. For instance, the Three Gorges Project in China is the world largest hydropower station, with an installed capacity of 22,500 MW, equivalent to a cumulative reduction of 34 million ton standard coal, 74.8 million ton CO_2 and 0.68 million ton SO_2. Clean energy is supplied for Central China, East China, South China, and Chongqing. Secondly, the

resultant reservoir serves the most important function of flood control in the world, directly protecting the fertile Jiang-Han plain, Wuhan and other major cities in the downstream area. Thirdly, the project is furnished with the world's largest shiplock, which will greatly improve the navigability of the Yangtze mainstream that has long been known as a "golden watercourse," with the annual volume of cargo transport increased to 300 million ton and the transport cost reduced by 35–37 %. Fourthly, the reservoir replenishes the lower reach in the dry season using its huge storage capacity to mitigate the imbalance between water supply and demand. Owing to the function of flood control, power generation, navigation, and water supply, the Three Gorges Project has secured the safety of the Yangtze River, which goes through China from west to east, and played an important role in promoting well-coordinated development in the middle, east, and west parts of China. There are many projects like this in the world, for example, Itaipu Hydropower Station in Brazil and Hoover Dam in the USA. They have turned out an indispensable and important part of the infrastructures in their countries and an engine to push forward regional sustainable economic, social, and environmental development.

Relationship Between Hydropower and Water Storage Facility Construction and Socioeconomic Development

Geographically, hydropower development in the world is extremely imbalanced. The hydropower resources in Asia and Africa account for 61 % of the world total economic availability, but the output takes up 39 % of the world total only. With regard to the degree of hydropower development, there is a global average of 35 %, but only 25 % in Asia and 11 % in Africa (Figs. 6 and 7).

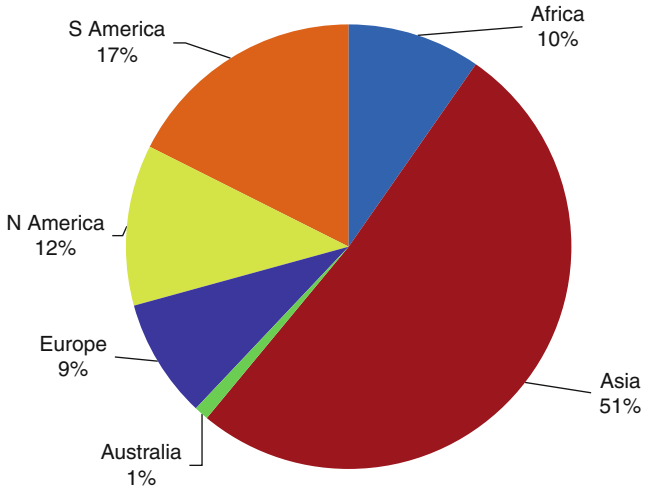

Fig. 6 Distribution of hydropower economic availability in the world

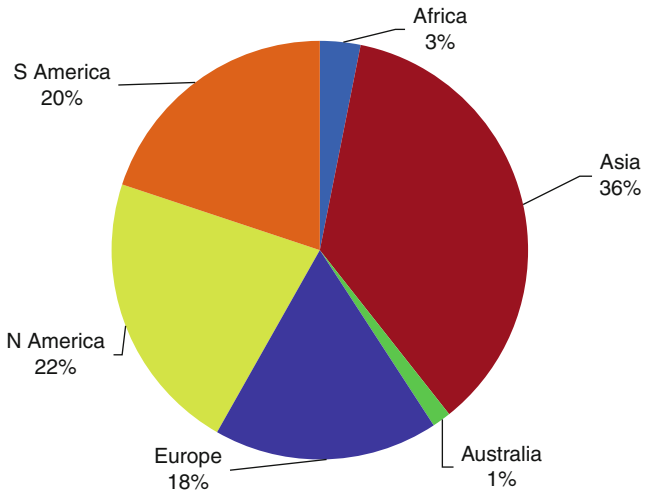

Fig. 7 Distribution of hydropower production by continent (in 2007)

Not only the comprehensive advantages that the dam has, but also the tight relation it has with socioeconomic development. This idea initiated from Berga (Berga 2008), the former president of ICOLD (International Commission on Large Dams). He thought the per capita storage capacity possessed by the country was closely related to the socioeconomic development. Follow this idea, the entry compares and analyzes per capita storage capacity index and the human development index (HDI) about more than 50 countries. The result clearly indicates how dam/reservoir development is related to socioeconomic development.

HDI, the weighted average of the per capita GDP, health and education which reflect the quality of life, is an overall index used to measure the level of socioeconomic development in the UN member countries. This index avoids the shortcoming that the per capita GDP is used as the sole index for measuring human development. HDI is a value ranging from 0 to 1, the closer it is to 1, the higher the human development level is. The countries with HDI higher than 0.9 are mostly developed countries, for example, Australia (0.970), USA (0.956), UK (0.947); those with HDI in the range of 0.8–0.9 are relatively developed countries, for example, Argentina (0.866), Russia (0.817), Brazil (0.813); while those with HDI below 0.5 are mostly less developed Asian and African countries, e.g., Rwanda (0.46), Burkina Faso (0.389), and Afghanistan (0.352).

As shown by the human development and dam/reservoir development data of over 50 countries in 2007, the countries with HDI above 0.9 had an average per capita storage capacity of 3,184 m^3, those with HDI in the range of 0.8–0.9 had 2,948 m^3, those with HDI in the range from 0.7 to 0.8 had 541 m^3, those with HDI in the range of 0.6–0.7 had 208 m^3, and those with HDI in the range of 0.5–0.6 had 125 m^3 only (Figs. 8 and 9). As seen from this fact, developed countries have a solid ground for securing water safety and coping with the changing water storage

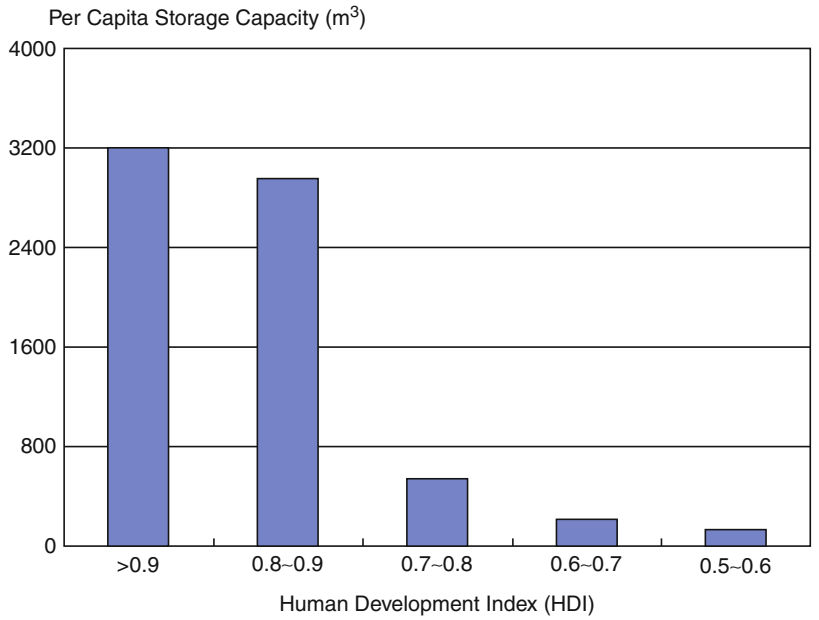

Fig. 8 Relationship between average per capita storage capacity and HDI

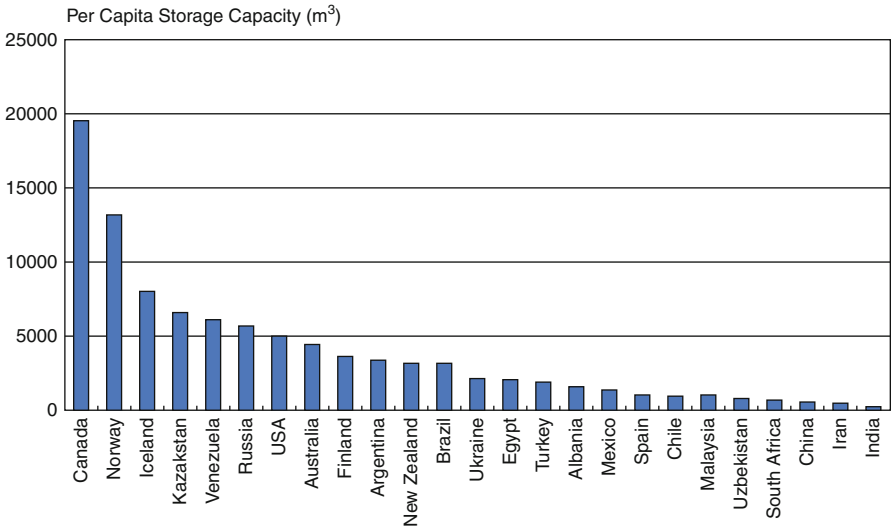

Fig. 9 Per capita storage capacity of typical countries

facilities, but developing countries still have a long way to go as limited by financial, technical, and human resources. As for a given country, despite exceptions, for example, Israel with HDI of 0.935 and a per capita storage capacity of 27 m^3, and Zambia with 0.481 and 1,072 m^3 respectively, the level of dam development in a country or region is directly proportional to the level of human development. The UN human development report also pointed out that "the distribution of global water infrastructures is reversely proportional to the distribution of global water risks."

Due to the varying extent effect, climate change represents different impacts and consequences to countries in different stages of development. Blair pointed out in his report: "the groups least responsible for climate change, i.e., the poor and vulnerable groups, are subject to the most adverse effects." Likewise, the poor or undeveloped countries that have not caused, are not causing, and will not cause significantly more greenhouse gas emissions are responsible for the cost of climate change. They are most easily subject to the effect of climate change and their adaptability is the most vulnerable. Countries in different stages of development have different objectives and priorities of water storage facilities, and also different concerns. For less developed countries, the consequence of global climate change is often catastrophic to the extent that, due to the inadequate storage capacity, subsequent extreme weather events occur frequently and bring about worse disasters. The construction of water storage facilities is a crucial matter relating to their surviving and getting rid of poverty. Just as stated in the World Declaration on Hydropower (2008) Development (Africa), water and electricity are materials to save life in less developed African countries. These countries are in desperate need of energy and water. With the dual benefit of water storage and power generation, multipurpose dams/reservoirs are critical for improving safe water supply. Also, they greatly mitigate the impacts posed on Africa by extreme weather events. Thus, the development of water and hydroenergy resources is of special significance for developing countries, especially the African countries, and one of the most urgent tasks to improve the livelihood.

To Accelerate Water Storage Infrastructure and Hydropower Development are a Common View of the International Community Today

Observed Impacts on Water and Future Changes in Water Demand and Availability

The IPCC (IPCC 2007a) has identified changes in a number of components of the hydrological cycle and systems which include: changing precipitation patterns; intensity and extremes; increasing melting of snow and glaciers; increasing atmospheric water vapor; and changes in soil moisture and runoff. These changes are consistent with the observed climate warming despite the fact that the components of the hydrological cycle and systems usually demonstrate a significant natural variability over various timescales.

Table 11 Climate-related observed trends of various components of the global freshwater systems (Modified from Table 1.3, Chap. 1. WGII of the IPCC AR4 (IPCC 2007a; IPCC 2007b))

Parameter	Observed changes	Period	Location/ catchment	Comments
Runoff/ streamflow	Annual increase of 5 %, winter increase of 25–90 %	1935–1999	Arctic drainage basin (Ob, Lena, Yenisei and Mackenzie)	Large impact of winter melting and thawing of permafrost. Summer has very little impact
	Onset of streamflow peaks 1–2 weeks earlier than before	1936–2000	Western North America, New England, Canada, and northern Eurasia	Early onset of spring
Increased runoff in the glacial basins in Peru	23 % increase in glacial melt	2001–2004	Yanamarey	Increased warming
	143 % increase	1953–1997	Llanganuco	
	169 % increase	2000–2004	Artesonraju	
Floods	Increasing catastrophic flood frequency (100–200 year flood)	Last few years	Russian Arctic rivers	Caused by earlier breakup of river ice accelerated by warming and heavy rainfall events
Hydrological droughts	29 % decrease in annual maximum streamflow	1847–1996	Southern Canada	Rise in temperature and increased streamflow
Water temperature	0.1–1.5 °C increases in lakes	40 years	Europe, North America, and Asia (100 stations)	Caused by atmospheric warming

Although there are regional variations (increasing or decreasing) in runoff changes, at the global scale, Milly et al. (Milly et al. 2005) have identified a coherent pattern of change in an annual runoff (Table 11).

Future changes in water demand and availability will arise from two fronts. First, main climatic parameters such as precipitation, temperature, and evaporation changes will drive water availability as well as demand. In the snow- and glaciers-melt-dependent rivers or water bodies, temperature is very important. Thermal expansion plays a major role in the process of sea level rise, which could affect surface water in the coastal areas.

Second, non-climatic drivers that would play major roles include population increase, food demand, increased income through economic development, lifestyle changes, and ecological water demand.

Major changes can be expected in flooding and droughts. In northern latitude countries, flooding from rain is projected, as most of the precipitation would be in the form of rain rather than snow. The timing of flooding will also change – early spring flooding could occur. If flood waters can be stored, this could be beneficial for

Table 12 Regional impacts on water resources (IPCC 2007b)

Region	Impacts of water
Africa	By 2020, between 75 and 250 million of people are projected to be exposed to increased water stress due to climate change
	By 2020, in some countries, yields from rain-fed agriculture could be reduced by up to 50 %
	By 2080, an increase of 5–8 % of arid and semiarid land in Africa is projected under a range of climate scenarios
Asia	By the 2050s, freshwater availability in Central, South, East, and South-East Asia, particularly in large river basins, is projected to decrease. Coastal areas, especially heavily populated megadelta regions in South, East, and South-East Asia, will be at greatest risk due to increased flooding from the sea and, in some megadeltas, flooding from the rivers
Australia and New Zealand	By 2030, water security problems are projected to intensify in southern and eastern Australia and, in New Zealand, in Northland and some eastern regions
Europe	Negative impacts will include increased risk of inland flash floods and more frequent coastal flooding and increased erosion (due to storminess and sea level rise)
	Mountainous areas will face glacier retreat, reduced snow cover (in some areas up to 60 % under high emissions scenarios by 2080)
	In southern Europe, climate change is projected to worsen conditions (high temperatures and drought) in a region already vulnerable to climate variability, and to reduce water availability, hydropower potential, summer tourism and, in general, crop productivity
Latin America	Changes in precipitation patterns and the disappearance of glaciers are projected to significantly affect water availability for human consumption, agriculture, and energy generation
North America	Warming in western mountains is projected to cause decreased snowpack, more winter flooding and reduced summer flows, exacerbating competition for over-allocated water resources
Small Islands	By mid-century, climate change is expected to reduce water resources in many small islands, e.g., in the Caribbean and Pacific, to the point where they become insufficient to meet demand during low-rainfall periods

hydropower and other uses. Droughts will result from low rainfall and high temperature. Table 12 below summarizes regional impacts of climate change of water.

Energy Consumption and Greenhouse Gas Emission Characteristics of Hydropower

Water storage means energy storage. Hydropower often pays for water storage. In addition, hydropower is a kind of energy with lower energy consumption and GHGs emission which is more important under the circumstance of global attention on climate change.

Energy Payback Ratio of Hydropower

The construction and operation of energy facilities also consume energy. The concept of energy payback ratio provides a way to better measure the overall benefits of different modes of energy development and better understand the advantage of hydropower in conserving energy, reducing emission dealing with climate change.

The use of energy payback emerged with the oil crisis occurred in the early 1970s. After the oil crisis, the energy agenda began to change significantly, resulting in issues like energy independence, air quality, and later climate change (Gagnon 2008). Many countries started to explore oil substitutes. One of the key problems that became apparent was the selection of efficient energy options for growing future demand. To identify appropriate solutions, policy-makers need to consider life-cycle assessments before taking decisions. Such life-cycle assessments must include energy payback as a central component. Energy payback may be a somewhat indirect measure of overall impact, and it provides a useful perspective on the origins of the real-world impacts. Therefore, the concept of energy payback was used to evaluate energy options in the form of Net Energy Analysis (NEA) by comparing the "net energy" for different energy options on a life-cycle basis.

One way to compare different energy options is to calculate the so-called life cycle Energy Payback Ratio (EPR). This is the ratio of total energy produced during that system's normal lifespan to the energy required to build, maintain, and fuel the system. The Energy Payback Ratio of a power plant is defined as the total energy produced over the lifetime of the plant divided by the energy needed to build, operate, fuel, and decommission it. White and Kulcinski (White and Kulcinski 1999) proposed a simple equation for calculating the Energy Payback Ratio, EPR,

$$\mathrm{EPR} = \frac{\mathrm{E_{nL}}}{(\mathrm{E_{matL}} + \mathrm{E_{conL}} + \mathrm{E_{opL}} + \mathrm{E_{decL}})}$$

in which, E_{nL} is the net electrical energy produced over a given plant lifetime L; E_{matL} is the total energy invested in materials used over a plant lifetime L; E_{conL} is the total energy invested in construction for a plant with lifetime L; E_{opL} is the total energy invested in operating the plant over the lifetime L; and E_{decL} is the total energy invested in decommissioning a plant after it has operated for a lifetime L. A high ratio indicates a good performance.

According to Gagnon (Gagnon 2005), the energy payback ratio of different modes of energy development is about 208–280 for hydropower with reservoir, 170–267 for hydropower run-of-river, 18–34 for wind power, 3–5 for biological energy, 3–6 for solar energy, 14–16 for nuclear energy, 2.5–5.1 for traditional thermal power, and only 1.6–3.3 for thermal power in CO_2 capture or storage technology (Fig. 10).

Greenhouse Gas Emission of Hydropower

Hydropower is a source of energy causing the least greenhouse gas emission. The unit CO_2 emission per MW is about 941–1,022 t for traditional thermal power,

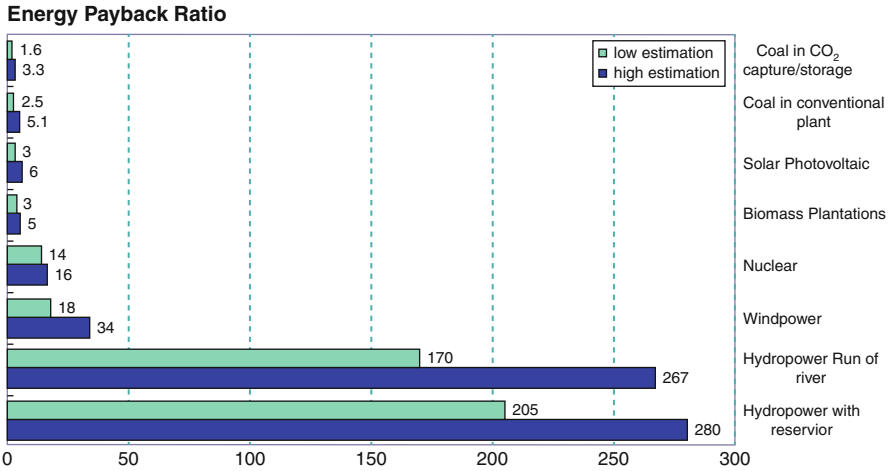

Fig. 10 Energy payback ratio by type

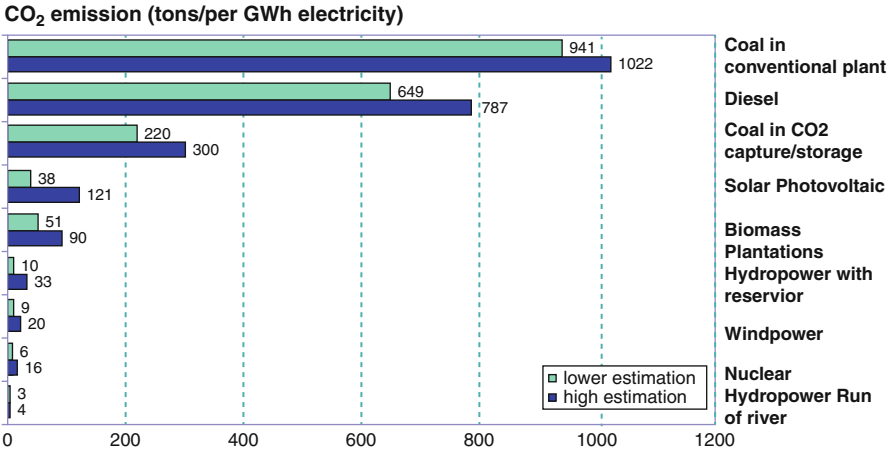

Fig. 11 Greenhouse gas emission by types

649–787 t for diesel power, 220–300 t for thermal power applying carbon recovery technology, 38–121 t for solar energy, 51–90 t for biological energy, 10–33 t for reservoir-type hydropower, 9–20 t for wind energy, 6–16 t for nuclear energy, and 3–4 t for runoff-river power, the least emission (Fig. 11).

Among various types of energies, hydropower has the highest energy pay back and lowest green house gas emission.

A Consensus on the Role of Hydropower and Dam in Adapting Climate Change has been Conducted in Wide Range by International Community

The world is faced with the problem of ever-increasing water shortage and also the problem of inadequate energy for economic development and domestic demand. For developing and undeveloped countries, which take up the majority of the world, the first task is to promote economic development and alleviate poverty. Just as Smt. Indira Gandhi (the late Prime Minister of India) said: "poverty is the worst enemy of the environment." There are 2 billion people without access to modern energy supply in the world today, 1.1 billion people without safe drinking water, 2.4 billion people in the lack of health facilities, and up to 211 million people affected by natural disasters each year. Hydropower is a source of energy renewable and capable of commercial development on a large scale. Under many circumstances, it is also an economically affordable option for poor areas to solve the issue of power supply. Large reservoirs with benefit of hydropower development are important facilities to secure safe water supply and mitigate flood/drought disasters effectively. In the twenty-first century, the world is confronted with worsening problems in sustainable development: soaring oil price, obvious consequence of climate change, and more urgent need to secure safe drinking water supply and power supply. Therefore, the demand of seek engineering solutions, for example, accelerated hydropower development and more reservoirs/dams, remains the most effective measure. To develop and utilize water and hydroenergy resources is an irresistible trend of development.

Having reviewed the issue of hydropower development again, relevant organizations in the world have raised the understanding of hydropower development to a new level at several summits and seminars of milestone significance.

The Johannesburg World Summit on Sustainable Development from August 26 to September 4, 2004 endorsed two important documents, the "Plan of Implementation" and the "Johannesburg Declaration on Sustainable Development," setting forth the indicators and timetable of renewable energy sources on the globe. This document includes:

Article 9: Take actions and improve efforts to work together at all levels to improve access to reliable and affordable energy services for sustainable development sufficient to facilitate the achievement of the Millennium development goals, including the goal of halving the proportion of people in poverty by 2015, and as a means to generate other important services that mitigate poverty.

Article 20: Develop and disseminate alternative energy technologies with the aim of giving a greater share of the energy mix to renewable energies, improving energy efficiency and greater reliance on advanced energy technologies, including cleaner fossil fuel technologies.

And the sustainable use of traditional energy resources, which could meet the growing need for energy services in the longer term to achieve sustainable development.

Diversity energy supply by developing advanced, cleaner, more efficient, affordable and cost-effective energy technologies, including fossil fuel technologies and renewable energy technologies, hydro included, and their transfer to developing countries on concessional terms as mutually agreed. With a sense of urgency, substantially increase the global share of renewable energy sources with the objective of increasing its contribution to total energy supply, recognizing the role of national and voluntary regional targets as well as initiatives, and ensuring that energy policies are supportive to developing countries' efforts to eradicate poverty.

At the conferences on drinking water, energy, health, agriculture, biodiversity, and other topics, attention is given to renewable energy likewise. It is emphasized by many that the renewable energy sources will take up 10 % of various energies by 2010 or 2015.

In October 2004, the UN Symposium on Hydropower and Sustainable Development was held successfully in Beijing and attended by the government organizations, nongovernment green environmental protection organizations, and resettler representatives from 44 advanced and developing countries, the relevant UN organizations, the World Bank, and other financial institutions. The seminar passed the "Beijing Declaration on Hydropower and Sustainable Development," which confirmed the strategic importance of hydropower to sustainable development and highlighted the sustainability of hydropower development in economic, social, and environmental aspects. This is the first discussion and summarization of the hot topics in hydropower development over the past two decades, greatly directive to hydropower development in the world.

In November 2008, the ICOLD, IHA, ICID, AU and other international organizations published the World Declaration on Hydropower (2008) (Africa) in Paris, France, stressing the importance of dam and hydropower development to the sustainable development in Africa, appealing to grasp the opportunity of hydropower development, causing the organizations which have signed the Declaration to fulfill their commitments, and assisting the African continent in joint efforts for hydropower development.

In March 2009, the Fifth World Water Forum in Istanbul adopted the Ministerial Declaration, stating that, in consideration of the difficulty in energy, food security, and poverty eradication, all countries unanimously agreed to support various water-related development projects instructed by countries to construct new infrastructures on a large scale, repair, rehabilitate, and improve existing facilities, and ensure economic feasibility, environmental sustainability and social equality, to meet various demands for water storage, irrigation, power generation, navigation, and disaster alleviation.

Prospect of Hydropower Development

Hydropower Will Play a Fundamental Role in Adapting Climate Change

Up to February 2010, approximately 57 countries, including the 23-nation European Union have set a voluntary target for reducing emissions. To fulfill the ambitious target, hydropower is regarded as the priority as long as the country still has the potential hydropower which is available to be developed. For instance:

- China will cut its carbon intensity (CO_2 emissions per unit of gross domestic product (GDP)) by 40–45 % below 2005 levels by 2020. By then, renewable energy will account for more than 15 % in primary energy. Therefore, China's efforts to increase its hydropower installed capacity to 300–350 GW in 2020 as hydropower is sole clean, renewable, and economical energy, which can be developed on large scale and from technical aspect (Shucheng 2010).
- India has pledged carbon intensity (CO_2 emissions per unit of gross domestic product (GDP)) cuts of 20–25 % by 2020 based on 2005 level. As reported, India prepares to stably increase its hydropower generation to an appropriate proportion – 40 % in national power generation (currently the proportion of hydropower is 25 %).
- Brazil has pledged absolute emissions cuts of emissions by 36–39 % from BAU by 2020. This translates to a 15–18 % reduction from 2005 level (Fransen 2009). Besides the measure to slow deforestation, abundant potential hydropower is another effective way to reach its goal.
- The EU has pledged to reduce emissions 20 % below 1990 levels by 2020. Of which, Norway is the first developed country whose CO_2 emission reduction target is line with the stipulation of Kyoto Protocol. Prime Minister Jens Stoltenberg (Stoltenberg 2007) announced to the Labor Party annual congress that Norway's GHG emissions would be cut by 10 % more than its Kyoto commitment by 2012, and that the government had agreed to achieve emission cuts of 30 % by 2020. He also proposed that Norway should become carbon neutral by 2050, and called upon other rich countries to do likewise. The country has courage to stipulate so ambitious target, mainly because 99 % of its power is from hydroelectric plant.

Prospect of Hydropower Development in the World

Against the background of striving for development and dealing with climate change, dam and hydropower development meets an exceptional opportunity and will have a new spring. All countries include hydropower development and water storage facility construction in the priority of infrastructure construction, which increases the global total amount of investment considerably. For example, the USA and China invest large amounts in rehabilitating risky reservoirs, to stimulate domestic demand and economic development while completing infrastructures. Many countries consider hydropower as a priority target of development, with ambitious development plans provided to this effect. According to the statistical data of 2007, there was a total installed capacity under construction up to 158 GW and a proposed installed capacity of 344∼461 GW in the world (Table 13).

As judged from the distribution of installed capacities by continent, the hot spot of future hydropower development is Asia, and then South America and Africa. These three continents take up 95 % of the global installed capacity under construction and 86 % of the proposed global installed capacity (Figs. 12 and 13).

Table 13 Proposed hydropower development in the world Unit (MW)

	Africa	Asia	Oceania	Europe	North America	South America	Total
Hydro capacity under construction	7,489	130,479	160	2,408	5,940	11,327	157,803
Planned hydro capacity	24,236–84,048	224,368–241,699	416–2,489	11,029–13,820	18,435–43,645	65,693–75,556	344,176–461,257

Developing Country is Facing Tough Work to be Forehead in Adapting Climate Change

Due to the varying extent effect, climate change represents different impacts and consequences to countries in different stages of development. As Blair (Blair and Climate Group 2008) pointed out in his report, the change in climate is the same whether the emissions originate in New York or Shanghai. And of course, the most vulnerable to the impact of climate change live in the poorest area of the world. Likewise, the poor or undeveloped countries that have not caused, are not causing, and will not cause significantly more greenhouse gas emissions are responsible for the cost of climate change. They are most easily subject to the effect of climate change and their adaptability is the most vulnerable. Countries in different stages of development have different objectives and priorities of water storage facilities, and also different concerns. For less developed countries, the consequence of global climate change is often catastrophic to the extent that, due to the inadequate storage capacity, subsequent extreme weather events occur frequently and bring about worse disasters. The construction of water storage facilities is a crucial matter relating to their surviving and getting rid of poverty. Just as stated in the World Declaration on Hydropower Development (2008), a reliable electricity supply, taken for granted in many parts of the world, can be a life-saving commodity in the less developed African nations. In general, both energy and water needs are critical in these nations, so the obvious multiple benefits of hydro schemes (particularly when storage reservoirs are included) are of special significance in Africa. The effects of extreme climatic conditions (large-scale floods and regular droughts) that Africa suffers from can be vastly mitigated by dam/reservoir schemes. Naturally, the supply of clean drinking water and irrigation water to enhance food security are major additional benefits of hydro schemes. Thus, the development of water and hydropower resources is of special significance for developing countries, especially the African countries, and one of the most urgent tasks to improve the livelihood.

To Accelerate Hydropower Development Needs New Concepts

At the Session on Water Storage Facilities during the Fifth World Water Forum in March 2009, water security was defined as to maintain necessary hydrological conditions and water storage facilities for maintaining a healthy ecosystem in the climate change, ever-increasing regional socioeconomic demand (including energy demand), and other conditions. In the country with a relatively high level of water security, the problem of water will not cause any major impacts on the poor. To maintain a healthy and robust water ecosystem is greatly significant for ensuring the water security of the poor and the vulnerable groups. Therefore, one needs to know "why to do this?" "how to do," and "for whom (equality)" while constructing water infrastructures. The construction of new water storage facilities should follow the principle of sustainable development. However, the approval, investment, and implementation of new schemes should consider the protection of endangered

species, provision of information for the public and sharing of benefits by all stakeholders, including downstream ecosystem users. This definition reflects the international community's re-recognition of water security against the background of global climate change, and shows their concern about equality, poverty reduction, and other water-relating social issues in the present new situation.

Hydropower development is a practice involving water security and energy security. In the past decade or so, however, hydropower development, especially the construction of subsequent large-scale water storage facilities was subject to incisive criticism from all walks of life, and the reply and response to such criticism was still pale. As the voice of striving for development and coping with climate change runs higher and higher in the world, the voice against dam construction is weakened to some extent. This change helps creating a good international opinion for the development of water and hydroenergy resources. Nevertheless, in the twenty-first century, the construction and operation of a dam and reservoir can no longer be considered as a purely scientific and technical matter. A wide range of other aspects are involved: economic, social, and environmental. While it is clear today that water and energy schemes can be built to be safe, economic, and in harmony with the environment, mitigating environmental pacts remains a high priority for the profession, and must continue to be so. Water storage infrastructure construction must be speeded up in a sustainable way, and joint actions should be taken to minimize the adverse impacts caused by the development, and base water development and management on new concepts, to make a greater progress in maintaining man harmonious with water and man harmonious with nature. In the light of this, the following four points are critical:

First of all, the attitude to nature should shift away from simply exploiting natural resources and adopting restoration measures, but should aim to protect the natural environment at an early stage of planning;
Second, decision making should not only be based on technical and economic feasibility, but also on social equity and environmental requirement.
Third, project operation and management should not only involve traditional techniques to ensure safety, but should also play a role in protecting the ecosystem. Examples are ensuring minimum flows, and appropriate operation of reservoirs.

Finally, benefit-sharing should be more inclusive, rather than just relating to a region or state. All stakeholders should be involved. One should remember that the members related to the project have the right to benefit from a project.

Joint Efforts are Expected in a Better and Sustainable Way for Hydropower and Dam Development

The international community has made unremitting efforts and fruitful achievements in pushing forward the sustainable utilization of water and hydroenergy resources on the globe. For example, the ICOLD has issued the World Declaration on

Hydropower (Africa) (2008) together with the AU, UPDEA, IHA, ICID, and WEC. This declaration is intended to call on all the stakeholders of dam and hydropower development to engage themselves into speeding up hydropower development in Africa while being faced with the tremendous potential and the golden opportunity in Africa. Being confronted with the great potential, the ICOLD is preparing for the World Hydropower Declaration to ally all forces of the international community to push forward the course of hydropower development in Asia.

It was hardly imaginable that the supporters and opposers of dams could discuss the issue of global development peacefully. The common view regarding hydropower development on a big scale fully reflects that the demand of development is the ground of the main and common view today. Due to the complicated and global issue of climate change, the process of water and hydroenergy resources development and utilization involves numerous stakeholders. In the new century, no country or organization can meet the challenge by itself. Better communication and cooperation are needed to cope with global climate change by making great efforts to hydropower development.

Strategies of Hydropower Sector in Adapting Climate Change

Water storage infrastructure has advantages on comprehensive utilization of water and energy. The practice in many countries especially in the developing world shows water and energy development plays an important role in the context of poverty mitigation and driving socioeconomic development. The experience all over world demonstrates that water and energy can be developed in a reliable, cheap, and environmental-friendly way (Araujo et al. 2010). However, hydropower can be an effective measure to anti-climate change on the one hand; it is also sensitive and vulnerable in front of the climate change on the other as hydropower is a sector which is highly subject to the natural condition such as landform, river runoff, etc. Therefore, analyzing possible impacts and set adapting strategies are urgently needed either for energy saving and GHGs emission reduction or its own development.

Possible Impacts on Hydropower

Possible Impacts Scenarios of Climate Change on Hydropower Sector

It is certain future climate changes will pose some challenges to the hydropower industry. Depending on rate and magnitude of climate change, future impacts on the hydropower industry could be mixed. In some regions, the industry will benefit, but in some others it is likely to be adversely impacted. In both cases, the hydropower industry has to adapt to the changed climatic conditions. Three potential climate change scenarios could emerge (Mirza 2008):

- Increased frequency and magnitude of drought
- Increased frequency and magnitude of flood
- Both above

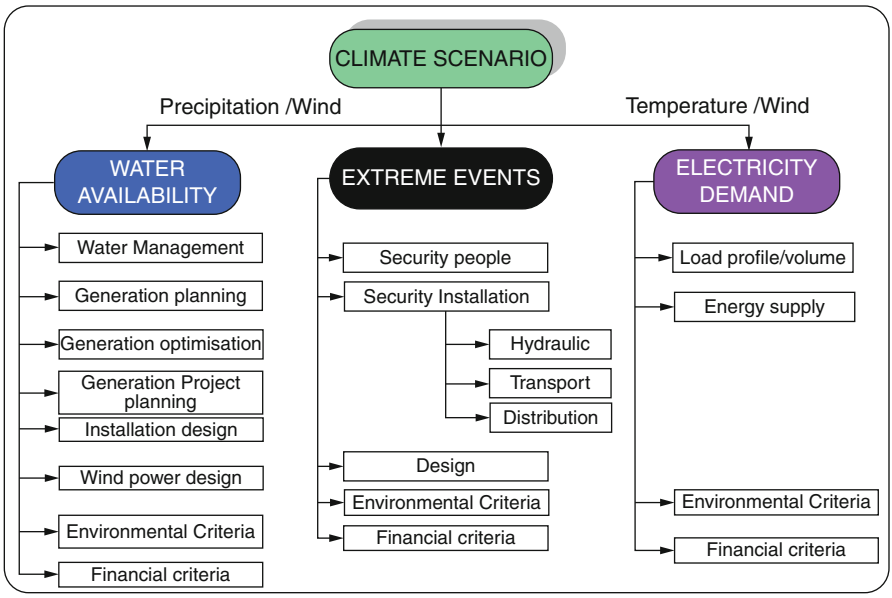

Fig. 14 Most important fields of activities in the hydropower sector that might be affected by climate change (Roy and Desrochers 2002)

In analyzing the impact of climate change on hydroelectric supply, Roy and Desrochers (Roy and Desrochers 2002) first identified the most important activities that might be affected by climate change (Fig. 14). Generally, three climate parameters, precipitation, temperature, and wind, are highly related to hydropower generation. Increases in temperature (and wind as well) result in higher evaporation, which reduce inflow and increase water losses from reservoirs.

All three factors point to less (or, at least, less flexible) hydroelectric capacity at existing powerhouses. Reduced flows in rivers and higher temperatures reduce the capabilities of thermal electric generation; high temperatures also reduce transmission capabilities.

The fields of activities can be arranged in three different groups (first-level concerns) according to the anticipated affects related to the modification of:

- The hydrological regime → water availability
- The thermal regime → electricity demand
- The occurrence of extreme events

Possible Impacts on Hydropower by Continents

The consequences will include modifications in flow seasonality and consequently hydropower. The changes in temperatures and precipitations will thus have impacts

on the runoff, which will increase by 10–40 % from 2050 in the high latitudes, and decrease by 10–30 % in the mid-latitudes (IPCC 2007a).

Changes in the average climate may not have serious impacts on hydropower for short and medium term, but extreme weather events will eventually affect hydropower generation. In the past few decades, extreme weather events have caused significant impacts on hydropower production around the world, especially in the countries of South America.

Africa

In 2007, the water level of Lake Volta, the largest man-made lake in West Africa, which normally supplies 60 % of Ghana's energy needs, was at an all times low (which is 71.65 m) 1.5 m below the critical minimum, as a result of low rainfall. The lack of water in the lake created a 300 MW power shortfall. Similar episodes were also reported in 1993 and 1994 (Mirza 2008).

Europe

Possible changes in hydropower in Europe are mixed. By the 2070s, potential may decline by 6 % overall or by 20–50 % around the Mediterranean. However, increases of 15–20 % are projected in Northern and Eastern Europe, while stable patterns are projected for Western and Central Europe (Alcamo et al. 2007).

According to the study performed by Lehner et al. (Lehner et al. 2005), the results show that, following moderate climate and global change scenario assumptions, severe future alterations in discharge regimes have to be expected, leading to unstable regional trends in hydropower potentials with reductions of 25 % and more for southern and south-eastern European countries.

The results of the analysis of the consequences of probable climate changes for the Nordic (Scandinavia) electricity system demonstrate that climate change leads to a considerable increase in hydro inflow during the winter season as well as reduced demand for heating (Mo et al. 2006). Almost all of the increase in inflow can be utilized by the hydro production system.

Australia and New Zealand

Flows in New Zealand's larger mountain-fed rivers are likely to increase benefiting hydroelectricity generation and irrigation supply (Hennessy et al. 2007).

From the early 2000s, Hydro Tasmania, operating on six major catchments on island (Australia) and having over 30 storages in these catchments has been pursuing greater insight into climate change and its potential impacts on its operations. These storages have a fill and empty cycle of approximately a decade and are used to support the hydro generation system during periods of drought and associated low inflows (Brewster et al. 2008). A review of the existing 80 years of hydrological records has shown a decline in yields especially over the past 30 years. There was a change in inflows around the 1950s with a drier period post 1950s (historical record 1924–2000).

A further catalyst to starting to explore climate change was the recent decline in inflows to the Perth water supply system in Western Australia. The records showed a

significant reduction (i.e., 38 % of long-term average) in the mid-1970s and a further reduction (70 % of long-term average) around the mid-1990s.

Asia

China's climate has witnessed significant change over the past 50 years. These changes include increased average temperatures, rising sea levels, glacier retreat, reduced annual precipitation in north and northeast China, and a significant increase in southern and northwestern China. Extreme weather and climatic events are projected to become more frequent in the future, and water resource scarcity will continue across the country. The case study of the Chaobai river in the Hai river basin, used to supply water to Beijing, demonstrated that the inflow to the Miyum reservoir had been decreasing as a result of rainfall changes and human activities in recent years. The overall runoff in the basin from 2000 to 2005 has decreased by about 66 %. Climate change projections using SRES A2 and B2 scenarios suggest that average annual temperature may increase by 2.4–2.8 °C and precipitation may increase around 4–5 % by 2050, increasing average annual inflow into the reservoir. While climate change projections indicate increased reservoir inflow in the long term, inflows may continue to decline in the medium term, according to SRES A2 scenario, necessitating adaption measures to assure adequate water supply for Beijing city (Jun 2010).

Based on the analysis of three hydropower projects in India, Sri Lanka, and Vietnam, the resulting impact on hydropower projects was indentified (Iimi 2007). Water streams discharges tend to increase with rainfall and decrease with temperature. The rainy season would likely have higher water levels, but in the lean season water resources would become even more limited. The amount of energy generated would be affected to a certain extent, but the project viability may not change so much. Comparing the three cases, it is suggested that having larger installed capacity and some storage capacity might be useful to accommodate future hydrological series and seasonality.

Tajikistan, with economically feasible hydropower potential amounts to 263 TWh/year may experience significant impact on its power output as a result of changes in river basin runoff (Cruz et al. 2007).

South America

Over the next decades, Andean intertropical glaciers are very likely to disappear, affecting water availability and hydropower generation in South America. Runoff changes from precipitation variability will also affect hydropower generation in many Latin American countries (Magrin et al. 2007). Hydropower is the main electrical energy source for most countries in Latin America, and is vulnerable to large-scale and persistent rainfall anomalies due to El Niño and La Niña, for example, in Colombia, Venezuela, Peru, Chile, Brazil, Uruguay, and Argentina. On the other hand, increased energy demand, combined with drought, caused a virtual breakdown in hydroelectricity generation in most parts of Brazil in 2001, contributing to a GDP reduction of 1.5 % or about US$10 billion.

However, the results found are fundamentally dependent on the climate projections which, in turn, are still highly uncertain with respect to the future evolution

of greenhouse gas emissions, greenhouse gas concentrations in the atmosphere, and global climate change (GCC) (Pereira de Lucena et al. 2009).

North and Central America

In the USA, hydropower yields in the Colorado River will likely decrease significantly. Diminished snowmelt runoff could lead to a decrease in the potential hydropower production, which now comprises about 15 % of California's in-state electricity production. If temperature rises to the medium warming range and precipitation decreases 10–30 %, hydropower output may be reduced up to 30 %. It has to be noted, there is uncertainty in future precipitation projections. It is also possible that precipitation may increase and expand hydropower production potential (California Climate Center (CCC) 2006).

In 2001, prolonged droughts caused the water levels in the Great Lakes to fall, resulting in significant reduction in hydropower generation at both the Niagara and Sault St. Marie power stations in Canada (Field et al. 2007). A similar low flow in 1965 caused a 20 % decrease in generation (Mirza 2004, 2008). In the Columbia river basin, runoff required for hydropower generation in the summer will likely conflict with other environmental needs.

Prognosis for the Pacific Northwest (PNW) hydropower supply under climate change has been worse than anticipated (Markoff and Cullen 2008). Differences between the predictions of individual climate models are found to contribute more to overall uncertainty than do divergent emissions pathways. Uncertainty in predictions of precipitation change appears to be more important with respect to impact on PNW hydropower than uncertainty in predictions of temperature change.

The management adaptation potential of the Peribonka River water resource system (Quebec, Canada) is investigated in the context of the evolution of climate change. The main results indicate that annual mean hydropower would decrease by 1.8 % for the period 2010–2039 and then increase by 9.3 % and 18.3 % during the periods 2040–2069 and 2070–2099, respectively. Overall, the reliability of a reservoir would decrease and the vulnerability increase as the climate changes (Minville et al. 2009).

Hydropower generation will be affected by changes in water availability, particularly in snowmelt-dominated basins, where impacts have already been reported. Hydropower production at facilities that are operated to meet multiple objectives (e.g., flood-risk reduction, irrigation, municipal and industrial water supply, navigation, in-stream flow augmentation, and water quality) may be especially vulnerable to changes (Brekke et al. 2009).

Adapting Strategies

In this context, adaption (Fig. 15) of the hydropower industry to climate change may not be simple and straightforward.

Many hydropower reservoirs and their operating criteria have been built based on the largest single observed or modeled event. But in the future, both magnitude and

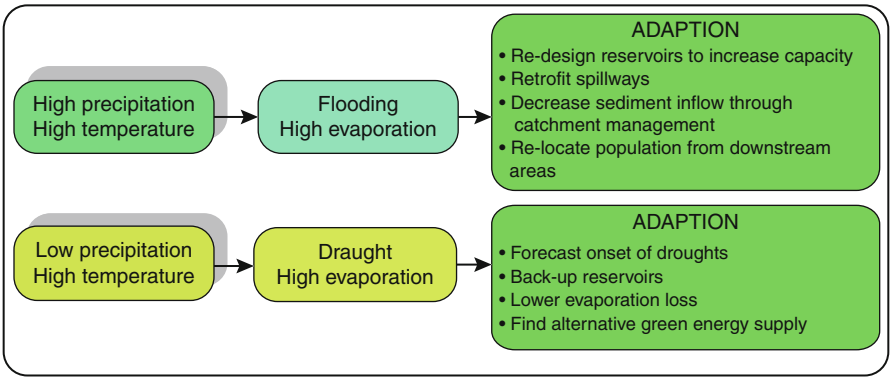

Fig. 15 Possible future scenarios and adaption options (Mirza 2008)

frequency of extreme events is likely to increase. So hydropower reservoirs may not be able to hold extra water or be able to generate electricity in the case of a rapid drop in water level caused by a drought triggered by the failure of rainfall. Retrofitting of spillways or redesigning reservoirs to increase capacity may be possible options. However, in many cases, retrofitting could be expensive and therefore not feasible. The economic and engineering lifecycles of many hydropower projects either recently built or under construction are within the time lines of climate change.

Another major potential obstacle is mainstreaming climate change into policy planning. Hydropower planners often talk about the uncertainty of scenarios projected by the climate models. Many studies of climate change impacts use the output of one or several global climate models (GCM) to project future climate. GCM temperature and precipitation output and historical records are used as input to a hydrologic model to derive stream flow. For instance, if the river is a managed system with reservoirs, a water management or optimization model may be used to model reservoir operating rules. Figure 16 is a schematic of this methodology.

Those modeling climate agree with uncertainty of scenarios, but that does not mean the planners should not act until the level of uncertainty becomes smaller than at present. For future adaption, one solution could be to use a range of scenarios to capture the uncertainty.

The hydropower sector usually relies on historical hydrometeorological time series for operational strategies and future investment planning. Potential global warming affects global precipitation patterns and enhances melting of glaciers, which in turn affect seasonal runoff. Assuming future flows as stationary extension of measured runoff series is no longer a probable scenario in a warming climate. There is need for developing mechanisms for adjustment of historical time series based on historical and possible future climate trends. These adjustments need to take into account the time frame of possible scenarios or planning horizons. Different methods for sophisticated risk analysis accounting for climate change must be explored and extensively used (Sveinsson et al. 2008).

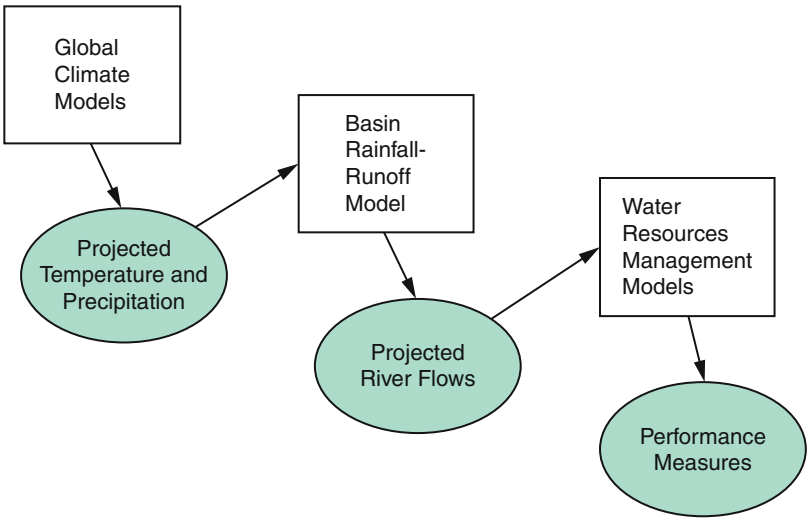

Fig. 16 Schematic for climate change impact studies for water resources (Western States Water Council (WSWC) 2009)

New Emerging Hydropower Technologies

The studies and the values of the World Energy Council (2004), the International Hydropower Association, and the European Small Hydropower Association clearly show us that the usage of hydropower will certainly change within the next 20–50 years. Some countries will increase their amount of hydroelectricity produced, whereas in other countries less water will be available. Therefore, new hydropower technologies are being actively tested in a number of countries.

There are many small dams in the world and the majority of them do not have a hydropower component. While this is not always an economic option, there is a significant market niche of this "sleeping" hydro potential in this area. Energy potential can be recovered by installing hydropower plants in irrigation, drinking water networks or even water treatment, and navigation waterways infrastructure. For such schemes, electricity generation is not the first priority, but the second (ESHA 2010).

Electric power is also being developed from nontraditional water sources (also called "hydrokinetics"), including river and ocean currents. The basic concept behind hydrokinetic power is not new. For centuries, people have harnessed the power of river currents by installing water wheels of various sorts to turn shafts or belts. River current energy conversion systems are electromechanical energy converters that convert kinetic energy of river water into other usable forms of energy. Over the past few decades, a number of reports on technical and economic feasibility of this technology have emerged (Khan et al. 2008). Installation of instream (kinetic) turbines directly in rivers, without a dam or other impoundment may provide an effective alternative means for generating power. Such systems would potentially

require little or no civil work, cause less environmental impact, and may possess significant economic value. However, the potentials of this technology as an effective source of alternative energy have not yet been explored to a great extent.

Ocean or marine energy using offshore plants also can also be attributed to hydropower. There are five main technologies, such as tidal power plants, current power plants, wave power plants, sea warmth power plants, and osmotic power plants, which could be used in future to produce electricity.

The data on hydrokinetic potential worldwide are still very preliminary. Estimates in the USA have ranged from minimums of 23 GW to maximums of 400 GW (Kosnik 2008). An independent market assessment estimated the worldwide potential of ocean wave energy economic contribution in the electricity market to be in the order of 2,000 TWh/year and is comparable to the amount of electricity currently produced worldwide by large-scale hydroelectric projects. According to Pike Research's study, "Hydrokinetic and Ocean Energy" (2009), in the best scenario case, the ocean energy industry could yield global power generation capacity of up to 200 GW by 2025.

In 2009, the USA had installed hydrokinetic generation capacity of less than 1 megawatt (MW), as compared to more than 77,000 MW of conventional hydroelectric generation capacity. Many hydrokinetic development projects are underway in the USA – as of 2009, the Federal Energy Regulatory Commission (FERC) has issued 146 preliminary applications to study development of 9,000 MW of proposed hydrokinetic generation capacity. Most of them are inland river projects and around half are designated to hold free flow power on the Missouri and Mississippi Rivers (Center 2009).

Any potential power will be located primarily along the coasts, where current wave and tidal prototypes are being employed, but future hydrokinetic technologies will also take advantage of the wave power in streams and rivers. This will benefit many of the inland states. First commercial projects of wave energy have been recently commissioned in Portugal, Scotland, and other countries.

Conclusion and Future Directions

Climate change is regarded as the most severe challenge for the human being. The view on accelerating hydropower development and ensuring adequate water storage infrastructure to mitigate and adapt climate change has been widely accepted by international community. In view of water storage capacity or hydropower development, a developed country has well conducted a complete network whereas developing country is facing tough work to be forehead. Many countries stipulate ambitious plan to accelerate hydropower development in order to fulfill their voluntary target for reducing emissions. It can be expected that hydropower development will have a great leap forward in the future.

However, in the new century, the construction and operation of a dam, reservoir, or a hydro plant can no longer be considered as a purely scientific and technical matter on the one hand and become more open and transparent on the other. The

inquiry and criticism on large-scaled water infrastructure are kept receiving from various paths, whereas the response on it is inadequate. To eliminate the misunderstanding and get support for further development at global scope, cooperation among various stakeholders, government authorities, knowledge institutions, business companies, civil societies, and local communities is the key to the development and implementation of effective and sustainable water solutions.

Abstract

Nuclear energy is attracting revived interest as a potential alternate for electric power generation in the event of increased concerns about global warming. Compared to energy produced by combustion of a carbon atom in coal, fission of a U-235 atom will produce about 10 millions times more energy. However, storage of the nuclear waste is an environmental issue. This chapter has four sections with a major focus on introduction of nuclear power plants and reprocessing of spent nuclear fuels. Different nuclear fuel cycles and nuclear power reactors are introduced in the first section, and the cost–benefits of different energy sources are compared. Fuel burnup and formation of fission products are discussed along with operational impacts and risk analyses in the second section. The third section discusses design of nuclear structural components and various degradation modes. Section four discusses reprocessing issues of nuclear spent fuels. Reprocessing of spent nuclear fuel may be an economically viable option and reduces high-radioactive load in the nuclear waste repositories as well. However, there is a concern about proliferation of weapons-grade plutonium separated during reprocessing. Containment of radionuclides in different waste forms is also discussed in this section.

Introduction to Nuclear Energy

Radioactive decay of heavy metals such as uranium, plutonium, thorium, etc., can be converted into a useful energy form. Radioactivity occurs by emission of charged particles (such as α and β) and electromagnetic waves (γ ray). For heavier nuclei (elements with atomic number>40), more neutrons are required for a stable configuration so that the electrostatic repulsion force between the protons can be overcome (Jevremovic 2005). When the nucleus has too many or too few neutrons, it will be in a nonequilibrium condition. In order to reach a stable configuration, the nucleus undergoes a spontaneous transformation by rearranging its constituent particles. This is accomplished by the emission of an alpha particle, a beta particle (either β− or β+), a neutron, or a proton. Depending on the energy conservation, gamma radiation may or may not be present during the radioactive decay. In brief, when atoms containing nuclei in the nonequilibrium condition try to reach stable condition, the excess energy of the nuclei is emitted as radiation. In this process, the material disintegrates. According to Einstein's principle ($E = mc^2$), the disintegrated matter is converted into energy. For example, burning of 1 kg of uranium in a nuclear reactor results in conversion of 0.87 g of matter into energy which amounts to $(0.8 \times 10^{-3}\ \text{kg}) \times (3.0 \times 10^{8}\ \text{m/s})^2 = 7.8 \times 10^{13}$ J. For comparison, combustion of 1 kg of gasoline will release only 5×10^{7} J of energy, six orders of magnitude smaller than 1 kg of uranium (Murray 2001). In addition to high specific energy, the nuclear energy has an advantage of not releasing carbon dioxide into the atmosphere. Combustion of 1 kg of gasoline will release about 3.2 kg of carbon dioxide to the environment. An anthracite coal–based power plant will release about 1.2 kg of CO_2

for every KWh electricity generated, whereas the lifetime CO_2 emission of nuclear power plants, considering the electricity used for mining and processing operations from fossil fuel power plants, will be 100–140 g of CO_2 /kWh electricity generated (Storm van Leeuwen and Smith 2005).

The major advantages of nuclear energy are:

High specific energy
No CO_2 emission
Spent fuel can be reprocessed and reused, thus conserving natural resources
Possibility to produce more nuclear fuel than consumed by using fast breeder reactors
Lower operating cost in terms of fuel cost compared to fossil fuel power plants

Disadvantages are:

- Large capital cost and longer construction time of power plants
- Long-term storage of nuclear waste which is an issue
- Exposure to radioactivity in case of accidents
- Potential proliferation of weapons-grade fuel during reprocessing

Nuclear power plants attract more safety and environmental concerns from the public than other power plants. This chapter addresses some of the environmental issues associated with nuclear power generation. The first three sections introduce nuclear fuel cycles, nuclear power reactors, and issues on operational safety. Information on nuclear spent fuels reprocessing, waste management, and long-term storage is given in the last section.

Nuclear Fuel Cycles

Conversion of nuclear energy can be achieved by fission or fusion reactions. Most of the commercial nuclear power reactors operate based on nuclear fission reaction. The average energy of neutrons used for power generation is about 0.1 eV, which are called thermal neutrons. Neutrons that have energy in the order of 2 MeV are called fast neutrons. Uranium is the most common fissile material used in the nuclear reactors. Naturally mined uranium has 99.24 % U-238, 0.72 % U-235, and 0.0054 % U-234. U-235 is a fissile isotope. Fissile isotopes are the ones that undergo fission reaction upon absorption of slow neutrons (neutrons having energy <0.4 eV). When a neutron is absorbed by U-235, the isotope gains extra energy and transforms to U-236 in an excited state (Murray 2001):

$$^{235}_{92}U + ^{1}_{0}n \rightarrow ^{235}_{92}U* \quad (1)$$

Since the excited U-236 has a higher mass than U-236 in ground state, the difference in mass is converted into energy of 6.54 MeV. Each fission of U-235 yields about

190 MeV of useful energy. This energy is used for further fission reaction. A continuous and self-sustaining fission chain reaction is required for nuclear power generation. This is achieved by containing a critical mass of uranium, which is about 50 kg of U-235 in the nuclear reactor. For each megawatt-day of thermal energy, 1.3 g of U-235 is consumed (Knief 1992).

The natural isotope U-235 and artificial isotopes such as Pu-239 and U-233 require only slow (thermal) neutrons to induce fission. On the other hand, U-238, which is abundant in nature, can only be activated by fast neutrons of at least 0.9 MeV to initiate fission. If the fission occurs by thermal or slow neutrons, the material is considered as "fissile." If a material is converted into a "fissile" material by irradiation, then that material is classified as a "fertile" material. For example, fertile materials such as U-238 and Th-232 can be used for generating "fissile" materials such as Pu-239 and U-233, respectively, by the following neutron reactions (Murray 2001):

$$^{238}_{92}U + {}^{1}_{0}n \rightarrow {}^{239}_{91}U \rightarrow {}^{239}_{93}Np + {}^{0}_{-1}e \rightarrow {}^{239}_{94}Pu + {}^{0}_{-1}e \tag{2}$$

$$^{232}_{90}Th + {}^{1}_{0}n \rightarrow {}^{233}_{90}Th \rightarrow {}^{233}_{91}Pa + {}^{0}_{-1}e \rightarrow {}^{233}_{92}U + {}^{0}_{-1}e \tag{3}$$

Nuclear fuel cycle describes different stages of preparation, use, safe storage, and reprocessing of the spent fuel. The fuel cycle starts by mining of fuel ore and ends by reprocessing. If reprocessing is not carried out, then it is called as once-through nuclear cycle. The fuels that can be used in the nuclear power reactors are uranium, plutonium, minor actinides, and thorium. Most of the commercial nuclear reactors use uranium as a fuel with different levels of enrichment depending on the type of reactor. Thorium is also used in some countries at a small scale. This section will focus on only these two fuels.

Uranium Fuel Cycle

Mining and Extraction: Uranium ore is mined in several forms, most notably as uranite (UO_2), pitchblende ($UO_3 + U_2O_5$), coffinite ($U(SiO_4)_{1-x}(OH)_{4x}$), brannerite (UTi_2O_6), davidite ($REE(Y,U)(Ti,Fe)_{20}O_{38}$; REEs = rare earth elements), and thucolite (U-containing pyrobitumen) (Dahlkamp 1993). Uranium mining process is similar to mining of other metals such as copper, gold, etc. The mines can be of open-pit or underground type. In some cases, in situ leaching of ore is carried out without deep excavating of the earth. Lower-grade ores are concentrated by using a heap leaching process. The excavated ores are collected as heaps and a leaching agent (mostly low concentration of sulfuric acid) is sprayed on the heaps and drained through the ore collection. In this process, uranium is preferentially leached out of the oxide ore and carried by the draining leaching agent. This solution is further processed.

In situ leaching process is used by some mining companies. In this process, the surface of the earth is not disturbed by drilling or excavating operations. Instead, a leaching agent (mild acid/alkaline solution containing oxidizers such as hydrogen peroxide) is pumped through the porous surface of the ore deposits. The solution

passing through the ore will leach out the uranium. The uranium-containing solution is collected for further processing.

During heap leaching and in situ leaching processes, the surrounding groundwater is continuously monitored for any contamination. Even after shutdown of the mining operation, the monitoring continues. Recent international mining laws require that the mining companies set aside required amount of funds for reclamation of the environment in the neighborhood of the mining operation. This fund will be in place for the required environmental remediation even if the company goes out of business.

The uranium-rich ore from mill, U_3O_8, often called as yellow cake though the actual color is khaki, is purified further either by a solvent extraction or by an ion exchange process. The U_3O_8 is dissolved in nitric acid to form uranyl nitrate ($UO_2(NO_3)_2$), which is then treated with ammonia to produce ammonium diuranate ($(NH_4)_2U_2O_7$). This compound is then reduced in a hydrogen atmosphere to form uranite (UO_2). It should be noted that this UO_2 is not the final form of fuel that can be used in the reactor. It requires enrichment of U-235 isotope to more than 3.5 % from 0.7 %. In order to accomplish the enrichment process efficiently, the material needs to be in the form of a gas. Therefore, UO_2 should be first converted to uranium hexafluoride gas (UF_6), get enriched, and converted back to UO_2. In order to form UF_6, UO_2 is treated with HF, which results in UF_4. Further fluorination of UF_4 renders UF_6. Now the UF_6 is taken for enrichment process (Morss et al. 2006).

Enrichment of Uranium

U-235 is a fissile material that utilizes thermal neutrons, which is only 0.7 % in the natural uranium source. Stable operation of a critical reactor requires fissile nuclei. Therefore, the ratio between fissile (U-235) and nonfissile (U-238) should be high in a reactor for stable power generation. Typically, the U-235 content in a fuel should be more than 3.5 %. This can be achieved by the following enrichment methods (Krass et al. 1983):

- Gaseous diffusion
- Gas centrifuge
- Jet nozzle/aerodynamic separation
- Electromagnetic separation

Gaseous Diffusion

Separation of U-235 isotope by gaseous diffusion process occurs because of the difference in velocity of the gas molecules. The rate of diffusion of a gas through an ideal porous medium is inversely proportional to the square root of the molecular weight of the gas. Therefore, when UF_6 is passed through a porous tube, lighter U-235 isotopes will escape the porous container faster than their U-238 counterparts and thus be collected separately. Figure 1 schematically illustrates the working principle of a gas diffusion separator. In this arrangement, compressed UF_6 gas is contained in a large vessel under pressure and allowed to pass through a porous channel that acts as a diffusion barrier layer. The porous layer is an essential

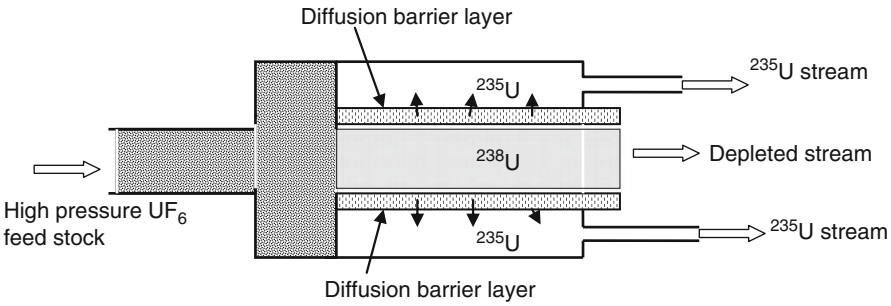

Fig. 1 Uranium enrichment by gaseous diffusion process

component of the diffusion separator because the efficiency of the U-235 enrichment process in the UF_6 stream is determined by the ability of the porous layer permeating the gas molecules. The barrier layer has to withstand the working pressure and be stable in the corrosive UF_6 atmosphere, and the pores should be tiny, in the order of 30–300 times the diameter of a single U atom, around 10 nm, and uniformly distributed in the order of billions per square centimeter area. The barrier layer thickness is around 5–6 mm. The material of construction is a classified information because enrichment of U-235 to more than 80 % becomes a weapons-grade material. Plasma-sprayed Zr, Ta, and Mo coatings of required thickness and porosity can be used as diffusion layer. Silver–zinc alloy pipes after selective etching with HCl also could serve as a diffusion barrier (Makhijani et al. 2004).

Since the velocity of diffusion varies only by 0.4 % between U-238 and U-235, multiple stages of gas passage are required to achieve the required enrichment for commercial reactors. In the diffusion cascade, the outlet of the depleted stream is bifurcated by redirecting 50 % of the depleted stream back to the previous stage and the remaining 50 % to the inlet of the next stage. This way one may require 4000 diffusion stages to obtain 99 % $^{235}UF_6$.

Gas Centrifuge

In this process, UF_6 is passed through rapidly spinning cylinders in series. The centrifugal action drives the heavier $^{238}UF_6$ molecules to the wall of the rotating container. Lighter $^{235}UF_6$ molecules are retained closer to the center of the container. Circulation of the gas from bottom to top helps separate the heavier and lighter molecules and pass to next separation stages. Figure 2 schematically illustrates the gas centrifuge (Olander 1978).

The cylinders are heavy in order to impart very high kinetic energy to the gas molecules and rotated at very high speed, in the order of 100,000 revolutions per minute. The linear velocity may approach the speed of sound in the material of construction. Therefore, the centrifuges are very sturdy. Nevertheless, this process requires 40–50 times less energy than the gaseous diffusion process to achieve the same level of enrichment. The diffusion process will consume about 4–5 % of the energy that the enriched fuel will generate in its cycle time. Furthermore, amount of

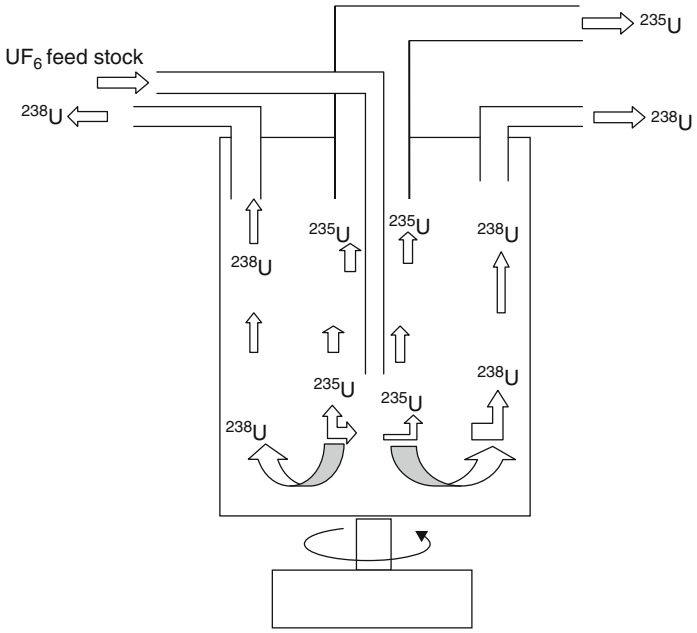

Fig. 2 Schematic of gas centrifuge for enrichment of U-235

waste heat generated during UF_6 compression for the diffusion process is much higher. This results in utilization of a significant amount of coolants such as Freon-12, etc., in order to cool the gas in the intermediate compression stages. Gas centrifuge process is more advantageous than gas diffusion process considering aforementioned issues.

Electromagnetic Isotope Separation

This process can be used as a stand-alone method for enriching uranium from the feedstock of natural uranium or in tandem with the gaseous diffusion process for producing highly enriched uranium from the low-enriched stream. It should be noted that commercial reactors do not require highly enriched uranium. The electromagnetic separator works on the principle that the radius of the trajectory of a particle traveling in a magnetic field is determined by its mass. The heavier the particle, the larger will be the radius, provided that the particles have the same charge and travel at the same speed. In this process, UCl_4 plasma is generated by heating a solid UCl_4 material and bombarding it with high-energy electrons. This process ionizes uranium. The uranium ions are then accelerated through a strong magnetic field. When these ions complete a half circle, the lighter U-235 ions are nearer to the inside wall of the semicircle channel, and heavier depleted U-238 ions are separated at the outer wall of the circular channel. This process requires a large amount of energy to maintain a high magnetic field. However, the rate of U-235 separation is lower than the other processes (Knief 1992).

Jet Nozzle/Aerodynamic Separation

In this process, UF_6 is pressurized with helium or hydrogen gas and sent through a bank of small circular pipes. The curved pipelines ensure that the heavier molecules stay at the outer surface and lighter U-235 stay at the inner surface of the circular path. This process is again energy intensive because compressing lighter gases such as He and H requires more energy. The compression process will be carried out at multiple stages with intercoolers in order to increase the thermal efficiency of the system. Therefore, the entire process results in generation of a significant amount of waste heat and utilization of a large amount of coolants/refrigerants, and both these outcomes lead to environmental concerns (Olander 1978).

Conversion of UF_6 to UO_2

The enriched UF_6 gas stream with 3.5 % U-235 is taken for fuel rod preparation. The first step is conversion of UF_6 back to UO_2. Oxide fuel is preferred because of its high melting point that shows resistance for meltdown. Metallic fuels (in the form of U or its alloys such as U–Mo, U–Si, U-Zr, etc.) have been used in some experimental fast breeder reactors. Most of the commercial reactors use oxide fuels such as UO_2 or mixed oxide fuels such as a blend of Pu-239 and depleted uranium (Galkin et al. 1982).

UF_6 can be converted to UO_2 using three different chemical routes such as:

1. UF_6 is reacted with hydrogen and steam to form UO_2.
2. UF_6 is sent through water and thus hydrolyzed. NH_4OH is added to this hydrolyzed solution to precipitate ammonium diuranate. This precipitate is then reduced in hydrogen at 820 °C to form UO_2.
3. In this method, a gaseous mixture of CO_2 and NH_3 is hydrolyzed in water to form ammonium uranyl carbonate. This precipitate is then treated with steam and hydrogen at 500–600 °C to form UO_2.

The UO_2 is then purified by several washing cycles, dried, and mixed with an organic binder to press as cylindrical pellets. The compacted pellets are sintered at high temperature (1400–1700 °C). The solid UO_2 pellets are machined by fine grinding operation to final dimensions which are typically about 1 cm in diameter and 1.5 cm in length depending on the type of reactor (boiling water or pressurized water).

Fuel Rod Assemblies

The cylindrical fuel pellets are stacked in a fuel-clad tube with a nominal diameter of 1 cm and length of 3.6 m. Then the tubes are backfilled with helium at about three atmospheres to improve the thermal conductivity and heat transfer. The fuel rods are bundled with a thin encasing tube to prevent density variation that may affect the thermohydraulics of the reactor core. In a typical BWR fuel bundle, there are about 96 fuel rods. The BWR reactor core contains about 360–800 fuel assemblies depending on the capacity of the nuclear reactor. In PWR reactors, the fuel assembly contains a matrix of 14 × 14 and 17 × 17 fuel rods. The PWR bundles are about

4 m long. The reactor core contains about 120–193 bundles, depending on the capacity of the reaction. In case of heavy water reactions, U-235 enrichment is not required. Natural uranium (U-238) is loaded into the fuel bundles that have 380 tubes (Knief 1992).

Thorium

The isotope ^{232}Th is about 3–4 times more abundant on earth than uranium. This fertile isotope can be used for producing fissile ^{233}U isotopes. The neutron absorption cross section of ^{232}Th is also about three times that of U-238 (7.4 barns vs. 2.7 barns, where 1 barn = 10^{-24} cm^2). The number of neutrons liberated per neutron absorbed is greater than 2.0 over a wide range of thermal neutron spectrum for U-233. Therefore, the ^{232}Th–^{233}U fuel cycle can operate in wide spectra of neutrons such as fast, epithermal, and thermal. Thorium oxide is chemically more stable than UO_2 and has a low fission product release rate. ThO_2 also has a better thermal conductivity than UO_2. Furthermore, (Th, Pu)O_2 mixed oxide fuel is more attractive than (U, Pu)O_2 fuel because Pu is not bred in the (Th, Pu)O_2 and the presence of ^{232}U makes the spent fuel more proliferation resistant (Thorium fuel cycle).

Some of the limitations of ThO_2 fuel are as follows: Melting point of ThO_2 is 3350 °C. Therefore, the sintering temperature is higher than 2000 °C. Reprocessing requires heavy shielding because of the presence of remitting ^{232}U with 73.6 years of half-life. Because of its high chemical stability, ThO_2 cannot be easily dissolved in HNO_3 for reprocessing. It requires addition of .005 M HF to 13 M HNO_3, which makes the stainless steel containers used in reprocessing more prone to corrosion attack even after adding 0.1 M $Al(NO_3)_3$ as inhibitor.

Fuel Burnup

Fuel burnup gives information about the fuel utilization as how much energy has been extracted from the fuel as a nuclear fuel source. It is expressed as megawatt-days per metric ton (MWd/ton). The generation (II) commercial reactors were designed for a burnup of 40 GWd/ton. During nuclear fission, fission products build up and poison the sustainability of the chain reaction. For example, xenon-135 (cross section 2 million barns), samarium-149 (75,000 barns), and Gd-157 (200,000 barns) poison the reactor core which is a serious problem (Knief 1992).

In order to operate the reactor for longer time/cycle, between shutdown for fuel change, excess fuel is added. This high reactivity of the excess fuel needs to be balanced by neutron-absorbing materials in addition to control rods. These are called burnable poisons. Compounds of B and Gd act as burnable poison whose neutron absorption capacity decreases with fuel burnup. By using neutron poison, the burnup of fuel in a modern reactor can achieve a burnup of 60 GWd/t (Murray 2001; Knief 1992).

Higher-enriched fuel in the advanced light water reactors can achieve a burnup rate of 90 GWd/t. Since the fast neutron reactors can handle fission product accumulation without affecting its performance, the burnup rate can be around 200 GWd/t. The deep burn modular helium reactor that utilizes ceramic-coated plutonium-based fuel can achieve a burnup rate of around 500 GWd/t (Rudling et al. 2008).

Types of Nuclear Reactors

Depending on the coolant and moderator, the reactors can be classified as:

Light water reactor
- Boiling water reactor
- Pressurized water

Heavy water moderated reactor
- CANDU
- Advanced heavy water reactors

Graphite-moderated reactors

Thermal breeder reactors
- Molten salt breeder reactor
- Light water breeder reactor

Fast neutron reactors
- Liquid metal fast breeder reactor
- Gas-cooled fast breeder reactor

Boiling Water Reactors

The original design was developed by the General Electric Company. Figure 3 schematically illustrates the major components of a BWR system. Different power generation capabilities are 200 MW_e, 650 MW_e, and 1250 MW_e. Here, the subscript "e" in the MW_e represents electrical energy as the output. The capacity is also expressed in terms of thermal energy as output. The efficiency of converting thermal energy into electrical energy is around 30 %. Therefore, for a given MW_e output, the corresponding thermal energy will be at least three times higher. It should be noted

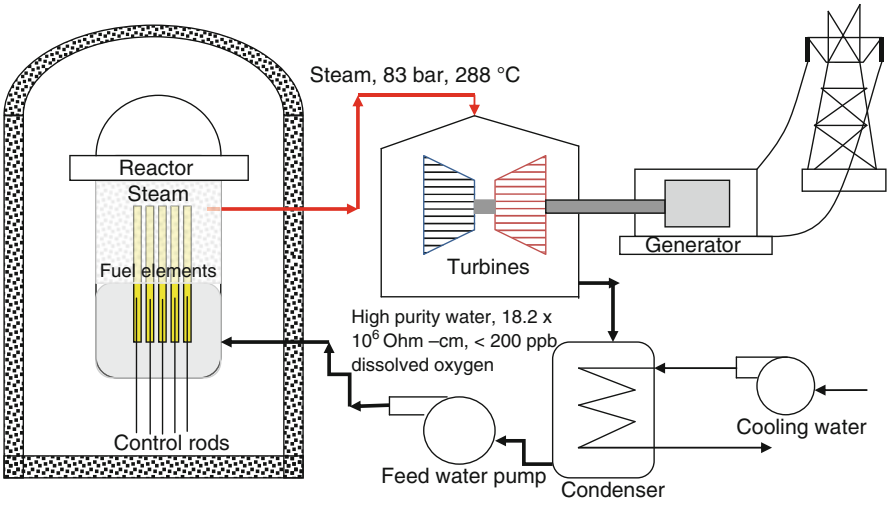

Fig. 3 Schematic diagram of system flow in a boiling water nuclear reactor. Only critical components are shown

that feedwater enters the reactor vessel at a pressure of about 70–85 bar and leaves as steam at 288 °C to run the steam turbines. The active core height is about 3–8 m that is placed in a reactor vessel of 22 m height. The bottom of the vessel is occupied by the control rod and drive mechanism. The space above the reactor core is occupied by the steam separator–dryer system components. The inner diameter of the vessel is about 6.4 m (for 1250 MW_e reactor). The wall of the reactor is made of 15 cm thick carbon steel clad with stainless steel. The stainless steel surface is exposed to the water/steam phases (Murray 2001; Knief 1992). Since a single coolant loop is used for heat transfer and steam generation, the water used in the BWR system is of ultrahigh purity with an electrical resistance of 18.2 megohm-cm. In order to minimize corrosion, the dissolved oxygen in the water is controlled below 200 parts per billion (ppb) by purging with ultrahigh-purity argon or hydrogen. The dissolved oxygen content of water exposed to ambient atmosphere is around 8 parts per million (ppm). Purging with nitrogen could lead to formation of NO_x-related compounds by radiolysis. Very high electric resistance of the water and low oxygen content result in low corrosion rates of the pressure boundary components.

Pressurized Water Reactors

Developed by Westinghouse Electric Company, they are based on the experience of nuclear submarine reactors. The power generation capability of PWR ranges from 60 MWe to 1450 MWe. Figure 4 schematically illustrates the major components of the PWR system. The PWR has two coolant circulation loops. The primary loop that removes heat from the reactor core is contained within the reactor vessel and used for transferring heat to a secondary coolant loop. Steam formation takes place in the secondary loop which runs the steam turbine for power generation. The water of the

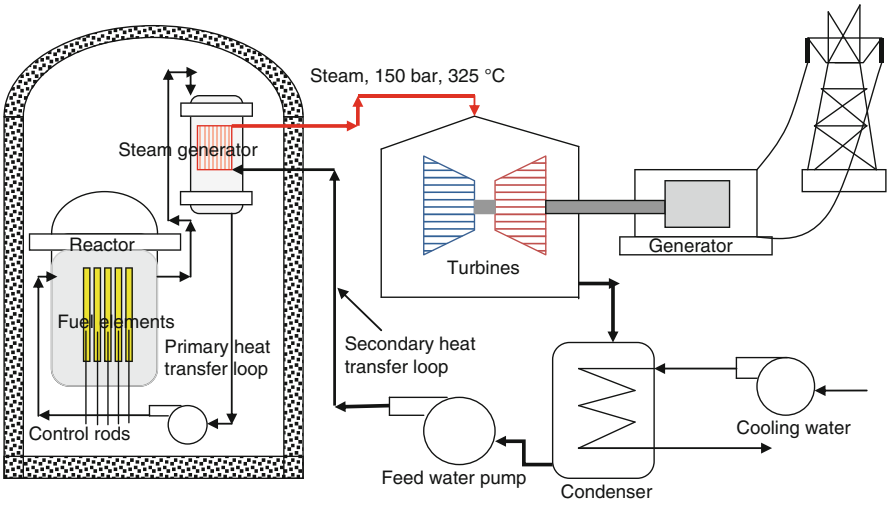

Fig. 4 Schematic diagram of system flow in a pressurized water nuclear reactor. Only critical components are shown

primary loop contains 1200–1800 ppm boron in the form of boric acid. Boron is added as moderator/neutron absorber. In order to balance the acidic pH due to boric acid, LiOH is added in the water to maintain a neutral pH at room temperature. The addition of boron and lithium compounds increases the ionic conductivity of the primary loop water. This may lead to increased corrosion rate. Since oxygen reduction reaction is the cathodic reaction in most of the corrosion mechanisms, the dissolved oxygen of the primary water is reduced to less than 5 ppb by purging with ultrahigh-purity hydrogen.

The primary loop contains lithiated and borated water at a pressure of about 150 bar (atmospheres). The core outlet temperature of the primary loop water is at about 350 °C. This primary loop heats the water in the secondary loop to above 290 °C and 70–85 bar. The secondary loop conditions are identical to that of BWR steam conditions. The main difference between the PWR and BWR is that the steam entering the turbines of PWR does not contain any radioactivity. A typical PWR reactor vessel is about 13 meters tall and 6.2 meters in diameter. The wall of the vessel is made of 23 cm thick ferritic–bainitic steel with 3 mm stainless steel clad that is exposed to the water/steam environment. The secondary loop, also called the steam generator, is 21 meters high and 4.5 meters in diameter (Murray 2001; Knief 1992).

Heavy Water Moderated Reactors

In light water reactors, the water is used as a moderator and coolant. An ideal moderator will have low mass, high neutron scattering cross section, and low neutron absorption cross section. Light water more rapidly moderates neutrons than heavy water. Therefore, fissile material such as U-235 is required for sustaining the chain reaction. In case of heavy water moderated reactors, high-energy neutrons are available for fission of U-238. Therefore, enrichment of U-235 is not required. However, preparation of heavy water is also a tedious process since deuterium is available in nature with a ratio of 1:7000 along with regular hydrogen in water. The separation of deuterium from water is an energy-intensive process.

In CANDU-PHW system, the primary heavy water coolant is pumped through a series of pressure tubes that also housed the fuel rods. The heavy water is contained in a vessel called calandria, which is about 7.6 m in diameter and about 4 m tall. There are about 380 calandria tubes. Each calandria tube contains one pressure tube through which the coolant flows (CANDU Reactors).

Graphite-Moderated Reactors

These reactors are fueled by natural uranium and moderated by graphite, and the coolant is an inert gas. Advanced gas-cooled reactors use helium as a heat transfer medium. Helium flows through the reactor core and exits at 740 °C with a pressure of about 50 bar. The heated gas is fed through the steam generator which produces superheated steam at 510 °C under a pressure of 170 bars. The reactor vessel is of prestressed concrete strengthened with vertical and circumferential prestressing steel cables. The dimensions of the vessel are 28 m high × 30 m in diameter. The reactor

core size is about 6.3 m × 8.5 m. There are six sets of helium loops and steam generators that produce about 1160 MWe power. Running the generators by gas turbines using the helium is possible (Murray 2001; Knief 1992).

Nuclear Reactor Safety

Radiation Effect

Three types of radiation damage can occur when high-energy particles impinge on a target. These are (Shapiro 1990):

- Transmutation of the constituent atoms of the target to new atoms of new material
- Displacement of atoms from their normal lattice positions in the structure of materials
- Ionization–removal of electrons of atoms that are present in the trajectory of the charged particles and formation of ion pairs

Alpha and beta particles have only low penetrating power and can be stopped by very thin layer of materials. Alpha particles produce a linear path of specific ionization per unit length of travel because of its high mass and charge. Smaller path and charge of particles result in a nonlinear path and very low specific ionization. Gamma rays have higher penetrating power than the alpha and beta particles. Therefore, a heavy shielding is required to stop gamma radiation.

Accumulation of fission products in the core of the nuclear reactor poses a potential safety threat among the public. Therefore, integrity of the fuel is important throughout the operating cycle. A set of specified operating parameters limits is determined for every reactor to assure safety of operation. These limits are generally the upper limitation on total reactor power which determines the maximum reactor core temperature that will not result in a meltdown. Fuel integrity is ensured by avoiding hot spots in the core. This is carried out by controlling the ratio of peak power to average power. The other important parameters that control the safe operation of the nuclear reactor core are the limit on the control rod position, difference between the power generation in the bottom half of the core and the top half, symmetry of power generation across the core, maximum reactor coolant temperature, minimum coolant flow, and maximum system pressure.

Under normal operating conditions, a negligible amount of radioactivity will get into the coolant (Murray 2001). Since abnormal conditions can exist, a design basis accident is postulated. In this hypothetical accident condition, a loss of coolant is assumed. Loss of coolant can occur either by a breakage of coolant piping or a failure of jet pumps supplying the coolant. Loss of coolant would result in an increase in the temperature of the nuclear core. When the temperature exceeds the melting point of fuel and cladding, the fuel tubes will be damaged and fission products will be released. The reactors are provided with safety measures such as safety rods and

emergency core cooling system (ECCS) to safeguard the reactor against loss of coolant accident. The safety rods reduce the reactor power immediately upon loss of coolant flow through the reactor core. The emergency core cooling system consists of auxiliary pumps that supply cooling water to bring down the temperature.

In order to minimize the effect of radiation, the nuclear plant is normally located several kilometers away from any population centers. The fission products that might be released, in case of an accident, will be contained within the steel-reinforced concrete reactor building. The concrete building can withstand high internal pressures and is designed to have a very minimal rate of leak.

Loss of Pressure Faults: If there is a leak in the PWR system, the vessel pressure may drop from nominal 2250 psi to lower values. The safe system in the PWR is activated which pumps water from the borated water storage tank. A large rupture in the coolant system will significantly decrease the vessel pressure and increase the concrete containment pressure. When the vessel pressure drops to 600 psi, water from the core flooding tank will be pumped to the core by a pressurized nitrogen gas stream. If the primary loop pressure drops below 500 psi, then water from the borated water storage tank is pumped to the core by the low-pressure injection pumps (Knief 1992).

Probabilistic Risk Assessment (PRA)

One objective of PRA is to find the chance of an undesired event occurring in a nuclear reactor and analyze its potential causes (Fullwood and Hall 1988). The event can be damage in the core, breach of containment, release of radioactivity, etc. The first step in the risk assessment is to investigate all of the possible failure modes of equipment and/or processes. Event trees are constructed to study the process flow. Fault trees are constructed using the principles of Boolean algebra that trace causes of failures and their effects mathematically. The ultimate objective of the probability risk assessment is to determine risks to people by calculating using the relation

$$\text{Risk} = \text{frequency} \times \text{consequences},$$

where frequency is the number of times per year of operation of a reactor that an undesired incident is expected to occur and consequences refers to quantifications of fatalities related directly or indirectly to the event.

Each nuclear power plant and the local government are required to have plans in place for emergency, in case of accidents occurring, and there is a potential for release of radioactivity. Mock accident drills are carried out periodically that resemble actions to be taken in a real accident. Many organizations also involve in such drills to make a coordinated effort to safeguard the life of residents in case of an accident. These organizations include radiation protection staff, police and fire departments, highway patrol, public health officers, and medical response personnel.

If the members of the public suffer loss due to accidents involving reactors or transportation of fuel, they are then compensated by nuclear insurance. The nuclear utilities pay the insurance premium to private insurances to cover any accidents to the public.

Nuclear Accidents

Safety goals are set either by regulatory authorities or by the utilities for safe operation of nuclear power plants.

The probabilistic design targets for LWR nuclear power plants are (IAEA 2001):

- A frequency of occurrence of severe core damage that is below about 10^{-4} events per plant operating year for existing nuclear plants
- Achievement of an improved goal of not more than 10^{-5} severe core damage events per plant operating year for future reactors
- Practical elimination of accident sequences that could lead to large early radioactive releases

In spite of strict safety regulations, there were accidents in the nuclear power plants. Postaccident analyses of accidents clearly indicated that these accidents were the results of severe violations of specifications and regulatory instructions.

Three Mile Island

A nuclear reactor at the Three Mile Island (TMI) facility failed on March 28, 1979, due to an accident. The accident was considered as the result of a combination of design deficiencies, equipment failure, and operation error. The accident was first triggered by a valve failure in the feedwater system. Since the feedwater system malfunctioned, the turbine generator automatically tripped, and the control rods were driven into the reactor to reduce its power. At this stage, water could have been supplied to the reactor by three backup feedwater pumps. However, there was an operator error as the valve to the steam generator was left closed by mistake. Therefore, the steam generators went dry increasing the temperature and the pressure of the primary water coolant to 2355 psi. This increase in the pressure set the relief valve on. This valve was stuck open due to a mechanical failure. The open valve let the coolant drain off from the primary system that led to a series of malfunctions and the meltdown of the core. The escape of the coolant water also resulted in spillage of some radioactivity. However, it was estimated that the highest possible dose of exposure was only 100 mrems or 1 millisievert, where 1 sievert is equivalent to 1 J/kg of energy release. It should be noted that a person taking a flight from the East Coast to the West Coast in the USA will have a radiation dose of 5 mrems due to cosmic rays.

The Chernobyl Accident

The Chernobyl accident occurred not because of operational abnormality but because of gross violation of operating rules and regulations. People who were in the vicinity of the damaged reactor received a radiation dose of 100 to 1500 rems. More than 135,000 people were evacuated from a 30 km zone.

Design Considerations and Life Prediction of Nuclear Components

In nuclear reactors, passive components such as pressure vessels and piping systems show very low failure probabilities. Therefore, failures of these components only have limited contributions to plant risk. On the other hand, components within a reactor core must tolerate high-temperature water, stress, vibration, and an intense neutron field. Degradation of materials in this environment can adversely affect the performance and in some cases lead to sudden failure. Degradation of materials in a nuclear power plant is very complex. There are over 25 different metal alloys within the primary and secondary systems. In addition, there are additional systems with complex nature such as the concrete containment vessel, instrumentation and control, and other support facilities. The combination of diverse set of materials, complex and harsh environment, and load conditions makes the degradation process very complicated.

The service failures of passive components occur because of the following mechanisms:

- Corrosion fatigue
- Thermal fatigue
- Stress corrosion cracking
- Corrosion attack
- Erosion and cavitation
- Flow-accelerated corrosion – i.e., erosion corrosion
- High-cycle vibration fatigue
- Water hammer

The in-core components are subjected to radiation-assisted failure mechanisms such as radiation-induced segregation, swelling, radiation creep relaxation, radiation-induced hardening, etc. The degradation of materials by radiation is considered first.

Fuel and Fuel Cladding

The fuel cladding helps contain the radioactive fission products. If the integrity of the cladding is maintained intact without cracking, rupturing, or melting during a reactor

transient, the radioactive fission products are contained within the fuel rod. Transients in reactor operation or hypothetical accidents could weaken the cladding because of a temperature increase, embrittlement by oxidation, or overstressing by swelling of the fuel because of mismatch in thermal expansion (pellet–clad mechanical interaction) or high fission gas pressure. These events alone or in combination can cause cracking or rupture of the cladding and release of the radioactive products to the coolant. The fuel cladding failure models consider several mechanisms such as cracking due to hydride formation, swelling of the clad because of differential pressure between the fuel rod gap and the coolant, thermal expansion of the fuel and clad, elastic and plastic straining of the clad, interference between adjacent ballooning rods, the effect of grids and azimuthal variations in temperature and straining caused by pellet eccentricity, and stress corrosion cracking induced by pellet–clad interaction in the presence of corrosive fission products such as iodine.

Zirconium-Based Alloys

Zirconium alloys are widely used in nuclear reactors as fuel cladding and other core internals because of their low thermal neutron absorption cross section and high corrosion resistance (Grobe et al. 2009; Choo et al. 1995). Zircaloy-2 (Zr-2) and Zircaloy-4 (Zr-4) are used in low-burnup fuel cladding applications. Modern Zr alloys such as ZIRLO^{TM} (Zr–1Sn–1Nb–0.1Fe) and M5^{TM} (Zr–1Nb–0.05Fe–0.015Cr) are candidate materials for high-burnup fuel claddings. During *in-reactor* irradiation, the Zr alloys undergo a number of changes. Most notable is corrosion by reaction with coolant water and subsequent formation of a thick oxide layer and hydrogen intake in solid solution. A large volume of data is available on the corrosion, creep, high-temperature oxidation, and hydride formation behaviors of Zircaloys that are used in the low-burnup fuel cladding application (Shoesmith 2006). On the other hand, only a limited amount of data is available on the oxidation and degradation behaviors of the modern Zr–Nb alloys intended for high-burnup application.

The available data for Zircaloy-2 and Zircaloy-4 cannot be directly correlated with ZIRLO^{TM} (Zr–1Sn–1Nb–0.1Fe) and M5^{TM} (Zr–1Nb–0.05Fe–0.015Cr) because of distinctly different microstructures. The Zircaloy-2 and Zircaloy-4 contain α-solid solution (hcp structure) at the normal operating and dry storage temperatures, whereas the Zr–Nb alloys show a mixture of α(Zr) + β(Nb) phases at the normal operating and dry storage conditions. The presence of the β(Nb) phase significantly alters the oxidation rate of the Zr–1Nb alloys, especially at the phase boundaries (Kiran Kumar et al. 2010). However, a detailed mechanism of the oxidation kinetics at the Nb-rich phase and phase boundary (where depletion of Nb is anticipated) is not available. It should be noted that thermodynamically Nb has a lower affinity to oxygen than Zr. Zr–1Nb alloy (M5) will have lower creep strength than Sn-containing alloys. It was postulated that the mechanical strength would be drastically increased upon irradiation in the reactor (Holt 1974). Furthermore, Zr alloy is capable of dissolving oxygen up to 29 at% during the oxidation process according to the zirconium–oxygen phase diagram reported by Domagala and McPherson (Domagala and McPherson 1954). Inspection of phase diagram of the

Zr–O binary indicates high amount of oxygen in the solid solution. The dissolved oxygen in Zr would act as an α-phase stabilizer and also impart creep resistance by solid solution strengthening. Yilmazbahyan et al. (2006) reported the Zr alloy–oxide interface enriched with oxygen up to its solid solution limit (29 at%) for a depth of 160–560 nm inside the metal substrate. Recently Ni et al. (2011) reported the presence of a suboxide layer in addition to an oxygen-rich region at the metal/oxide interface of the ZIRLO during the pretransition steam oxidation stage (prior to breakaway oxidation). The suboxide contained 50 at% oxygen for a thickness of 130 nm, and the metal beneath the suboxide contained 29 at% oxygen for a layer thickness of about 150 nm. Mechanical behavior of the oxygen-rich regions was not reported in detail in any of the literature; however, it is anticipated that these localized solid solution strengthened layers play a significant role in the integrity of the fuel cladding. Furthermore, the presence of a layer with oxygen concentration gradient across the metal/oxide interface greatly improves the adherence of the oxide layer. During temperature spikes, as experienced in the accidental conditions, the oxide layer and the Zr-alloy substrate undergo phase transformations. Volume changes associated with the phase transformations result in residual stresses that cause breakdown of the oxide. The presence of a graded layer would be beneficial since a large strain can be accommodated by this layer. Zr alloys that showed breakaway oxidation essentially had sharp oxygen profiles across the metal/oxide interface without any concentration gradient.

Silicon Carbide

Recent accidents in the Fukushima nuclear reactors of the Tokyo Electric Power Company, Japan, and associated worldwide concerns about the safe operation of nuclear power plants have reignited the interest in developing fuels that can contain fission products under meltdown conditions. Development of a passive LWR design that can withstand loss of coolant condition without replenishing the primary coolant, as occurred in the Fukushima nuclear power plant (I), requires substantial changes in the configuration of the reactor core geometry (Hejzlar et al. 1997). However, such design changes are very expensive and cannot be implemented easily in the existing LWRs. Recently, high-melting reactor core design based on sintered silicon carbide encasement of the UO_2 pellets within the Zircaloy cladding has been proposed (Lippmann et al. 2001). Since the proposed design changes occur only within the standard Zircaloy cladding, application of such modifications in the nuclear reactors that are already in service will be viable and less expensive.

Silicon carbide is a candidate material for one of the four coating layers of tristructural isotropic (TRISO) fuel particles to be used in high-temperature gas reactors. Among various polymorphs of SiC, β-SiC, having a cubic (zinc blende) lattice structure with two interpenetrating fcc lattices, one of carbon and the other of Si displaced by ¼<111>, is considered for various nuclear applications because of its refractoriness, low activation, good mechanical properties, and resistance to radiation damage (Henager et al. 2008). SiC is also considered as a fuel cladding material for Generation III light water reactors (LWRs), specifically by Westinghouse Electric Company. The Westinghouse concept for SiC-based cladding has a

monolithic SiC tube wound with SiC fiber tows. The SiC fibers are infiltrated with SiC deposited using chemical vapor infiltration (CVI) (Hallstadius et al. 2012). Silicon carbide is a ceramic material that has a good thermal conductivity (120 Wm^{-1} K^{-1}), a high sublimation point, and a high bending strength up to 1873 K. It is resistant to oxidation in steam and air up to 1300 °C and stable under neutron irradiation (Bloom 1998; Senor et al. 1996). In order to contain the fission products (especially the gases) under aggressive service conditions, the SiC overlay needs to be gas tight. The manufacture of UO_2 pellet encased with a thin SiC layer is complicated because enough space in between the SiC and UO_2 should be provided in order to accommodate the fission products and minimize the interaction between SiC and UO_2 at high off-normal temperatures.

The SiC-based fuel cladding is considered to be superior to Zr-based cladding because of the following advantages:

- SiC absorbs 25 % less thermal neutrons than the Zr alloy.
- No hydrogen pickup by SiC during normal operation.
- Superior mechanical properties such as SiC retains its mechanical strength even at very high temperatures (1100 °C), failure temperature in excess of 2000 °C, much slower degradation, and no meltdown.

All these factors make this material tolerant to loss of coolant accident (LOCA) conditions. However, stability of SiC in high-temperature water relevant to the LWR conditions should be demonstrated before deploying this material for commercial Generation III water reactor applications.

In high-temperature environments relevant to the very high-temperature gas-cooled reactors, the oxidation of SiC is limited by oxygen concentration and formation of a protective SiO_2 layer by following the reaction (Opila and Hann 1997):

$$2SiC + 3O_2(g) \rightarrow 2SiO_2 + 2CO(g) \tag{4}$$

However, in water vapor–containing environments, in addition to the oxidation reaction (2), a simultaneous volatilization reaction (3) was considered in order to estimate the steady-state oxide layer thickness (Opila 2003):

$$SiC + 3H_2O(g) \rightarrow SiO_2 + 3H_2(g) + CO(g) \tag{5}$$

$$SiO_2 + 2H_2O(g) \rightarrow Si(OH)_4(g) \tag{6}$$

The oxidation rate was limited by the transport of water vapor through the SiO_2 layer, and the thickness of the SiO_2 was a function of water vapor pressure. Since water availability is not a limiting factor in the light water reactors, the stability of the protective SiO_2 layer on the SiC surface in high-temperature water should be investigated in detail. Corrosion behavior of SiC in oxygenated and deoxygenated water at 290 °C was reported by Hirayama et al. (1989) in 1989, as a function of pH. The corrosion rate in oxygenated high-pH conditions was observed to obey a linear

rate law indicating absence of a protective film on the SiC surface. On the other hand, formation of amorphous, graphitic, and diamond-like carbon films was observed (Kraft et al. 1998; Gogotsi et al. 1996) on the chemical-vapor-deposited (CVD) SiC exposed to water at 100–200 MPa and 400–800 °C. Formation of a protective silica scale was not observed under the supercritical water oxidation conditions. In the oxygenated high-temperature water, the following reactions can occur (Dahlkamp 1993):

$$SiC + 2H_2O + 1/2O_2(\text{dissolved}) \rightarrow SiO_2 + CO + 2H_2 \quad (7)$$

$$SiC + 2H_2O + O_2(\text{dissolved}) \rightarrow SiO_2 + CO_2 + 2H_2 \quad (8)$$

$$SiC + 2H_2O + 2O_2 \rightarrow Si(OH)_4 + CO_2 \quad (9)$$

$$SiO_2 + H_2O \rightarrow 2H^+ + SiO_3^{2-} \quad (10)$$

$$CO_2 + H_2O \rightarrow 2H^+ + CO_3^{2-} \quad (11)$$

In the deoxygenated high-temperature water, the proposed surface reactions are

$$SiC + 2H_2O \rightarrow SiO_2 + CH_4 \quad (12)$$

$$SiC + 4H_2O \rightarrow Si(OH)_4 + CH_4 \quad (13)$$

$$Si(OH)_4 \rightarrow H_2SiO_4^{2-} + 2H^+ \quad (14)$$

The above reactions indicate that the corrosion rate of SiC is determined by the kinetics of the formation of a protective SiO_2 layer and its dissolution. Formation of gaseous phases like CH_4, CO, and CO_2 affects the morphology and defect structure of the surface layer that in turn detrimentally affects the protectiveness of the SiO_2 layer. Furthermore, corrosion resistance of the SiC is affected by the physical and chemical properties of the grain boundaries in addition to the purity and microstructure of the material. High-purity CVD SiC showed higher corrosion resistance than sintered SiC in distilled water at 360 °C (Kim et al. 2003). Localized corrosion was reported (Tan et al. 2009) on the SiC samples exposed to supercritical water at 500° C and deoxygenated high-purity water at 300 °C. The localized corrosion in supercritical water was attributed to high-intensity residual strains present in the small grains. Low-angle grain boundaries (Σ3, coincidence site lattices) showed better corrosion resistance than the general boundaries. The pit formation in deoxygenated (and subsequently hydrogenated) water at 300 °C during long exposure times was attributed to soluble silicon hydroxides and loss of silicon. The pits disappeared after reexposure of the samples to the test solution. Therefore, the pitting could be a transition corrosion mechanism of SiC exposed to hydrogenated water for an extended period of time (>4000 h).

It is well established by molecular dynamics simulations and experimental results that at room temperature water (both in gas and liquid phases) adsorbs preferentially on Si sites by a dissociative chemisorption process (Cicero et al. 2004; Liu

et al. 2012). The reactivity of Si-terminated SiC surface with water manifests into a corrosion process (by formation of Si–H and Si–OH bonds, reactions 10 and 11). Recently, nanocrystalline 3C–SiC has been used as electrodes for high-efficiency electrochemical hydrogen evolution (He et al. 2012). On the other hand, water dissociation on the C-terminated surface is reported to be energetically unfavorable even at high temperature (Liu et al. 2010). The relaxed H. . .H distance between H_3^+O and Si–H site is reported to be 0.125 nm, whereas for C–H site the corresponding distance of H. . .H is 0.275 nm. The larger H_2O–SiC distance of the C-terminated surface and relatively small binding energy (<0.05 eV) result in physic-sorption or no bonding at all (Shen and Pantelides 2013). Therefore, it is possible to improve the corrosion resistance of the SiC by having only the C-terminated surface. However, it should be noted that the structure of carbon is important in determining its activity toward water. For example, if the carbon is present as diamond form, then water adsorption by dissociative chemisorption is a possibility (Okamoto 1998). Furthermore, atomic hydrogen will etch both graphitic and diamond forms of carbon. The reaction of water with Si-terminated surface is associated with the interaction of lone pair of electrons of O atom in the H_2O with the *3-d* orbitals of the nearest Si atoms (as electron acceptors). Therefore, the corrosion resistance of SiC could be improved by tying the oxygen with an oxide-forming element that will have more stability in the PWR conditions, for example, Ti. Li et al. (2013) reported that, based on the ab initio calculations, Ti–C bonds are thermodynamically more stable than Ti–Si bonds and the β-SiC (111)/α-Ti(0001) interface shows large work of adhesion. Both titanium silicon carbide and titanium carbide showed better resistance to hydrothermal corrosion than SiC (Zhang et al. 2010; Shimada et al. 2006).

Irradiation Effects

Irradiation-assisted stress corrosion cracking (IASCC) has been drawing more attention over the years and has become potentially a critical phenomenon for core internals in light water reactors (LWRs). Alloys of iron and nickel base and oxygen-free copper are the materials found to be affected by IASCC. It is widely recognized that IASCC is a result of the interaction of irradiation, material, environment, temperature, and stress. The complexity of IASCC arises from the fact that irradiation has an impact on all the other variables listed above so that the knowledge available on SCC of materials in unirradiated environmental conditions is not sufficient to solve the IASCC problem. Because irradiation can alter the microstructure and microchemistry of the material, can affect the aggressiveness of the environment by water radiolysis, can increase the temperature of the parts by gamma heating, and can change the component stresses through relaxation of creep or by radiation hardening, interpretation of wide range of issues influencing IASCC requires specialized knowledge covering fracture mechanics, electrochemistry, physical metallurgy, and core neutronics. IASCC may have a higher potential to occur in fusion reactor components because of the higher dose rate of neutron

irradiation than in LWRs. Components of the blanket and first wall cooling system, divertor cooling system, and vacuum vessel cooling system are potential problem sites where IASCC could occur. Though the mechanism of IASCC is not fully understood, factors affecting it are well documented, especially the effect of radiation on the environment and on material properties. Among the radiation effects, some are fluence dependent and some are flux dependent, while both fluence and flux cause joint effects. Radiation-induced segregation (RIS), radiation-induced microstructures, and radiation creep relaxation are fluence dependent, while radiolysis and to some extent RIS are flux dependent. The ratio of thermal to fast neutron flux affects transmutation.

Environment-Assisted Cracking (EAC) of Austenitic Stainless Steel in High-Temperature Water

EAC of stainless alloys in high-temperature water occurs due to the synergistic interaction of stress, environment, and material. Generally, active path corrosion cracking and hydrogen cracking are the mechanisms involved in EAC. Crack initiation and crack propagation are two distinct events, which are controlled by environmental, mechanical, and material variables. Water chemistry and microchemistry of the material play a vital role in initiating the SCC. Dissolved oxygen and CO_2 and the presence of Cl^- and SO_4^{2-} are deleterious from an environmental point of view, and inclusions such as MnS, segregation of Si and P, sensitized microstructure, and the presence of secondary phases such as sigma, laves, chi, etc., are detrimental from a material point of view.

EAC of Unirradiated Ferritic/Martensitic Steels

Ferritic stainless steels (>17 % Cr) are considered to have better SCC resistance than austenitic stainless steels. This is true only when the Ni, Cu, and Co contents are below certain levels (Bond and Dundar 1977). However, 8–12 % Cr steels are subjected to both SCC and hydrogen embrittlement. Apart from the environmental factors such as dissolved oxygen, presence of sulfate and chloride ions, etc., microstructural condition of the material also controls the cracking behavior. Untempered martensite and acicular bainite phases are found to be more prone to hydrogen cracking than tempered martensite and bainite + ferrite phases (Kerr et al. 1987). Generally it is observed that pitting is associated with the initiation of SCC or corrosion fatigue in this type of material. Mostly intergranular cracking is observed along the prior austenite grain boundaries. However, it is not very clear why only the prior austenite grain boundaries are the most preferred site for cracking and not other boundaries such as interlath boundaries or interfaces between two martensite packets. Probably certain solute elements segregated in the austenite grain boundaries may have more affinity to hydrogen, as discussed by Leslie (1977). But, Auger electron spectroscopy carried out on these fracture surfaces did not throw much light

on this aspect. Hydrogen cracking resistance of ferritic/martensitic steel is significant for fusion wall application because direct transmutation, water–lithium interactions, radiolysis of water, and corrosion could charge hydrogen into the steel. Hydrogen cracking could be enhanced by other irradiation damage mechanisms such as RIS, increased defect density, etc.

Environmental Aspect

Radiolysis

Radiolysis is a complex issue affected by water chemistry, neutron flux (not fluence), flow rate, temperature, etc. Radiation causes decomposition of water into many species which affect the corrosion potential. At high hydrogen levels (>1 ppm), radiolysis is sufficiently suppressed so that it has very little effect on changing the corrosion potential (Maziasz and McHargue 1987). The interior of the cracks was not found to be polarized by radiation, as the corrosion potentials of cracks and tight crevices were not altered.

Flux Dependence

The structural materials are exposed to temperatures of 290–350 °C in water reactors. In the case of a BWR, the temperature is constant at 288 °C, whereas in a PWR, the temperature varies with location to a maximum of 400 °C in the baffle plates. The fast flux in a BWR is around 7×10^{17} n/m^2 s (E > 1 MeV), and in a PWR, it is 20–30 % higher than in a BWR. Radiation damage in materials is quantified in terms of displacements per atom (dpa) as calculated by approved methods. Empirically 1.4 dpa per 10^{25} neutrons (n)/m^2 (E > 1 MeV) is used for LWRs. From this, the fast flux can be back calculated to be 10^{-7} dpa/s in the core of LWRs and 1.5–4 $\times$ 10^{-7} dpa/s in test reactors. In fast reactors, the fast flux is given approximately as 10^{-6} dpa/s, and the temperature also is higher (>370 °C) in fast reactors. So, the data generated in fast reactors cannot be compared with those of LWRs. The thermal to fast flux ratio also is an important issue. The thermal neutrons are those which are in thermal equilibrium with neighboring atoms and with energies below 0.5 eV.

Radiation Water Chemistry and Corrosion Potential

Radiation causes breakdown of water into primary species (H^+, e^-_{aq}) and molecules such as H_2O_2, O_2, H_2, etc. The concentration of species is proportional to the square root of the radiation flux. Fast neutron radiation has a stronger effect on water chemistry than other types of radiation such as thermal neutrons, beta particles, and gamma radiation (Suzuki et al. 1991). This feature is because of the higher linear energy transfer (LET) and the higher neutron flux of fast neutrons.

It is generally believed that the corrosion potential has more influence than the concentration of oxidizing and reducing species in controlling SCC. The initial concentrations of oxygen and hydrogen are found to be important in determining the final corrosion potential after irradiation. Though a large increase in

concentration of some species occurs after irradiation, the change in corrosion potential is not drastic. When hydrogen is present at more than 200 ppb and at 0 ppb O_2, there is no radiation-induced elevation of corrosion potential, whereas the presence of H_2O_2 increases the corrosion potential.

Crack Initiation and Propagation

It is generally observed that SCC initiation preferentially occurs at sites like pits and second phase particles. Preferential dissolution of secondary phases or inclusions creates a crevice where the local electrolyte chemistry and local strain level become more favorable for SCC initiation by a slip dissolution mechanism. In the case of IASCC, irradiated microstructural features (like Cr depletion, Si and P segregation, etc.) and the presence of hard phases such as oxides make the crack initiation process much easier. Oxide particles effectively participate in IASCC initiation by two proposed mechanisms as follows: (1) Oxides are hard to deform. So, under load, the shear stress at the interface of the oxide matrix increases to very high levels as the ductile matrix around the particle deforms. This results in failure in the bonding, creating a crevice where the local chemistry of the electrolyte changes to more a conducive condition for promoting SCC. (2) Alternately, the oxide could fracture creating a microcrack which can either extend into the matrix or create a very high stress intensity for easy SCC initiation.

Strain at crack initiation (SCI) was proposed as the definition for IASCC initiation in slow strain rate tensile testing (SSRT) at 10^{-7} s^{-1} strain rate. It was defined as the strain at which the stress–strain curve of SSRTs began to depart from that of tensile tests, when plotted using the same coordinates. Higher SCI means SCC initiation starts at higher strain. Though the intergranular (IG) fracture ratio decreases with decreasing dissolved oxygen (DO), it increases inversely below 10 ppb of DO. These phenomena may indicate the continuum of initiation of IASCC from BWR conditions to PWR conditions.

Crack Propagation: Gamma ray irradiation is not expected to affect the microstructure or microchemistry of the material. However, it decomposes water into many kinds of radiolytic products of which hydrogen peroxide (H_2O_2) is very important to IASCC. In the 288 °C BWR environment, gamma irradiation accelerated the crack growth to varying degrees depending on the water chemistry, flux, etc. For example, the average crack growth rates in unirradiated, irradiated with gamma ray for fluxes of 5×10^6, and 9×10^6 R/h were 7.2×10^{-10}, 1×10^{-9}, and 1.3×10^{-9} m/s, respectively. From these values, the crack growth rates in low-conductivity pure water could be observed to be marginally affected by gamma ray irradiation.

The effect of dissolved oxygen (DO) on crack velocity with additions of Na_2SO_4 is similar in both irradiated and unirradiated test conditions. Addition of sulfate ions showed more effect in accelerating the crack growth than did irradiation. DO also had a similar effect. Suppressing the DO content decreased the crack growth rate. Though crack velocity increased with sulfate ions as in the case of the unirradiated

condition, DO had a major effect in controlling the crack behavior in the irradiated condition also. Nitrate additions were found to be less aggressive than sulfate additions in a BWR environment for 304 SS. Dissolved hydrogen showed greater beneficial effect in suppressing crack growth. The mechanism of crack growth mitigation by hydrogen injection could be explained by analyzing the corrosion potential of the system. The presence of molecules like H_2O_2 and O_2 increases the free corrosion potential which falls into the cracking range, and hence, the crack velocity is enhanced following the slip dissolution model and Faraday's law. Whereas when hydrogen is introduced into the environment, it helps the recombination of species and thus reduces the corrosion potential well below the cracking range. IASCC tests were carried out on irradiated stainless steel samples under BWR condition using the slow strain rate testing method. They presented average crack growth data by dividing the maximum crack depth by total test duration. The maximum crack growth rate divided by the test time was suppressed by hydrogen water chemistry (HWC) below 3×10^{21} neutrons (n)/cm^2, but not above 3×10^{21} n/cm^2. It was observed that variations in either fluence level (3×10^{20}–9×10^{21} n/cm^2; $E > 1$ MeV) or flux level (1.5×10^{13}–7.6×10^{13} n/cm^2 s) did not affect the crack velocity drastically (a maximum of a factor of two).

Critical Issues on Selection of Candidate Materials for Advanced Nuclear Reactors

Advanced systems selected for Generation IV reactors require high operating temperatures in the range of 500–1000 °C, depending on the coolant and longer service life. The fuels of the advanced reactors will have very high-burnup capabilities and fast neutron spectra. The construction materials of Generation IV reactors will be exposed to severe environmental conditions in combination with increased radiation damage. Therefore, selection of structural materials for advanced reactors requires a thorough understanding of materials' behavior in the extreme service conditions.

The structural materials of advanced nuclear reactors will undergo degradation primarily due to three factors, viz., (1) exposure to high temperature and service stresses (high-temperature degradation), (2) irradiation damage, and (3) interaction with service environments. The first two factors are common among all the types of reactors, and therefore, the data generated at high temperatures and irradiation levels relevant to the service conditions can be used for material qualification for different type of reactors, as the operating temperature of most of the advanced reactors is in the range of 500–800 °C. However, the third factor, interaction with environment, is reactor specific. The material should possess higher resistance to corrosion attack in the service environment. Among the various types of advanced reactors, liquid metal (particularly liquid sodium and lead–bismuth eutectic)-cooled fast reactors are considered in this study. Some of the critical issues pertaining to each major degradation modes will be discussed in this presentation.

The materials considered for advanced reactor structural applications can be classified into three major categories viz., (1) ferritic–martensitic-type Fe–Cr alloys,

(2) austenitic alloys (stainless steels and Ni–Cr–Mo alloys), and (3) oxide dispersion strengthened (ODS) alloys. Refractory metal-based alloys are not considered in this work. Merits and disadvantages of the first two categories of the materials will be analyzed based on the critical degradation issues.

High-Temperature Degradation

Major Issues and Temperature Limits

The major issues of high-temperature degradation are phase stability, oxidation, and creep–fatigue interaction. It is widely believed that thermal effects will offset the irradiation effects at high temperatures because of increased diffusivities and stress relaxation effects. This may be true for annihilation of point defects. However, effect of radiation-induced segregation could be aggravated at high temperatures.

Available literature data indicate that the maximum service temperatures of different alloys are limited by chemistry and microstructure. For example, ferritic/martensitic steel with a maximum Cr content of 12 % can service up to 650 °C and austenitic stainless steels up to 800 °C, nickel-based alloys up to 900 °C, and ODS alloys up to 1050 °C. The interaction of creep–fatigue is considered to be of primary importance.

Fatigue, Creep, and Creep–Fatigue Interaction

Creep or creep–fatigue interaction of structural materials at elevated temperatures over a long period of time in advanced reactor environments is a critical issue. High temperature and the temperature gradient during start-ups, in-services, and shut-downs induce both static and cyclic thermal stresses. These constitute the stress factors that generate creep and creep–fatigue interaction. In addition, components such as thread roots in steam turbine casing bolts, pipe, and branch connections in reactors endure multiaxial stresses.

The earlier studies (Brinkman and Korth 1973) investigated the effect of heat-to-heat variation on fatigue and creep–fatigue resistance of type 304 stainless steel at 593 °C. Carbide precipitation was considered as the reason of increasing low-cycle fatigue (LCF) resistance. Additionally, a fairly uniform distribution of inter- and intragranular carbides $M_{23}C_6$ was considered to increase the resistance to the tensile hold time effect. Generally, zero hold time tests revealed transgranular fracture surfaces, while intergranular features were obtained even with hold times as short as 0.01 h. This is also illustrated by the studies of Schaaf (1988) (Fig. 5). The creep–fatigue failure can be categorized into three modes: fatigue-dominated failure with almost transgranular features, creep–fatigue interaction (both transgranular and intergranular), and creep-dominated failure with mainly intergranular cracks.

In recent years, creep–fatigue properties of liquid metal fast breeder reactor (LMFBR) candidate structural materials, such as austenitic 304 L, 304NG, 316LN, and AISI 321, were investigated at 600 °C (Rho and Nam 2002; Nilsson 1988; Min and Nam 2003). It was observed that nitrogen addition improved fatigue life under creep–fatigue condition. The density of Cr-rich carbides formed at the grain boundary of 304NG (0.08 % N) was lower than that of 304 L (0.03 % N). Planar slip planes

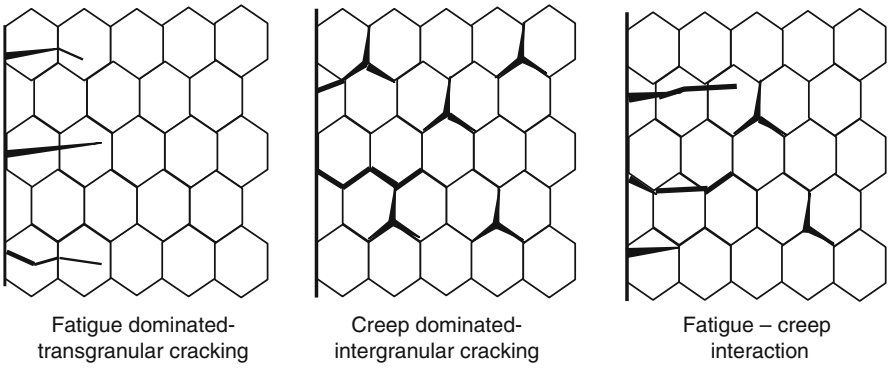

Fig. 5 The three failure modes: fatigue dominated (*left*), creep–fatigue interaction (*left*), creep dominated (*middle*) (Van Der Schaaf 1988)

of 316LN initiated under creep–fatigue interaction probably enhanced stress concentration immediately next to grain boundaries and promoted intergranular fatigue fracture. In the case of AISI 321, it was observed that the creep–fatigue life of TiC-aged specimen was 40 % longer than that of $Cr_{23}C_6$ aged, although the two carbide densities at grain boundaries were similar. It is suggested that the interfacial free energy between TiC and grains is lower than that between $Cr_{23}C_6$ and grains in AISI 321.

In addition, irradiation creep accumulates in reactor materials. It is known that irradiation creep has very weak temperature dependence. However, creep remains high at temperatures as low as 60 °C (Grossbeck et al. 1990). It is postulated that migration of vacancies and migration of interstitials are two independent mechanisms of irradiation creep. The effect of irradiation is to lower the endurance of plastic strain range.

So far, most of the experimental studies on creep–fatigue interaction were conducted by using low-cycle fatigue tests with and without tensile strain hold in air at temperatures ranging from 400 to 600 °C. The accumulated data in simulated reactor environments at high temperature up to 800 °C is inadequate for a better understanding of the creep–fatigue interaction mechanism. For example, oxidation and solubility of alloying elements in high-temperature liquid metal have to be considered as possible factors affecting creep–fatigue behavior. Also, carbide precipitation at component weld joints and heat-affected zone (HAZ) may have different behaviors from base metals.

Creep–Fatigue Life Prediction

In this section, selected creep–fatigue life prediction methods are reviewed without considering the irradiation effects.

Suauzay et al. (2004) analyzed their experimental results of creep–fatigue behavior of 316LN at 500 °C using linear damage accumulation model. This model is based on Miner's rule, expressed as

$$\frac{N_F}{N_F^{pf}} + \frac{t_F}{t_F^{relax}} = 1 \tag{15}$$

N_F: number of cycles to failure for a t_h hold time ($t_n > 0$)
N_F^{Pf}: number of cycles to failure in pure fatigue, based on the Coffin–Manson relation ($t_n = 0$)
$t_F = N_F t_h$
t_F^{creep}: failure time in pure creep condition given as
$t_F^{creep} = H / \sigma^r$, where H and r are creep coefficients

$$t_F^{relax} = N_F \int_0^{t_h} \frac{dt}{t_F^{creep}\sigma(t)} \tag{16}$$

Tsuji and Nakajima (1994) evaluated the damage accumulation of Hastelloy-XR in HTGR environment at 700–950 °C by applying the life fraction rule and ductility exhaustion rule. The creep damage during strain holding time was given as

$$D_{cL} = \sum_i \left(\Delta t_i / \Delta t_{Ri}\right)^n \tag{17}$$

D_{CL}: creep damage by life fraction rule
Δt_i: strain holding period for particular temperature and stress
t_{Ri}: rupture time based on the Larson–Miller parameter
n: number cycles for failure in the experimental condition with trapezoidal strain wave form (fatigue–creep components)

The ductility-exhaustion rule is given as

$$D_{cd} = \sum_i \left(\dot{\varepsilon}_{\min} \Delta t_i / \varepsilon_{Ri}\right)^n \tag{18}$$

D_{cd}: creep damage by ductility exhaustion rule
Δt_i: strain holding period for particular temperature and stress
$\dot{\varepsilon}_{\min}$: minimum creep rate calculated from the Larson–Miller parameter
ε_{Ri}: strain at rupture

It was observed that the ductility exhaustion rule predicted the fatigue life under the effective creep condition more successfully than the life fraction rule.

Most of the creep–fatigue life prediction models are based on phenomenology of failures. For example, ferritic/martensitic steels and nickel-based superalloys showed damage accumulation at the crack tip or crack process zones. In these materials even compressive stress hold times were found to affect the damage accumulation. In case of austenitic stainless steels, creep–fatigue damage occurs by grain boundary cavitation, and tensile hold time is considered to be more

important. The proposed damage accumulation function based on grain boundary cavitation phenomenon is given as (Nam 2002)

$$D_{C-F} = \Delta\varepsilon_p^m \left\{ \frac{\exp\left(-Q_g/RT\right)}{T} \int_0^t \sigma(t)dt \right\}^{2/3} \tag{19}$$

$\Delta\varepsilon_p$: plastic strain range
m: strain exponent
Q_g: activation energy for grain boundary diffusion
R: gas constant
T: temperature

When the damage function is plotted against experimental creep–fatigue life, as shown in Fig. 6, a linear relationship was observed with a slope of −1.66. Consideration of creep–fatigue life of different types of austenitic stainless steels at 600–700 °C revealed that the slope varies from −1.62 to −1.66. Therefore, the proposed damage function can be used for life prediction in the given experimental conditions.

It should be noted that most of the life prediction methodologies are based on the data generated using smooth tensile specimens. In these cases, the events of crack initiation and crack propagation were not distinguished. In service conditions, inspection and monitoring methods require data on crack initiation time and crack velocity to evaluate the integrity of the components.

Yokobori (Yokobori and Yokobori 2001) considered the crack initiation and crack propagation issues for creep–fatigue interaction based on critical notch opening displacement criterion. According to these authors, the crack initiation event is complete when the defect size reaches 5 μm, a dimension that can be resolved by optical microscopy. Crack initiation is considered to occur when a critical strain is

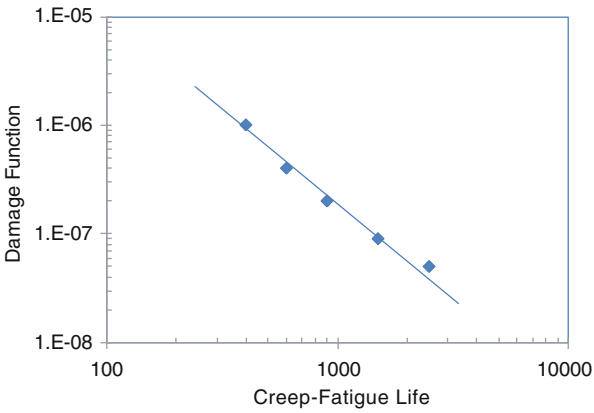

Fig. 6 Normalized Coffin–Manson plot for AISI 316 stainless steel (Nam 2002)

reached by some atomistic rearrangement by time-dependent plastic flow. This process in creep–fatigue interaction is thermally activated and aided by stress field. Based on these considerations, the time for crack initiation was given as

$$1/t_i = \frac{A_1}{\varepsilon_c} \exp\left(\frac{-\Delta H - \Phi(\sigma_g)}{RT}\right) \tag{20}$$

t_i: time for crack initiation
ε_c: critical strain required for crack initiation
A_1: material constant
ΔH: activation energy for plastic flow

$$\Phi(\sigma_g) = \Delta f \ln\left(\frac{K_I}{G\sqrt{b}}\right) \tag{21}$$

Δf: energy coefficient
K_I: stress intensity factor $= \alpha\, a^{1/2} \sigma_g$
G : modulus of rigidity
b: burgers vector

Similar expressions can also be written for crack propagation. The expression for crack propagation is

$$\frac{da}{dt} = B\sigma_g^m K_I^n \left[\frac{-\left\{\Delta H_g - \Delta f \ln\left(\frac{K_I}{G\sqrt{b}}\right)\right\}}{RT}\right] \tag{22}$$

The major advantage of the above approach is its ability to take various boundary conditions, such as environmental degradation (reduction in ΔH_g due to liquid metal) and irradiation effects, into account.

Radiation Damage

Radiation Damage of Microstructure

Among the radiation effects, some are fluence dependent and some are flux dependent, while both fluence and flux cause joint effects. Radiation-induced segregation (RIS), radiation-induced microstructures, and radiation creep relaxation are fluence dependent, while RIS is flux dependent to some extent.

Figure 7 illustrates schematically the collision of an energetic particle (either a neutron, an electron, or a proton) with a lattice atom generating radiation damage (Maziasz 1993). If the energy transfer of the elastic collision is greater than the displacement threshold (E_d), a primary knock-on atom (PKA) is generated. PKA can displace additional atoms through the lattice if it has sufficient energy until the energy of all the atoms has been reduced below E_d (Capdevila et al. 2008).

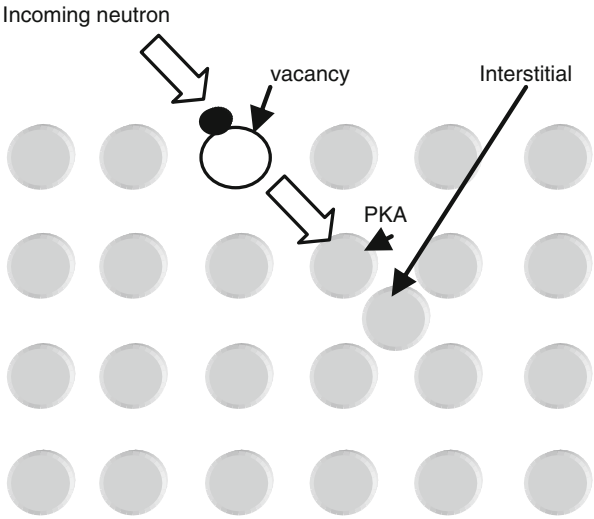

Fig. 7 Schematic illustration of generation of a primary knock-on atom (PKA) (Maziasz 1993)

The Frenkel pair, consisting of a vacancy and self-interstitial atom (SIA), could be considered as the fundamental component of radiation damage (Fullwood and Hall 1988).

The extent of radiation damage is a function of temperature. Several extensive reviews on microstructural evolution in irradiated austenitic stainless steels are available, which report a transition of microstructural damage approximately at 300 °C. At high temperatures (>300 °C), vacancy clusters in austenitic stainless steels become thermally unstable. The presence of voids and swelling is observed at higher temperatures. Under certain conditions small gas-filled bubbles can grow to form voids, referred to as swelling, as the volume of material increases beyond the size limitation dictated by the thermodynamic equilibrium of gas. Both hydrogen and helium play an important role in swelling of a material. A swelling rate of 1 % per dpa is maintained at temperatures above 425 °C. The lower limit of temperature for swelling is observed to be affected by displacement rate.

Radiation-Induced Microchemistry

In austenitic stainless steels, depletion of Cr and Fe and enrichment of Ni have been observed. The Cr and Fe have higher diffusivity than Ni. Therefore, they migrate away from the interface, enriching the boundary with Ni. This could be attributed to the inverse Kirkendall segregation. Segregation of Si and P at grain boundaries is observed by an uphill diffusion process. Along with Cr and Fe, minor alloying elements such as Mn, Ti, and Mo also get depleted at grain boundaries. Mn levels drop to 0.5 at% at grain boundaries in type 304 SS. In type 316 SS, more than 50 % depletion of Mo after irradiation to 3 dpa has been reported (Cookson and Was 1995). For the same level of irradiation, enrichment of Si occurred to levels of about 6–8 at%. Nickel-silicide precipitation also has often been reported to form at dislocation loops at temperatures >380 °C and at higher doses (>20 dpa) (Kimura

et al. 1996). At higher doses (PWR relevant, >10 dpa) sulfur segregation can be expected due to the burnup of Mn in MnS inclusions and subsequent release of S. Radiation-induced Cr depletion could retard carbide formation at grain boundaries. Radiation-induced segregation of Ni and Si could lead to formation of γ' or G phase at higher temperatures (Shiba et al. 1996).

Mechanical Properties

In general, it is observed that with increases in irradiation dose, the yield strength of the material increases. The ultimate tensile strength also increases, but the increase is not as great as for the yield strength. Formation of higher densities of vacancies and interstitials is attributed as the cause for this increase. Suzuki et al. (Holt 1974) reported increases in strength for various grades of austenitic stainless steels with increase in neutron fluence as shown in Fig. 8. However, a saturation level is reached at the 3×10^{25} n/m^2 fluence level (E > 1 MeV) beyond which no significant increase in strength could be observed. The increase in yield strength ($\Delta\sigma$) of the 304 SS irradiated in BWR environment at 288 °C showed a relation of $\Delta\sigma = 1.1 \times 10^{-3} \times$ (neutron fluence, n/m^2)$^{0.27}$. It was observed that type 304 SS was more prone to irradiation hardening than was type 316. Composition has two effects, viz., (1) certain alloy elements help nucleate Frank loops and (2) stacking fault energy (SFE) is altered. Low SFE results in more hardening. Also a low SFE can lead to nucleation of twins as an alternative deformation mechanism to dislocation glide. Alloying elements such as Ni, Mo, and C increase the SFE in austenitic stainless steel, and Cr, Si, Mn, and N tend to decrease the SFE.

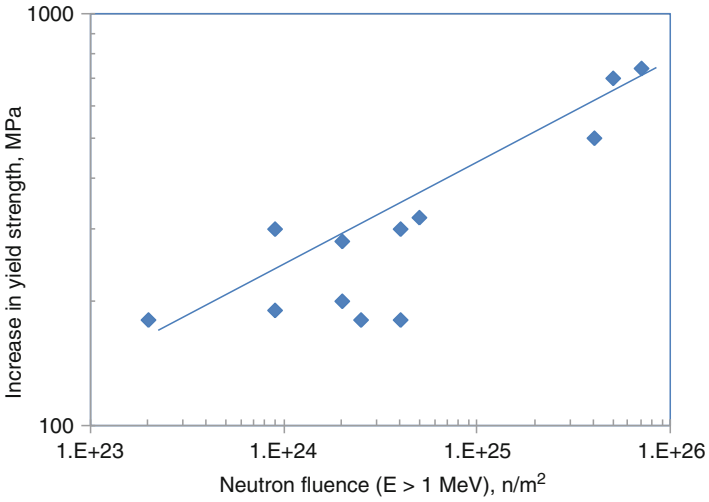

Fig. 8 Typical relation between the increase of the 0.2 % yield stress of austenitic stainless steels and neutron fluence (E > 1 MeV) after irradiation in BWR environment at 288 °C (Koyama et al. 2007)

Loss of work hardening and uniform elongation is observed after irradiation. The elongation decreases significantly with increasing dose. This kind of loss in work hardening and hence uniform ductility could be attributed to the irradiated microstructure, where annihilation of barriers occurs due to their interaction with dislocation. Interacting with obstacles, dislocations multiply in unirradiated material which results in development of back stresses and hence work hardening of the material. However, in irradiated conditions, the obstacles such as loops and voids can be destroyed when they interact with moving dislocations, resulting in work softening. This behavior causes flow localization, and hence, the slip band spacing increases, ultimately reducing the macroscopic deformation. At higher temperatures (above 600 °C), the ductility is observed to be severely affected by He embrittlement. When a large void population develops near 400 °C, the fracture mode is observed to be transgranular channel. The reduction of fracture toughness of irradiated SS can be attributed to the higher population of voids so that fracture occurs at an early stage by dislocation channeling or highly heterogeneous deformation–decohesion ahead of the crack tip[23]. RIS of Ni at voids also results in brittle behavior of a material. This preferential segregation of Ni at voids results in matrix depletion of Ni and hence destabilizes the austenite. The strain-induced martensite transformation, possible in the destabilized austenite, acts as low-energy path for crack propagation [24]. This mechanism for cracking resulted in quasi-cleavage fracture with an overall fracture toughness of 80 MPa $m^{1/2}$ after the austenitic material has been irradiated to high dose (1.6×10^{23} n/cm^2) at 425 °C.

Irradiation hardening and softening are important factors in determining the fusion reactor life limits as creep properties are affected by these changes. In ferritic steels, the irradiation hardening is attributed to the formation of small defect clusters and dislocation loops, with associated precipitation of small carbides such as M_2C, M_6C, etc. Kimura et al. (1996) studied the irradiation hardening behavior of 9Cr-2 WV steel and reported saturation of irradiation hardening at a dose level of about 10–15 dpa. Irradiating at above 430 °C resulted in softening at dose levels of 40–60 dpa. Swelling was found to be associated only with hardening, in this study.

Shiba et al. (1996) investigated the response of F82H steel to irradiation at low damage levels (<1 dpa) for 300–500 °C. They observed hardening only at 300 °C. However, no softening was observed when irradiated at 520 °C. Interestingly for these test conditions, no change in DBTT was observed between irradiated and unirradiated Charpy impact tested samples. However, the upper shelf energies were lower for irradiated samples.

Klueh and Alexander (1996) conducted a detailed study on Charpy impact toughness of different types of low-activation steels irradiated at 0–24 dpa. They observed that 9Cr-2 W-type steels were least affected by irradiation. In terms of microstructure, they found that steels with 100 % martensitic structure showed superior impact toughness properties after irradiation than steels with dual microstructures such as bainite + ferrite or martensite + ferrite. By changing the composition and microstructure, the effect of irradiation on toughness could be favorably modified.

Typical 12 % Cr steel shows very little void swelling (only 0.1 % volume change for a dose of 90 dpa at 400 °C). It is generally observed that 9 % Cr steel shows better impact toughness and DBTT values after irradiation than 12 % Cr steel. However, by controlling the phase content (either 100 % martensite or at least less than 20 % delta ferrite) and with uniform distribution of carbide/carbonitride phases, much improved mechanical properties could be achieved. In the case of 9 % Cr steel, the volumetric swelling was around 0.1 % at 100 dpa and 400 °C which is similar to that for 12 % Cr steel. After 90–100 dpa, the rate of swelling of 9 % Cr steel was reported to be approximately 0.01 %/dpa.

Irradiation Creep

Two groups of mechanisms have been proposed for irradiation creep, viz., (1) irradiation-induced creep and (2) irradiation-enhanced creep.

Irradiation-Induced Creep. Depending on the nucleation and growth of dislocation loops, two types of mechanisms are observed, viz.:

1. Stress-induced preferred nucleation (SIPN)
2. Stress-induced preferential absorption (SIPA)

For the case of SIPN, interstitial loops are assumed to nucleate preferentially on planes perpendicular to the tensile stress, and vacancy loops nucleate preferentially on the planes parallel to the applied stress.

For the SIPA mechanism, interstitials are preferentially absorbed by the loops oriented perpendicular to the tensile stress so that there is an elongation in the direction of stress.

Irradiation-Enhanced Creep. It is postulated that irradiation accelerates the thermal creep by producing excess vacancies and interstitials and thus facilitating the easier dislocation movements. For example, jogs in the form of nonglissile edge dislocation segments on a screw dislocation can be moved by the point defects produced by irradiation, otherwise not possible.

Fretting

Fretting results from low-amplitude motion between the tube and the support plates of the steam generators in the nuclear power plants. These flow-induced, low-amplitude vibrations occur during the normal operation of steam generator, in spite of the use of anti-vibration supports, wherein two fluids are flowing in countercurrent manner. Several parameters including fluid flow, vibration frequency, and impact force affect fretting. The flow-induced vibrations also lead to cyclic loading that will be random in nature. As per the US Nuclear Regulatory Commission, the USA has 27 nuclear power plants that use Inconel Alloy 600 (Ni, >72 %; Cr, 14–17 %; and Fe, 6–10 % form major constituents) and 42 that use Alloy 690 (Ni, >58 %; Cr, 27–31 %; and Fe, 7–11 % form major constituents) as tubing material. To improve mechanochemical properties, these materials are subjected to

mill annealing (Alloy 600) or thermal treatment (Alloy 600 or 690), which forms the important factor, other than the alloy composition, in determining its degradation. The tube support plates are typically fabricated using 405 ferritic stainless steels. While the primary reason for degradation and failure of the tubes used to be thinning of tubing material due to water flow, the recent failures and inspections indicate that accelerated degradation is becoming an issue of concern. At the center of this is the failure of steam generator tubes in January 2012, after less than 3 years of operation, at the San Onofre plant in California which led to the leakage of radioactive material from inside the tubes to the outside water. While the migration from Alloy 600 to 690 was primarily conducted due to improved corrosion resistance of Alloy 690 (provided by higher chromium content), the mechanical properties of Alloy 690 are not superior to that of Alloy 600. Therefore, Alloy 690 would be expected to be more susceptible to mechanically induced failure such as fretting and fatigue. Moreover, since the steam generator transfers excess heat from reactor core to outside, these tubes are exposed to extreme temperatures and (~320 °C) and pressures (~150 bar). Preliminary reports from the San Onofre nuclear plant indicated that the accelerated degradation was in part due to increased fretting from flow-induced vibration. This type of cyclic loading, in addition to the normal load (contact stress) due to fretting conditions, results in damage accumulation beneath the contacting surface of Alloy 690. The mechanism of fretting in LWR environments is complex because the failure occurs due to a combination of several synergistic processes such as fretting fatigue, fretting corrosion, and fretting wear. The material removal occurs in the following stages: (1) formation of highly plastic deformed surface layer, (2) fracture of the work-hardened layer, and (3) removal of wear debris and propagation of cracks in the deformed subsurface. The localized material loss due to fretting has two consequences in the LWR environment, namely, (1) accelerated corrosion of small worn-out areas that become anodes and large unaffected areas that act as cathodes and (2) fatigue crack initiation from the worn-out area that acts as a stress concentrator. Another important aspect is the microstructure of the alloy. Greater resistance to wear was observed with the large grain structures and coarse carbides along the grain boundaries of nickel-based alloys. Carbide morphology also influenced the wear resistance. Continuous grain boundary carbides showed increased propensity to crack formation (and hence low wear resistance) as compared to discrete grain boundary carbides.

Cast Stainless Steel Components

Cast stainless steels are extensively used in light water reactors (LWRs) as alloys for coolant piping and auxiliary piping components such as pump casings, valve bodies and fittings, elbows, and nozzles. Similar to the weld microstructure of austenitic stainless steels, the cast microstructure also contains delta ferrite. The ferrite content varies from 3 % to 12 % in welds and up to 40 % in cast austenitic stainless steel components. The delta ferrite is required to mitigate hot cracking

during solidification and control the intergranular corrosion. Mechanical strength and stress corrosion cracking resistance are improved by the ferrite phase present in the austenite matrix. Depending on the chemical composition, the primary solidification phase could be austenite or ferrite. When the primary solidification phase is austenite, the ferrite is present as interdendrites. Partitioning of the solute elements occur in the interdendritic regions that affect the chemical and mechanical properties when compared to the equiaxed wrought microstructures. The heterogeneity in the chemical composition also results in detrimental microstructural changes such as spinodal decomposition and precipitation of topologically close packed (TCP) phases during long time exposures to service temperatures that lead to thermal embrittlement.

The popular grades of cast austenite + ferrite duplex structure stainless steels in nuclear service are the CF3 and CF8 series of alloys. Among these, the CF3, CF3A, CF3M, CF8, CF8A, and CF8M are the most widely used alloys (equivalents of 304 and 316 wrought grades). These alloys typically have 17–21 wt% Cr and 8–13 wt% Ni. The digit following the letters CF refers to the carbon content of the alloys "3" for 0.03 % and "8" for 0.08 %. The fourth letter "A" denotes higher ferrite control which raises strength above that of the normal CF grades, and the letter "M" denotes addition of Mo to the nominal compositions of CF grade alloys. The macroscopic cast structure is generally divided into two categories depending on the casting process, namely, (1) static cast structure which contains columnar grain structure at the ends and equiaxed (randomly speckled) grains at the center (Calonne et al. 2004) and (2) centrifugally cast structure which contains long columnar grains at the outer wall and a mixture of equiaxed and columnar structures in the inner regions (Anderson et al. 2007).

Embrittlement due to thermal aging of cast stainless steels at service conditions in the temperature range of 280–320 °C has been a major concern (Chung and Leax 1990). The main transformations are the spinodal decomposition of α into α and a chromium-rich phase α′, precipitation of a G phase ($Ni_{16}Ti_6Si_7$), ε, and π (a nitride phase). Primarily, the formation of Cr-rich α′ (martensite) phase strengthens ferrite and decreases the toughness. With increased temperature (>550 °C), other embrittling phases such as σ, χ, η, $M_{23}C_6$ carbide, and γ_2 austenite are form aided by the presence of the ferrite/austenite interfaces. Sigma phase is a tetragonal crystal composed of $(Cr,Mo)_x$ $(Ni,Fe)_y$. The chi (χ) phase is a body-centered cubic with a typical composition of $Fe_{36}Cr_{12}Mo_{10}$. The typical stoichiometry of the Laves (η) phase is Fe_2Mo with a hexagonal structure. These topologically close packed (TCP) phases have large lattice parameters and large number of atoms in a lattice that show directional properties. Since these TCP phases nucleate at the high surface energy sites (grain boundaries and phase boundaries), cohesive strength of the grains is significantly reduced and brittle failure is often observed. It is important to note that the cold working accelerates the formation of the TCP phases by increased diffusion. Therefore, formation of Laves phase in cold-worked structure can be a high possibility even at reactor service temperatures.

Corrosion fatigue data for cast stainless steels in water containing 200 ppb and 8 ppm of dissolved oxygen (DO) at 289 °C have been generated and compiled by

Shack and Kassner of the Argonne National Laboratory (Shack and Kassner). In general, the corrosion fatigue crack growth rate is assumed to be related to the air fatigue crack growth through a power law given as

$$(da/dt)_{env} = A\,(da/dt)^{m}{}_{air} \tag{23}$$

For stress ratio R $<$ 0.9, A $= 4.5 \times 10^{-5}$ for DO $=$ 200 ppb, and A $= 1.5 \times 10^{-4}$ for DO $=$ 8 ppm, m $=$ 0.5.

Kawaguchi et al. (1997) studied the thermal embrittlement behavior of centrifugally cast CF8M duplex stainless steel after aging at 300–450 °C for up to 40,000 h. The aging treatment was quantified by a temper parameter denoted as P and given as $P = \log(t) + 0.4343(Q/R)(T_1{}^{-1} - T_2{}^{-1})$, where t = aging time, Q = activation energy for the embrittlement (typically 100 kJ/mol), T = temperature, and R = gas constant. The ferrite content of the samples varied from 15 % to 17.5 %. Spinodal decomposition of δ-ferrite to Cr-rich α′ phase (size, 5 nm) was observed after the following aging conditions: 300 °C for 10^4 h, 350 °C for 3000 h, and 450 °C for 300 h. The precipitation of larger (~50 nm) G phase was observed only at longer aging times than that required for spinodal decomposition and at higher temperatures. For example, aging at 300 °C for 40,000 h did not show the presence of G phase. Thermal aging at 350 °C for 10^4 h and 450 °C for 3000 h showed occurrence of the G phase. Spinodal decomposition was considered the main reason for the thermal embrittlement behavior of the CF8M cast stainless steel based on the Charpy V-notch energy of 230 J that decreased from the 300 J of the as-cast samples.

The use of subsize CT samples for the evaluation of the fracture toughness and the validation of the results with 1 T-CT samples was investigated by Jayet-Gendrot et al. (1998). Mini-CT specimens (5 mm thick) were extracted from the skin of the cast stainless steel elbows of a PWR unit that underwent 86,898 h of service at around 323 °C. The J-integral values of the mini-CT specimens (82 kJ/m^2 at 0.2 mm of Δa offset) were observed to be in good agreement with those derived from the 1 T-CT specimens. The effect of thermal aging on the low-cycle fatigue (LCF) behavior of the cast stainless steel in room temperature air was evaluated by Kwon et al. (2001). The samples were evaluated in as-cast and aged conditions (430 °C for 300 and 1800 h), and the LCF behavior was described by the relation

$$\frac{\Delta\varepsilon_t}{2} = \left[\frac{\sigma_f'}{E}\right] N_f^b + \varepsilon_f' N_f^c \tag{24}$$

where $\Delta\varepsilon_t$ = total strain range, σ_f' = fatigue strength coefficient, E = Young's modulus, b = Basquin's exponent, ε_f' = fatigue ductility coefficient, c = fatigue ductility exponent, and N_f = cycles to failure. The values of (σ_f'/E), $(-b)$, (ε_f'), and $(-c)$ of the 300 h aged samples were higher than that of un-aged samples. However, increasing the aging time to 1800 h resulted in lower values than that of the un-aged samples.

Jeong et al. (2009) evaluated the effect of strain hardening on the environmental fatigue behavior of CF8M under PWR conditions. The material was taken in the

as-cast condition with 25 % ferrite. The tests were carried out at 316 °C and 15 MPa with 30 ml of dissolved hydrogen per kg of H_2O and < 5 ppb of DO. Cyclic hardening was observed during the initial 200 cycles that showed peak loads which increased with increase in the strain amplitude. The fatigue test data points were scattered within the ASME design curve and the ASME mean curve. The same group also evaluated the effect of strain rate on the fatigue behavior (Jeong et al. 2011). The strain rate was varied from 0.004 % s^{-1} to 0.04 % s^{-1}. The number of cycles to failure increased with increase in the strain rate almost by an order of magnitude. The increase in the strain amplitude from 0.4 % to 0.8 % decreased the number of cycles to failure (from 2750 to 150 cycles at 0.004 % s^{-1} and from 13,500 cycles to 1500 cycles at 0.04 % s^{-1} strain rate).

Cicero et al. (2009) analyzed a CASS CF8M component (motor-operated valve of the reactor water cleanup (RWCU) system of a BWR unit) that was in service for 40 years using FITNET-FFS procedure and the ASME code. The ferrite content of the component was about 15 %. If the ferrite content was more than 10 %, the aging effect due to service temperature was needed to be considered for structural integrity analysis. The RWCU system was subjected to more than 60 major thermal cycles in the temperature range of 30–300 °C and a stable operating temperature of ~250 °C in 14 years. There were other minor temperature excursions at around 250 °C. The maximum service stress calculated at the neck of the valve was about 86 MPa, and the critical flaw size was much larger than that could be detected by inspection techniques. Wang et al. (2010) used nano-indentation technique to evaluate the thermal aging damage mechanism of the CASS. The specimens were aged at 400 °C for 100–3000 h representing service life of 0.7–21.48 years according to the corresponding Arrhenius relation. Dislocation pileup at the Cr-rich clusters of α′ spinodal decomposed phase was attributed to the observed embrittlement.

Cost–Benefit Analysis

Nuclear power is highly competitive with other forms of power generation such as fossil fuel power and renewable energy-based power generation. The cost of fuel is much less than that of fossil fuels. However, the capital cost is high because of increased margin of safety precautions and cost involved toward storage of spent fuels. While calculating the cost of nuclear power, the cost involved in waste management and decommissioning cost are fully considered (Economics of Nuclear Power).

In 2010, the cost of 1 kg of uranium as UO_2 reactor fuel is calculated as $ 2555. At 45,000 MW-day/ton burnup, 360,000 kWh electrical energy can be generated per kg of fuel. Therefore, the fuel cost per kWh energy is 0.77 cent. The US electricity production cost using different fuel sources in the year 2008 is given in Table 1. This includes cost of fuel, operation, and maintenance. Capital cost is not considered.

Table 1 Cost comparison of electricity generation in the USA using different fuel sources (for the year 2008)

Fuel source	Cost ($/kWh)
Oil	0.18
Gas	0.082
Coal	0.033
Nuclear	0.02

Table 2 Typical composition of nuclear fuel and spent nuclear fuel

	Fresh nuclear fuel	Spent nuclear fuel
235 U	3.3	0.81
238 U	96.7	94.30
236 U	–	0.51
239 Pu	–	0.52
240 Pu	–	0.21
241 Pu	–	0.10
242 Pu	–	0.05
Fission product	–	3.5

The capital cost includes:

- Bare plant – engineering, procurement, and construction (EPC)
- The owner's cost (land, cooling infrastructure, administration and associated buildings, site works, switch yard, transmission, project management, license, etc.)
- Cost escalation due to increased labor and materials
- Inflation
- Financing and interest of financing

The typical construction period of a nuclear power plant is about 48–54 months. Decommissioning cost is about 9–15 % of initial capital cost, which is about 0.1–0.2 cent per kWh of energy generated in the USA. The EPC cost in the year 2008 was about $ 3000/kW.

Spent Fuel and Reprocessing

When the spent fuel assembly is removed from the reactor, it is stored at the reactor site and allowed to cool before reprocessing or disposal. Typical compositions of fresh and spent fuels are listed in Table 2.

Most of the commercial reactor spent fuels are in water-filled swimming-pool-type structures. This type of arrangement is chosen because water is inexpensive, has good heat transfer coefficient by convection, and provides shielding, and visibility in water gives an opportunity to detect undesired events, if any. The limitation of water as a cooling medium in spent nuclear fuel is that water is a neutron monitor and active electrolyte for corrosion reactions.

The typical PWR operating cycle is about one year when 1/3 of the core is replaced with new fuel. After one year of operation, the fuel assembly, which weighs about 1300 lbs, is removed from the core and transferred to an interim storage facility. The radiation levels of the unshielded fuel assembly are more than millions of rems per hour.

The spent fuel assemblies are placed in vertical stainless steel racks. In order to prevent reaching critical conditions of the spent nuclear fuel assemblies, these are stored in well-separated conditions. Furthermore, neutron-absolving materials such as boron carbide or boron rods are inserted to inhibit neutron multiplication. The pool storage facility is designed only for interim storage – until the spent fuel is cooled down to low temperature. The remnant radioactive decay has subsided. Afterward the spent fuel will be taken for reprocessing or, in the absence of reprocessing, to a long-term storage facility.

Dry Storage

As an alternate to wet pool storage, dry storage using metal casks and concrete modules is practical. The heat generated during radioactive decay of the spent fuel is removed by the force convection of air, in case of modular concrete vault storage. Metal casks are provided with fins for faster heat transfer. These metal casks, if properly designed, can also be used for transportation of spent nuclear fuels.

For transportation of spent nuclear fuel, the metal casks are provided with (1) protection against direct radiation exposure to workers and the public, (2) provision for radioactive heat removal, and (3) neutron absorbers to prevent criticality. The metal casks can contain about 7 PWR assemblies or 18 BWR assemblies. The body of the cask is made of stainless steel of 5 m long and 1.5 m wide. Shielding is provided by depleted uranium or lead metal. It has an outer stainless steel shell and a corrugated stainless steel jacket that circulates water as neutron shielding fins are provided for external air forced cooling and minimal impact damage.

The spent fuel casks for transportation are constructed so sturdily that it can withstand the impact of being dropped from a height of 10 m onto an unyielding surface (metal anvil) and pass the crash test of a 130 km/h locomotive crash on a stationary cask-loaded tractor-trailer rig. It can also withstand fire for up to a 125 min burn in JP-4 fuel at 980–1150 °C.

Transmutation

Transmutation of transuranic elements such as plutonium, neptunium, americium, and curium can be conducted by irradiating with fast neutrons. In this process, the original actinide isotopes are transformed to radioactive and nonradioactive fission products. This process is important for nuclear waste management, since the isotopes of actinides have half-lives of thousands of years and alpha emitters. Transmuting these isotopes to short-lived fission products helps eliminate the radioactive hazardous associated with long-lived radionuclides.

Reprocessing

The spent fuel contains about 3.5 % fission products that predominantly contain neutron poisons such as Xe^{135} and I-137. Accumulation of fission products and depletion of fissile U-235 in the nuclear fuel make the sustainability of the nuclear chain reaction very difficult. Therefore, the nuclear fuel is removed from the reactor core. Currently, about 10,500 tons (of heavy metal) of spent fuel is disposed every year from nuclear reactors. The purpose of reprocessing is to separate the actinides from the fission products so that it can be reused as nuclear fuel. This decreases the burden on uranium mining and results in a more sustainable use of nuclear energy as a renewable energy source. Reprocessing can be carried over using aqueous or nonaqueous processes.

Aqueous Reprocessing

The aqueous process is based on the solvent extraction. Figure 9 illustrates the process flow. First, the spent nuclear fuel is dissolved in nitric acid. The Zircaloy cladding is removed separately. The aqueous solution containing dissolved spent fuel is taken for the solvent extraction in an organic solution of kerosene containing tributyl phosphate (TBP). When the aqueous solution comes in contact with the organic TBP, hexavalent uranium (U^{6+}) and tetravalent plutonium (Pu^{4+}) are

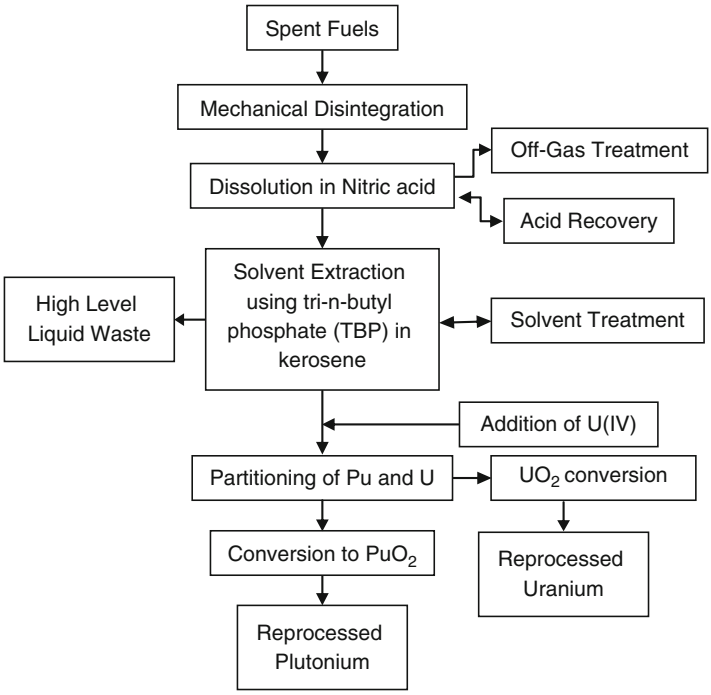

Fig. 9 Flow diagram of PUREX process of reprocessing spent nuclear oxide fuels

extracted by TBP. Almost all the fission products remain in the nitric acid solution which is extracted as high-level liquid waste. In the solvent extraction partitioning step, Pu^{4+} is reduced to Pu^{3+} by adding Li^{+} as a reductant. The Pu^{3+} is removed by dissolving in nitric acid solution. The recovered Pu can be used as a raw material for fast breeder reactor fuels in the future. The uranium species remaining in the solution can be recovered by processing through a series of scrubbing columns and purification columns. The purified uranium can be enriched and used as a fuel after converting to UO_2. The ability to separate plutonium from uranium is considered a potential proliferation concern. Therefore, modifications are made in the PUREX process to avoid separation of plutonium.

In the modified processes, uranium is separated while keeping Pu, minor actinides, and fission products in the waste solution. Later, the actinides are separated as a group. Another modification of the PUREX process is coprocessing. If the intent of reprocessing of spent fuel is to use the recovered actinides for producing mixed oxide fuel (MOX), then coprocessing is the right method. In this process, partitioning of U or Pu does not take place. Therefore, proliferation of Pu for weapon is not a concern. In the coprocessing method, 30 vol.% TBP in n-dodecane is used as solvent and a 2.5 M HNO_3 solution is used as scrub solution. The aqueous feed solution containing 4.2 M HNO_3, 2 M UO_2, + Pu, and 1.25 M FP is fed through solvent extraction column of TBP in n-dodecane. Uranium and plutonium are complexed with the TBP, and thus, fission products are separated. The U + Pu complexed with organic phase is washed with dilute nitric acid. The resulting nitrate solution of U + Pu is treated with peroxides or oxalates to form precipitates of U + Pu peroxide or oxalate. These oxalate precipitates are calcined to form UO_3 or U_3O_8 and reduced in hydrogen atmosphere to form UO_2. There are several variations in the PUREX process. Table 3 lists these modified PUREX processes.

Pyroprocessing

Pyrochemical or pyrometallurgical processing using LiCl–KCl molten salt systems is considered one of the most feasible alternatives to the PUREX process for safe and proliferation-resistant recovery of nuclear fuel elements from the spent fuels. This technology may also be useful for separating actinides from the high-level waste generated by the PUREX process. Pyrometallurgical process is preferred because of the stability of the molten salts to high radiation and shorter cooling times (OCDE/NEA Report). Reprocessing of metallic fuels involves separation of actinides from the fission products by electro-transport in a molten salt electrolyte. Since rare earth elements (as part of fission products) have similar chemical properties as that of actinides and show neutronic poison effect, separation of fission products is important for efficiently recycling the actinides. Spent oxide fuels also can be reprocessed by the pyrometallurgical electrorefining method. In this case, the spent oxide fuel is reduced to metal form by lithium (Koyama et al. 2007) or chlorinated in the presence of a reductant such as carbon (Yang et al. 1997) before anodic dissolution or direct dissolution in the presence of an oxidizer such as $CdCl_2$ into the molten salt (Koyama et al. 1997).

Table 3 Variations of aqueous–organic reprocessing of nuclear spent oxide fuels (Adopted from the Nuclear Technology Review Supplement, International Atomic Energy Agency, Vienna, 2008)

Process	Purpose	Special aspects
DIAMEX	Extraction of minor actinides and lanthanides from HLLW	**Diam**ide **ex**traction process solvent based on amides as alternate to phosphorous reagent generates minimum organic waste as the solvent is totally combustible
TOGDA	Ditto	**T**etra-**o**ctyl-**di**g**l**ycol-**a**mide Amide similar to DIAMEX
TRUEX	**Tr**ansuranic (**TRU**) element **ex**traction from HLLW	Extraction by using **c**arbamoyl **m**ethyl **p**hosphine **o**xide (CMPO) together with TBP
SANEX-N	**S**elective **a**cti**n**ide **ex**traction process for group separation of actinides from lanthanides	Process for separating actinides from lanthanides from HLLW by using neutral N-bearing extractants, viz., bis-triazinyl-pyridines (BTPs)
SANEX-S	Ditto	Use of acidic S-bearing extractants, for example, synergistic mixture of Cyanex-301 with 2,2-bipyridyl
TALSPEAK	Ditto	**T**rivalent **a**ctinide–**l**anthanide **s**eparation by **p**hosphorus reagent **e**xtraction from **a**queous **k**omplexes. Use of HDEHP as extractant and DRPA as the selective actinide complexing agent
ARTIST	Ditto	**A**mide-based **r**adio-resources **t**reatment with **i**nterim **s**torage of **t**ransuranics. This process is made up of (1) phosphorus-free **b**ranched **a**lkyl **m**ono**a**mides (BAMA) for separation of U and Pu, (2) TOGDA for actinide and lanthanide recovery, and (3) N-donor ligand for actinide–lanthanide separation
SESAME	**S**elective **e**xtraction and **s**eparation of **a**mericium by **m**eans of **e**lectrolysis	Process for separating Am from Cm by oxidation of Am to A (VI), subsequent extraction with TBP for separation from Cm
CSEX	**Cs e**xtraction	Using calix-crown extractants
CCD-PEG	Extraction of Cs and Sr from raffinate	**C**hlorinated **c**obalt **di**carbollide and **p**oly**e**thylene **g**lycol (CCD-PEG) in sulfone-based solvent is planned for extraction of Cs and Sr from UREX raffinate
SREX	**Sr ex**traction	Using dicyclohexano-18-crown-6 ether
GANEX	Uranium extraction + other processes for further separation	A series of five solvent extraction flow sheets that perform the following operations: (1) recovery of Tc and U (UREX); (2) recovery of Cs and Sr (CCD-PEG); (3) recovery of Pu and Np (NPEX); (4) recovery of Am, Cm, and rare earth fission products (TRUEX); and (5) separation of Am and Cm from the rare earth fission products (Cyanex-301)

The major advantages of the pyroprocessing spent fuel are as follows:

- The process is proliferation resistant since Pu is not separated from minor actinides.
- Interim storage of spent nuclear fuel may not be required since the pyroprocessing is capable of handling spent fuels in hot conditions as the process takes place in temperatures greater than 500 degrees Celsius.
- No liquid wastage is generated for disposal. Therefore, waste management becomes easy.
- The process can be adopted for in-line reprocessing at the reactor site.
- This process can accept several forms of fuel such as uranium oxide, carbide, nitride, mixed oxides, and pure heavy metals.
- Very short turnaround time results in cost saving.
- Generation of minimum transuranic waste.

The limitations of the process are requirements of facilities with oxygen- and moisture-free environment, arid construction materials that withstand very high temperature, and highly corrosive molten halide environment.

Reprocessing of Spent Metallic Fuel

Metallic fuels are used in experimental fast breeder reactors with liquid sodium as coolant. Reprocessing of this spent fuel (U–Zr, U–Pu + Zr alloys) is carried on by first chopping them into small pieces, loaded onto an anode basket made of SS, and dissolving them by applying anodic potential in an electrorefining cell. The electrolyte is typically an eutectic of LiCl–KCl at 500 °C. By applying an anodic potential to the stainless steel basket containing the chopped fuels, the pellets are oxidized and dissolved in the molten salt. Dissolved actinides are present as chlorides in the molten salt. Lanthanides in the fission product are converted to lanthanide chlorides and dissolved in the molten salt. Addition of $CdCl_2$ to the LiCl–KCl mixture helps transfer most of the actinides and lanthanides as chlorides in the molten salt bath. Gaseous fission products are out-gased. Undissolved cladding materials and noble fission products will be recovered as solids from the reprocessing cell.

During the electrorefining process, uranium is recovered from the molten salt by application of a constant cathodic current density to a steel cathode in a shape of a cylindrical rod, as shown in Fig. 10. The resultant cathodic potential is just sufficient to electrodeposit only uranium onto the steel cathode. After depositing uranium, when the ratio of plutonium to uranium is greater than 2 (Pu/U $>$ 2), now the electrodeposition process is continued with liquid cadmium as cathode. In this step, plutonium is recovered along with americium (Am) in the form of Pu–xAmxCd6 compound. More than 10 wt% of Pu is collected using this method. A high separation factor between actinides and rare earths within a MClx–LiCl–KCl system has also been reported when liquid bismuth is used as liquid cathode. After the actinide recovery, the molten salt is solidified and scrubbed to remove fission products through a zeolite column.

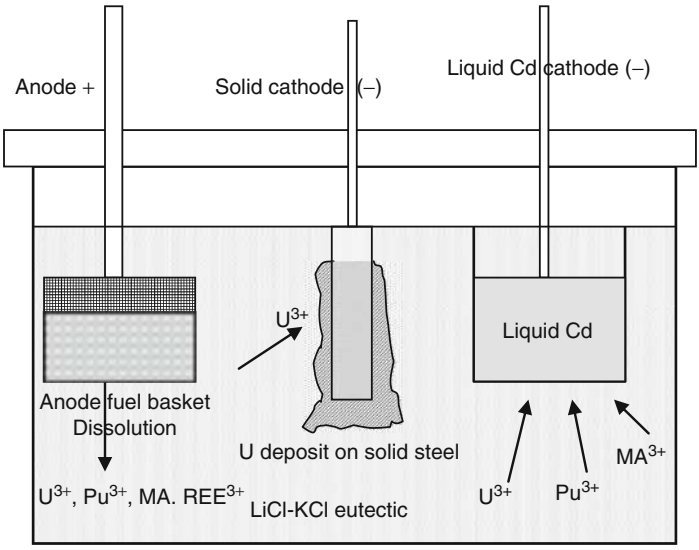

Fig. 10 Schematic arrangement of electrorefining cell for pyroprocessing of spent nuclear fuel in molten LiCl–KCl

Table 4 Redox potentials and activity coefficients of actinides in LiCl–KCl eutectic melt at different temperatures (Roy et al. 1996, pp 2487–2492)

	Potential at different temperatures of LiCl–KCl (V vs. Cl^-/Cl_2) (γ = activity coefficient)			
Actinide system	673 K	723 K	773 K	823 K
U(III)/U	−2.53 ($\gamma = 2 \times 10^{-3}$)	−2.49 ($\gamma = 3.1 \times 10^{-3}$)	−2.45	−2.42
Pu(III)/Pu	−2.845 ($\gamma = 1 \times 10^{-3}$)	−2.808 ($\gamma = 2.3 \times 10^{-3}$)	−2.775 ($\gamma = 4.1 \times 10^{-3}$)	–
Am(II)/Am	–	−2.843	–	–

The redox potentials of actinides and lanthanides are given in Tables 4 and 5, respectively. The lanthanides show more negative potentials than actinides. Among the actinides, uranium shows less negative reduction potential than plutonium and americium. Therefore, under a sufficient cathodic polarization, uranium will be reduced first. Electrodeposition of the uranium on the solid steel cathode decreases the concentration of the uranium (III) ions in the melt. Therefore, the redox potential of U(III) will move to more negative potentials with continuation of the electrorefining process. The electrorefining process is switched to liquid cadmium cathode because of the following reasons: (1) Liquid cadmium as cathode decreases the activity of actinides other than uranium as shown in Table 6; (2) the lower activity coefficient brings the redox potentials of all actinides closer so that these elements can be deposited together; and (3) recovery of Pu along with other minor actinides gives better proliferation resistance.

Table 5 Redox potentials of lanthanides dissolved in LiCl–KCl eutectic at 450 °C

Redox couple	Reduction potential at 450 °C, V vs. Cl^-/Cl_2
La^{3+}/La	−3.1 (Kuznetsov et al. 2005)
Ce^{3+}/Ce	−3.26 (Castrillejo et al. 2002)
Nd^{3+}/Nd	−3.02 (Hamel et al. 2004)
Dy^{3+}/Dy^{2+}	−3.32 (Castrillejo et al. 2005a)
Dy^{2+}/Dy	−3.36 (IAEA 2001)
Gd^{3+}/Gd	−3.15 (Caravaca et al. 2007)
Pr^{3+}/Pr	−3.41 (Castrillejo et al. 2005b)

Table 6 Activity coefficients of actinides in liquid cadmium at 450 °C

Element	Activity coefficient in liquid cadmium at 450 °C
U	15
Np	2.8×10^{-3}
Pu	3.1×10^{-5}
Am	1.1×10^{-4}

The five orders of magnitude smaller activity coefficient of Pu as compared to that of U could be attributed to formation of $PuCd_6$ compounds in the liquid Cd cathode (Shirai et al. 2000). When Pu is electrodeposited onto liquid cadmium cathode, the reduction potential is shifted by 0.3 V in the positive direction as compared to the electrodeposition onto a solid surface. This shift in the positive direction brings the reduction potential of Pu closer to the reduction potential of U(III). The shift in the reduction potential of PU(III) in liquid cadmium cathode can be explained by using the Nernst equation:

$$Pu^{3+} + 3\,e^- \rightarrow Pu \tag{25}$$

$$E^1 = E^0 + \frac{2.3RT}{3F}\log\frac{[Pu^{3+}]}{[\gamma Pu]} \tag{26}$$

Since the value of γ is 3.1×10^{-5} in the liquid cadmium, the redox potential is shifted almost by 0.25 V in the positive direction. Sustained operation of the electrometallurgical reprocessing cell results in accumulation of fission products in the electrolyte and depletion of the uranium ions in the salt. The variation in composition of the electrolyte could potentially alter the operating conditions of the cell because of the significant changes in the thermophysical properties and interfacial electrochemical behavior of the molten salt systems. For better process control, a detailed database of the electrochemical properties of the molten salt system is required. When multiple fission product elements are present in the electrolyte, the reduction behavior of the actinides could significantly be altered because of possible underpotential reduction of lanthanides and slower diffusion kinetics of actinides. This is important for determining limits on the use of the molten salt electrolyte before it needs to be purified or disposed.

Thermodynamic and transport properties of binary LnX_3–MX systems have been investigated widely (Gaune-Escard et al. 1994; Takagi et al. 1997; Gong et al. 2005) where Ln = La, Ce, Pr, Nd, Gd, Tb, and Eu; M = Li, L, Na, Cs, and Rb; and X = F, Cl, I, and Br. Addition of lanthanide chloride to alkali metal chloride results in formation of a variety of stoichiometric compounds such as M_3LnCl_6, MLn_2Cl_7, M_2LnCl_5, $M_3Ln_5Cl_{18}$, etc. Formation of compounds and complexes in the molten salt system affects the electrical conductivity and other thermophysical properties. Stoichiometric compounds show minimum electrical conductivity. Structural disordering increases the number of current carriers and improves the conductivity. The specific electrical conductivity of $LnCl_3$ ranged from 0.11 to 0.4 Sm^{-1} at 1000–1250 K. The activation energy for electrical conduction was about 28–30 kJ/mol. Polymerization of the melt was reported to play a significant role in increasing the electrical conductivity of the molten salt system[2]. Existence of octahedral complex anions of $LnCl_6^{3-}$ in the $LnCl_3$ melts and formation of dimers have been proposed by the following reaction (Ikeda et al. 1988):

$$2LnCl_6^{3-} \rightarrow Ln_2Cl_{11}^{5-} + Cl^- \tag{27}$$

Since free Cl^- ions are produced by the above dimerization reaction, the conductivity of the melt increases. Both polymerization of melt and presence of free chloride ions could affect the activity and mobility of the cations, and in turn the separation kinetics could be altered.

Standard potentials of actinides in LiCl–KCl eutectic salt and separation of the actinides from rare earths by electrorefining have been widely reported by many research groups (Sakamura et al. 1998; Roy et al. 1996; Serrano and Taxil 1999). Recently, Castrillejo and coworkers (2005c) reported electrochemical behavior of a series of lanthanide elements in LiCl–KCl eutectic melt in the temperature range of 400–550 °C.

Cyclic voltammetry results of binary, ternary, and quaternary $LnCl_3$-$(LiCl–KCl)_{Eutectic}$ systems at 500 °C indicate that the incipient potentials of cathodic reduction waves shifted to less negative values with increased additions of lanthanide components. The positive shift in the potential of reduction wave is, in general, associated with two phenomena, viz., (1) under potential deposition, the interaction of reducing species (R) with the substrate (S) is energetically more favorable than the species–species (R-R) interaction, and (2) when two species (A and B) are present in the electrolyte, formation of a compound (A_nB_m) is more favorable by having a negative free energy ($-\Delta G$), and the deposition potential is positively shifted from the redox potential of the more negative species by an amount ($-\Delta G/nF$) (Cohen 1983). The CV results of binary system (single component lanthanide addition) do not show any underpotential deposition of pure lanthanide elements. However, in this investigation, addition of more than one lanthanide chloride in the LiCl–KCl eutectic resulted in considerable shift in the incipient potential of the cathodic wave. According to Hume-Rothery principles, atoms having similar size (size difference <15 %) and electronegativity will preferentially form solid solutions and not compounds. Therefore, elements of lanthanide series will not form compounds

within them but can form solid solutions. The commercially available mischmetal is such an extended solid solution of various lanthanide elements that is separated from naturally occurring monazite mineral. Easy formation of solid solution of lanthanide elements indicates that this is a thermodynamically more favorable process. Therefore, any change in the free energy of formation of solid solution will be reflected in shifting the cathodic wave potential to positive direction with reference to the individual elements' reduction potential.

The other possible reason for the positive shift in the reduction potential of multicomponent lanthanide system could be because of lowered stability of the lanthanide clusters in the molten alkali salt. Generally, solvation of Ln(III) in LiCl–KCl eutectic mixture forms clusters of $[Ln(KCl)_n]^{3+}$ and $[Ln(LiCl)_n]^{3+}$, with the coordination number, n, varying from 4 to 9. The presence of a single lanthanide component in the alkali molten salt results in coordination numbers 6–9. Model calculations of Hazebroucq et al. (2005) indicated that the stable coordination number for Gd (III) was 6 and for La (III) it was 7–8. When multiple lanthanide components are present, the coordination of the solvated clusters is significantly affected and their stability is reduced. Therefore, the positive shift in the reduction potential for multicomponent system could be attributed to the change in stability of the solvated clusters in the molten salt.

Recovery of Rare Earth Elements (REEs) from Fission Products

Rare earth elements are part of strategic materials used in various important energy and defense applications. Separation of rare earth elements from fission products could help reduce the burden on nuclear waste management and reduce the impact on the environment during mining operation of extraction of these strategic materials. Rare earth elements such as neodymium and samarium are used in producing high-strength permanent magnets that are used in various applications such as motors and electronic components. Rare earth oxides are used in laser applications. Almost 38 % of REEs find application as phosphors and solid-state lighting device. Mischmetals are used for manufacturing AB5-type nickel–cobalt hydrides that are used as cathodes for metal hydride batteries and hydrogen storage for electric vehicle applications. Rare earth oxides are extensively used as catalysts for various chemical processes such as methane reformation, fluid cracking, oil refining, and water–gas shift reactions. Furthermore, rare earth oxides are used in fuel cell and high-temperature battery applications as catalysts and membranes. Rare earth elements are used in thermal barrier coatings and strategic alloys as well. Therefore, separation of lanthanide elements from fission products is important from both strategic and environmental points of view.

It is observed that addition of multicomponent lanthanides (more than 5 wt%) to the LiCl–KCl eutectic shifted the reduction potential to less negative values which might hinder the effective separation of actinides from the lanthanides. One possible way of minimizing this effect is to remove the lanthanides as the electrorefining progresses so that accumulation of lanthanide is minimized. Separation of lanthanide can be made possible by using a bipolar cell and a bipolar membrane that has a high diffusion coefficient to lanthanide series. The design of the cell is given in Fig. 11.

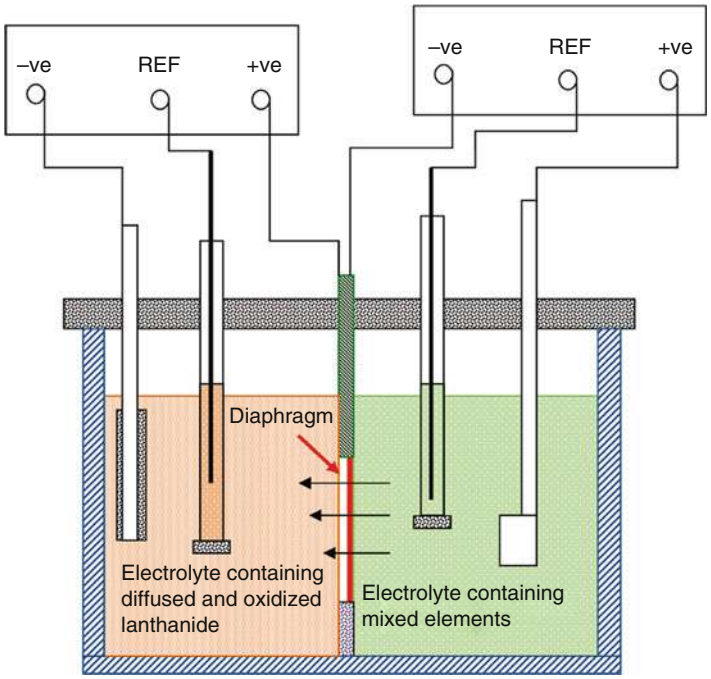

Fig. 11 Schematic of bipolar cell with metal diaphragm that preferentially alloys with select lanthanide(s) and allows diffusion of lanthanide elements to the other side

Working Principle of the Bipolar Cell for Separation of Lanthanides: Figure 11 schematically illustrates the construction of the bipolar cell. Two compartments are connected by a thin metal diaphragm. This metal diaphragm will preferentially alloy with a particular lanthanide element, for example, neodymium. The right-side compartment will contain molten salt of multicomponent additions that needs to be electrolyzed. The diaphragm as a cathode, an inert electrode as an anode, and Ag/AgCl as a reference electrode will complete the electrical circuit. Depending on the applied potential, a particular lanthanide element that has a higher alloying affinity with the diaphragm metal will deposit onto the diaphragm and diffuse out to the left compartment because of a concentration gradient and a small electric field across the diaphragm. In the left compartment, the diaphragm is connected to a positive terminal of another electric circuit. Therefore, depending on the anodic potential applied to the diaphragm, the diffused lanthanide element will dissolve into the electrolyte of the left-side compartment. The oxidized lanthanide species will get reduced at the cathode of the left-side compartment and thus separated from the other species.

The main issue of this design is construction of a stable diaphragm that is thin enough to allow a required flux of the lanthanide. Aluminum diaphragms can be used for separating Nd. Nickel diaphragm also can be used. A thin diaphragm of Ni can be prepared by electroless deposition onto an organic substrate.

Pyroprocessing of Spent Oxide Fuels

Spent nuclear oxide fuels also can be reprocessed using molten salt refining technique as that of metal oxide fuels. The electroreduction technique used for directly reducing uranium oxide to uranium is similar to the technique of the FFC Cambridge process proposed for directly reducing TiO_2 to Ti (Chen et al. 2000). Alternately, the oxide fuels can be reduced by using lithium. The first step in chemical reduction of UO_2 is to convert the material to U_3O_8. Similarly, PuO_2 is also converted to Pu_2O_3 before reacting with lithium. The proposed reactions are

$$U_3O_8 + 16\,Li \rightarrow 3U + 8Li_2O \qquad \Delta G = -871.8\ kJ \tag{28}$$

$$Pu_2O_3 + 6\,Li \rightarrow 2\,Pu + 3\,Li_2O \qquad \Delta G = 18.8\ kJ \tag{29}$$

$$Am_2O_3 + 6\,Li \rightarrow 2\,Am + 3\,Li_2O \qquad \Delta G = 23.18\ kJ \tag{30}$$

Mixed oxide spent fuels can be electrochemically reduced more easily than UO_2 in a LiCl bath at 650 °C. In the uranium oxide electroreduction cell as presently conceived, a platinum (Pt) wire is used as the anode.[1] The Pt wire is slowly etched away as the electrolytic reduction proceeds because of the highly oxidizing conditions and attack by lithium (Li). The cell is operated at 650 °C with a LiCl–Li_2O electrolyte. The overall cell reaction is as follows:

$$UO_2 \rightarrow U\,(\text{cathode}) + O_2 \uparrow (\text{anode}) \tag{31}$$

The Li_2O content varies from 1 to 8 wt% for the Li-assisted chemical reduction of UO_2 by participating in the following reactions:

$$2Li_2O \rightarrow 4Li + O_2 \uparrow \tag{32}$$

$$4Li + UO_2 \rightarrow U + 2Li_2O \tag{33}$$

Although the reduction of Li_2O to Li increases the reduction rate of the spent oxide fuel, the Li diffuses through the salt electrolyte and attacks Pt, thereby degrading the anode. To decrease degradation of the Pt anode, a secondary electric circuit is provided to oxidize the Li to Li(I). Provision of a more refractory anode that withstands the highly oxidizing conditions and attack by Li would greatly simplify operation of the cell.

Therefore, finding an alternative anode material is vital before the electrolytic cell is put into production. Platinum metal is highly resistant to oxidation under normal conditions, but not under high anodic potential at 650 °C in a corrosive Li containing molten chloride electrolyte. Several materials are worthy of consideration as inert anodes. Various nickel-based super alloys such as Haynes 263, Haynes 75, Inconel 718, Inconel X-750, Inconel 713 LC, Inconel MA 754, Nimonic 80A, and Nimonic 90 have been investigated by KAERI.[2] It was noted that increasing the chrome (Cr) contents of the above alloy increased the stress on the surface layer and

increased the corrosion rate. Elements such as aluminum (Al) and titanium (Ti) improved the corrosion resistance by forming a more protective layer. It should be pointed out that these test conditions did not include metallic Li in the electrolyte. The solubility of Li in LiCl was more than 0.6 mol%. Oxidizing environment was created by purging argon + 10 % O_2 gas into LiCl + 3 wt% Li_2O electrolyte at 650 °C. Boron-doped diamond as a potential anode material has also been reported (Storm van Leeuwen and Smith 2005).

Inert anode material for electrolytic reduction of the spent fuel in LiCl + Li_2O electrolyte should satisfy the following requirements:

- The material should have comparable electrical conductivity to that of platinum.
- The material should not be consumed by the electrochemical/chemical reaction so that the dimensions remain stable throughout the electrolytic process without altering the cell voltage significantly.
- The material should be resistant to corrosion by lithium in the molten salt.
- The protective oxide layer of the material must not dissolve in the basic flux of Li_2O present in the molten salt.
- The material must be stable in the highly oxidizing potentials encountered at ~650 °C in LiCl + Li_2O electrolyte.
- The material should possess sufficient mechanical properties (such as creep strength and fracture toughness) in order to withstand thermal shock and service-related stresses.

The material fulfilling the above requirements can be a metal or an alloy with high electronic conductivity. The material can also be a composite (cermet) or made of metal/alloy coated with external oxide/carbide/nitride. This article describes the investigation of inert anode materials for use in an electrochemical cell by simulating the corrosive environment of the spent nuclear fuels with LiCl and LiCl + Li_2O molten mixtures.

Containment of Radionuclide

Development of next-generation nuclear waste forms capable of reliable and safe immobilization of radionuclide is a significant challenge that limits the imminent nuclear renaissance to meet the energy demands. Among the nuclear wastes, Cs and Sr are considered critical because of the high activities of ^{134}Cs (half-life, 2 years), ^{137}Cs (half-life, 30.17 years), and ^{90}Sr (half-life, 28.8 years). Removal of these isotopes will significantly reduce the radioactive load on a geological repository (Wigeland et al. 2006). These radionuclides are separated from the low-level nuclear wastes using an ion-exchange process and combined with high-level waste fraction and then immobilized in a glass or ceramic form. The following transmutation reactions take place during radioactive decay of ^{137}Cs and ^{90}Sr:

$$^{137}\mathrm{Cs} \rightarrow ^{137}{*}\,\mathrm{Ba} + \beta(\text{half life}: 30.17\ \text{years}) \rightarrow ^{137}\mathrm{Ba} + \gamma(2.55\ \text{min}) \quad (34)$$

$$^{90}\mathrm{Sr} \rightarrow ^{90}\mathrm{Y} + \beta(\text{half life}: 30.17\ \text{years}) \rightarrow ^{90}\mathrm{Zr} + \beta(64.1\ \text{h}) \quad (35)$$

The decay of ^{137}Cs emits beta particles with energy ranging from 0.089 to 1.454 MeV and gamma rays with 0.475–1.168 MeV energy (Lide 1997). The beta and gamma decays of the radionuclides could detrimentally affect the stability of the host material. Furthermore, formation of the transmuted elements in the host materials alters the electronic structure and chemical composition of the waste form. Most of the investigations so far have concentrated on the effect of radiation damage such as swelling, bubble formation, and leachability on the structural stability of the waste form. Very little attention has been paid on the effect of electronic structure changes during the decay of constituent radioisotopes in the waste form. For example, when the Cs^+ transmutes to $Ba^{2+} + e^-(\beta) + \gamma$, the single valent Cs is replaced with divalent Ba. Therefore, the host material should be able to accommodate the valence and associated ionic radius changes. Recently, Jiang et al. (2009) from LANL reported for the first time the modeling of the chemical evolution of CsCl to BaCl due to radioactive decay using ab initio calculations. In the modeling calculations, these authors considered CsCl crystal as a representative waste form.

Crystalline silicotitanate (CST) and (Ba,Cs) hollandite ceramics are considered potential candidates for the specific immobilization of Cs. The sodium silicotitanate ($Na_2SiTi_2O_7$. $7H_2O$) is ion-exchanged to form hydrogen crystalline silicotitanate ($H_2SiTi_2O_7.1.5H_2O$). This material effectively sequesters both Cs and Sr (Celestian et al. 2008). The hollandite for Cs sequestration has a formula of $(Ba_xCs_y)(M_{2x+y}Ti_{8-2x-y}O_{16})$, where M is trivalent cations such as Fe^{3+}, Al^{3+}, and Ti^{3+} and $x + y < 2$. Celestian et al.[4] showed that selective ion exchange of Cs in the H-crystalline silicotitanate (H-CST) is achieved by repulsive forces between the Cs^+ and H_2O dipole that lead to a series of events at the molecular-scale level such as rotation of H_2O by 159° followed by bending away of hydroxyl group by 0.055 nm displacement which makes TiO_6 to rotate about 5.6°. The rotation of the TiO_6 columns results in a structural transformation that changes the initial $P4_2/mbc$ space group of the H-CST to $P4_2/mcm$ of Cs-CST. During this transformation, an initial elliptical eight-membered ring (8MR) channel becomes a circular one that opens up a new site for Cs^+ occupancy at the center of the channel (known as Cs1 site) in addition to the initial Cs2 site which is outside the 8MR window. A minimum occupancy of 0.15 at the Cs2 site is required to initiate the structural transformation and formation of the new Cs1 sites. The above hypothesis for the selective ion-exchange mechanism of Cs in the H-CST material indicates that the interaction of Cs^+ and H_2O dipole/hydroxyl groups is very important not only for the site selectivity but also for the stability of the Cs-CST structure. It is not clear how the radioactive transmutation of Cs^+ to Ba^{2+} will affect the stability of the Cs-CST structure over an extended period of time. In case of the hollandite, structural transformation from tetragonal to monoclinic at

room temperature is reported with increased Ba occupancy in $Ba_xFe_{2x}Ti_{8-2x}O_{16}$ (Carter 2004).

Nuclear Waste Management

All types of radioactive waste can be disposed of if the disposal method provides protection for the health and safety of people and the environment. Members of the European Union (EU) produce about 7000 m^3 of high-level waste from 143 nuclear power plants. Disposal in deep underground engineered facilities is considered the best solution for managing high-level and long-lived radioactive wastes. High-level waste is mixed with glass and vitrified. The vitrified waste is stored for 30–50 years and allowed to cool. After cooling, the waste is placed in an iron shell container. The iron container is placed inside a copper shell, which is evacuated and backfilled with an inert gas and sealed. The copper canister is buried in a deep permanent repository with engineered barriers. Swedish and Finnish nuclear waste repository models are based on copper canisters, since copper is considered to be stable in clay environments devoid of oxygen. Several countries plan to use this approach of permanent storage of the high-level radioactive waste.

When the amounts of radioactive waste in surface storage increase, the sustainability of storage in the long term and the associated safety and security implications are of concern. Geological disposal promises to provide containment and isolation of radioactive waste from the human environment for the very long periods required. Safety concerns due to possible human intrusion into the waste are very much reduced as compared to surface storage, owing mainly to the significant depths under the surface at which geological repositories will be located. In the USA, long-term storage of nuclear waste in Yucca Mountain was considered an option. The Yucca Mountain repository was based on different layers of engineered barriers to nuclear waste storage such as a 300 m deep geological barrier, a Ti-alloy drip shield to prevent water seeping through rock faults falling on the canister surface, an outer wall of canister made of Ni–22Cr–13Mo–3Fe alloy, and a thicker inner wall of canister made of type 304 stainless steel. Recently the US Department of Energy filed a motion with the Nuclear Regulatory Commission to withdraw the license application for a high-level nuclear waste repository at Yucca Mountain. Therefore, the spent fuel assemblies from the nuclear power plants will be stored on-site in the utility facilities for longer time.

Future Direction

Meltdown of the nuclear core is considered the severest form of nuclear accident, since the probability of release of radioactivity is high in this condition. In order to prevent core meltdown, Western nuclear power plants are provided with two or four emergency core cooling systems (ECCS). This system consists of

high-pressure coolant injection system, depressurization system, low-pressure coolant injection system, core spray system, containment spray system, isolation cooling system, and emergency electrical system. The emergency electrical system consists of diesel generators, motor generator flywheels, and batteries. In case of an emergency situation, the control rods are moved completely inside the reactor core and the power is reduced considerably. Any loss of coolant will trigger the ECCS. There are two or four ECCS in a reactor to ensure that at least one will respond and meltdown will be avoided. However, if all ECCS fail as in the case of Fukushima nuclear plants in March 11, 2011, meltdown of the core is initiated. It should be noted that the Fukushima nuclear disaster is not due to operator error or gross violation of safety regulations unlike the accidents reported in the Three Mile Island or Chernobyl. The plant suffered a major damage because of an earthquake of 9.0 in a Richter scale. The reactors were designed for a maximum ground acceleration of 0.18 g (1.74 m/s^2), whereas the earthquake caused a ground acceleration of 0.35 g (3.43 m/s^2). Therefore, the reactors were shut down automatically. This would have triggered the insertion of control rods and ECCS. However, a tsunami of 20 m tall waves followed the earthquake and flooded the power plant. The plant was designed only for a tsunami of 5.7 m. The flooding situation knocked down the emergency power and prevented any assistance reaching the power plant. The batteries provided in the emergency electrical system were not adequate to pump the required volume of coolant to the core. The power required for running coolant pumps or other electrical systems triggered a cascade of accidents in the Fukushima nuclear plant that released radioactive gases into the environment causing displacement of several thousand people living around the power plant.

In order to cool the core, several measures were taken by the Fukushima power plant officials. Adding water to the degraded core can result in several consequences such as (Kuan and Hanson 1991):

- Hydrogen production
- Change in the geometry of core
- Pressurization of the system due to high rate of steam generation
- Steam explosion
- Re-criticality of the core when enough neutron absorbers are not present

The core damage occurs in several stages as explained below (Cookson and Was 1995):

Pre-damage Stage: If the core is not fully immersed in water, then the upper portion of the core will be exposed to steam in the reactor. Now the core will start to heat up at a rate of 0.3–1 °C/s.

Ballooning and Bursting of Fuel Rods: When the temperature reaches > 1100 K, the Zircaloy cladding will balloon up because of the rapid heating and burst. This altered geometry of the fuel rod will affect the geometry of the coolant flow channels in the core. Some locations will have restricted access to the coolant

because of the ballooning effect. If sufficient water is added, core damage can be suppressed at this stage.

Rapid Oxidation: This stage is initiated at 1500 K. When Zircaloy reacts with steam, hydrogen is produced as given by the following reaction and a large amount of heat is released:

$$Zr + 2H_2O \rightarrow ZrO_2 + 4H_2 + 6.5\ MJ/kg\ of\ Zr$$

If water is added at sufficient rate and volume, the core will be quenched and progression of damage could be stopped. If the water is not sufficient or the rate of heat removal is less than the rate of heat generated, the damage propagates to the next stage.

Debris Bed Formation: When the temperature reaches 1700 K, the molten control materials will flow to the lower part of the core (which is submerged in the water) where the temperature is low and solidify. At 2150 K melting of Zircaloy occurs. Molten Zircaloy along with dissolved UO_2 may flow downward and solidify at the lower portion of the core. These solidified debris will form a cohesive bed leading to restricted flow of coolant in the lower region of the core.

Relocation of Lower Plenum: When molten core materials (which are experiencing 1500–2150 K) fall to the lower region of the core which is at ~550 K, steam is generated rapidly leading to occurrence of steam explosion. Furthermore, this steam oxidizes any unoxidized molten Zircaloy which generates hydrogen at a faster rate. These reactions lead to overpressurization of the system. Re-criticality also may occur in the relocated core debris when the control materials are not present in the required concentration.

Understanding of the sequence of core damage is necessary to design preventive measures of core meltdown. Future work on nuclear safety should concentrate on a reliable ECCS that can be operated even in the worst-case scenario as experienced in the Tohoku Tsunami. Future work also should focus on a reliable system, with public acceptance, for a long-term safe storage of nuclear spent fuel.

Future Fuel Cladding Materials: Zr–Sn alloys such as Zircaloy-2 and Zircaloy-4 are currently used as fuel cladding tubes in the current light water reactors because of their low neutron absorption cross sections for thermal neutrons, reasonable creep resistance, and corrosion resistance in high-temperature high-pressure water (Wray and Marra 2011). These cladding materials perform well under normal operating conditions and give a reasonable safety margin under design basis accident (DBA) scenarios. However, under beyond design basis accident (BDBA) conditions, such as a loss-of-coolant accident event that occurred in the Fukushima Daiichi power plant, zirconium-based cladding materials undergo severe degradation because the peak clad temperature (PCT) exceeds the design limit of 1204 °C (Charit and Murty 2008). When the Zr-alloy cladding is exposed to high-temperature steam environment, an exothermic Zr-steam reaction generates more heat than that of radioactive decay which in turn oxidizes the entire cladding material. The current US design regulation (10 code of Federal Regulation 50.46) limits the equivalent cladding reacted (ECR)

thickness to 17 % of the initial cladding thickness under DBA conditions. Furthermore, copious amount of hydrogen is generated during the steam oxidation reaction of zirconium that may result in explosion. Therefore, one of the goals of the Fuel Cycle R&D program is to develop high-performance LWR fuel and cladding materials that are resistant against different severe accident scenarios. In addition to the enhanced safety margin, the next-generation fuel clads should have the required properties to perform under high-burnup operating conditions (> 40 MWd/kg of U). At a high level of burnup, high fission gas pressures are realized along with higher creep deformation. In addition, neutron damage to the cladding makes it more susceptible to failure. There could be situations of fuel cladding chemical interaction (FCCI) involving fuel constituent redistribution (Carmack et al. 2009). Hence, improved cladding and matrix materials for pin-type and dispersion-type fuels with low FCCI potential, high strength, radiation tolerance, and high-temperature oxidation resistance are highly desirable for accident-tolerant fuel cladding materials.

Recently, renewed interest has emerged in aluminum-bearing ferritic alloys despite the neutronic penalty in LWR applications. For example, the APMT alloy (nominal composition, Fe-22 Cr-5 Al-3 Mo- < 0.05C, wt%) is being considered for its extreme high-temperature oxidation resistance even beyond 1200 °C due to the protective nature of alumina-based scale (Terrani et al. 2013). This alloy is conventionally used in high-temperature furnace elements. While the alloy has shown promise in terms of oxidation resistance at elevated temperatures, this alloy has not been adequately assessed for advanced fuel cladding applications. Furthermore, addition of "reactive" elements such as Y, Hf, Zr, etc., has been considered to improve the oxidation resistance of alumina-forming alloys (Guo et al. 2014). The details of growth stresses during steam oxidation of alumina layers and the effect of reactive elements on the diffusion and electronic behavior of the oxide layers are not studied in detail. Such an understanding is pertinent for the design of new FeCrAlRE cladding materials that show improved LOCA resistance. In addition to FeCrAl alloys, other materials such as Mo (Nelson et al. 2013) and ferritic ODS alloys (Klueh et al. 2005) are also actively investigated for fuel cladding applications. The design of the new cladding alloy will be based on the following considerations (Knief 1992; Pint et al. 2013):

- The target mechanical properties under unirradiated conditions:
  - The tensile strength at room temperature will be greater than 600 MPa.
  - The yield strength at 1200 °C will be about 100 MPa (versus ~50 MPa of the Zr-4 alloy at 800 °C).
  - A 100 h creep rupture strength at 1200 °C will be about 50 MPa (versus 5 MPa at 800 °C of the Zr-4 alloy).
  - Elastic modulus ~100 GPa at 1200 °C.
- Understanding irradiation effects:
  - Formation of dislocation loops and α′ phase; phase stability.
  - Fracture toughness after irradiation to 20 dpa level is ~50 MPa√m (compared to 12–15 MPa√m of Zr alloy); dimensional changes <1 % at 20 dpa.

- Understanding of corrosion behavior:
  - Cr-rich oxide layer that is expected to impart resistance to aqueous corrosion
  - Al_2O_3 layers associated with the high-temperature oxidation resistance (>600 °C)
  - Effect of reactive elements (actinides, Zr, Hf, Sc, etc.) on the diffusivity of Al^{3+}, $V_{Al}{}^{3-}$ $V_O{}^{2+}$, and O^{2-} and adhesion of oxide layer
  - Understanding the origin of oxide growth stresses during steam oxidation, electronic properties, and the stability of oxide layer under LOCA condition

It is well documented (Lim et al. 2013) that higher concentration of Cr in ferritic steel leads to Cr-rich α′ and σ phase formation during thermal aging between 350 °C and 550 °C. Since the normal operating temperature of the LWR falls in the embrittling temperature range, the effect of spinodal decomposition should be considered. It is observed that Al partitions to Fe-α phase and the partitioning factor increases with the aging time in Fe–20Cr–5Al ODS alloy (Capdevila et al. 2008). Under the LOCA condition, the α′ phase would be dissolved in the matrix, and therefore, spinodal decomposition may not be an issue. Since the formation of α′ does not affect the distribution of scale-forming Al, high-temperature oxidation resistance of the alloy may not be impaired by the embrittlement aging at low temperatures. However, ductility will be severely affected. The low-temperature (up to ~350 °C) corrosion resistance of the FeCrAlRE alloys will be imparted by a Cr-rich oxide layer in the high-temperature high-pressure water under normal operating conditions. The required oxidation resistance under LOCA conditions could be attributed to the formation of an impervious α-Al_2O_3 film which is stable at temperatures above 1040 °C. Transient aluminum oxides such as γ-Al_2O_3 and δ or θ-Al_2O_3 are stable at temperature ranges 500–800 °C and 800–1040 °C, respectively. The transformation of transient oxides into α-Al_2O_3 is accompanied by a 10 % volume contraction that results in accumulation of tensile stresses. If the oxide scale contains multiple oxide phases, the mismatch in the coefficient of thermal expansion again leads to build up of stresses. When starvation of oxygen occurs during high-temperature exposure, generation of oxygen vacancies ($V_O{}^{2+}$) is expected at the expense of oxygen sublattice ($O_O{}^x$) following the reaction:

$$O_O{}^x \rightarrow \tfrac{1}{2}\, O_2 + V_O{}^{2+} + 2e^- \tag{36}$$

Similarly, under oxygen-rich conditions, aluminum ion vacancies could be generated by incorporating the oxygen atoms into the lattice from the adsorbed oxygen molecule following the reaction:

$$\tfrac{1}{2}\, O_2 \rightarrow O_O{}^x + 2/3\, V_{Al}{}^{3-} + 2h^+ \tag{37}$$

These cation and anion vacancies are important in the formation of oxide layer through the reaction

$$2V_{Al}{}^{3-} + 3V_O{}^{2+} + 2Al_{Al}{}^x + 3O_O{}^x \rightarrow Al_2O_3 \tag{38}$$

However, when the concentration of the vacancies reaches a nonequilibrium condition, the stability of the oxide layer is affected by forming porosity either at the oxide/atmosphere interface due to condensation of oxygen vacancies or at the oxide/metal interface due to condensation of cation vacancies. Since grain boundaries act as short circuit diffusion paths for the transportation of atoms and ions, the presence of aliovalent ions in the oxide layer and reactive elements at the grain boundaries of the alloy could significantly alter the diffusivities of both oxygen and aluminum species. Hindering the diffusion of species that form an oxide will significantly decrease the oxidation rate. In addition to affecting the diffusivities, the RE can also modify the electronic states of the oxide layer and thereby affect the oxidation kinetics (Heuer et al. 2011).

Abstract

CO_2 capture and geological storage (CCS) is one of the most promising technologies to reduce greenhouse gas emissions and mitigate climate change in a fossil fuel-dependent world. If fully implemented, CCS may contribute to reduce 20 % of global emissions from fossil fuels by 2050 and 55 % by the end of this century. The complete CCS chain consists of capturing CO_2 from large stationary sources such as coal-fired power plants and heavy industries and transport and store it in appropriate geological reservoirs such as petroleum fields, saline aquifers, and coal seams, therefore returning carbon emitted from fossil fuels (as CO_2) back to geological sinks.

Recent studies have shown that geological reservoirs can safely store for many centuries the entire greenhouse gas (GHG) global emissions. In this chapter, we present a comprehensive summary of the latest advances in CCS research and technologies that can be used to store significant quantities of CO_2 for geological periods of time and therefore considerably contribute to GHG emission reduction.

Introduction

CO_2 capture and geological storage (CCGS or simply CCS) is the integrated process where carbon dioxide is captured and separated at stationary sources, transported to an adequate storage site, and injected into the porous space of deep

underground rock formations. Given the world's current dependence on fossil fuels, which is expected to last for no less than a century, the storage of carbon dioxide in geological reservoirs is a recognized viable mitigation option, with potential to be applied in a worldwide scale and therefore having a measurable impact on the reduction of the escalating emissions of greenhouse gases. The latest assessment report from the Intergovernmental Panel on Climate Change (IPCC), published in 2014, recognizes the importance of CCS technologies to reduce the lifecycle of greenhouse gas emissions from fossil fuel power plants, in order to keep the global temperature rise below 2 °C by 2100 (IPCC 2014). Since the increase in carbon dioxide concentration in the atmosphere is the outcome of continuous burning of fossil fuels extracted from the subsurface, the underlying motto of CO_2 geological storage is to "put the carbon back to the ground," hopefully reestablishing the equilibrium of this unbalanced carbon cycle (Greenhouse Gas R&D Programme 2001).

It is common ground that the reduction and stabilization of greenhouse gas emissions can only be achieved through a portfolio of solutions, including renewable sources, nuclear power, improved energy efficiency and fuel switching at power generation and end-use level, and carbon capture and storage, with increasing contributions at different levels (Pacala and Socolow 2004; IPCC 2005; IEA 2008a). From a recent assessment from the International Energy Agency (IEA) published in 2012, CCS is expected to contribute with at least one-sixth of the emission reduction (14 % of the cumulative emission reduction between 2015 and 2050) in a scenario where the global temperature rise is limited to 2 °C by 2050 (Fig. 1) (IEA 2012). Scenarios that exclude CCS would result in a cost increase to achieve emission stabilization in 2050 by at least 40 % (IEA 2012).

CO_2 sources that are suitable for CCS projects must be large stationary facilities, usually venting more than 100,000 metric tons of CO_2 per year (IPCC 2005). These usually include power-generation facilities (e.g., gas- or coal-fired power plants), natural gas processing plants, refineries, ethylene plants, hydrogen-producing plants from CH_4 reform and coal gasification, and cement and steel industries, among others. Depending on the type of source, costs, and technology maturity, CO_2 can be captured and separated from other gases using post-combustion, precombustion, or oxy-combustion technological routes. These systems will be further explained in detail in this chapter. Following separation, CO_2 may be transported using pipelines and/or ships to a storage site, where it is compressed and injected in the subsurface through wells (Rubin 2008). Transportation distances are an important factor to be evaluated in CCS projects, due to the elevated cost of pipelines. Most countries that are willing to develop CCS projects have been carrying out surveys to map their large stationary sources of CO_2 and the potential geological storage sites. This will provide an optimized source-sink match, in order to reduce transportation of CO_2 from the capture source to storage site.

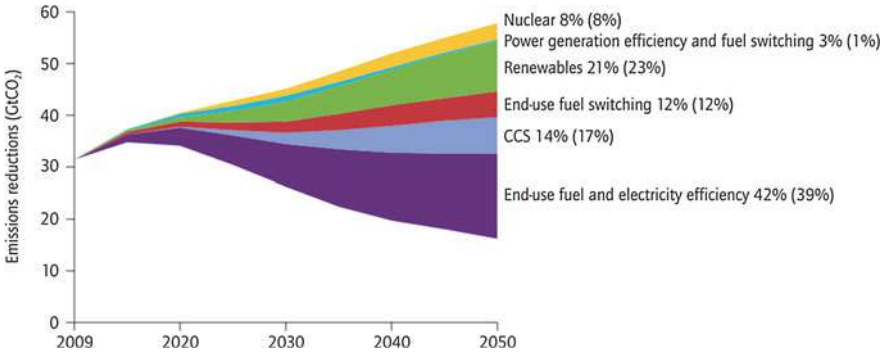

Fig. 1 CO_2 emission reduction scenario from the IEA for the twenty-first century: lower limit of the graphic corresponds to the 2DS scenario – reduction of CO_2 emissions to approximately half of the emissions in 2009, in order to limit the global temperature rise to 2 °C by 2050 – relative to the baseline 6DS scenario, or "business as usual" (upper limit), where global temperature could rise up to 6 °C. *IEA Energy Technology Perspectives* © OECD/IEA, 2012 (IEA 2012)

The most appropriate geological reservoirs for CO_2 storage are sedimentary units such as oil and gas fields, deep saline aquifers, and coal deposits. These types of formations have large storage capacity in their porous space and are evenly distributed worldwide (Bachu 2003). Estimated capacities for oil and gas fields range between 675 and 900 billion metric tons (Gt) of CO_2; for saline aquifers between 1,000 and 10,000 Gt; and coal beds between 3 and 200 Gt (IPCC 2005). These estimations are still highly uncertain, as they depend on selection criteria for validating a potential storage site (which may vary significantly for each assessment) and the methodology employed to calculate the effective pore volume available for storage (Bradshaw et al. 2007; Bachu et al. 2007). These methods and criteria will be further discussed in this chapter. Nevertheless, it is worth noting that even considering the lowest capacity estimations, storage volume of geological reservoirs is enough to contain 10 times the accumulated global emissions until 2050 (ca. 155 Gt CO_2) (IEA 2009).

CCS in geological media is in its early stages of worldwide deployment. Currently (as of 2015), there are 13 large-scale CCS projects in operation, although only three of those are dedicated geological storage operations. In the other projects, CO_2 is used for enhanced oil recovery purposes (EOR, see following sections), with questionable emission reduction results. Nine projects are under construction and expected to be operational in 2016 (IEA 2013). An up-to-date status of CCS projects worldwide (operating and planned) can be found on the Global CCS Institute (GCCSI) website (Large Scale CCS Projects 2015).

The first and most notorious large-scale CCS project was started in 1996, in the Sleipner gas field in the North Sea, operated by Norway-based oil company Statoil. In order to avoid a government-imposed tax for offshore greenhouse gas emissions,

Statoil started to strip CO_2 from the natural gas extracted in this field, reinjecting it in the Utsira formation, a saline aquifer 800 m below the sea floor and hundreds of meters above the Sleipner gas field. Approximately 1 million metric tons (Mt) of CO_2 are injected in this formation each year. The project is still ongoing, and its success has been a benchmark for CCS development (Korbøl and Kaddour 1995; Torp and Gale 2004). In 2004, Statoil and BP (British Petroleum) started a similar project in the In Salah gas field, in Algeria, reinjecting stripped CO_2 from natural gas below the gas-water contact in the same formation, 1800 m below the surface. The injection was suspended in 2011, and future operations are under review (IEA 2008a). The Snøhvit natural gas field in the Barents Sea is another asset operated by Statoil with dedicated geological storage. The company started capturing CO_2 from the produced gas in 2008 and injecting it offshore, through a submarine pipeline approximately 160 km from the Norwegian coast. In this project, 0.7 Mt of CO_2 are captured and stored each year (Snøhvit 2015). One of the most relevant CO_2-EOR projects is the Weyburn-Midale, a transnational operation (USA/Canada) where CO_2 is captured at the Great Plains Synfuels Plant and transported through a 320 km pipeline to the city of Weyburn, in the province of Saskatchewan (Canada), where it is injected into the mature Weyburn-Midale oil field for enhanced oil recovery (Greenhouse Gas R&D Programme 2004). In 2014, an important milestone was reached in CCS development – the first demonstration project in the power sector went operational, with the inauguration of the new capture plant in the Boundary Dam coal-fired power station in Canada. The plant captures CO_2 using a post-combustion process (see next section), which is transported and injected in the previously mentioned Weyburn oil field, supplementing the existing supply from the Great Plains plant. When fully operational, the project is expected to capture and store one million tons of CO_2 per year (Boundary Dam Carbon Capture Project 2015).

In total, the existing 13 CCS projects presently (2014) inject more than 27 million tons of CO_2 per year (Large Scale CCS Projects 2015). Current global emissions of CO_2 amount to *ca.* 36 *billion* metric tons per year (data from 2013), of which ca. 60 % (22 Gt) come from large-scale stationary sources (Le Quéré et al. 2014). This means that approximately 800 times the current storage ratio will be necessary to deal with the present emissions. From these numbers it would appear to be an overwhelming task, but the deployment of CCS projects, both in commercial or demonstration scale, has been steadily increasing in number in the past years, as well as the injection rates.

The aim of this chapter is to present an overview of the main technologies and processes employed to capture and separate CO_2 from stationary sources. Subsequently, storage options will be presented in detail, describing the main reservoirs and the methods employed to estimate their volumetric capacity. Safety issues and potential risks for human health and the environment derived from CO_2 storage will also be covered. The trapping mechanisms of CO_2 in a reservoir and the methods employed to investigate and monitor its interaction with the reservoir are described next. The last section will discuss the current knowledge gaps and requirements in

CCS research that still need to be addressed in order to achieve the expected goals in CO_2 emission reduction perspectives.

CO_2 Capture

CO_2 capture from industrial processes is well known and in use in different applications such as natural gas processing and chemical production (Markewitz et al. 2012). The separated CO_2 is however vented to the atmosphere, as, for example, in natural gas processing. The main purpose of CO_2 capture applied to geological storage is to produce a concentrated CO_2 stream (normally >90 %) to transport and inject in an adequate site.

To obtain CO_2 for storage purposes, it is necessary to separate this gas from a mixture of gases and pressurize it to permit transport and storage, requiring energy. There is currently no mature process for removing CO_2 from large sources, as, for example, power plants (Markewitz et al. 2012; Li et al. 2013). This process adds cost and reduces overall energy efficiency to no less than 25 %, e.g., in a coal-fired power plant, depending on the efficiency of the facility (IEA 2008b). With the current typical amine separation process, a cost of ca. 80 % in the electricity will be added in a new pulverized coal plant and ca. 35 % for a new advanced gasification power plant (Li et al. 2013).

CO_2 capture systems can be divided in three main technological routes, depending on the technology used and its applications (Fig. 2). The following sections will describe each of these systems in more detail.

Post-combustion System

In post-combustion, CO_2 is removed from flue gas, separating CO_2 from conventional diluted flue gas stream (N_2, O_2, H_2O, NO_x, and SO_x). The latter two are produced by combustion of fossil fuel or biomass, and their concentration also must be reduced to avoid solvent degradation (Blomen et al. 2009; Feron 2010; Kothandaraman et al. 2009). In this process, air is used for combustion, resulting in flue gas at nearly atmospheric pressure with a low CO_2 concentration (3–15 % by volume) (IPCC 2005; Figueroa et al. 2008; Yang et al. 2008). Different techniques can be used to capture CO_2 from post-combustion flue gas, such as absorption by a chemical sorbent, separation by membranes, adsorption in solids, and cryogenic separation. Absorption technology, using ammonia-based solvents such as monoethanolamine (MEA), plays a dominant role in the present and probably will continue to do so in the near future (IEA 2008b; Blomen et al. 2009; Zhao et al. 2008). Conventional aqueous amine process is a high-energy intensive approach, and their use for CO_2 capture will decrease power plant efficiency, so the improvement of known technologies and the development of new ones are imperative for the success of post-combustion capture processes (Bara et al. 2009a).

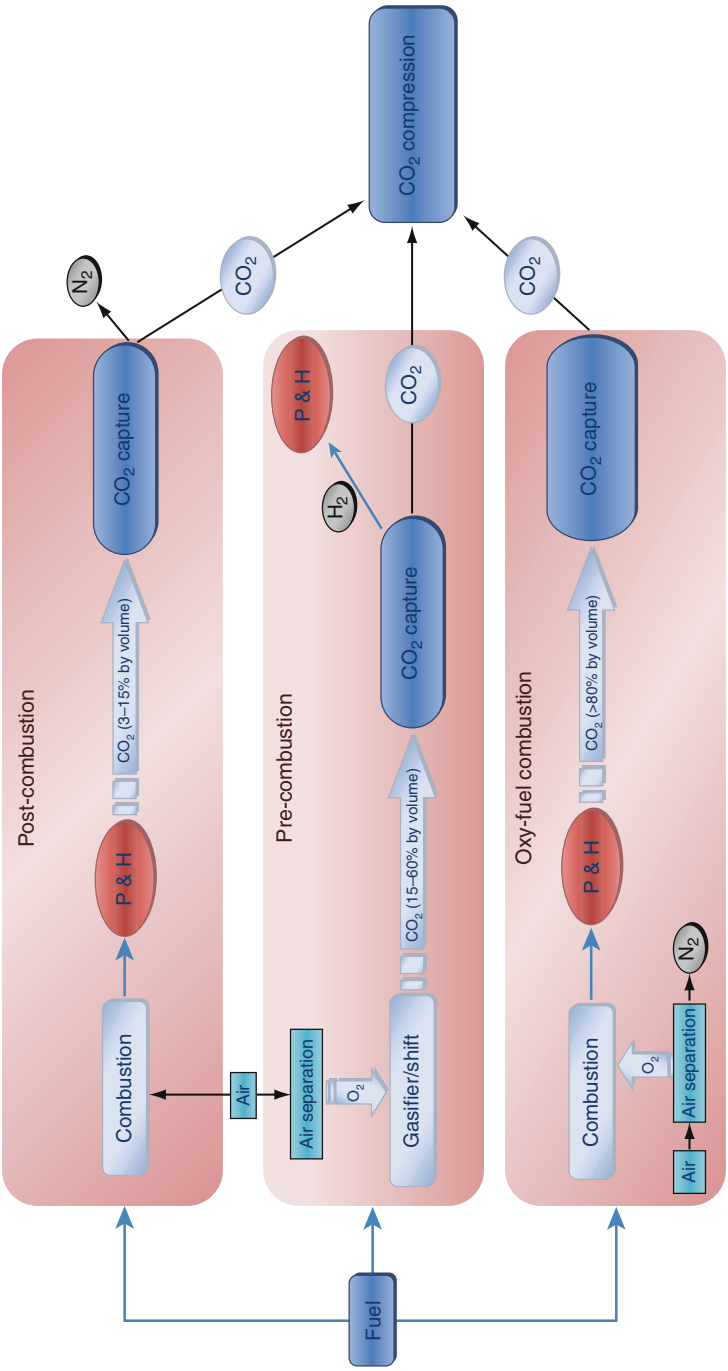

Fig. 2 Diagram illustrating CO_2 capture routes in power generation using fossil fuels (P&H: power and heat)

Precombustion System

In the precombustion system, CO_2 is separated from H_2, which is used as a fuel. Initially, coal, biomass, or natural gas is reacted with steam or oxygen in a gasification process to decompose the fuel in synthesis gas (*syngas*, mainly composed of CO + H_2) which is reacted in a water-gas shift reactor producing CO_2 and more H_2 (Blomen et al. 2009; Kanniche et al. 2010). The shift conversion produces a stream with a high CO_2 concentration (15–60 % by volume), resulting in higher partial pressure of CO_2 making it easier to separate, when compared to the post-combustion system, allowing the use of different solvents with lower regeneration energy requirements.

CO_2 can be separated by a physical or a physical/chemical absorption process, which is the most utilized technology. Membrane and solid sorbents can also be used, as well as cryogenic separation (IPCC 2005; Blomen et al. 2009). The disadvantage of precombustion methods is the total capital costs of the generating facility, which is very high (Sabouni et al. 2014).

Oxy-combustion System

In oxy-combustion, the oxygen is initially separated from air in an air separation unit, commonly through low-temperature cryogenic separation, and used in fuel combustion, producing a flue gas with a high CO_2 concentration (>80 %). Reacting fuel with almost pure oxygen results in a high-temperature flue gas containing mainly CO_2 and water that can be recycled to the burner to control the temperature (IPCC 2005; Blomen et al. 2009). The main advantage of oxy-combustion is the significant increase of the CO_2 partial pressure (Kanniche et al. 2010). CO_2 can be easily separated from the flue gas, for example, by cryogenic methods.

Chemical Looping

The chemical looping system can be considered as a variant of oxy-combustion system (IEA 2008b). In this process, oxygen is supplied for the fuel combustion/oxidation without direct contact with air, using a metal oxide as an oxygen carrier (Abad et al. 2006; Corbella et al. 2005; De Diego et al. 2005). The flue gas contains only water and CO_2. Water may be condensed and CO_2 compressed for transport and storage (Fig. 3).

Technological Options for CO_2 Separation

In the whole carbon capture and storage-integrated process, the CO_2 separation stage contributes with 70–80 % of the costs, so the possibility of reducing operating costs

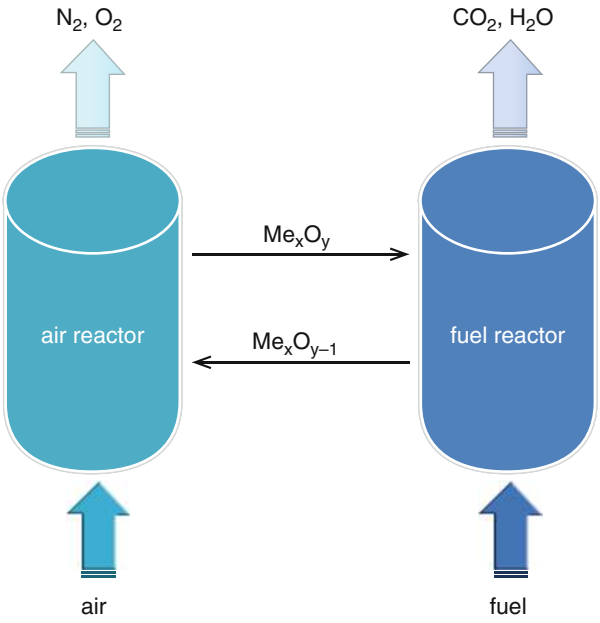

Fig. 3 A simplified scheme of the chemical looping process

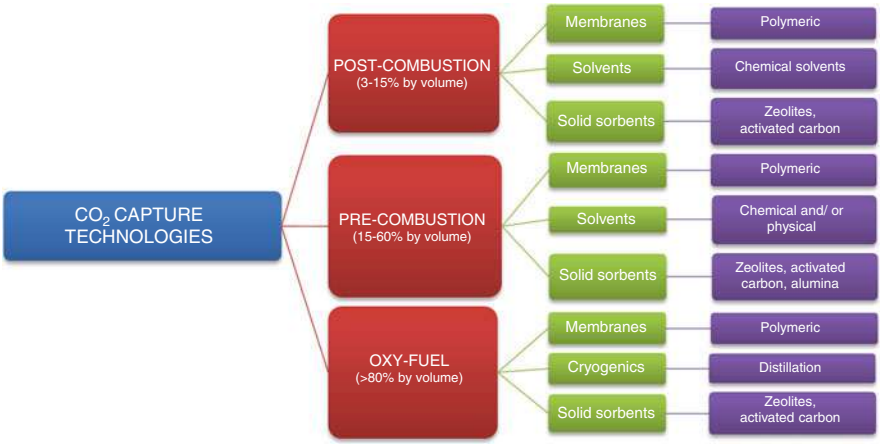

Fig. 4 Available technologies for CO_2 capture and separation

of CO_2 capture is an important issue to make CCS viable (Blomen et al. 2009; Feron & Hendriks 2005). Another important aspect to investigate is the environmental impact of CCS implementation. A critical study of all available and in development technologies is imperative to the carbon capture aiming the CO_2 long-term storage. Figure 4 presents a scheme of the technologies available for CO_2 capture.

Solvents

To capture CO_2 from a stream, it is possible to use solvents that may interact with CO_2 either by chemical or physical absorption. The choice of the solvent depends on the characteristics of the flue gas, like CO_2 partial pressure and concentration. The chemical absorption is independent of the CO_2 pressure due to the chemical character of the interaction solvent CO_2 and can be used even in low CO_2 pressure and concentration. On the other hand, when compared to physical solvents, chemical solvents need thermal energy to release CO_2, while physical solvents release CO_2 by flash desorption. In post-combustion technologies, amines are the most used chemical solvent, and in precombustion technology both chemical and physical solvents can be employed or a mixture of both. Membranes and solid sorbents can be used in post-combustion, precombustion, and oxy-fuel routes, but a technological improvement is needed to transform these options in attractive alternatives from both technological and economical point of view.

Amines

The use of aqueous amine solutions in CO_2 separation is the most mature technology and has been used in the industry for decades (IPCC 2005; IEA 2008b).

The absorption by amines in water is a well-known commercial technology of CO_2 separation: for example, in natural gas, CO_2 and H_2S are removed via an amine-based scrubber, capturing the acid gases by a chemical reaction with amines and releasing the natural gas. The acid gases are then driven off by heating the amine solution, which is regenerated. This process is energy intensive (Bara et al. 2009b; Pennline et al. 2008; Hicks et al. 2008). Figure 5 presents a typical cyclic process of the use of aqueous amine solutions in CO_2 capture. In the first vessel occurs the chemical absorption, and in the second vessel CO_2 undergoes heat-induced desorption followed by the solvent recuperation.

In addition to energy penalty, it is known that *N*-methyldiethanolamine (MDEA) and diethanolamine (DEA) used for gas treatment and monoethanolamine (MEA) used for CO_2 post-combustion separation decompose causing environmental problems due to generated waste (IPCC 2005; Pannocchia et al. 2007; Lepaumier et al. 2009; Ramdin et al. 2012).

Despite being used for a long time, the search for a better understanding of the chemistry involved in amine-CO_2 interactions is crucial to find an optimal formulation to lower the costs. In this sense, a study presented the results for CO_2 absorption capacity for seventy-six different amine solutions indicating that there are still possibilities to improve the CO_2 absorption capacity of aqueous amine solutions. Seven amines were found to exhibit significant absorption capacity, most of them comparable to the industry standard monoethanolamine (MEA). Most of the selected amines, one primary, three secondary, and three tertiary, have a number of structural features in common like steric hindrance and hydroxyl functionality 2 or 3 carbons from nitrogen (Puxty et al. 2009). These results indicate that there are

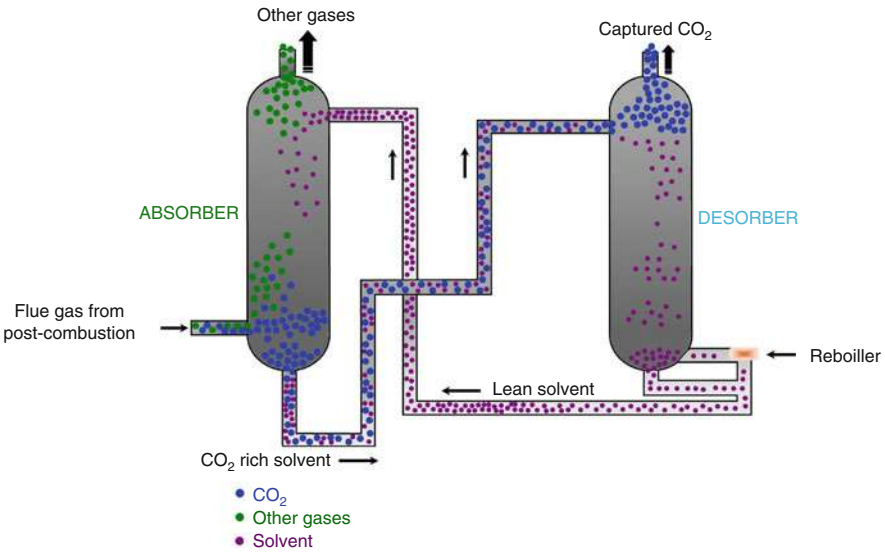

Fig. 5 Process of CO_2 capture using an aqueous amine solution

still possibilities to improve the CO_2 absorption capacity of aqueous amine solutions. The main issues regarding new amine research and development are related to reduction of energy requirements, minimizing corrosion of scrubbers, allowing higher amine concentration, and improving regeneration procedures (Figueroa et al. 2008). The advances in the development of CO_2 capture technologies utilizing absorption by aqueous amine solvents or new absorption systems need an accurate understanding of the chemical process occurring during the absorption/desorption steps (Perinu et al. 2014).

Physical Solvents

Physical solvents are so called for promoting a weaker bond between the solvent and carbon dioxide, when compared to chemical solvents. In this case, CO_2 is absorbed without a chemical reaction, so this class of solvent is suitable for CO_2 removal from flue gas with a higher CO_2 partial pressure. Current state-of-the-art physical solvents are glycol-based solvents like Selexol and methanol-based Rectisol (Blomen et al. 2009) as well as propylene carbonate (fluor process) (Figueroa et al. 2008). The main advantage of the physical solvents over amine solutions is the lower energy requirements for CO_2 absorption. However, these solvents present also some drawbacks, such as low CO_2 absorption capacity when compared to chemical solvents, the capacity of absorb significant quantity of hydrocarbon, and the need of high circulation rates resulting in high capital and operating expenses (Kumar et al. 2014).

Solid Sorbents

Solid sorbents can be used to react with CO_2 in a two-step process. Initially, a stable compound is produced, followed by releasing of CO_2 in the subsequent step, with regeneration of the original compound. These materials can overcome the amine drawback, energy penalty, and solvent decomposition, because of their lower energy requirements, cost advantage, and easiness of applicability over a relatively wide range of temperatures and pressures (Xu et al. 2003). A great number of physical adsorbent materials can be considered for CO_2 capture such as zeolites and zeolite-like materials, activated carbons, metal-organic frameworks, and aerogel-based materials (Sabouni et al. 2014; Kong et al. 2014). Several important criteria should be satisfied for a material before then can be considered as a suitable adsorbent for CO_2 capture from flue gas and compete with the present technologies: high adsorption capacity, high selectivity for CO_2, adequate adsorption/desorption kinetics, sorbent regeneration, stability during repeated adsorption/desorption cycling, mechanical strength, and low cost (Sabouni et al. 2014; Samanta et al. 2011; Wang et al. 2014). These attributes will rarely be fitted for one single adsorbent but are desirable for an ideal solid physisorbent material. However, a useful adsorbent should capture CO_2 from flue gas stream economically and effectively (Samanta et al. 2011).

Zeolites

Zeolitic materials comprise the largest group of the oxide molecular sieves and are used for many applications, as catalysis, gas separation and purification, and ion exchange. Zeolites X, Y, A, ZSM, and chabazites have been widely studied to be used in the field of adsorbents (Zhang et al. 2008). Zeolites have high thermal, mechanical, and chemical stability characteristics that, allied with the porous size and stable crystal structure, make these materials good candidates to be used in CO_2 adsorption processes and are among the most investigated in literature for adsorption and separation (Sabouni et al. 2014; Walton et al. 2006; García-Pérez et al. 2007).

Metal-Organic Frameworks

Metal-organic frameworks (MOFs) represent a new emerging class of crystalline porous materials formed by metal-based nodes (e.g., Al^{3+}, Cr^{3+}, Cu^{2+}, Zn^{2+}) with well-defined coordination geometry and organic bridging ligands (e.g., carboxylate, pyridyl). These structures offer advantages for CO_2 absorption: ordered structure, high storage capacity possible with low energy penalty for CO_2 recovery, high thermal stability, adjustable chemical functionality, and extra-high porosity, among others (Figueroa et al. 2008; Sabouni et al. 2014; Millward and Yaghi 2005; Wang et al. 2011a).

Membranes

Membranes are being used in many industrial separations and are currently dominated by polymeric membranes offering the advantage of cheap production on large scale when compared to metallic proton-conducting or ceramic membranes (IEA 2008b; Yang et al. 2008; Franz and Scherer 2010). Nevertheless, the membranes are low-cost options for processes that do not require a high-purity gas stream. Besides that, there are some other points related to the performance of membranes that limit their uses in carbon capture. For example, the low concentration of carbon dioxide in the flue gas indicates that a large volume of gases needs to be processed; the membranes are not resistant to temperature, demanding flue gas cooling prior the membrane separation; and extra power is required to create a pressure difference across the membrane (IEA 2008b; Powell and Qiao 2006).

Membranes are a promising technology in future for carbon capture but are still in a research and development phase, necessary to make their costs and performance attractive. The technology presents as main drawback the lack of stability under the reforming environment (Sabouni et al. 2014).

Ionic Liquids and Poly(ionic Liquids)

Room temperature ionic liquids (RTILs) are liquid salts at room temperatures (Scovazzo et al. 2004; Shin and Lee 2008). The several possible combinations of cations and anions allow designing more efficient solvents for process and products (Carvalho et al. 2009). Due to the excellent properties of RTIL like negligible vapor pressure at room temperature, a stable liquid range of over 300 K, the great CO_2 solubility, and the density greater than water, there is a growing interest to use this kind of solvents in gas separation (Shin and Lee 2008; Raeissi and Peters 2008).

As mentioned before, these compounds may combine good physical and chemical characteristics and the ability of selective dissolution of different organic and inorganic compounds by varying the composition of the ionic liquid being good candidates to be used in industrial applications (Bara et al. 2009b). The main problem with the RTIL is the costs. However, considering the small scale on which these solvents are produced, certainly the increased consumption would make the price lower. The capacity of reuse of these solvents must also be taken into account, as well as the energy save and the possibility of producing a specific and optimized ionic solvent for a particular reaction or application. Even if RTILs are more expensive when compared to common organic solvents, their unique properties allied to appropriated engineering designs can offset the costs (Bara et al. 2009b). Nevertheless, the CO_2 solubilities in conventional ILs are still too low to compete with amines in a post-combustion process (Ramdin et al. 2012; Kumar et al. 2014).

Table 1 presents some of the commonly used cations and anions in the RTIL synthesis.

The anion exchange in RTIL makes possible to alter significantly the ionic liquid properties. The cation is responsible for the ionic compound existence in the liquid

Table 1 Most commonly employed anions and cations in ionic liquid synthesis

Some cations and anions for ionic liquid synthesis			
Cations			
 N,N-Dialkylpiperidinium	 1,2-Dialkylpyrazolium	 N-Alkyl-thiazolium	 Trialkylsulfonium
 1,1-Dialkylpyrolidinium	 Tetraalkylammonium	 N,N-Alkyl-imidazolium	 N-Alkylpyridinium
Anions			
 Hexafluorophosphate	 Tetrafluoroborate	 Trifluoroacetate	 bis-trifluoromethylsulfonylimide

state at room temperature, but it is the anion that controls properties such as solubility and stability (Welton 2004). The alkyl side chain in the cation may play a role in the CO_2 solubility, increasing alkyl chain increases CO_2 solubility; however, the effect is not as important as the substitution of the anion (Raeissi and Peters 2008; Muldoon et al. 2007). Ionic liquids can be tailored to act as a chemical solvent reacting with the CO_2. The CO_2 absorption capacity was greatly improved by functionalizing conventional ILs with an amine moiety (Ramdin et al. 2012). Ionic liquids can absorb CO_2 by an equimolar capture mechanism. In this case it is possible to tune the ILs stability, absorption capacity, and absorption enthalpy by varying the anions with different pKa values (Wang et al. 2011b).

To find new materials for the purpose of CO_2 separation, it is important to study the solubility of CO_2 in these solvents and understand the solvent-CO_2 interaction. It was pointed out that CO_2 presents high solubility in imidazolium-based ionic liquids even in low pressures (Shin and Lee 2008; Blasig et al. 2007; Tang et al. 2005a). Several works related the behavior of the solubility of different gases in 1-*n*-butyl-3-methyl imidazolium hexafluorophosphate [bmim]PF_6 ionic liquids showing that CO_2 presents a superior solubility when compared to other gases like ethane, propane, and oxygen, while carbon oxide, nitrogen, and hydrogen showed solubilities below the detection method (Anthony et al. 2005). The role of the anion was studied by comparing the solubility as a function of both pressure and temperature for a series of gases in 1-*n*-butyl-3-methyl imidazolium tetrafluoroborate [bmim]BF_4, 1-*n*-butyl-3-methyl imidazolium

hexafluorophosphate [bmim]PF_6, and 1-*n*-butyl-3-methyl imidazolium bis(trifluoromethylsulfonyl)imide [bmim]Tf_2N. The latter had the largest affinity for CO_2 in all experimental conditions (Raeissi and Peters 2008; Anthony et al. 2005).

Besides the imidazolium cation, methyl-tributylammonium, butyl-methyl pyrrolidinium, and tri-isobutyl-methyl phosphonium p-toluenesulfonate were tested using Tf_2N as anion which, independent of the cation, had the largest affinity to CO_2, suggesting that the nature of the anion has the strongest influence on the gas solubility (Anthony et al. 2005).

A solubility study of SO_2 and CO_2 was carried out in 1-n-hexyl-3-methyl imidazolium bis(trifluoromethylsulfonyl)imide [hmim]Tf_2N, showing that SO_2 presents a larger solubility in this ionic liquid when compared to CO_2 (Anderson et al. 2006).

Quaternary ammonium polyethers manufactured by Evonik Degussa GmbH company, TEGO IL K5, TEGO IL P9, and TEGO IL P51P, were screened as potential solvents for CO_2 capture. The selection of these ionic liquids was based on the NETL and University of Pittsburgh idea of an "ideal" physical solvent for CO_2 capture (Pennline et al. 2008). Besides the characteristics like low vapor pressure, thermal stability, nonproduction of unwanted by-products, adequate viscosity, density, and ability to dissolve CO_2 at different temperatures and pressures, these solvents were evaluated according to Pearson's "hard and soft acid-base principles" aiming to maximizing the CO_2 solubility. CO_2 is a Pearson "hard acid" having a strong affinity with Pearson "hard bases," in this case the selected ionic liquids (Pennline et al. 2008).

Tang and coworkers first reported that making the ionic liquids in the polymeric form (poly(ionic liquid) – PLI) significantly increases the ability of CO_2 sorption when compared to ionic liquids. Poly(ionic liquids) synthesized from ammonium-based monomers present a CO_2 sorption capacity of 6.0–7.6 times higher than the RTIL (Tang et al. 2005a; Tang et al. 2005b). Besides that the CO_2 sorption and desorption are faster and completely reversible indicating that PLI are more suitable for industrial CO_2 capture and conversion when compared to ILs. These interesting results increased the research in PLI gas separation and sorption, and the related studies are among the most active in PLI field (Yuan et al. 2013). Poly(ionic liquids) based on tetraalkylammonium and a poly(p-vinylbenzyl trimethylammonium hexafluorophosphate) were studied, and the latter presented the highest CO_2 absorption capacity as well as a high selectivity for CO_2 in CO_2/N_2 mixtures. Both materials can be reused several times (Supasitmongkol and Styring 2010). The tetraalkylammonium-based PLIs present higher CO_2 sorption capacities than the imidazolium ones (Yuan and Antonietti 2011). New poly(ionic liquids) were obtained from melt condensation reaction of the imidazolium-based ionic liquids with symmetrical ester and hydroxyl groups. The results indicated that PLIs present higher CO_2 sorption capacity than IL except for the ionic liquid containing the hydroxyl group. This result is probably due to the association of the CO_2 with the anion and the hydrogen-bonding interactions between the hydroxyl groups of the IL and CO_2 (Xiong et al. 2012). A series of PLIs based on poly(urethane) structures were synthesized and presents a good performance when compared to ILs and

traditional solvents used in precombustion process as well as PLIs presented in literature. It is worth to note that these PLIs are based on poly(urethane), a versatile low-cost material (Magalhaes et al. 2014). The studies performed on PLIs for CO_2 capture demonstrated that the effects of anion, cation, and backbone were much different from those of room temperature ionic liquids. Cation seems to play a major role unlike IL, and the CO_2 sorption capacity decreases from ammonium > pyridinium > phosphonium > imidazolium (Yuan et al. 2013).

CO_2 Storage

Storing CO_2 in the subsurface is technologically feasible but far from a trivial endeavor. A large effort of multidisciplinary research is needed before any large-scale injection operation is started. Selection of a storage site is usually aided by a source-sink matching survey, which will limit the viable region for injection to those located close to large stationary CO_2 sources. Geological criteria will then determine whether a given formation in the selected area is suitable for injection. These criteria are basically related to the reservoir storage capacity, the containment capability, and the injectivity of CO_2. Geological characterization methods, such as those used in the oil industry, will be required for this evaluation, often being an expensive and time-consuming step.

Even if a suitable site is found, environmental and regulation issues must be assessed as well to ensure that the storage complex will operate within local safety standards and legislation. Furthermore, site operations must have a positive public acceptance, especially by local communities in the vicinity of the storage complex.

This section will review some of the technical aspects related to the injection of CO_2 and the characteristics of the geological media for storage and containment.

Technical Aspects

CO_2 is injected in a reservoir through an injection well, which is in many aspects similar to oil and gas production wells. However, wellbore materials have to be carefully selected. Cement and steel commonly employed for completion of production wells may experience corrosion by wet CO_2 (an acid media that reacts strongly with cement, leaching components resulting in structural damage) (Scherer et al. 2005). Steel casings may also be corroded by this media.

CO_2 needs to be compressed in the surface to reach the reservoir. Ideally, it should be stored underground in a supercritical phase – a state where CO_2 has gas-like viscosity (therefore with high mobility) and high density, which is advantageous for maximizing storage per pore volume. This state is reached when both temperature and pressure of CO_2 are both above 31.1 °C and 73.9 bar, respectively. Since there is an increase in pressure and temperature with depth in the Earth's crust (geothermal and hydrostatic gradients, averaging *ca.* 30 °C and 100 bar per kilometer, respectively), at approximately 800 m depth, CO_2 is likely to be found

in a supercritical state. One ton of CO_2 occupies 509 m^3 at surface conditions, and the same amount occupies only 1.39 m^3 at 1000 m depth (temperature of 35 °C and pressure of 102 bar) (Bentham and Kirby 2005).

Description of the Geological Media

The geological media used to store CO_2 are similar in many ways to a petroleum system. A storage system is composed of a reservoir and a caprock and may or may not contain a trap (Holt et al. 1995). A geological reservoir is a porous and permeable rock (commonly a sedimentary rock) that contains fluids such as water, oil (liquid hydrocarbons) and natural gas (light hydrocarbons), CO_2, or H_2S, among others, and can be used to safely store CO_2. Porosity is the space within rock matrix (e.g., in between sand grains) and/or rock fractures that contains fluids, which will be partly occupied by CO_2 during storage. A reservoir is preferentially a sedimentary rock (e.g., sandstone, limestone, coal) or less commonly a fractured metamorphic or igneous rock (e.g., basalts). Other less known (in terms of operation and performance) target reservoirs include oil shales, gas hydrates within marine sediments, and engineered salt caverns (IPCC 2005). These options are less investigated and will not be discussed here.

CO_2 stored in common geological conditions is typically found in a gas or supercritical phase, with density lower than water (*ca.* 600–800 kg/m^3) (Fig. 6), and therefore, it will tend to move upward in the reservoir and overburden sequence, until it seeps on the surface (Gunter et al. 2004). To ensure that the CO_2 will be

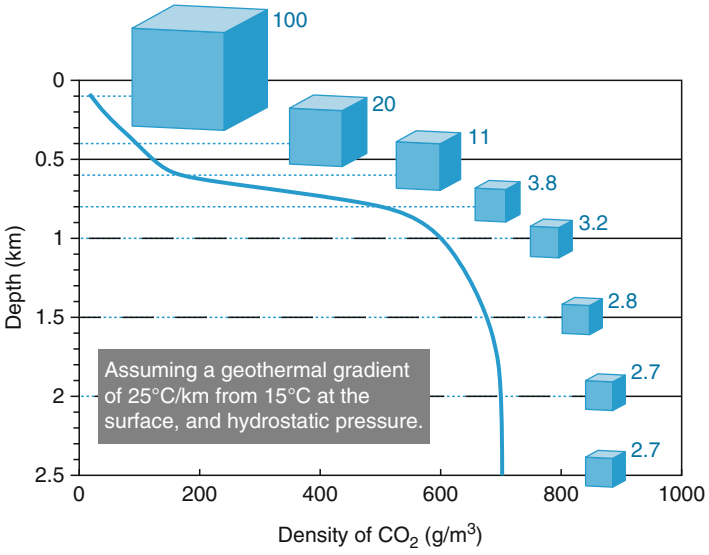

Fig. 6 Variation of CO_2 density with depth, assuming hydrostatic pressure and a geothermal gradient of 25 °C/km from 15 °C at the surface (IPCC 2005)

retained after injection, it is necessary that the reservoir be sealed with an overlying impermeable caprock (with permeability typically lower than 0.1 mD). This caprock will prevent migration of CO_2 out of the reservoir and allow other trapping mechanisms starting to operate (see following sections). Impermeable caprocks are commonly sedimentary rocks such as mudstones, limestones, or evaporites.

Injectivity

Injectivity is the ability of CO_2 to flow from the well into the reservoir and is directly related to the reservoir permeability, which is a measure of the degree of connection between the rock pores. This property is not easily predicted, as different techniques can be employed to evaluate it (using core samples, interpretation of well log data, and well testing), often resulting in conflicting data. Also, it is susceptible to minimum heterogeneities of the reservoir and is highly anisotropic (it varies significantly with the direction of measurement).

Ideally, a permeability higher than 100 mD is required to provide good injectivity. However, in some cases, the reservoir is not sufficiently permeable to allow high rates of CO_2 inflow, and it may require an artificial enhancement through well stimulation (by injection of chemicals or induction of fractures) to improve injectivity. The number and array of wells is also important to optimize injection rates.

In the next section, the most important geological reservoirs for CO_2 storage will be described in more detail.

Reservoir Options

As mentioned previously, there are three main groups of reservoirs that are more likely to be used in a CO_2 storage operation: petroleum fields, saline aquifers, and coal deposits (Fig. 7). The first two are already in their commercial phase, and the

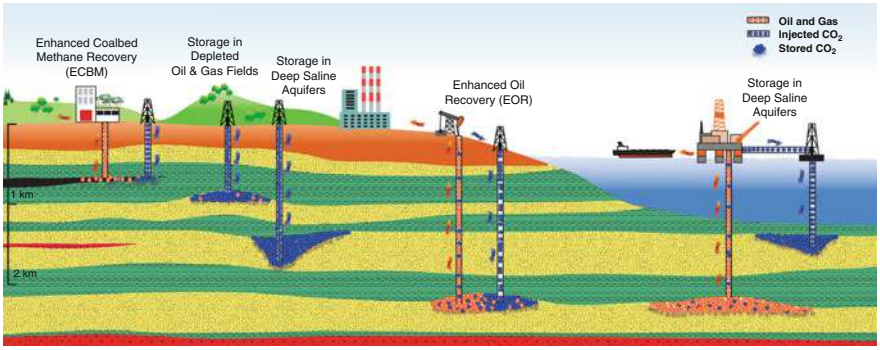

Fig. 7 Scheme of the possible reservoir options for CO_2 storage

latter, although proven in pilot scale, still needs to be demonstrated in larger scale (Van Bergen et al. 2004).

Oil and Gas Fields

Petroleum reservoirs are appealing targets for CO_2 storage, for several reasons. First, the trapping efficiency within these reservoirs is endorsed by the fact that they were capable of holding hydrocarbons for millions of years. Also, these formations are often well studied by oil companies, with plenty of data available. Finally, the injection of CO_2 has been already carried out in many oil fields (especially in the USA) for several years, to increase the pressure in the reservoir and improve the oil/gas recovery rates (a method known as *enhanced oil recovery* – EOR) (Gozalpour et al. 2005). CO_2 injection, often alternated with water, will mix with the residual oil forming a single phase (depending on reservoir pressure and temperature and oil properties) or, eventually, displace the petroleum and water phases to occupy pore space within the structural trap of the field. Mixing CO_2 with oil within a reservoir typically reduces oil viscosity and increases oil recovery by 8–15 % of the residual oil left after primary and secondary (water injection) recovery (NETL 2010; Blunt et al. 1993). Immiscible EOR with CO_2, i.e., related to the physical displacement of oil with CO_2, is also possible, but in this case recovery factors are typically lower than miscible EOR (Taber et al. 1997a, b).

Enhanced oil recovery using CO_2 is a proven technique that has been carried out by the oil industry since the 1970s to maximize oil exploration in mature fields, with approximately 140 projects in operation in 2010, the majority located in the Permian Basin in west Texas (USA) (IEA 2013; Gozalpour et al. 2005). In 2013, the first offshore CO_2-EOR project was started by the Brazilian oil company Petrobas, in the Lula field, one of the major ones in the Pre-Salt area in the south Atlantic Ocean (GC Institute 2014).

Unfortunately, the net emission reductions associated with an EOR project most likely will not be quite significant, as more fossil fuels are produced in the process, which will be consumed, generating additional CO_2. Furthermore, in many EOR projects currently running in the USA, CO_2 is not captured from anthropogenic sources but instead extracted from natural accumulations in the Colorado and New Mexico states and transported through an extensive pipeline network.

It is difficult to estimate how much CO_2 will remain stored in EOR projects, as it depends on the field structure, the recovery rates and injection methods, and the operation strategy after CO_2 breaks through in the production wells. To maximize CO_2 storage in EOR projects, the CO_2 produced together with oil must be separated and reinjected in the same or other reservoir.

Until 2010, approximately 560 Mt of CO_2 have been injected in petroleum fields by EOR projects in the USA only. Currently, ca. 60 Mt of CO_2 are injected every year in that country (NETL 2010). Despite its arguable benefits for emission reductions, CO_2 EOR is an activity with significant potential for CCS development. It is estimated that up to 80 % of oil reservoirs worldwide might be suitable for CO_2

injection based upon oil recovery criteria alone (Taber et al. 1997a, b), with an overall capacity between 675 and 900 Gt CO_2 (IPCC 2005).

Saline Aquifers

Saline aquifers are formations that are geologically similar to oil and gas fields, save for the fact that its pores are filled mostly with highly saline water (brine). Salinity of these formation waters should be above levels that make them unsuitable for human consumption, which usually means concentrations higher than 10 g/L. Usually, only aquifers with salinity higher than seawater (35 g/L) are considered suitable for storage projects.

As already mentioned, an ideal reservoir should be deeper than *ca*. 800 m, for a higher likelihood of CO_2 being in a supercritical phase, with a high density and gas-like viscosity, therefore maximizing pore-volume filling and mobility within the reservoir (Pruess and Garcia 2002). Both porosity and permeability of the reservoir should be sufficiently high so as to ensure constant injection of CO_2 for the time duration of the project (usually a few years, at least). Since the CO_2 injected will displace the original fluid, a low permeability may cause clogging and reservoir overpressures that may result in hydraulic fractures of the reservoir. Physicochemical interactions between CO_2 and reservoir rock and fluids should not deteriorate reservoir quality close to injection wells during injection phase (this topic will be described in greater detail further in the chapter).

To be eligible for CO_2 storage, a saline aquifer must present an overlying caprock with low permeability, being continuous and with minimum amounts of faults and fractures over the range of the estimated storage area. Moreover, this formation must resist the hydraulic overpressure imposed during the injection phase.

The great advantage of saline aquifers over other storage reservoirs is their enormous theoretical capacity and worldwide availability, with uniform distribution. On the other hand, there is much less information and data available for saline aquifers, since the economic incentive for their study is nearly absent. Therefore, global storage capacity estimations for deep saline formations have been roughly estimated thus far, between 1,000 and 10,000 Gt CO_2 (IPCC 2005).

Coal Fields

Coalbeds are able to trap CO_2 by adsorption (see next section), and most of the world coal resources are unminable (usually because of high depths), therefore being potential targets for CO_2 storage. Like in oil fields, storage in coalbeds may be economically interesting, as the injected CO_2 can be adsorbed by the coal matrix, displacing the naturally occurring methane from coal, which can be produced through wells – a technique known as *enhanced coalbed methane recovery* (ECBM). A key issue for storage in coal is the identification of suitable coalbeds. A detailed characterization of the coal is necessary to evaluate composition, rank, nonorganic material

content, permeability, and adsorption capacity, providing the necessary information for site selection. In addition, technical limitations related to coal permeability, which is typically lower than in common conventional reservoirs, have to be considered. The injection of CO_2 is known to cause coal swelling, which further decreases permeability and, consequently, injectivity (Day et al. 2010). Reactivity of coal with CO_2 and/or formation water is another issue that requires investigation, since the interactions of coal macerals (organic matter) with CO_2 are largely unknown and may lead to alterations that modify the coal matrix and its adsorption behavior toward CO_2, methane, and other gases (Reeves and Schoeling 2001).

Due to these limitations, CO_2 storage in coalbeds is still in the early stages of development, compared to the other reservoir options, with a few ECBM demonstration projects currently deployed. ECBM tests and demonstrations have been carried out in the USA, in the San Juan Basin (Colorado), where many commercial coalbed methane (CBM) operations are in place (Gale and Freund 2001; Stevens et al. 2001). An ECBM pilot project was started in 2009 in southern Brazil (Carbometano/Porto Batista project) to evaluate the potential for methane recovery and CO_2 storage of the coal reserves in this country (Beck et al. 2011).

Trapping Mechanisms of CO_2 in Geological Media

There are at least six trapping mechanisms that can keep CO_2 confined in a storage complex for long periods of time. These mechanisms, discussed in detail in this section and depicted in Fig. 8, may vary significantly with time and space within the reservoir (IPCC 2005).

Structural and Stratigraphic Trapping

CO_2 may fill "closed" structural or stratigraphic traps in a similar fashion that oil and gas do in petroleum fields. In this case, CO_2 will be accommodated within the reservoir below the caprock, and after equilibrium, it will be stored as an immiscible and immobile plume underneath the caprock. CO_2 may occupy the entire pore volume of the reservoir within the trap from the top until its spill point, minus the volume of irreducible water (and oil and gas). This is the most important mechanism in the early stages of an injection operation, as CO_2 tends to migrate upward through the reservoir in only a few years, accumulating below the caprock.

Hydrodynamic and Residual Trapping

CO_2 injected in an "open" reservoir, i.e., a reservoir with a caprock without a closure or trap, may form an immiscible plume that will migrate upward and up dip, due to density differences between the CO_2 and water (or oil) phases. Forces acting

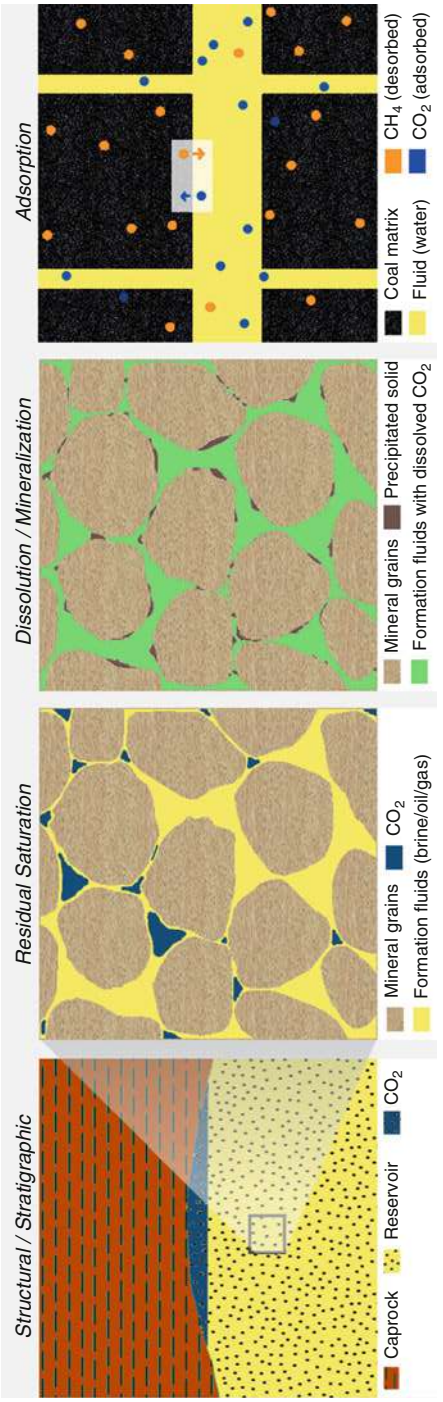

Fig. 8 Trapping mechanisms of stored CO_2 in geological reservoirs

against the displacement of CO_2 will retard plume movement and trap CO_2 within the reservoir for a certain period of time. The displacement of this plume will leave a CO_2 "tail" behind, in which storage occurs in pore space as residual gas at irreducible gas saturation (i.e., the minimum saturation of a fluid to be displaced in water media). As with the structural trapping, these mechanisms will also operate soon after CO_2 injection in a reservoir.

Dissolution and Mineralization Trapping

After injection, CO_2 will start to dissolve in formation water, and depending on factors like pH, a different proportion of dissolved species will form: H_2CO_3 (carbonic acid), HCO_3^- (bicarbonate), and CO_3^{2-} (carbonate). Once dissolved, CO_2 will be trapped within the reservoir aqueous phase as a dissolved species until geochemical conditions are changed (and proportion of dissolved species modified) or the fluids are displaced. Dissolved CO_2 may change drastically geochemical conditions of the media, mostly by increasing acidification of the aqueous phase, which in general enhances drastically the rate of dissolution of minerals present in the reservoir and caprock. Furthermore, the aqueous phase tends to be dried out in the vicinity of the CO_2-water interface, as the supercritical CO_2 absorbs water, leading to a more saturated brine (Kaszuba et al. 2003). This may set off the precipitation of minerals in this region, such as halite (NaCl). Dissolved CO_2 species and cations originated from dissolution of minerals or present in water may interact to form carbonates such as calcite ($CaCO_3$), magnesite ($MgCO_3$), and siderite ($FeCO_3$), among others. The type of carbonate formed will depend on pressure, temperature, and pH conditions, particularly on the activity of the cations dissolved in water and kinetics of reactions. Once in a solid phase, CO_2 will be stored within the reservoir until unlikely (in a period of $<$1,000 years) changes in pore water chemistry are drastic enough to dissolve carbonates and remove significant amounts of carbon off the storage complex.

Adsorption Trapping

Adsorption occurs when a gas molecule is bound to a solid surface by van der Waals forces. This is the main mechanism for trapping CO_2 in coal. CO_2 injected in a coal seam will migrate through its fracture network (denominated *cleat* system) as a free gas and diffuse through the coal matrix, being adsorbed in the microporous walls in coal. Binding strength is dependent on the pressure and temperature, with higher pressure and lower temperature favoring adsorption. Pressure and temperature will also control, together with the presence of other fluids (e.g., H_2S, H_2O), the quantity of CO_2 adsorbed in coal. CO_2 adsorption in coal may result in desorption of CH_4 owing to the lesser chemical affinity of the latter with coal. The desorbed methane is released as free gas to the cleat system and can be produced through wells (see Reservoir Options section above). After equilibrium,

and depending on conditions, ca. 5 % of the mass of CO_2 stored in coal will remain as free gas in the cleat system (and retained below an impermeable caprock) and 95 % as adsorbed CO_2. CO_2 will remain stored in coal if pressure and temperature conditions are unchanged. Changing pressure and temperature can only occur in a period smaller than 1,000 years by human intervention, through conventional mining, underground coal gasification, or depressurization of the seam as in coalbed methane production activities.

Storage Capacity Assessment

Estimating CO_2 storage capacity of a geological reservoir depends strongly on the methodology employed in calculations. Global capacity estimations available are largely inaccurate and conflicting, as they tend to be based on extrapolations of sparse data or erroneous assumptions (Bradshaw et al. 2007). A quick glance at some of these published assessments even reveals some world estimates that are lower than regional values. Many studies extrapolate values from a local or regional site to basin or continental scales, but the enormous geological variations that occur in storage complexes even within the same sedimentary basin make it nearly impossible for this upscaling to be precise.

Furthermore, capacity assessments were carried out using various approaches and methodologies. Recognizing these difficulties, the Carbon Sequestration Leadership Forum (CSLF), an international consortium for the development of CCS, launched in 2004 a task force to review and develop a standard methodology for storage capacity estimation. A comprehensive review of this methodology was presented by Bachu and Bradshaw in 2007 and is briefly explained in this section (Bradshaw et al. 2007; Bachu et al. 2007).

In this methodology, the different levels of capacity estimations are categorized in a resource pyramid (Fig. 9) (Bradshaw et al. 2007).

The first level, occupying the whole pyramid, is the *theoretical capacity* and represents the physical limit of what the storage system can accept. It can be either interpreted as the whole pore space available or pore space minus displaceable original fluids (water, oil, etc.) Either way, it represents the maximum upper limit to a capacity estimate. When technical cutoffs due to geological and/or engineering constraints are applied to the theoretical capacity assessment, an *effective capacity* upper limit is defined. Further restrictions due to legal and regulatory, infrastructure or economic barriers to storage result in a *practical capacity* subset. A final *matched capacity* estimation can be obtained by considering the previously mentioned source-sink matching assessment, taking into account proximity to stationary sources, injectivity, and supply rates of CO_2.

As this organization is more conceptual, it is unlikely that a capacity estimation assessment will result in precise values for each different category. In effect, the "resolution" of the data will depend largely on the scale considered. Estimations focused on a given site or local scale will probably give a higher level of resolution, while at larger scales (regional, basin, or country), this level of detail tends to decrease

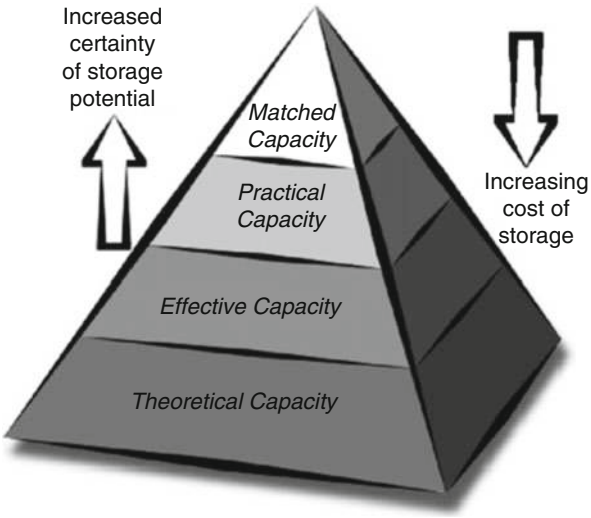

Fig. 9 Capacity estimation resource pyramid (Bachu et al. 2007)

significantly. Assessments at basin or country scale are more likely to be conducted by governments, while estimations at site or local scale will probably be run by project operators. Increasing resolution will usually result in higher costs of data acquisition. Next, a brief description of capacity estimation methods (and their current gaps and difficulties) for each main reservoir option is presented (Bradshaw et al. 2007; Bachu et al. 2007).

Petroleum Fields

Estimation of storage capacity in oil or gas fields is the most straightforward of all potential targets, as the oil industry gathers plenty of data from these reservoirs before and during exploration, to establish the precise amount of petroleum reserves and resources. Furthermore, oil and gas fields are discrete volumes with fairly well-defined boundaries, which allow for a more precise assessment.

On the other hand, petroleum production history and methods in a reservoir will influence directly the available storage space for CO_2. Secondary or tertiary recovery techniques (injection of water or other substances for improved production) can reduce the available space. Also, if the reservoir is in hydrodynamic contact with underlying aquifers, water may flood the reservoir during oil/gas production, occupying the previously oil-filled space. Injection of CO_2 can partially displace the water, although not all of the original oil-saturated volume will be available for storage, due to residual saturation or viscous fingering effects. It is assumed that injection of CO_2 in a petroleum field will be carried out until the original reservoir pressure is restored. However, this is not always possible, as the oil and gas exploration may damage the formation and/or caprock, limiting the maximum pressure. In other cases, injection can be performed beyond the original pressure,

as long as it does not compromise the safety of containment by the caprock, exceeding the rock-fracturing threshold or capillary entry pressure of this formation.

Theoretical capacities for petroleum reservoirs can be calculated based on geometrical parameters (reservoir area and thickness), physical and hydrodynamic properties such as CO_2 density and water saturation, and other data gathered from exploration activities, such as recovery factors, injected and produced water volumes. The *effective* storage capacity can then be obtained by applying a capacity coefficient (<1), which is dependent on buoyancy, mobility, heterogeneity, water saturation, and aquifer strength. These phenomena are site specific and the contribution to this coefficient is widely varied and difficult to estimate, usually being based on reservoir simulations (Bradshaw et al. 2007; Bachu et al. 2007).

Saline Aquifers

Capacity estimations for aquifers are difficult to estimate. The various trapping mechanisms that operate in these reservoirs have different capacities that are interrelated, and since these mechanisms act over different time intervals, the storage capacity associated with each one will also be time dependent. Considering a reservoir filling down to the spill point, the theoretical volume available will be dependent on the geometric volume (trap area and average thickness), porosity, and irreducible water saturation (the amount of water that is unable to move from the rock pores). The *effective* storage volume can be obtained applying a capacity coefficient (<1) to the theoretical volume, that for trap heterogeneity, CO_2 buoyancy, and sweep efficiency. This coefficient is highly site specific and can only be obtained by reservoir simulations (Bradshaw et al. 2007; Bachu et al. 2007).

Coalbeds

Storage capacity in coal can be estimated by analogy with CBM (coalbed methane) reserve estimation, which implies the determination of *initial* gas in place (IGIP) and *producible* gas in place (PGIP) for a given coal seam. The initial gas in place (IGIP) is usually calculated from the coalbed average thickness and area, bulk coal density, and gas content, subtracting the weight fractions of mineral and moisture contents. The gas content, in turn, is related to the adsorption capacity of coal, which depends on pressure, temperature, and coal characteristics, following a pressure-dependent isotherm that has to be determined in each case.

For estimation of storage capacity, it is assumed that CO_2 replaces the original gas content (primarily methane), due to the higher affinity with the coal matrix. The *theoretical* capacity for storage would then be equivalent to the IGIP, as if all the coal is accessed by CO_2, adsorbing at 100 % saturation. The *effective* capacity will be equivalent to the estimated *producible* gas in place (PGIP), in the case of gas production from coal seams. This producible content is a fraction of the IGIP, obtained by multiplying it by a recovery factor and a completion factor (which

represent actual fractions that can be produced and effective regions of the coal that contribute to gas production, respectively) (Bradshaw et al. 2007; Bachu et al. 2007).

Predicting the Fate of CO_2 Stored in Reservoirs: Experimental and Numerical Modeling

Several physicochemical alterations in the storage complex are triggered by massive injections of CO_2 into a geological reservoir, affecting both reservoir and caprock for large distances and long periods of time.

These phenomena and the complex interplay among them are not yet fully understood and have been extensively investigated ever since CCS started to develop worldwide. It involves the study of the geochemistry of the CO_2-water-rock interactions and the flow behavior of the different phases in the porous and fractured media present in the storage complex, as well as their impact on the geomechanical properties. This research ultimately aims to estimate the partition of the injected CO_2 among the different trapping mechanisms in a given time period (injection phase, earlier years, and geological time frames) and to unravel reservoir and caprock changes during injection and thousands of years later. To carry out these investigations, it is necessary to rely on both experimental and numerical modeling tools (Gaus 2010; Ketzer et al. 2009). By means of laboratory experiments, the conditions in the geological media can be simulated using actual reservoir and caprock samples, which are then analyzed for mineralogical changes following reactions with carbon dioxide and formation fluids. As experiments are limited by time constraints, complementary numerical simulations can be employed, by running kinetic and flow models spanning several years. The next sections will describe these methods with more detail.

Experimental Modeling

Laboratory experiments aim to simulate the interactions between CO_2 and the formation fluids and minerals (either reservoir or caprock), in similar conditions as those found in the geologic media (Kaszuba et al. 2013). In a straightforward approach, experiments can be carried out in static conditions, in which the reactants (CO_2, fluid, and rock samples) are introduced in a pressurized vessel and held at constant pressure and temperature for a certain period of time, usually ranging from hours to months (depending on the sample mineralogy). Pressure and temperature conditions for the experiments are usually set to replicate the reservoir environment, although more reactive conditions may be employed, in order to increase the chemical reactivity of the system reducing the time for the experiment (Kaszuba et al. 2003). Experiments with more reactive conditions should be taken carefully, as they may lead to flawed results, since the dissolution and precipitation kinetics of each mineral in a rock sample have a different dependence on temperature (Lasaga

1984). It is important for the quality of the results that the reactants are well characterized before and after the experiment. Ideally, for longer experiments, fluid samples should be collected from time to time from the reactor and analyzed. Characterization of the fluid phase is usually carried out through standard water analysis techniques such as chromatography and atomic absorption for quantification of ions, as well as pH and conductivity measurements. The mineral phase characterization often relies on imaging techniques such as scanning tunneling microscopy (STM), which provides a qualitative analysis of texture and crystalline habit, and optical microscopy for determination of sample mineralogy. Other techniques such as X-ray diffraction (useful for clay minerals) and, more recently, X-ray micro- and nanotomography, for 3D pore/channel structure visualization, may be employed. Materials employed for the vessel construction are an important issue, as they may suffer corrosion during the experiment. Stainless steels are well suited for experiments with distilled water or solutions with very low salinity, but more resistant alloys (such as titanium nitride or Hastelloy©) are needed for experiments with higher salinity brines, especially for longer experiments.

The methodology for batch experiments may vary significantly and is not a consensus among researchers on this field. Several key parameters are likely to be varied in the experiment design, such as the water/rock/vessel volume ratio, the rock sample physical aspect (crushed or unbroken), the depressurization procedure, and the pretreatment of products for characterization (addition of chemicals for solution conservation and carbon content fixation, filtration and desiccation of solid material, etc.) at the end of the experiment.

A more sophisticated approach, and possibly a more realistic simulation, consists of flow-through experiments, in which a core plug sample of the reservoir rock is placed in a tubular sealed reactor and subjected to a high-pressure continuous flow of either pure CO_2 or a saline solution saturated with CO_2 (Luquot and Gouze 2009). Ideally, the sample should be also submitted to radial and/or axial confining pressures during the experiment, using a Hassler-type cell (a similar tubular reactor, in which a radial load is applied to the sample). This results in a more realistic simulation of the overburden pressures existing in a geologic reservoir. With this design it is also possible to evaluate the rock permeability and its variations with mineral dissolution and precipitation. Using computerized X-ray tomography with proper resolution, it is possible to evaluate changes in porosity after a flow-through experiment, placing the reactor cell in the tomography scanner at selected time intervals.

A wide range of experiment designs are possible for this method, by changing the flowing phases, flow rates, fluid-mixing method, core size, and form of placement in the reactor, among others. Characterization techniques employed for both solution and minerals are essentially the same as used in batch experiments.

Numerical Modeling

Numerical simulations play an important role in the investigation of the interactions between carbon dioxide and the reservoir. It is the only method that allows to

estimate the consequences of a large-scale CO_2 injection to the reservoir and caprock in a geological timescale, thus being complementary to the laboratory experiments (Tsang et al. 2007).

However, the complexity of this natural system makes it nearly impossible for it to be simulated with high accuracy taking into account all the physicochemical transformations involved – multiphase flow of the different fluids, transport of mass and heat, geomechanical alterations, surface and interface interactions, and geochemical and biogeochemical reactions.

Fully coupled modeling tools capable of dealing with every possible phenomenon simultaneously and at different scales (from pore to basin) are not available so far and are not likely to be in the short term. Several existing numerical codes are able to partially integrate the simulation of these phenomena, and the choice for the appropriate code must take into account the reservoir and caprock properties, as well as the time and spatial scales of interest for the investigation.

In the early stages of injection of CO_2, simulations must target potential injectivity issues such as clogging by obstruction of pore throats or fracturing near the well by excessive pressure. For this, geomechanical and pore-scale flow models would be well suited. However, chemical reactions may also play an important role in this stage, especially with more reactive storage sites such as carbonatic or carbonate-rich reservoirs, which dissolve fast with increased acidification of the brine by CO_2 dissolution. Rapid dissolution may benefit CO_2 injectivity by increasing porosity and permeability, but an extensive dissolution of carbonate cement might be a risk, as it could induce fractures and activate faults in both reservoir and caprock. Another known effect is the brine desiccation caused by supercritical CO_2-absorbing water from the aqueous phase. In highly saline reservoirs, this may cause rapid precipitation of salts such as halite or anhydrite, affecting injectivity by clogging the pores. Hence, geochemical simulation tools may also be necessary to model the possible mineral dissolution and precipitation processes in the vicinity of injection wells.

In the long-term, large-scale reservoir simulations that take into account the sedimentary deposition environment which leads to heterogeneities in the formations will help to determine the CO_2 phase displacement in the reservoir. Accurate models for the calculation of CO_2 solubility and the chemical reaction kinetics of less reactive silicate minerals are also important, to estimate the amount of carbon trapped by dissolution in the aqueous phase, or safely stored in a solid phase by mineralization, after several years.

Geochemical modeling of CO_2-water-rock interactions is often divided in two approaches. One is the determination of the thermodynamic state of equilibrium of the CO_2-water-rock system, considering every chemical reaction involved within the water phase (speciation) and its equilibrium with the gas (CO_2) and solid (minerals) phases. This is accomplished by solving a system of equations involving the equilibrium constants for every chemical process involved and the activities for each species – which in turn requires a model for calculating activity coefficients. From this kind of model, it is possible to estimate the solubility of CO_2 in the formation fluid (if an appropriate equation of state for CO_2 at the reservoir pressure

and temperature conditions is used), as well as mineral saturation states at equilibrium, i.e., the tendency for a mineral to precipitate or dissolve in order to reach thermodynamic equilibrium.

A second approach is to model the kinetics of dissolution and precipitation of the reservoir and caprock minerals with time. Usually, a generic rate law for these processes is employed for all minerals, which depends on a rate constant, the specific reactive surface of the mineral, temperature, pH, and deviation from the equilibrium state. Unfortunately, very few kinetic studies have been carried out at the usual pressure and temperature conditions of storage reservoirs; therefore, existing data are often not accurate enough. Furthermore, the reactive surface of a mineral is another major source of errors – it may vary considerably for a given mineral depending on crystalline structure, chemical environment, depositional and diagenetic processes, coating by inert materials, etc. Usually, geometric estimations of the mineral surface are employed, as they have been found to be well correlated to measured values (using BET gas adsorption isotherms).

Geochemical calculations as described above are *static* models, as they do not consider the displacement of fluids (CO_2, water, oil/gas) and transport of mass and heat. The step-up on simulating approaches is to incorporate the geochemical transformations in fluid flow and transport models based on the Darcy equation for flow in porous media, coupled with advective, dispersive, and diffusive mass and heat transport. This coupling of flow and transport equations with chemical reactivity results in so-called *reactive transport* models (Steefel et al. 2005) and are possibly one of the most employed tools for numerical simulations in CO_2 geological storage research.

A wide range of numerical codes have been used in simulation studies applied to CO_2 geological storage. The US Geological Survey's PHREEQC (Parkhurst and Appelo 1999) is among the most employed ones. This code is capable of performing thermodynamic equilibrium calculations, both in aqueous phase and with the inclusion of mineral and gas phases. Kinetics of mineral dissolution and precipitation can also be included, introducing user-customizable rate laws. One-dimensional reactive transport simulations are also possible with this code. For more elaborate flow and reactive transport modeling studies, the current state-of-the-art code is TOUGHREACT, a modification of the TOUGH2 code (a 3D multiphase flow model for porous and fractured media, developed at the Lawrence Berkeley National Laboratory) (Xu et al. 2006) that couples chemical reactivity with the multiphase flow equations. Many other programs have been used in CCS studies though, and several others are under development. The strongest efforts are focused in the inclusion of geochemical and geomechanical effects into existing reservoir simulators.

Another important issue that also needs to be addressed by investigations in this area is the lack of reliable thermodynamic data and kinetic parameters in the specific conditions for CO_2 storage. Thermodynamic constants of aqueous and mineral phase equilibria have been used for decades through the available databases included in commercial codes without much regard for its origins. Current databases date from the 1980s and are far from accurate, as the initial missing entries

were in many cases completed through fittings and extrapolations from a few existing values at the time, and little effort has been put later to improve this situation. As for kinetics of dissolution and precipitation of minerals, rate laws and constants available so far have been mostly obtained at ambient conditions and extrapolated for use in numerical simulations at reservoir conditions. Furthermore, rate constant values are difficult to reproduce among experiments, for several reasons. First, the very slow rates of dissolution of some minerals make them difficult to determine experimentally. Experimental methodologies and settings are not standardized and may reflect on the values obtained. Rates may also vary significantly depending on the sample source, heterogeneities, and available reactive surface. One approach that has been adopted to minimize these issues was to fit several existing data into a general rate law (Palandri and Kharaka 2004).

Despite the existing knowledge of water-rock interactions, it is clear that the inclusion of carbon dioxide in this system requires a great research effort in developing both experimental and numerical methodologies and instruments, in order to improve the means to better understand the fate of CO_2 in a storage reservoir.

Safety of Geological Storage

Storage safety is a key issue for CCS projects. Carbon dioxide is a noncombustible low-toxicity gas, present in small concentrations in the atmosphere (0.04 % in volume), but in higher concentrations, it can be dangerous to human health and the environment. Until now, a single lethal event of major proportion has been registered caused by leakage of CO_2 from the subsurface and was due to natural causes. In 1986, 1.6 Mt of carbon dioxide were released abruptly from the bottom of the volcanic crater lake Nyos, in Cameroon. The gas was released overnight, and the plume descended over a valley, displacing air and suffocating over 1700 people and thousands of livestock in a nearby village. However ominous it may seem, the incident was very singular and highly unlikely to be repeated in nature, not to mention in engineered storage reservoirs, but it serves as a reminder of the hazards of high CO_2 concentrations.

Therefore, in any CCS project, safety measures and risk assessments must be carefully performed to evaluate potential sources of CO_2 leakages or seepages away from the storage complex, with indications of remediation actions in case of containment failures (Wilson and Gerard 2007). Figure 10 presents the most important escape routes for stored CO_2 that have to be evaluated in a risk assessment.

Once injected in a reservoir, CO_2 can be considered safely stored if at least 99 % of the injected quantity is retained in the reservoir for at least 1,000 years (Benson and Cole 2008).

Large engineered storage sites for gases or waste are not new concepts. In Europe and the USA, underground facilities have been used for decades to store natural gas during low-demand periods (summer seasons), many of which are located near urbanized localities (Katz and Tek 1981). Underground repositories for long-lived radioactive waste from nuclear power plants are employed and under

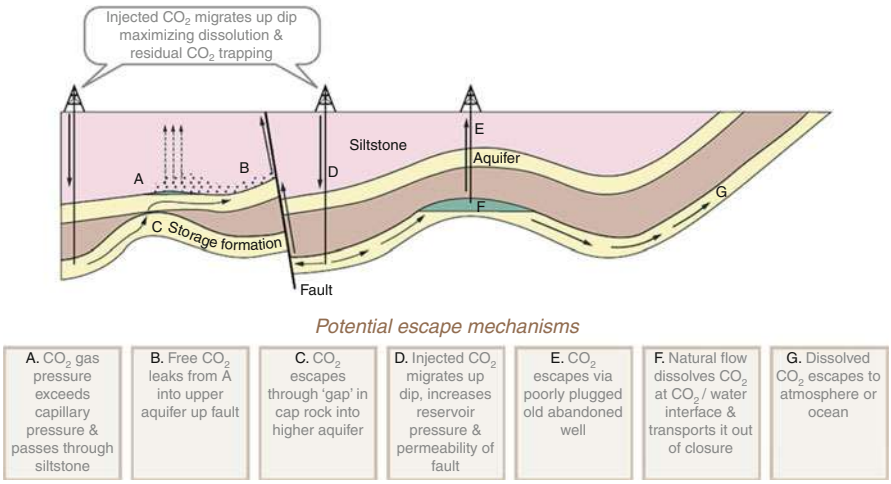

Fig. 10 Potential escape pathways for stored CO_2 in a geological formation (IPCC 2005)

construction. Research in this area has consolidated a considerable know-how on geological storage and containment of these materials for long periods of time (NEA 2008).

The safety of subsurface storage can also be vowed by the several existing natural accumulations of carbon dioxide, which can be used to gather further knowledge on containment conditions (Baines and Worden 2004). These natural CO_2 fields range from shallow (100 meters) to deep (up to 5 km) reservoirs, with high-purity (>90 %) carbon dioxide accumulations around the world that can be used as analogs to investigate the consequences of long-term storage of CO_2 in both limestone and sandstone lithologies (Pearce 1996). Many of these natural occurrences are exploited and primarily used for enhanced oil recovery (EOR) projects (see Reservoir Options section), particularly in the USA. The McElmo Dome in southwestern Colorado is the best documented natural CO_2 reservoir and the world's largest supply of commercial carbon dioxide, with 1.6 Gt of original carbon dioxide in place. A large part of the 14.6 Mt of CO_2 produced annually is transported to the Permian Basin by an 800 km long pipeline since 1984. There is no episode of CO_2 leakage from the field to the surface detected by an alarm system installed on the surface since the beginning of its exploration in 1976 (Stevens et al. 2000).

Monitoring Stored CO_2

The deployment of any CO_2 storage project will most likely require, by regulating organisms, a constant monitoring and verification of the storage complex, usually operated during the injection phase and in the first years or decades following site abandonment (depending on specific regulations). Most monitoring techniques rely

on proven technology which has already been in use for years in many applications, including oil and gas exploration, natural gas underground storage, and waste disposal. The choice for the appropriate monitoring methods and instruments will depend on the storage complex characteristics and regulatory requirements.

Among the most important techniques for monitoring CO_2 in the reservoir are geophysical methods such as seismic, electromagnetic, and gravity imaging, which allow to track the CO_2 plume displacement in the host formation. Other important methods include geochemical monitoring, which relies on measuring changes in formation water (and/or gas) composition, collected in observation wells to evaluate changes caused by the injection of CO_2, and atmospheric and surface monitoring, for detecting leakages and seepages of CO_2 in the air and soil, in the surrounding areas of the storage complex (Arts and Winthaegen 2005).

Monitoring activities differ according to the stage in which a CCS project is found. The first stage is the site selection and characterization, where the monitoring role is to gather enough data to establish accurate baseline conditions, to be compared with upcoming measurements. During the operational phase, usually taking place over a period of 30–50 years, monitoring is focused on ensuring operational safety and assessing injection well conditions, tracking migration of injected CO_2, and updating storage performance predictions, usually comparing with data from simulations, laboratory experiments, and previous field tests. After operations are finished (when injection of CO_2 is stopped), a closure phase ensues. In this stage that may last years or decades (depending on the project or regulations), injection wells are plugged and abandoned and must be monitored for a certain period of time. Most monitoring activities should also be continued during this period in order to demonstrate storage safety and performance. In a post-closure stage, the storage complex will most likely be handed to regulatory authorities, who would maintain data records. Further monitoring would no longer be needed, except in case of ongoing leakages or legal disputes or in case additional data is required for future projects (Benson 2007).

Future Directions

CCS is a transition technology to an alternative energy future, possibly based on renewable sources. Optimism for its success is based on industrial experience – many of the technologies needed for implementation of CCS projects in commercial scale are already available and mature. But even proponents acknowledge that there are several issues that need to be dealt with before it can achieve widespread application with a significant impact in reducing emissions of greenhouse gases, especially when those regarding integration, cost-reduction, and scaling up of known technologies in large-scale commercial projects. Nevertheless, CCS is the only available technology with potential to ensure the protection of climate, while preserving the value of fossil fuel reserves and of the existing infrastructure, guaranteeing a sustainable use of these resources whenever necessary. Furthermore, CCS is only viable option for reducing large-scale CO_2 emissions from industrial

sectors such as cement, steel, chemical, and refining, which represent one-fifth of global emissions (IEA 2013).

CCS has been progressing steadily, although at a slower pace than would be desired to meet the expectations and emission reductions required (IEA 2013). As mentioned earlier, the current amount of CO_2 stored in large-scale demonstration or commercial projects is approximately 27 million tons per year, roughly 0.1 % of the global emissions from large stationary sources that can be captured and stored. While it is very unlikely that all the emissions from these sources will be captured and stored, it is expected that by 2050 this number is multiplied 100-fold, with CCS operations routinely used in all applicable process, storing over 7000 Mt annually, according to the latest technology road map for CCS from the IEA (released in 2013) (IEA 2013). Most of the existing CCS projects are in the oil and gas production and refining sectors, operated by petroleum companies, the majority of them for EOR purposes. It was not until recently, in 2014, that the first long-expected integrated CCS project in the power generation sector started operating, at demonstration scale (the Boundary Dam project in Canada, operated by SaskPower energy company). Other industrial areas have shown nearly absent advances in actions to integrate CCS in their activities (only two demonstration projects at iron and steel plants and one in coal-to-liquid process are in planning stages) (IEA 2013).

The latest progress report from the Global CCS Institute (released in February 2014) indicates that there are 60 large-scale projects worldwide (more than 1 $MtCO_2$/year) integrating capture and storage – 13 in operation and 47 in different planning stages (identification, evaluation, definition) (GCSSI 2014). Unfortunately, recent history has shown that many of the planned operations ended up being canceled at the final investment decision, mostly due to the elevated costs associated with a CCS project. Indeed, the absence or uncertainty of an economic sustainable model for this activity is possibly one of the main reasons for the slow pace of CCS deployment so far. Governments are expected to contribute in these initial efforts, funding research and demonstration projects (and even funding pipeline networks, since they could be shared by more than one project), but it is widely accepted that an economic driver has to be established to stimulate the private sector to participate in CCS initiatives. With the current conditions, commercial power plants and industrial facilities will not invest in CCS owing to the elevated costs and reduced efficiency and energy outputs. CCS coupled to coal-fired power generation increases the costs between 40 % and 60 % (yet the end cost would still be comparable or less than that from photovoltaic of offshore wind generation costs). Injection of CO_2 in deep saline aquifers, which are possibly the most suitable reservoirs for storage, has no economic return by itself and requires some form of incentive to be deployed, as was the case in the Sleipner project, with Norway's government taxes imposed over CO_2 emissions offshore. The inclusion of CO_2 geological storage in the UN Framework Convention on Climate Change Clean Development Mechanism (CDM) is one solution that has been advocated strongly by many governments and stakeholders, as a means to establish an economic driver for CCS projects. The CDM is a mechanism established in the

Kyoto Protocol that provides means for companies and countries to offset their CO_2 emissions by investing in projects with proved emission reductions (such as CCS operations) in developing countries. Following many years of negotiations, CCS has finally been accepted to be included in the CDM in 2011, although many issues still need to be worked out before it starts going operative (UNFCCC 2011).

More recently, the utilization of CO_2 in activities that could provide it with some economic value has been proposed. While it has been used in several applications for many years, the amounts involved are too small to add a significant contribution to an effective reduction of emissions. Between 80 Mt and 120 Mt of CO_2 are sold commercially each year for many applications, with the majority (more than 60 Mt) being used for enhanced oil recovery (EOR) (IPCC 2005; IEA 2013; GCCSI 2011).

In the chain of a CCS integrated operation, the major bottleneck in the total cost is the capture and separation of CO_2 from the stationary source, being responsible for approximately 70 % of the global cost in a project. Capture and separation technologies have long been used in the industry to remove CO_2 from flue gas streams; however, there is still a strong need to develop and test new technologies (especially in view of the large scales required for CCS projects). In particular, the main challenges in capture technologies at the moment include: (i) diminishing costs of post-combustion capture, which are mainly related to energy penalty required for regeneration of solvents and (ii) developing novel, promising technologies such as oxy-combustion via chemical looping and ionic liquids.

While storage costs are usually much lower than those of capture and separation, the challenge remains in terms of the long time frame – usually 5–10 years – that is necessary for the site selection and characterization phases that are necessary for a given project.

Another important issue for the full-scale deployment of storage is related to scaling up the rate of CO_2 that must be injected per storage site. Even though CCS has been demonstrated in commercial scale (storage >1 Mt/year) by the projects mentioned earlier, future storage projects will have to increase this rate several times. It is agreed that CO_2 injection must reach rates at least comparable to those of oil and gas extraction (IEA 2013).

The peculiar characteristics of CO_2 and its interaction with each part of the CCS chain require continuous research to improve existing technologies and materials, such as new CO_2-resistant cements for injection wells, development of high-pressure compressors adapted for CO_2, and corrosion-resistant pipelines for transport, among others.

Demonstrating safety of storage is also a key point in the development of this technology. This requires the improvement of existing and developing new monitoring techniques, which in turn can only be achieved through field testing in pilot- and demonstration-scale sites of injection. Successful demonstration of storage and monitoring techniques will further improve public perception of CCS as well. Geologic storage of CO_2 is a relatively new concept to which most of the population is very unfamiliar overall. Communicating and introducing this technology to general public is a challenging task that has to be carefully addressed in order to succeed.

The recognition of CCS as an important technology for greenhouse gas emission reductions resulted in a prompt effort by several countries' administrations in developing regulatory marks and legislations for this activity. However, the majority of nations (mostly non-OECD) still require regulations for this activity to be introduced in their legal system, and this presents a series of difficulties. First, the categorization of CO_2 in a CCS project is a matter of discussion – it is usually unclear whether it should be treated as waste, commodity, or other nature. Legal responsibilities over environmental damage due to leakages need to be properly defined by regulators, for which a clear distinction of the storage complex boundaries is imperative. Liability for stored CO_2 over the years is another issue that requires careful analysis, since storage periods are likely to be much longer than the lifetime of a site operator.

For all the potential that CCS in geological reservoirs has in becoming an important solution for the climate crisis, it was patently shown that many issues and gaps in this integrated technology are yet to be resolved to achieve this objective. And as with most of the challenges mankind has faced, this will probably hardly succeed if not through a global determination in solving it, mostly through the combined efforts of academia, industry, and government sectors.

and ionic liquids-based system are discussed as the typical and emerging state of the art for chemical absorption. Furthermore, new solvent selection, novel reactors, and system intergradation have been analyzed. The key issues to hinder the application of chemical absorption are discussed, such as water-consumption-related issues, environmental effects, and economical factors. Finally, some industry applications and future directions are discussed.

Principle of Chemical Absorption

Introduction

Chemical absorption is one of the most effective methods for CO_2 separation and capture nowadays. Being of low equipment cost, high removal efficiency, stable operation conditions, and mature technology background, chemical absorption has already been widely applied to chemical engineering, food industry, and other fields.

Chemical absorption is based on the solubility difference between CO_2 and the other gas components in mixed gases. The difference between chemical absorption and physical absorption is whether CO_2 reacts with the absorbent during the absorption process. Chemical absorption can be classified into nonrecycling processes and recycling processes. For the former processes, the rich CO_2 solution cannot be regenerated. While for the latter processes, the absorbent can be recovered by the cycle of absorption and regeneration.

Mechanism of Chemical Absorption

During the chemical absorption process, the CO_2 solubility depends on the physical solubility in the absorbent, the chemical reaction equilibrium constant, the chemical equivalent ratio, and other factors. In addition, in cases where the chemical absorbent solution is a strong or weak electrolyte, dilute solution theory does not fit. Solubility of gases in the chemical absorbent is characterized by a uniform solubility increase with pressure. The higher the pressure, the lower the solubility enhancement is. In that case, the relationship between partial pressure and gas solubility is more complex than that of physical absorption.

A vapor–liquid equilibrium under the following conditions is the simplest chemical absorption balance.

It is assumed that:

1. Only one chemical reaction happens in the system.
2. The activity coefficient does not relate to the composition of the components, and it is considered to be one in the simplest case.
3. The physical solubility of gas x_{ph} is negligible relative to the chemical solubility of gas x_{ch}, that is to say, the total solubility can be written as follows:

$$X = X_{ph} + X_{ch} \approx X_{ch} \tag{1}$$

The chemical reaction equation can be written in the following form:

$$nA + mB = kC + 1D + \cdots \tag{2}$$

or

$$A + \frac{m}{n}B = \frac{k}{n}C + \frac{l}{n}D + \ldots \tag{3}$$

In the formula,

A – dissolved gas
B – chemical absorbent
C, D – reaction products
n, m, k, l – stoichiometric coefficients

According to assumption Eq. 2, the equilibrium constant can be viewed as the function of the concentrations of the reaction components. If reactant A is consumed for x mol and the initial concentration of chemical absorbent B is B_0, when the system reaches another equilibrium state

$$K_p = \frac{\left(\frac{k}{n}x\right)^{\frac{k}{n}}\left(\frac{1}{n}x\right)^{\frac{1}{n}}\ldots}{x_\phi\left(B_o - \frac{m}{n}x\right)^{\frac{m}{n}}} = i\frac{x^h}{x_\phi(B_o - jx)^j} \tag{4}$$

In the formula,

$$i = (k/n)^{\frac{k}{n}}(l/n)^{\frac{1}{n}}\cdots, h = (k + l + \cdots)/n$$

$j = m/n$ – the ratio of the stoichiometric reaction coefficients between dissolved gas and consumed absorbents.
h is the total mole number or ions number of reaction products generated per mole gas.
j is the mole number of consumed chemical absorbents per mole gas. If the first condition is correct, then the coefficients of i, h, and j are all integers.

Equation 4 can be turned into the equation expressed in gas-phase equilibrium form by equilibrium constant of physical solubility.

$$X_{ph} = \frac{P_A}{K_{ph}} = \frac{P_A}{K_H} \tag{5}$$

P_A is the partial pressure of gas A, K_{ph} is physical equilibrium constant of gas A, and K_H is Henry equilibrium constant

$$P_A = K_{ph}\frac{ix^h}{K_P(B_0 - jx)^j} = K\frac{x^h}{(B_o - j_x)^j} \tag{6}$$

Under these assumptions, K only relates with the temperature. What's more, K reflects the state of gas–liquid phase physical equilibrium and chemical equilibrium.

$$K_{ph} = A_1 e^{\frac{-\Delta H}{RT}} \text{ and } K_P = A_2 e^{\frac{-\Delta H}{RT}} \tag{7}$$

ΔH_1 and ΔH_2 are the enthalpy change during the process of physical dissolution and chemical reactions, respectively. A_1 and A_2 are deviation coefficients.

$$K = i\frac{K_{ph}}{K_P} = (A_1 - A_2)e^{\frac{-\Delta H}{RT}} \tag{8}$$

ΔH – the total enthalpy change during the gas dissolution process with chemical reactions.

Here, the utilization efficiency of chemical absorbent is defined as $\alpha = x/B_0$. T also reflects the state of chemical reactions. Equation 6 can be written as

$$P_A = K\frac{(\alpha B_o)^h}{(B_o - j\alpha B_o)^j} = KB_o^{h-j}\frac{\alpha^h}{(1 - j\alpha)^j} \tag{9}$$

Thus, no less than three constants were introduced into the vapor–liquid equilibrium equations. These constants can be measured by individual methods or obtained from a chemical solubility database.

According to Eqs. 6 and 9, the chemical equivalents affect the curvature of the balance curve greatly, when K is equal to B_0. Hence, the chemical absorbent of high h value, of which h is above 1, is hard to regenerate with a decrease of pressure. However, this absorbent is easy to regenerate with a decrease of pressure under the condition of purification or lower gas partial pressure.

Derived from Eq. 6, the increase of the initial absorbent concentration causes a drop of the gas partial pressure above the absorbent when the gas concentration in the solution stays constant. As Eq. 9 shows, the effect of the absorbent concentration is different only judged by $(h - j)$ when α stays constant.

If $x \to 0$, Eq. 6 can be written in the following form:

$$P_A = \frac{iK_{ph}}{K_P} \cdot \frac{X^h}{B_0^j} = K_{ch}x^h \tag{10}$$

Equation 9 can be written in the following form:

$$P_A = KB_0^{h-j}a^h \tag{11}$$

According to Eq. 11, during the process of chemical absorption, if $x \rightarrow 0$, the Henry law can be applied only when h equals 1. That is to say, one mole gas involved in the chemical reactions can produce only one mole product.

In many cases, the experimental data can be described by Eq. 6. The coefficients i, h, and j are all integers in the equation. For more complicated processes, such as two or more continuous and parallel reactions occurring during the process, the coefficients i, h, and j can be fractions, and they relate with x_{ph}. However, the meaning of the coefficients does not change at every case, and it reflects the relative relationship between chemical equivalents.

Equation 6 can be used for calculation only when the relationship between $K\,ph/K\,P$ and the components of the solution is considered. The reason is that for Eqs. 4 and 6, the concentration of the solution should be replaced by the activity of the solution.

The equation for a real solution is

$$K_{P,T} = \frac{\left(\frac{k}{n} a_C\right)^{k/n} \left(\frac{l}{n} a_D\right)^{l/n}}{a_{ph} (a_B)^{m/n}} \tag{12}$$

$K_{P,T}$ – equilibrium thermodynamic constant.

As a$i = \gamma i Xi$, hence

$$P_A = \frac{K_{ph} i}{K_P} \cdot \frac{x_{ch}^h}{(B_0 - jx)^j} \cdot \frac{\gamma_n^k \gamma_n^l}{\gamma_B^j} = \frac{K_{ph} K_\gamma}{K_P} \cdot \frac{X_{ch}^h}{(B_0 - jx)^j} \cdots \tag{13}$$

The coefficient related with chemical products and the activity of the absorbent.

By comparison of Eqs. 6 and 13, the two equations are consistent with each other when the change of the activity of solution components is mutually compensated, that is to say, $\gamma \neq 1$ and K_γ stay constant.

Both the relationship between K_{ph} and x and the relationship between K_{ph} and B have additional effects on the gas dissolution for chemical absorption processes.

$$K_{ph} = K_H e^{(ax + bB)} \tag{14}$$

In this equation, a and b are constants, x is solubility, and B is the concentration.

Figure 1a shows the relationship between gas solubility and partial pressure above the surface. Curve 1 and curve 2 describe the chemical absorption process. Curve 3, curve 4, and curve 5 are descriptions of the physical absorption process.

Figure 1b shows the relationship between gas partial pressure above the solution surface and temperature.

When the reaction between the absorbent and the gas is completed, that is to say ($j\alpha \rightarrow 1$), the gas solubility only depends on the physical absorption process. Hence, with the increase of operation pressure, the gas solubility increases at this time.

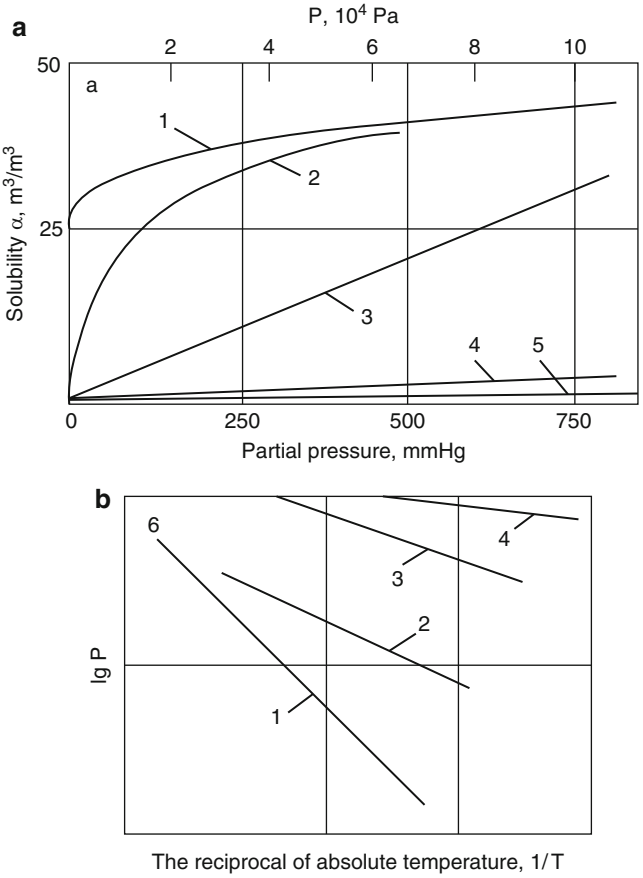

Fig. 1 The equilibrium pressure and temperature curve in the gas–liquid system. The meanings of the curves in the figures are listed as follows: (*1*) When the temperature is 20 °C, CO_2 is injected into the MEA (monoethanolamine) solution of 2.5 mol/L (chemical absorption). (*2*) When the temperature is 60 °C, CO_2 is injected into the solution of 25 % K_2CO_3 + 10 % DEA (diethanolamine), (chemical absorption). (*3*) When the temperature is 25 °C, C_2H_2 is injected into the *N*,*N*-dimethylformamide solution (physical absorption). (*4*) When the temperature is 25 °C, C_2H_2 is injected into the propylene carbonate solution (physical absorption). (*5*) When the temperature is 25 °C, C_2H_2 is injected into the water (physical absorption) (Semeonova and Lieyijiesi 1982)

Chemical absorption is different from physical absorption that the solution heat during the chemical absorption process is rather huge; even reaches 83.3 ∼ 125.8 kJ/mol. Hence, the gas solubility is affected strongly by the temperature. The lower the concentration of gas absorbed, the more the solution heat per gram of gas. The gas concentration above the surface of a regenerated absorbent solution is usually low, and the partial pressure above the surface of the solution

increases with the temperature. Compared to physical absorption, chemical absorption is fit for fine purification.

The operation pressure has little effect on the absorption capacity of an absorbent. Chemical absorption is particularly good for the case that the absorption gas concentration is not high.

Above all, the best method to regenerate an absorbent is to raise the operation temperature. The decrease of operation pressure is not a good choice. It is especially suitable for a strong absorbent, that is to say, ΔH and $K P$ are large. With the decrease of ΔH and $K P$, the characteristics of a chemical absorbent are more like those of a physical absorbent, and the process setup needs to vary with that change.

Typical Chemical Absorption System

Amine-Based Systems

The idea of separating CO_2 from flue gas streams started in the 1970s, not with concern about the greenhouse effect, but as a potentially economic source of CO_2, mainly for enhanced oil recovery (EOR) operations. All the early plants capture CO_2 with processes based on chemical absorption using amine-based solvents.

Typical amine-based absorbents can be classified into three categories by the number of active hydrogen atoms adjacent to the nitrogen atom, primary amine with two hydrogen atoms, secondary amine with one hydrogen atom, and tertiary amine without hydrogen atom. Judged by the number of active nitrogen atoms, the amine-based absorbents can be classified into monoamine and multi-amines. The reaction mechanism between alkanolamines and CO_2 can be expressed by the following description (Blauwhoff et al. 1984):

1. Reaction mechanism between CO_2 and primary amines or secondary amines
   When a primary amine and secondary alkanolamines are chosen to be the absorbents, the so-called zwitterions are formed at first due to the reaction between CO_2 and amines. After that, the zwitterions will react with alkanolamine and form carbamate. The detailed reactions are listed as follows, where R is an alkyl and R′ is H for primary amines and an alkyl for secondary amines (Industrial Development Bureau 2002):

$$\mathrm{RR'NH} + \mathrm{CO_2} \rightleftharpoons \mathrm{RR'NH^+COO^-}\,(\text{zwitterion}) \tag{15}$$

$$\mathrm{RR'NH} + \mathrm{RR'NH^+COO^-} \rightleftharpoons \mathrm{RR'NCOO^-}\,(\text{carbamate}) + \mathrm{RR'NH_2^+} \tag{16}$$

   The total reaction is

$$2\mathrm{RR'NH} + \mathrm{CO_2} \rightleftharpoons \mathrm{RR'NCOO^-} + \mathrm{RR'NH_2^+} \tag{17}$$

According to the total reaction, due to the restrictions of thermodynamics, the maximum CO_2 absorption capacity is 0.5 mol CO_2/mol absorbent. However, some amino acid root may be hydrolyzed into free amine.

$$RR'NCOO^- + H_2O \rightleftharpoons RR'NH + HCO_3^- \tag{18}$$

Hence, sometimes the maximum CO_2 absorption capacity exceeds 0.5 mol CO_2/mole absorbent. The characteristics for CO_2 absorption in amine solution are high reaction rate and low CO_2 absorption capacity.

2. Reaction mechanism between CO_2 and tertiary amines
There is no excess hydrogen atom adjacent to the nitrogen atom for tertiary amines so that no zwitterions are produced in the following process. The reaction mechanism can be depicted by the following equations, where R, R′, and R″ are alkyls (Industrial Development Bureau 2002):

$$RR'R''N + H_2O + CO_2 \rightleftharpoons RR'R''NH^+ + HCO_3^- \tag{19}$$

According to the above equation, there is no thermodynamic restriction for tertiary amines. The maximum CO_2 absorption capacity is 1 mol CO_2/mol absorbent. However, the absorption rate is rather low for tertiary amines.

3. Reaction mechanism between CO_2 and sterically hindered amines
The huge functional groups adjacent to the nitrogen atom can hinder the binding of CO_2 and alkanolamine so as to reduce the stability of the amino acid root. Hence, the maximum absorption capacity for sterically hindered amines is the same as for tertiary amines. What's more, the absorption rate is close to that of primary and secondary amines. Take AMP (aminomethylpropanol) as an example: The reaction mechanism of CO_2 and AMP can be described by the following equation, where R is $C(CH_3)_2CH_2OH$ (Mandal and Bandyopadhyay 2006a):

$$CO_2 + RNH_2 + H_2O \rightleftharpoons RNH_3^+ + HCO_3^- \tag{20}$$

A continuous scrubbing system is used to separate CO_2 from the flue gas stream. As illustrated in Fig. 2, the flue gas is transported into the absorber after removing the dust and other air pollutants, especially SO_2 and NO*x*. If necessary, the flue gas should also go through some cooling process and pressure enhancement process before it is sent to the absorber by the blower. Flue gas enters into the bottom of the packed column and contacts with the lean CO_2 absorbent injected from the top of the absorber directly and in counterflow. CO_2 in the flue gas reacts with the chemical absorbent and forms some weak salts so that CO_2 is separated from the flue gas by the absorber. The rich CO_2 solution is pumped to the regenerator, which is also called stripper. However, the rich CO_2 solution needs to pass a lean/rich solution heat exchanger before it enters into the regenerator. The lean/rich solution heat exchanger aims to optimize the heat cycle of the whole process. It can heat the rich CO_2 solution to a higher temperature that is closer to the stripping temperature. It can also decrease the

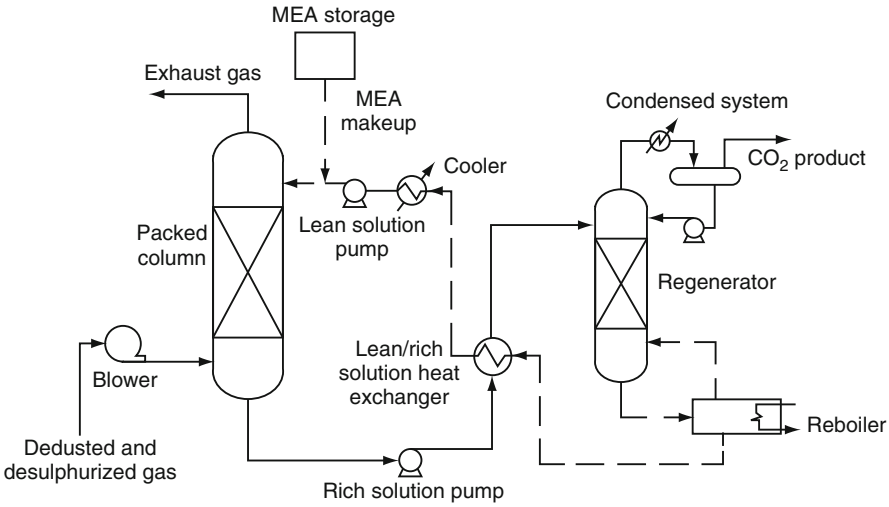

Fig. 2 Flow sheet for CO_2 capture from flue gases using amine-based systems (Rubin and Rao 2002)

lean CO_2 solution to a temperature which is much closer to the absorption temperature. CO_2 is regenerated in the stripper due to diverse reactions occurring at the higher temperature. The heat of the stripper is supplied by the reboiler. Then, the gas at the top of the stripper should be cooled to separate vapor from CO_2. The solution regenerated at the bottom of the stripper is sent back to the absorber.

Although amines have been used for many years, particularly in the removal of acid gases from natural gas, there is still enough space for process improvement. Amines are available in three forms (primary, secondary, and tertiary), each with its advantages and disadvantages as a CO_2 solvent. In addition to options for the amine, additives can be used to improve system performance. Furthermore, design optimization is possible to decrease capital costs and reduce energy consumption.

Past studies have shown that amine-based CO_2 absorption systems are the most suitable ones for combustion-based power plants for the following reasons:

- These systems are effective for dilute CO_2 streams, such as coal combustion flue gases, which typically contain only about 10–12 % CO_2 by volume.
- Amine-based CO_2 capture systems are a proven technology that is commercially available and in use today.
- Amine-based systems are similar to other end-of-pipe environmental control systems used at power plants. These units are operated at ordinary temperature and pressure.
- A major effort is being made worldwide to improve this process in the light of its potential role in CO_2 abatement. Thus, one can anticipate future technology advances.

However, the amine systems used at low partial pressure conditions encountered with carbon dioxide in flue gases have inherent disadvantages:

- High heat of reaction which leads to the need for expensive cooling systems
- High regeneration energy needs which require large quantities of low-pressure steam and correspondingly large stripper column reboilers
- The need for large volume absorbers with expensive packings to provide adequate mass transfer surface for the carbon dioxide absorption and reaction
- The need to circulate large quantities of amine solvents because of practical limitations of carbon dioxide loadings
- A high parasitic power loss caused by the need to overcome the pressure drops in the large absorbers

These factors combined result in relatively high capital costs for the capture plant and high operating costs and consequential efficiency losses in host power plants where the capture plant is integrated. Furthermore, due to the viscosity of the amines, problems such as entraining, channeling, bubbling, and overflowing may happen. The amine-based systems also have problems with equipment corrosion.

Improvements to amine-based systems for post-combustion CO_2 capture are being pursued by a number of process developers. Some of them are Fluor, Mitsubishi Heavy Industries (MHI), and Cansolv Technologies, Inc. Fluor's Econamine FG Plus™ is a proprietary acid gas removal system that has demonstrated larger than 95 % availability with natural gas-fired power plants, specifically on a 350 t/day CO_2 capture plant in Bellingham, MA. It is currently the state-of-the-art commercial technology baseline. MHI has developed a new absorption process, referred to as KS series absorbents. An innovative factor in this development is the utilization of a new amine-type solvent for the capture of CO_2 from flue gas (America 2005). Cansolv Technologies, Inc. proposes to reduce costs by incorporating CO_2 capture in a single column with processes for capturing pollutants, such as SO_2, NO*x*, and Hg. DC1031 tertiary amine solvent has demonstrated fast mass transfer and good chemical stability with high capacity – a net of 0.5 mol of CO_2/mol of amine per cycle compared to 0.25 mol/mol for monoethanolamine (MEA) (Hakka 2007, Cansolv Technologies Inc., private communication).

R&D pathways to improved amine-based systems include modifying tower packing to reduce pressure drop and increase contacting area, increasing heat integration to reduce energy requirements, using additives to reduce corrosion and allow higher amine concentrations, and improving regeneration procedures.

Carbonate-Based Systems

Carbonate systems are based on the ability of a soluble carbonate to react with CO_2 to form bicarbonate, which can be heated to release CO_2 and revert to a carbonate. A major advantage of carbonates over amine-based systems is the

significantly lower energy required for regeneration. The University of Texas at Austin has been developing a K_2CO_3-based system in which the solvent is promoted with catalytic amounts of piperazine (PZ). The K_2CO_3/PZ system (5 M K; 2.5 M PZ) has an absorption rate 10–30 % faster than a 30 % solution of MEA and favorable equilibrium characteristics. A benefit is that oxygen is less soluble in K+/PZ solvents; however, piperazine is more expensive than MEA, so the economic impact of oxidative degradation will be about the same (Resnik et al. 2004). Analysis has indicated that the energy requirement is approximately 5 % lower with a higher loading capacity of 40 % versus 30 % for MEA. System integration studies indicate that improvements in structured packing can provide an additional 5 % energy savings, and multi-pressure stripping can reduce energy use by 5–15 % (Rochelle 2006, private communication).

The reaction mechanism between CO_2 and PZ can be expressed as follows:

$$\mathrm{PZ} + \mathrm{CO_2} + \mathrm{OH^-} \longleftrightarrow \mathrm{PZCOO^-} + \mathrm{H_2O} \tag{21}$$

$$\mathrm{PZ} + \mathrm{CO_2} + \mathrm{H_2O} \longleftrightarrow \mathrm{PZCOO^-} + \mathrm{H_3O^+} \tag{22}$$

$$\mathrm{PZ} + \mathrm{CO_2} + \mathrm{PZ} \longleftrightarrow \mathrm{PZCOO^-} + \mathrm{PZH^+} \tag{23}$$

$$\mathrm{PZ} + \mathrm{CO_2} + \mathrm{CO_3^{2-}} \longleftrightarrow \mathrm{PZCOO^-} + \mathrm{HCO_3^-} \tag{24}$$

$$\mathrm{PZ} + \mathrm{CO_2} + \mathrm{PZCOO^-} \longleftrightarrow \mathrm{PZCOO^-} + \mathrm{H^+PZCOO^-} \tag{25}$$

$$\mathrm{PZCOO^-} + \mathrm{CO_2} + \mathrm{H_2O} \longleftrightarrow \mathrm{PZ(COO^-)_2} + \mathrm{H_3O^+} \tag{26}$$

$$\mathrm{PZCOO^-} + \mathrm{CO_2} + \mathrm{PZ} \longleftrightarrow \mathrm{PZ(COO^-)_2} + \mathrm{PZH^+} \tag{27}$$

$$\mathrm{PZCOO^-} + \mathrm{CO_2} + \mathrm{CO_3^{2-}} \longleftrightarrow \mathrm{PZ(COO^-)_2} + \mathrm{HCO_3^-} \tag{28}$$

$$\mathrm{PZCOO^-} + \mathrm{CO_2} + \mathrm{PZCOO^-} \longleftrightarrow \mathrm{PZ(COO^-)_2} + \mathrm{H^+PZCOO^-} \tag{29}$$

$$\mathrm{CO_2} + \mathrm{OH^-} \longleftrightarrow \mathrm{HCO_3^-} \tag{30}$$

$$\mathrm{PZ} + \mathrm{CO_2} + \mathrm{H_2O} \longleftrightarrow \mathrm{PZH^+} + \mathrm{HCO_3^-} \tag{31}$$

$$\mathrm{PZCOO^-} + \mathrm{CO_2} + \mathrm{H_2O} \longleftrightarrow \mathrm{H^+PZCOO^-} + \mathrm{HCO_3^-} \tag{32}$$

The K+/PZ solvent was introduced by Cullinane as an alternative to the widely used MEA. According to Cullinane, the K+/PZ solvent has a higher CO_2 capacity than MEA because PZ is a secondary amine and potassium carbonate increases the absorption capacity. Furthermore, the rate of absorption was increased due to the presence of secondary amine groups in PZ, the high pK_a, and the large quantity of carbonate/bicarbonate. He reported a CO_2 absorption rate 1.5–3 times faster than with 30 wt% MEA.

The flow sheet of carbonate-based systems is similar to that of an amine-based system. Although the K+/PZ system has several advantages over amine-based systems, the technology is still not mature. Lots of experimental data on this idea is still lacking. The pros and cons of this system still need to be tested.

Ammonia-Based Systems

Ammonia-based wet scrubbing is similar in operation to amine systems. Ammonia and its derivatives react with CO_2 via various mechanisms, one of which is the reaction of ammonium carbonate (AC), CO_2, and water to form ammonium bicarbonate (ABC). The gas–liquid chemical reactions can be expressed by the following reaction equation:

$$NH_3(l) + CO_2(g) + H_2O(l) \longleftrightarrow NH_4HCO_3(s) \tag{33}$$

However, the actual steps of the chemical reaction are complex and must pass through several intermediate reaction steps:

$$2NH_3(g) + CO_2(g) \longleftrightarrow NH_2COONH_4(s) \tag{34}$$

The formed NH_2COONH_4 is further hydrolyzed:

$$NH_2COONH_4(s) + H_2O(l) \longleftrightarrow NH_4HCO_3(s) + NH_3(g) \tag{35}$$

Then, the NH_3 reacts with H_2O to form NH_4OH:

$$NH_3(g) + H_2O(l) \longleftrightarrow NH_4OH(l) \tag{36}$$

The hydrolyzed product NH_4HCO_3 of reaction reacts with NH_4OH to form $(NH_4)_2CO_3$:

$$NH_4HCO_3(s) + NH_4OH(l) \longleftrightarrow (NH4)_2CO_3(s) + H_2O(l) \tag{37}$$

The $(NH_4)_2CO_3$ then absorbs CO_2 to form ammonium bicarbonate:

$$(NH_4)_2CO_3(s) + H_2O(l) + CO_2(g) \longleftrightarrow 2NH_4HCO_3(g) \tag{38}$$

All the reaction equations are reversible. This reaction has a significantly lower heat of reaction than amine-based systems, resulting in energy savings, provided the absorption/desorption cycle can be limited to this mechanism. Ammonia-based absorption has a number of other advantages over amine-based systems, such as the potential for high CO_2 capacity, lack of degradation during absorption/regeneration, tolerance to oxygen in the flue gas, low cost, and potential for regeneration at high pressure. There is also the possibility of reaction with SO*x* and NO*x* – critical pollutants found in flue gas – to form fertilizer (ammonium sulfate and ammonium nitrate) as a salable by-product. Figure 3 gives the typical flow sheet for CO_2 capture from flue gases using aqueous ammonia systems (Resnik et al. 2006).

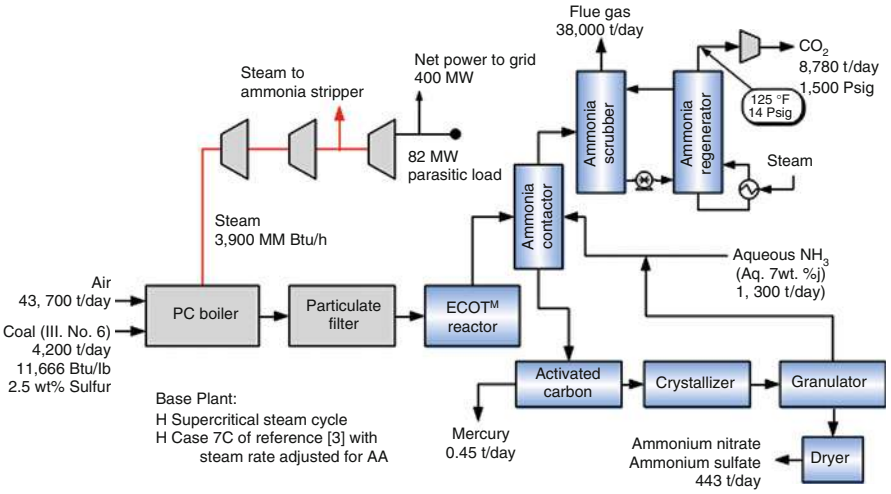

Fig. 3 Flow sheet for CO_2 capture from flue gases using aqueous ammonia systems (NETL 2007)

A few concerns are related to ammonia's higher volatility compared to that of MEA. One is that the flue gas must be cooled to the 288 ∼ 300 K range to enhance the CO_2 absorptivity of the ammonia compounds and to minimize ammonia vapor emissions during the absorption step. Additionally, there is concern over ammonia losses during regeneration, which occurs at elevated temperatures. R&D process improvements include process optimization to increase CO_2 loading and the use of various engineering techniques to eliminate ammonia vapor losses from the system during operation (Resnik et al. 2004, 2006; Yeh et al. 2005).

Another ammonia-based system, under development by Alstom, is the chilled ammonia process (CAP), which was first tested in a 5-MW pilot test in 2007 at We Energies Pleasant Prairie Power Plant. It was also tested in mid-2008 on AEP's 1,300-MW Mountaineer Plant in New Haven, WV, as a 30-MW (thermal) product validation with up to 100,000 t of CO_2 being captured per year. This process uses the same AC/ABC absorption chemistry as the aqueous system described above but differs in that no fertilizer is produced and a slurry of aqueous AC and ABC and solid ABC is circulated to capture CO_2 (Black 2006). The process operates at near-freezing temperatures (273–283 K), and the flue gas is cooled prior to absorption using chilled water and a series of direct contact coolers. Figure 4 gives the schematic of the chilled ammonia process. Technical hurdles associated with the technology include cooling the flue gas and absorber to maintain operating temperatures below 283 K required to reduce ammonia slip and achieve high CO_2 capacities and, for AC/ABC cycling, mitigating the ammonia slip during absorption and regeneration, achieving 90 % removal efficiencies in a single stage, and avoiding fouling of heat transfer and other equipment by ABC deposition as a result of absorber operation with a saturated solution. Both the aqueous and chilled ammonia

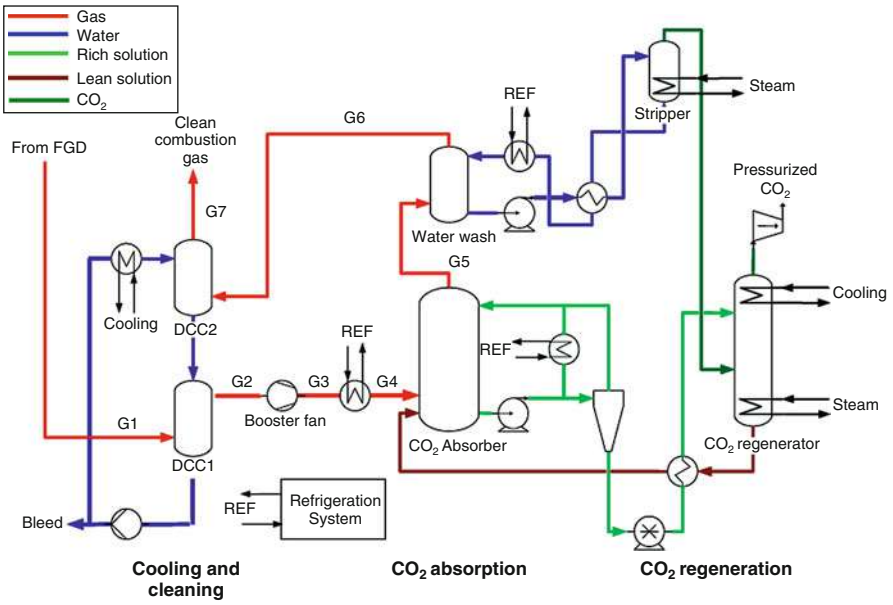

Fig. 4 Schematic of the chilled ammonia process (PT/PE Sector – Communications – November 2006, Chilled Ammonia Process for CO_2 Capture – content owner: Sean Black)

processes have the potential for improved energy efficiency over amine-based systems, if the hurdles can be overcome.

Membrane Absorption Systems

Membrane contactors have been considered a promising alternative to traditional packed columns for CO_2 capture in recent years. Membrane absorption technology combines the advantages of both membrane separation and chemical absorption, which has high specific surface area and high CO_2 selectivity. It can effectively reduce the equipment size and investment costs. Zhang and Cussler (1985a, b) firstly proposed using hollow fiber membrane contactors to replace the traditional packed tower for acid gases CO_2, H_2S removal. Membrane contactors are gas–liquid reactor to provide a barrier between the gas and liquid phases. The membranes do not offer selectivity, and the driving force for gas separation is a concentration gradient. As shown in Fig. 9, usually the gas phase (flue gas) flows in the shell side of the membrane contactor, while the liquid phase (aqueous CO_2 absorbent) flows in the tube side. The CO_2 molecules can pass through the membrane pores and react with the absorbent; however, the liquid absorbent could not permeate into the pores due to the membrane's high hydrophobic. Figure 5a shows the principle of membrane absorption for the CO_2 capture process. Figure 5b gives the true structure of a hollow fiber membrane, and Fig. 6 gives the experimental schematic of membrane absorption.

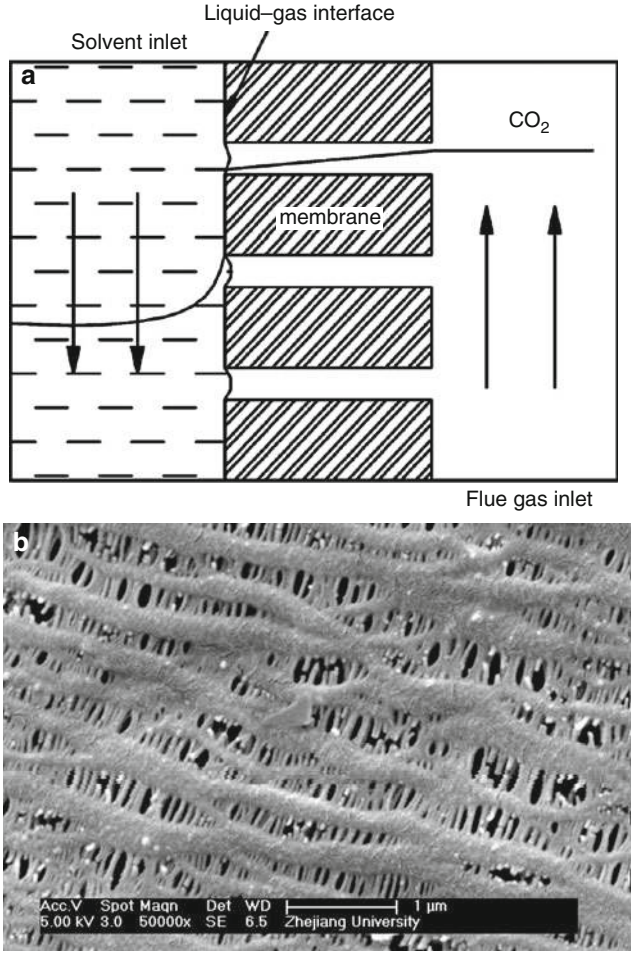

Fig. 5 (**a**) The principle of membrane absorption. (**b**) Typical structure of a hollow fiber membrane

Comparing with the traditional absorption contactors, membrane contactors have the following major advantages:

1. High specific surface area. The effective specific surface area of membrane contactor can be 1,500–3,000 m^2/m^3, which is much larger than that of packed column (100–800 m^2/m^3) [182].
2. Operational flexibility. Since the liquid phase and gas phase flow independently in the membrane contactors, the operating problems in packed columns can be avoided.
3. Linear scale-up. The modularity of membrane contactors makes it easy to scale up.

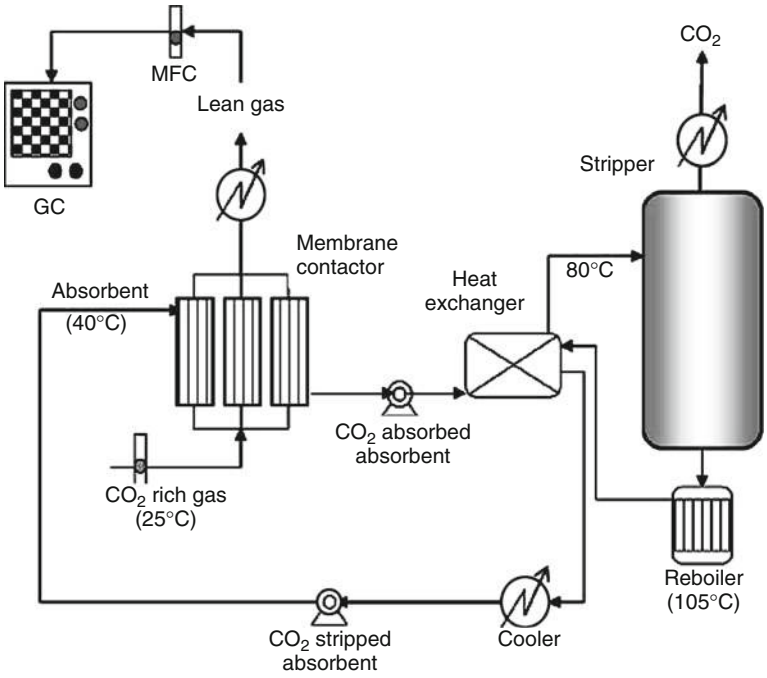

Fig. 6 Experimental schematic of CO_2 capture from flue gas by membrane absorption (Yeon et al. 2005)

4. Easy prediction. The gas–liquid contact area is constant for a membrane contactor, and it has no relationship to the operating conditions.

However, membrane contactors also have some disadvantages. First, the presence of membrane adds extra mass transfer resistance, which will result in a reduction in the overall mass transfer rate. But this negative impact can be potentially eliminated by the advantage of large interfacial mass transfer area. The main challenge for membrane contactor is the issue of membrane wetting, which leads to the deterioration of CO_2 absorption flux in long-term operation and limits its large-scale commercial application. In order to solve this problem, a number of studies have been conducted, including the selection of membrane materials, mechanism of membrane wetting, and prevention of membrane wetting (Pederson et al. 2000).

Enzyme-Based Systems

Biologically based capture systems are another potential avenue for improvements in CO_2 capture technology. These systems are based upon naturally occurring reactions of CO_2 in living organisms. One of these possibilities is the use of enzymes. An enzyme-based system, which achieves CO_2 capture and release by mimicking the

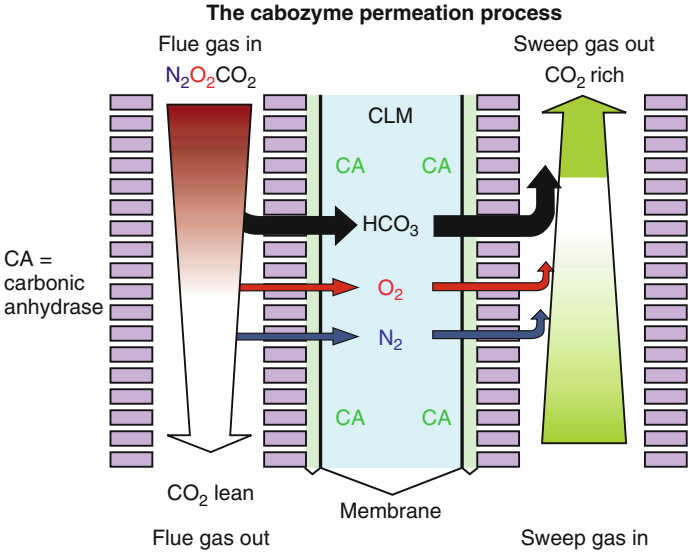

Fig. 7 Schematic of the carbozyme permeation process (Figueroa et al. 2008)

mechanism of the mammalian respiratory system, is under development by Carbozyme (see Fig. 7). The process, utilizing carbonic anhydrase (CA) in a hollow fiber contained liquid membrane, has demonstrated at laboratory scale the potential for 90 % CO_2 capture followed by regeneration at ambient conditions. This is a significant technical improvement over the MEA temperature swing absorption process. The CA process has been shown to have a very low heat of absorption that reduces the energy penalty typically associated with absorption processes.

The rate of CO_2 dissolution in water is limited by the rate of aqueous CO_2 hydration, and the CO_2-carrying capacity is limited by the buffering capacity. Adding the enzyme CA to the solution speeds up the rate of carbonic acid formation; CA has the ability to catalyze the hydration of 600,000 molecules of carbon dioxide per molecule of CA per second compared to a theoretical maximum rate of 1,400,000 (Trachtenberg et al. 1999). This fast turnover rate minimizes the amount of enzyme required. Coupled with a low makeup rate, due to a potential CA life of 6 months based on laboratory testing, this biomimetic membrane approach has the potential for a step change improvement in performance and cost for large-scale CO_2 capture in the power sector. Although the reported laboratory and economic results may be optimistic, the "carbozyme biomimetic process can afford a 17-fold increase in membrane area or a 17 times lower permeance value and still be competitive in cost with MEA technology" (Yang and Ciferno 2006). The idea behind this process is to use immobilized enzyme at the gas/liquid interface to increase the mass transfer and separation of CO_2 from flue gas. Technical challenges exist before this technology can be pilot tested in the field. These limitations include membrane boundary

layers, pore wetting, surface fouling (Boa and Trachtenberg 2006), loss of enzyme activity, long-term operation, and scale-up.

Key Technologies of Chemical Absorption Systems

Absorbent

The absorbent is one of the most important factors to affect the process of chemical absorption. The type of absorbent and the rational weight concentration/mixing weight ratio are the main characteristic parameters of chemical absorption technologies. An absorbent of high absorption rate and absorption capacity can help to minimize the equipment size and decrease the loss of absorbent, while an absorbent of lower regeneration energy consumption can basically decrease the total energy consumption of the whole process. The optimal choice of absorbent can make the chemical absorption technology more challenging than the other methods. What is more, the capital cost of absorbent, the physical and environmental properties of absorbent, and whether degradation reactions can occur with the other component in the flue gas are also important factors to be considered.

Properties of the Absorbent

The chemical absorbent for CO_2 capture should meet some basic requirements.

Absorption Capacity

Absorption capacity is the CO_2 solubility in the absorbent. The temperature and pressure effect on the solubility are the most important properties for an absorbent. The main index for the process such as circulation rate of absorbent, heat consumption and electricity consumption for regeneration process, operation conditions for regeneration, and the equipment size all depends on the solubility.

The Selectivity of Absorbent

The selectivity of absorbent refers to the ratio between the CO_2 solubility α_2 and the solubility α_1 of the other gas component which is closest to CO_2.

$$C = \frac{\alpha_2}{\alpha_1} = \frac{K_{ph,1}}{K_{ph,2}} \tag{39}$$

Among the equation,

C – selectivity coefficient
$K_{ph,\,i}$ – solubility coefficient of less dissolved component i

During the whole absorption process, the consumption of less dissolved gas, the possibility of complete separation of the mixed gases, the characteristics of the process, and many coefficients are related to the selectivity of the absorbent.

Saturated Vapor Pressure

In order to avoid the loss of absorbent during the operation, the vapor pressure under the absorption temperature should be low and the boiling point of the absorbent should be high enough. The requirement for the saturated vapor pressure depends on the pressure of the absorption process and the weight concentrations of the absorbent solution.

In some cases, an easily volatile absorbent like ammonia may be employed. However, it seems to be operated during the process that absorption temperature is low and operation pressure is high.

Boiling Point

To some extent, once the requirement for the saturated vapor pressure is met, the optimal boiling point for the absorbent should be generally above 423 K. In many cases, the boiling point of the absorbent is not expected to be high, that is to say, a low saturated vapor pressure is the ideal condition. It is necessary to carry out distillation when the by-products accumulate in the circulated solution. If the boiling point of the solution is too high, the distillation temperature has to be raised rather high to meet the requirements of energy consumption. Otherwise, the distillation should be carried out under high vacuum conditions. Factually, the boiling point of the absorbent is usually between 443 and 473 K. The saturated vapor pressure is usually up to 13.33 Pa at 303 K.

Freezing Point

The freezing point is also an important factor. Both the choice of the operation temperature and the storage condition depend on the freezing point. The mixed solution of absorbent, which usually refers to mixed solution composed of the absorbent and water, should not to be frozen easily.

Density

The density of the absorbent seldom affects the application of the absorbent. However, the density of the absorbent is better to be low when the other properties are the same.

Viscosity

The viscosity of the absorbent affects the heat transfer rate and mass transfer rate. Hence, it affects the size of the according equipment. It also has effects on the electricity consumption for solution transfer. Above all, the viscosity of the absorbent is better to be small when the other properties are the same.

Thermochemical Stability

The residence time of the absorbent in the system should be long. It usually needs to be completely changed every 6–18 months. Therefore, the thermochemical stability should be guaranteed. Even the degradation such as oxidizing which occurs very slowly should be considered during the choice of absorbent.

Another requirement for the absorbent is that the corrosion rate should be low and the market price should be not too high.

Absorbents for CO_2 Capture

Industry Used Absorbent

Until now, alkanolamines solution, alkali solution, and hot caustic potash solution have been widely used in many industries to separate CO_2 by chemical absorption methods, such as in the food industry, fertilizer industry, and so on. Table 1 lists the physical properties of the commonly used alkanolamines.

Maddox proposed a method to choose the absorbent (Maddox 1985). The CO_2 partial pressure and the CO_2 volume ratio before/after the chemical absorption process are considered to be the key factors. When the CO_2 partial pressure is no more than 103.4 kPa, the alkanolamine solutions are the best choices. In chemical absorption processes, the CO_2 partial pressure can be lower than 34.5 Pa. When the CO_2 partial pressure is 103.4–689.5 kPa, both the alkanolamine solutions and hot potassium carbonate solutions can decrease the CO_2 partial pressure to be lower than 6.9 kPa. When the CO_2 partial pressure is above 689.5 kPa, even the physical absorbent can decrease the CO_2 partial pressure to be 6.9–20.7 Pa.

According to Maddox's method on the selection of absorbent, alkanolamine solutions are the best choices for coal-fired power plants. The reason is that the coal-fired flue gas is usually of low CO_2 partial pressure, high volume, and high removal efficiency requirement of CO_2. Aqueous solutions of alkanolamines are the most commonly used chemical absorbents for the removal of acidic gases (CO_2 and H_2S) from natural, refinery, and synthesis gas streams. Among them, aqueous monoethanolamine (MEA) as a primary amine has been used extensively for this purpose, especially for removal of CO_2. It has several advantages over other commercial alkanolamines, such as high reactivity, low solvent cost, low molecular weight, and, thus, high absorbing capacity on a mass basis and reasonable thermal stability and thermal degradation rate. Generally speaking, MEA solution is currently the most widely used absorbent in fossil power plants.

To have a better understanding of the role played by MEA in the CO_2 capture process, the simple analysis on MEA is given according to the index raised above. Table 2 shows the evaluation for the conventional solvents MEA and MDEA (Kohl and Nielsen 1997).

Absorption and Regeneration Characteristics of CO_2 in MEA Solutions

A large number of studies have already been carried out in this field. Here is a brief introduction of absorption/regeneration characteristic data for MEA solutions.

The absorption rate and maximum net cycle capacity of several amines are given in Fig. 8.

Regeneration heat needs for the system are usually hard to measure. Generally speaking, the heat required to regenerate the solution in the desorber column of the CO_2 capture process (reboiler heat duty) can be described as the sum of three terms:

Table 1 The physical properties of commonly used alkanolamines (Kohl and Nielsen 1997)

Item	Monoethanolamine (MEA)	Diethanolamine (DEA)	Triethanolamine (TEA)	Methyldiethanolamine (MDEA)	Diisopropanolamine (DIPA)	Diethylene glycolamine (DGA)

[a]In the molecular formulae,

$$R = -CH_2CH_2OH$$

$$R' = -CH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HOH$$

Table 2 Comparison of MEA and MDEA in the CO_2 capture process

Monoethanolamine (MEA)	Methyldiethanolamine (MDEA)
+ Fast reaction	− Slow reaction
+ Low molecular weight → high solution capacity on a weight basis	− High molecular weight
− Low net (cyclic) capacity	+ High net (cyclic) capacity
− High heat of reaction with CO_2 (due to carbamate formation)	+ Low heat of reaction with CO_2
− High corrosion	+ Low corrosion
− Irreversible reaction products with carbonyl sulfide (COS) and carbon disulfide (CS_2)	+ Low degradation
− High vapor pressure	+ Low vapor pressure
+ Yellow chemical (good biodegradability)	− Red chemical (low biodegradability)
+ Low cost (+)	− High cost

$$q_{reb} = q_{sens} + q_{vap,H_2O} + q_{abs,CO_2} \tag{40}$$

where q_{sens} is the sensible heat to raise the solvent from the temperature downstream the rich-lean heat exchanger (RLHX) to the reboiler temperature, $q_{vap,\ H2O}$ is the heat of evaporation required to produce that part of the stripping steam in the reboiler which does not condense on its way up in the column and which is ultimately being condensed in the overhead condenser, and $q_{abs,\ CO2}$ is the overall heat required to desorb the CO_2 from the solution. The third term ($q_{abs,\ CO2}$) corresponds to the heat of absorption of the solvent with the CO_2. The same amount of heat that is being released in the exothermic reactions in the absorber column must be provided in the desorber column to reverse the absorption process and to drive out the CO_2. The heat of absorption consists of three terms (Kim et al. 2009):

1. Nonideal mixing
2. Dissolution of gas into the liquid
3. Chemical reaction

Heat must therefore be provided in the reboiler to break up the CO_2/solvent complex formed during the absorption process (heat of reaction) and to desorb the dissolved molecular CO_2 from the solution (heat of dissolution). Figure 9a shows the comparison of stripping heat needs for different absorbents, and Fig. 9b gives the distribution of energy associated in reboiler heat duty for different absorbents. Generally speaking, when the actual CO_2 loading is around 0.2 mol CO_2/mol MEA for the absorption/desorption process, the regeneration heat consumption is around 3.9–4.5 $MJ_{th}/kgCO_2$, which equals to ~1.6 $MJ_e/kgCO_2$ (Desideri and Paolucci 1999; Okabe et al. 2008). The heat of evaporation occupies the main energy consumption. Hence, it is meaningful to reduce the evaporation heat consumption for the MEA scrubbing process.

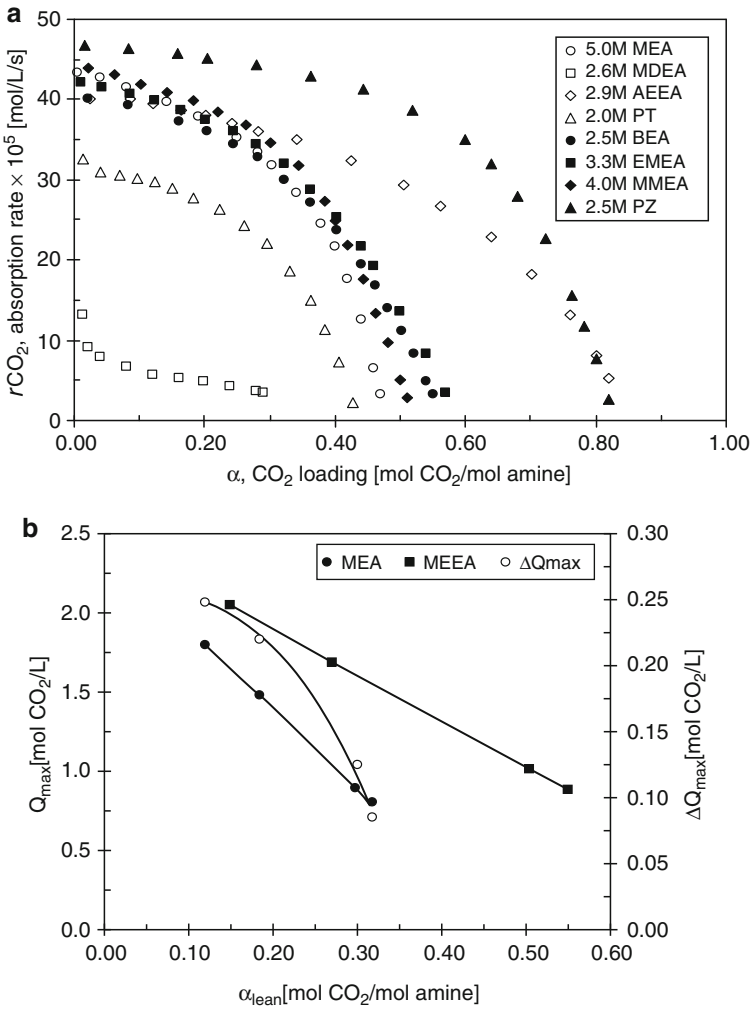

Fig. 8 (**a**) Absorption rate of CO_2 in amine-based solvent at 313 K. (**b**) Comparison of maximum net cycle capacity in 5 M MEA and 2.9 M AEEA (Mamun et al. 2007)

Degradation of MEA

The degradation of MEA in the flue gas is rather complicated. It may be caused by the following three main reasons: thermal degradation, oxidation degradation, and the formation of heat-stable salts. The detailed mechanisms are discussed here:

- Thermal degradation
- CO_2-induced degradation
- Degradation caused by COS and CS_2

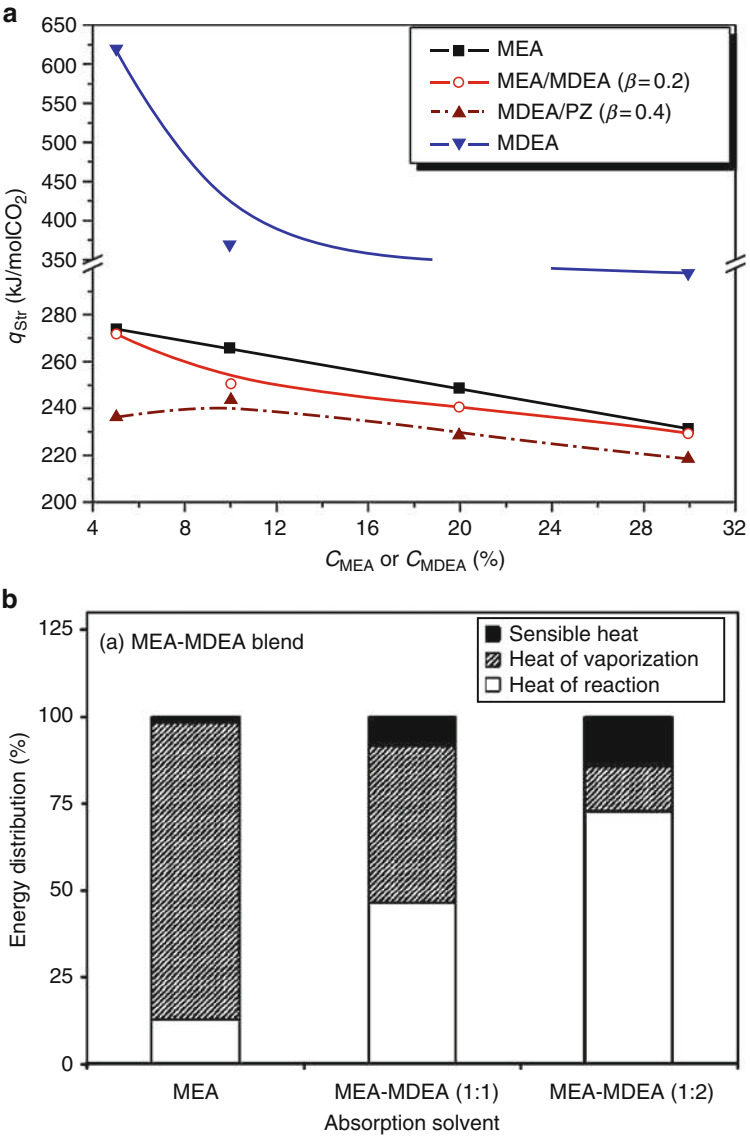

Fig. 9 (**a**) Stripping energy needs in solutions of different weight concentration. (**b**) Distribution of energy associated in reboiler heat duty for different absorbents (Sakwattanapong et al. 2005)

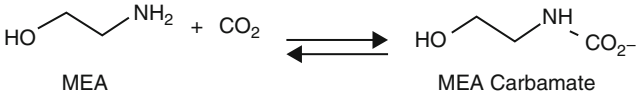
- Degradation caused by CO
- Formation of heat-stable salts and reaction of amines with strong acids
- Oxidation
- Sulfur and polysulfide degradation

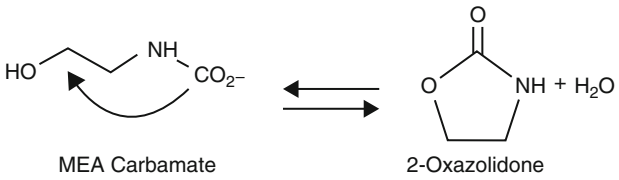
Thermal Degradation

Polderman (Polderman et al. 1955) describes the mechanism for thermal degradation of MEA by carbamate polymerization. In the absorber, MEA associates with CO_2 to form MEA carbamate as illustrated below.



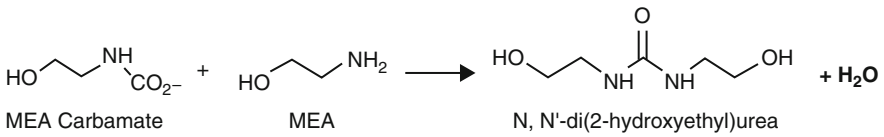
(41)

This reaction is normally reversed in the stripper, but in some cases the MEA carbamate will cyclize to form 2-oxazolidone, which is also a reversible reaction, as shown below:



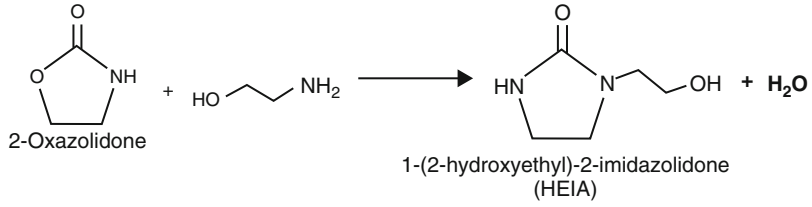
(42)

Yazvikova (Yazvikova et al. 1975) found that MEA carbamate can also react with a free MEA molecule and irreversibly dehydrolize to form *N*,*N*′-di(2-hydroxyethyl) urea.



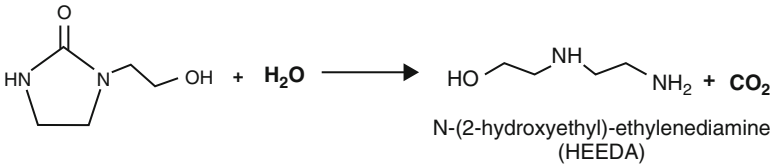
(43)

The former product, 2-oxazolidone, can then react with another molecule of MEA to form 1-(2-hydroxyethyl)-2-imidazolidone, which is sometimes referred to as HEIA.



(44)

HEIA can then be hydrolyzed to form *N*-(2-hydroxyethyl)-ethylenediamine or HEEDA.



(45)

These four species (2-oxazolidone, dihydroxyethylurea, HEIA, and HEEDA) plus further polymerization products are believed to be the main products of thermal degradation. The rate of formation of these products is a function of temperature (faster kinetics), CO_2 loading (more carbamate present), and MEA concentration.

Oxidation Degradation

The use of amines for CO_2 capture from flue gases involves one distinct difference and challenge from traditional amine acid gas capture: the presence of dioxygen (O_2) and its role in the oxidative degradation of the amine.

It is important to realize that degradation conditions will vary within the gas-treating plant. Different mechanisms may be involved in different parts of the plant. For instance, the highest O_2 concentration and the lowest temperature will occur within the absorber while the highest temperature and lowest O_2 content will be found in the reboiler.

Oxidation of most stable organic compounds is sluggish at room temperature and occurs readily only at high temperature. Obviously, the amines in flue gas capture applications experience a higher temperature but are still low relative to pyrolysis conditions. This low kinetic reactivity of dioxygen can be explained by considering spin conservation requirements. The ground state for O_2 is a triplet (a biradical). Most stable organic compounds and the dioxygen reduction products, H_2O and H_2O_2, are singlet molecules. The direct reaction of a triplet molecule with a singlet to give singlet products is a spin-forbidden process. This means that the reaction between dioxygen and a substrate should occur at a very low rate, which is determined by the time required for spin inversion to occur. This is generally a slow process except at elevated temperatures.

In reported studies of amine autoxidation, combinations of high O_2 partial pressures, higher than ambient process temperatures, and long reaction times (often several weeks) had to be employed to see substantial degrees of reaction. Metal ion spiking resulted in much faster reactions. The metal ions may directly react with amines, but in the presence of dioxygen, they may act as catalysts to activate the dioxygen. Metal complexes, due to their abilities to act as radicals with varied spin multiplicities, can provide spin-allowed pathways for reaction. Thus, the reaction of dioxygen and amines is spin-allowed if the number of electrons on a ternary complex (metal ion + amine + O_2) remains constant throughout the reaction.

- Dioxygen complex intermediates as oxidants. Amine complexes of Fe(II), Cu(I), and other metal ions have been shown or proposed to form dioxygen complexes, both stable and short-lived (Rubin and Rao 2002; Yeon et al. 2005). Oxidation of amines via dehydrogenation of the C–N bond has been demonstrated via Co

(II) dioxygen complexes, though the reaction was limited to amines with aromatic groups that could form conjugated imine products. Aliphatic amines such as tetraethylenepentamine did not oxidize in these cobalt systems, and the amine ligand/Co(II) system was well known to form stable dioxygen complexes (Schwartz 1982). Other metal complex dehydrogenations of coordinated amines which may proceed via short-lived O_2 complex intermediates include autoxidation of ethylenediamine (dehydrogenation of both C–N bonds) with Ru(II) (Lente and Fabian 1998; Van Eldik et al. 1992) and Os(II) (Goff and Rochelle 2006), macrocyclic amines with Fe(II) (Hakka and Ouimet 2006), and peptides with Co (II) (Liu et al. 1995). Whether or not dioxygen complexes are involved, dehydrogenation reactions (imine formation and subsequent imine products) of amines should be considered when in the presence of transition metal ions and dioxygen.

- Free radical pathways for autoxidation. In studies of the iron chelate hydrodesulfurization degradation, it was noticed that long (several days) exposure to air sparging at room temperature did not cause degradation. This was consistent with the predicted slow amino acid hydrolysis and oxidation by Fe(III). It was only after introducing the reducing agent H_2S that ligand degradation was detected. Iron chelates, synthesized with Fe(II) and converted to Fe(III) with air, also exhibited degradation. This chemistry can be explained in terms of dioxygen reduction products such as superoxide, peroxide, and hydroxyl radical.

It should be remembered that these reduction intermediates are weak acids and may exist in two protonation states in amine solutions. As shown by the pK_a values in Fig. 10, superoxide should exist in the anionic form and peroxide in both mono- and diprotonated forms, and the hydroxyl radical can also exist as the oxide radical anion. For example, with pK_a values of 11.7 and 11.8 (values at 298 K), both oxide radical anions and hydroxyl may exist in an unloaded (lean) amine solution, while high CO_2 loadings will lower the pH enough so that hydroxyl will predominate. The rate constant for reaction of the glycine anion has been reported to be ten times higher for hydroxyl than for the oxide radical ion.

For the amino acid chelants, it was noted that the most reactive species was the hydroxyl radical (HO·). Compilations of reaction rates show that compounds such as

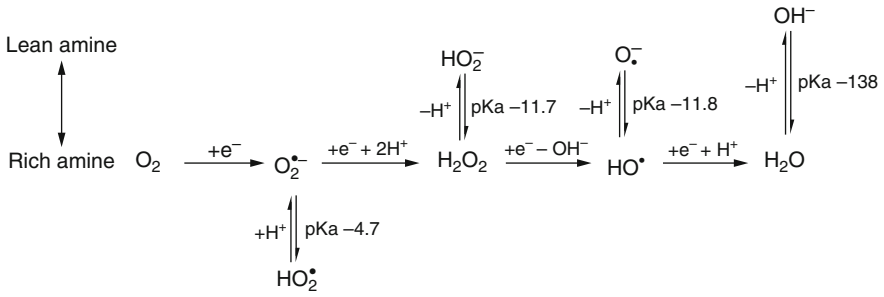


Fig. 10 Primary dioxygen reduction species at amine process conditions (Bedell 2009)

EDTA, NTA, HEDTA, and glycine have reaction rate constants of 10^9–10^{10} L/mol/s. Products that were seen to build up in solution had lower reactivities toward hydroxyl. For instance, the rate constant for oxalate (which can build up to problem levels in the process) was only 7.7×10^5. It was also shown that additives which had high hydroxyl radical rate constants (such as thiosulfate and sulfite) could act as hydroxyl radical scavengers. Because the rate constants were close to diffusion limitations and because of the high substrate concentrations, these additives could only act as competitive scavengers and not totally eliminate the degradation.

Data on reactivity of amines with dioxygen reduction intermediates are harder to find, but some of the results shown in Table 3 support the highest reactivity for hydroxyl. It should be mentioned that alternatives to the hydroxyl radical have been proposed to account for some subtle differences between Fe (II)/H_2O_2/O_2 reactions and reactions of hydroxyl produced via pulse radiolysis. For purposes of this discussion, it is easiest to consider the chemistry in terms of the hydroxyl radical.

Once the reaction has been initiated by formation of the carbon-based radicals, subsequent reaction with dioxygen should be extremely rapid, as shown by representative rate constants presented in Table 4. Figure 11 shows the reaction proposed for the dioxygenation of a MEA radical.

The further reaction of the organic peroxy radical involves abstraction of a hydrogen atom from another amine molecule in a scheme similar to what is often proposed in hydrocarbon autoxidations. This provides a potential chain step to

Table 3 Rate constants for dioxygen reduction intermediates at 298 K (Bedell 2009)

Reaction	Rate (L/mol/s)
Dioxygen: RH + O_2 → products	Slow
N-Propylpyrrolidine + O_2	1.1×10^{-3}
Superoxide: RH + $O_2^{\bullet -}$ → R · + HO_2^-	
$(HOCH_2)_3CNH_2$ + $O_2^{\bullet -}$	<0.42
Glycine + $O_2^{\bullet -}$	48.6
Glycine + HO_2^-	<0.001
Peroxide: RH + HO_2^- → R · + HO · + H_2O	Slow
Hydroxyl: RH + HO · → R · + H_2O	$10^8 - 10^{11}$
Ethylenediamine + HO	5.5×10^9
Ethylamine + HO	5.1×10^9
Triethylamine + HO	1×10^{10}
TEA + HO	8×10^9
$TEAH^+$ + HO	2×10^9

Table 4 Reaction of dioxygen with organic radicals (Bedell 2009)

Radical	pH	K (L/mol/s)
$H_2NCHCO_2^-$ (glycine)	7.9	1×10^9
$O_2CCH_2NHCHCO_2^-$ (IDA)	7	8×10^8
$CHOHCH(NH_2)CO_2^-$	7	2.4×10^9
$CH_2N(CH_3)_2$	10.4	3.5×10^9

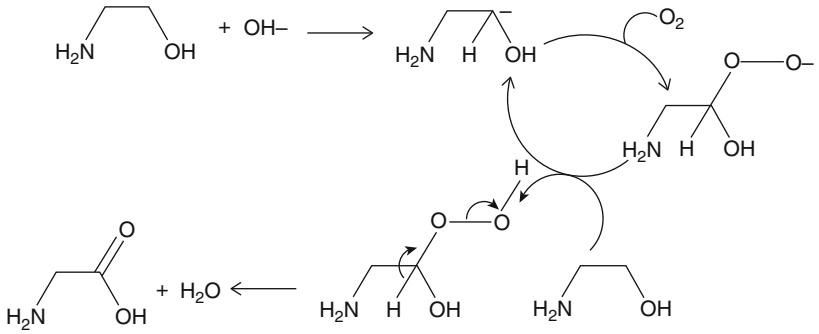

Fig. 11 Proposed reaction pathway for production of glycine from MEA (Bedell 2009)

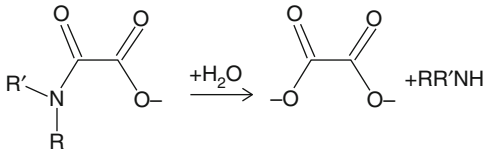
sustain further oxidation. Though glycine (the product shown above) has been noted as an MEA oxidation product, radical formation on the carbon adjacent to the nitrogen would be expected to yield glycolamide which has not been reported as a product. It is possible that glycolamide would hydrolyze to form glycolic acid and ammonia, both of which have been noted as MEA oxidation products. In the hydrodesulfurization chelant degradation chemistry, species such as a keto intermediate were detected by mass spectral analysis in freshly degraded solutions, though only oxalate and R′RNH (the expected hydrolysis products) were noted after several days as shown in the equation below:



(46)

Figure 12 summarizes the different radical chemistries. There are three potential pathways to form the organic radical:

1. The direct one-electron oxidation by a metal ion. As a high-temperature reaction, this is most likely to occur at reboiler conditions and of course requires the introduction of an appropriate metal ion by corrosion or fly ash leaching. Reoxidation of the metal ion can result in hydroxyl radical formation. The reoxidation process is expected to be faster than the reduction by reaction with the amine. Thus, in an oxygen-rich environment, metal ion reduction could be a limiting factor. The SO_2-derived sulfite ion is known to reduce metal ions such as Fe(III) and Co(III).
2. Abstraction of hydrogen atoms by hydroxyl radicals. This abstraction as well as the dioxygen reduction which produces it should proceed at low (absorber) temperatures.

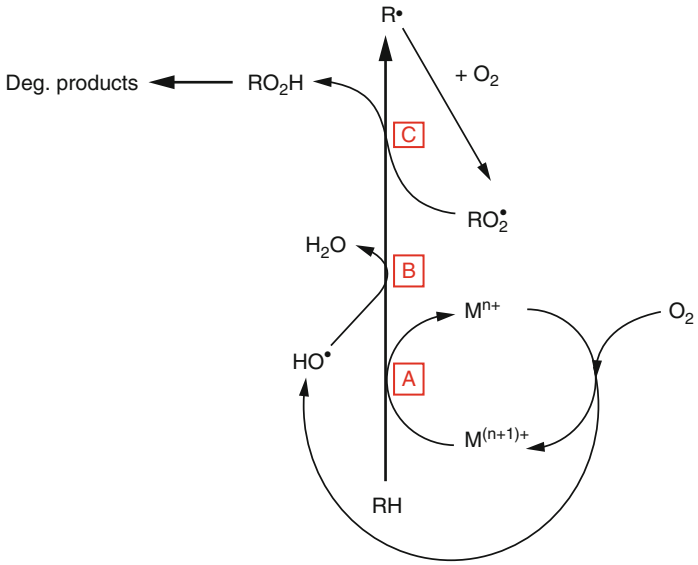


Fig. 12 Amine autoxidation routes (Bedell 2009)

3. Abstraction of hydrogen atoms by the organoperoxy radical.

The autoxidation mechanisms shown above all depend on initiation by metal ions. This underscores the need for good fly ash removal upstream of an amine scrubber. Corrosion, the other means for introducing metal ions, should be, for the most part, autocatalytic with respect to the formation of corrosive degradation products. Use of thermally stable amines and those amines not susceptible to degradation via CO_2 reactions should greatly reduce the corrosion rate and hence the amine autoxidation rate.

Additives to Reduce Degradation

Various types of additives have been proposed to reduce amine degradation.

1. Control of metal ions with chelating agents such as EDTA. Though some inhibition was noted, the effect was short-lived, possibly due to EDTA degradation. The use of iron chelates in hydrodesulfurization, however, showed that the ferrous EDTA chelates were very potent Fenton catalysts (activating intermediate peroxide as well as dioxygen toward hydroxyl radical format ions). Additionally, EDTA would be expected to increase the degree of metal ion solubilization from contaminant fly ash and could also be corrosive toward protective films formed on mild steels.
2. The use of potential hydroxyl radical scavengers. A recent patent claims the use of sulfite and thiosulfate to reduce amine consumption, though no examples were

given which quantified the effect on amine consumption. As discussed above, there is reason to believe that additives, which are capable of reducing hydroxyl radicals, may also be able to reduce metal ions and assist in their redox cycling to produce more degradation.

3. Formation of heat-stable salts and reaction of amines with strong acids. The existence of SO*x* and NO*x* in the flue gases may cause big problems for amine-based solvents. The reason is that the simultaneous existence of SO*x*/NO*x* and vapor in the flue gas has the possibility to form strong acids. The amine-based solvents will react with strong acids first. These reactions are much faster than the reactions between amines and CO_2. The salts formed in these reactions are generally heat stable.

However, the removal of heat-stable salts is usually very difficult. A schematic diagram, which simply describes the principles of HSS removal from MDEA solution using a three-compartment electrodialyzer, is shown in Fig. 13. As shown in Fig. 14, the feed solutions of NaOH and MDEA were added to compartments I and II, respectively. Two electrodes are positioned, one on either side parallel to the membranes. Applying a voltage to the electrodes generates an electric field. It is well known that the anion-exchange membrane permits the passage of anions only while

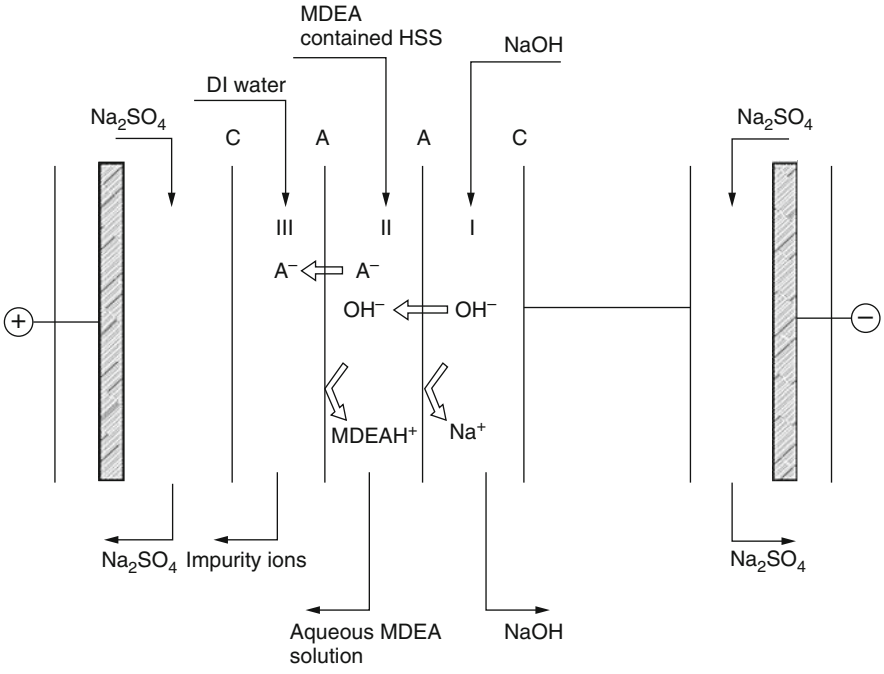

Fig. 13 Principles of HSS removal from aqueous solution of MDEA using a three-compartment ED (Meng et al. 2008)

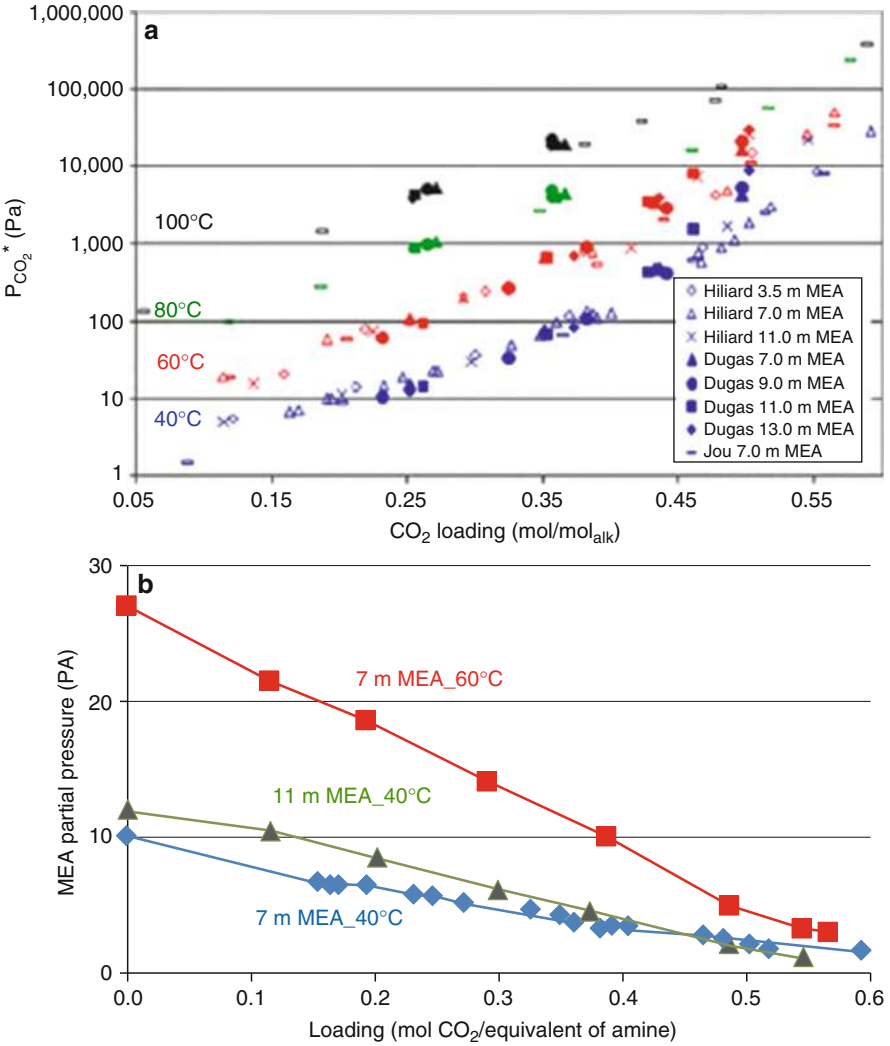

Fig. 14 (**a**) MEA–CO_2–H_2O system: CO_2 solubility comparison between FTIR technique and other methods. (**b**) MEA partial pressure in 7 and 11 m MEA systems for 313 and 333 K (Nguyen et al. 2010)

the cation-exchange membrane permits the passage of cations only. Therefore, OH^- in compartment I migrates through the anion-exchange membranes and then reacts with binding amine ($MDEAH^+ A^-$), as shown in Eq. 47:

$$OH^- + MDEAH^+A^- \rightarrow A^- + MDEA + H_2O \tag{47}$$

where A^- symbolizes impurity anions such as Cl^-, SO_4^{2-}, SCN^-, $HCOO^-$, H_3CCOO^-, and $H_3CH_2CCOO^-$. Once impurity anions such as Cl^-, SO_4^{2-}, SCN^-, $HCOO^-$, H_3CCOO^-, and $H_3CH_2CCOO^-$ were replaced by OH^- in compartment II, they would pass through anion-exchange membrane (AEMs) and reach compartment III under the action of DC electric field. The $[MDEAH]^+$ ions were kept and purified in compartment II. The same more matrixes could be settled in an electrodialysis apparatus according to the abovementioned arrangement principle.

Corrosion and Polarization Behavior of MEA

All amine-treating plants have experienced corrosion problems (Kohl and Nielsen 1997). Corrosion occurs in the forms of general, galvanic, crevice, pitting, intergranular, selective leaching, erosion, and stress corrosion cracking. The plant areas susceptible to corrosion are the bottom of absorbers, regenerators, reboiler bundles, pumps, and valves where the acid gas loading and temperatures are high (DuPart et al. 1993). According to a survey conducted for refinery plants (Rampin 2000), the process equipments that are frequently out of service due to severe corrosion problems are reboiler, rich amine exchanger, regenerator, condenser, absorber, and amine cooler. Although a number of factors contribute to severe corrosion, the major causes reported are poor plant design and operation, such as high flow velocity in pipelines, high operating temperature in reboiler and insufficient steam for solvent regeneration, and the presence of process contaminants.

Corrosion problems essentially lead to substantial expenditure in addition to the process costs. According to CC Technologies and NACE International (Koch 2001), in 1998, the plant expenditure due to corrosion in the USA was estimated at $276 billion while that for petroleum refining alone was $3.7 billion. Of this total, the maintenance-related expenses were estimated at $1.8 billion, the vessel turnaround expenses were at $1.4 billion, and the fouling-related costs were approximately $0.5 billion annually. This reflects a significant impact of corrosion problems in plant operations.

The corrosion mechanism at the interface between the carbon steel surface and the CO_2-loaded MEA aqueous solution was examined using the obtained results and previous work published in the literature. Let us consider chemical reactions taking place in the bulk solution due to CO_2 absorption (Eqs. 48, 49, 50, 51, and 52), possible electrochemical reactions due to corrosion (Eqs. 53, 54, 55, and 56), and possible chemical reactions due to formation of corrosion products (Eqs. 57 and 58; Veawab and Aroonwilas 2002).

Dissociation of water:

$$2H_2O \longleftrightarrow H_3O^+ + OH^- \tag{48}$$

Hydrolysis of CO_2:

$$2H_2O + CO_2 \longleftrightarrow H_3O^+ + HCO_3^- \tag{49}$$

Dissociation of bicarbonate ion:

$$H_2O + HCO_3^- \longleftrightarrow H_3O^+ + HCO_3^{2-} \tag{50}$$

Dissociation of protonated amine:

$$RNH_3^+ + H_2O \longleftrightarrow RNH_2 + H_3O^+ \tag{51}$$

Carbamate reversion:

$$RHNCOO^- + H_2O \longleftrightarrow RNH_2 + HCO_3^- \tag{52}$$

Iron dissolution:

$$Fe \longleftrightarrow Fe^2 + 2e^- \tag{53}$$

Reduction of hydronium ion:

$$2H_3O^+ + 2e^- \longleftrightarrow 2H_2O + H_2(g) \tag{54}$$

Reduction of bicarbonate ion:

$$2HCO_3^- + 2e^- \longleftrightarrow 2CO_3^{2-} + H_2(g) \tag{55}$$

Reduction of undissociated water:

$$2H_2O + 2e^- \longleftrightarrow 2OH^- + H_2(g) \tag{56}$$

Formation of ferrous hydroxide:

$$Fe^{2+} + 2OH^- \longleftrightarrow Fe(OH)_2 \tag{57}$$

Formation of ferrous carbonate:

$$Fe^{2+} + CO_3^{2-} \longleftrightarrow FeCO_3 \tag{58}$$

Essentially, corrosion occurs due to electrochemical reactions comprising anodic and cathodic reactions. The anodic reaction is iron dissolution (Eq. 53) while the cathodic reactions are reductions of oxidizers available in the solution. In the absence of O_2, some possible oxidizers in this system are H_3O^+, undissociated H_2O, and HCO_3^-. According to Veawab and Aroonwilas (Veawab and Aroonwilas 2002), undissociated H_2O and HCO_3^- are major oxidizers whereas H_3O^+ plays a minor role. As such, possible primary corrosion reactions are Eqs. 53, 55, and 56.

Previous studies show that factors listed below affect the corrosion and polarization behavior of MEA solution to different extent. Table 5 summarizes some of them: pH, conductivity, electrochemical parameters, and corrosion rate for uninhibited MEA-H_2O-CO_2 system.

Table 5 Summary of pH, conductivity, electrochemical parameters, and corrosion rate for an uninhibited MEA–H_2O–CO_2 system (Soosaiprakasam 2008)

- Increasing the O_2 partial pressure accelerates corrosion due to the increasing oxidizer concentration in the solution. Dissolved O_2 is required for the corrosion control that raises the system potential to passivation where a passive film of hematite ($\gamma - Fe_2O_3$) is established on the metal surface.
- A greater solution velocity causes a higher corrosion rate due to the enhancement of the transport rates of corroding agents between metal surface and bulk solution.
- Raising the solution temperature enhances the corrosion rate. This is the result of the increases in rates of iron dissolution and oxidizer reduction during the corrosion process.
- An increase in CO_2 loading in solution causes corrosion rate to increase. This is due to the increase in concentrations of corroding agents (HCO_3^- and H^+), which causes rates of oxidizer reduction to increase.
- An increase in amine concentration makes a solution more corrosive due to the increase in HCO_3^- available in the solution, which induces a greater rate of iron dissolution.
- The precorroded carbon steel corrodes faster than the nonprecorroded steel due to the faster rates of both iron dissolution and oxidizer reduction reactions.

Volatility of MEA

Amine volatility is a key screening criterion for amines to be used in CO_2 capture. Excessive volatility may result in significant economic losses and environmental impact. It also dictates the capital cost of the water wash.

There are several publications on the VLE (vapor–liquid model) of the binary MEA-H_2O system, but only few data on directly measured MEA volatility, more specifically the vapor-phase mole fraction of MEA. Lenard et al. (Harris et al. 2009) measured the gas-phase composition of MEA in binary aqueous solution (343 and 363 K) using gas chromatography. These data were represented using a three-parameter Redlich–Kister expansion. Cai et al. (1996) measured isobaric VLE at 101.3 and 66 kPa (373–443 K) using the standard curve of refraction index versus mole fraction of the binary mixture at 20 °C. The liquid phase activity coefficients were calculated with the UNIFAC group contribution model as published by Larsen et al. (1987). These data are in the high-temperature range. At temperatures relevant to absorption–stripping, McLees (2006) directly measured the volatility of MEA in a binary system (3.5, 7.0, 23.8 mMEA) as well as in blends having piperazine (PZ) as a promoter. PZ volatility was also measured for 0.9, 1.8, 2.5, and 3.6 m PZ. The data was obtained by hot gas Fourier transform infrared spectroscopy (FTIR). Efforts were also made to model the experimental data in terms of binary interaction parameters by utilizing the NRTL model within Aspen Plus®.

There have also been other thermodynamic measurements of MEA-H_2O. Touhara et al. (1982) measured the total pressure of this system at 298 and 308 K. Nath and Bender (1983) measured total pressure for pure substances as well as binary and ternary mixtures of alcohols, alkanolamines, and water from 60 °C to 95 °C in a vapor-recycle equilibrium cell. Specifically, the MEA-H_2O system was studied at 60 °C, 78 °C, and 91.7 °C. Activity coefficients for each system were calculated

Table 6 Amine volatilities and enthalpies for various systems at nominal lean loadings (Nguyen et al. 2010)

Solution	Loadings (mol CO_2/mol solvent)	Volatility (ppm)	$\Delta H_{apparent}^{\sim,excess}$ (kJ/mol)	ΔH^{vap} (kJ/mol)
7 m MDEA/ 2 m PZ	0.1	6/2	27/87	102/135
8 m PZ	0.29	8	37	85
12 m EDA	0.44	9	40	108
7 m MEA	0.45	31	33	55
5 m AMP	0.25	112	10	75

using the Wilson and UNIQUAC equations and were seen to have negative deviations from an ideal solution (Table 6).

New Type of Absorbent

Although MEA is considered to be the most reliable absorbent for CO_2 capture in power plants nowadays, there still exist a lot of inherent problems. The disadvantages of MEA include high enthalpy of reaction with CO_2, leading to higher regeneration energy consumption, the formation of a stable carbamate and also the formation of degradation products with COS or oxygen bearing gases, inability to remove mercaptans, vaporization losses because of high vapor pressure and more corrosiveness than many other alkanolamines, and, thus, the need for corrosion inhibitors when used in higher concentration. In addition, the market price of MEA is relatively high. Based on the analysis above, nowadays the laboratory research generally sets MEA as a base absorbent.

1. Aqueous ammonia

In 1997, Bai proposed to replace traditional amine solutions by aqueous ammonia solutions to capture CO_2 from coal-fired flue gas. The aqueous ammonia solutions have been testified to possess several advantages over MEA, such as higher absorption capacity, lower market price, and weaker erosion-degradation effects. With the efforts of worldwide researchers in recent years, understandings of the CO_2 capture by aqueous ammonia become much deeper and clearer.

Reaction Mechanism

- Reaction equations

Reactions described as follows, which are respectively proposed by Brooks and Audrieth (1946) Singh et al. (2007), Hatch and Pigford (1962), Thitakamol et al. (2007), Bai and Yeh (1997), Camacho et al. (2005), are widely accepted.

Reaction between NH_3 and CO_2:

$$2NH_3 + CO_2 \leftrightarrow NH_2COONH_4 \tag{59}$$

Hydrolysis of NH_2COONH_4:

$$NH_2COONH_4 + H_2O \leftrightarrow NH_4HCO_3 + NH_3 \quad (60)$$

Hydrolysis of NH_3:

$$NH_3 + H_2O \leftrightarrow NH_4OH \quad (61)$$

Reaction between products of hydrolysis (Eqs. 60 and 61):

$$NH_4HCO_3 + NH_4OH \leftrightarrow (NH_4)_2CO_3 + H_2O \quad (62)$$

$(NH_4)_2CO_3$ reacts with CO_2 and H_2O:

$$(NH_4)_2CO_3 + CO_2 + H_2O \leftrightarrow 2NH_4HCO_3 \quad (63)$$

The overall reaction of CO_2 absorption by aqueous ammonia can be usually expressed as the following equation:

$$NH_3 + CO_2 + H_2O \leftrightarrow NH_4HCO_3 \quad (64)$$

- Reaction products, process, and roles

In general, reactions among aqueous ammonia, carbon dioxide, and their derivates are extremely sensitive to the reaction time and controlled reaction conditions, e.g., concentration, temperature, pressure, and PH. However, during the whole reaction process, a stage has the great potential to appear, during which NH_2COO^-, HCO_3^-, and CO_3^{2-} coexist in the solution. The possible distribution of chemical species in three-phase system is illustrated in Fig. 15.

Recent studies show that carbamate formation dominates the early stage of absorption process due to the presence of excess ammonia. With the advancement of the reaction, CO_2 is introduced into the reaction system with a fixed flow rate while ammonia available to react decreases gradually. The bicarbonate formation hence becomes to act the major role in the later stage of the absorption process (Kim et al. 2008; Teramoto et al. 2004). The reaction steps are also understood as: formation of carbamate, formation of bicarbonate, release of protons, and conversion of carbamate into bicarbonate (Park et al. 2008; Vaidya and Kenig 2007). The ammonia is regarded as multiple roles, e.g., reactant, catalyst, base, and controller. It affects both the carbamate formation and carbonate formation.

Reaction Kinetics

The reaction rate constant for NH_3–CO_2 reaction system can be simply determined by Arrhenius equation:

$$\ln k = \ln \frac{A - E_a}{RT} \quad (65)$$

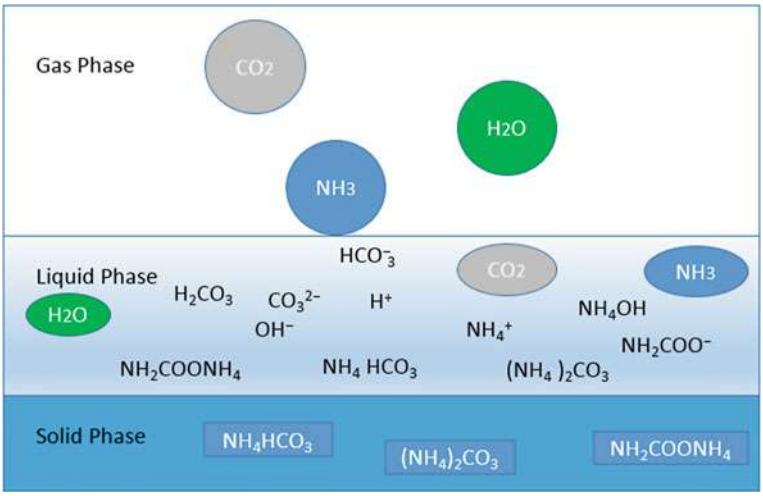

Fig. 15 Chemical species in the NH_3–CO_2–H_2O three-phase system

where A is the pre-exponential factor (s^{-1}) and E_a is the activation energy (kJ/mol).

However, as described from Eqs. 59, 60, 61, 62, 63, and 64, the actual reaction may contain several multistep reaction kinetic parameters rather than the overall reaction rate constant (Puxty et al. 2010; Rinker et al. 1995). A certain number of investigations have been carried out based on various mechanisms, e.g., single-equation mechanism, two-equation mechanism (Astarita, 1967; Horng and Li 2002), eight-equation mechanism(Wang et al. 2011; Ma'mun et al. 2006), zwitterionic mechanism (Caplow 1968; Derks et al. 2005; Danckwerts 1979; Aroonwilas and Veawab 2004; Derks and Versteeg 2009; Kumar et al. 2003), and termolecular mechanism (Crooks and Donnellan 1989; Harris et al. 2009). During the proposed mechanism for kinetics study, the single-equation mechanism is relatively easy to understand and widely studied. Some kinetic rate constants of CO_2 absorption by aqueous ammonia under different reaction conditions are summarized in Table 7.

Vapor–Liquid Equilibrium

Precise vapor–liquid equilibrium data is required parameters to design carbon capture processes using ammonia. Previous studies showed that the Extended UNIQUAC model was consistent with experimental data in terms of accuracy at the temperature range from 0 °C to 110 °C and at pressures up to 100 bar.

Figures 16 and 17, respectively, show the correlation between NH_3 partial pressure and solution CO_2 loading and the relationship between CO_2 partial pressure and solution CO_2 loading. Both of them are deserved from experiments at the temperature of 20 °C under ambient pressure. During these experiments, the amount of ammonia is constant while the amounts of carbon dioxide are various. It can be obtained from Figs. 16 and 17; NH_3 partial pressure decreases with the increase of

Table 7 Kinetic parameters of CO_2 absorption by ammonia based on single-equation mechanism

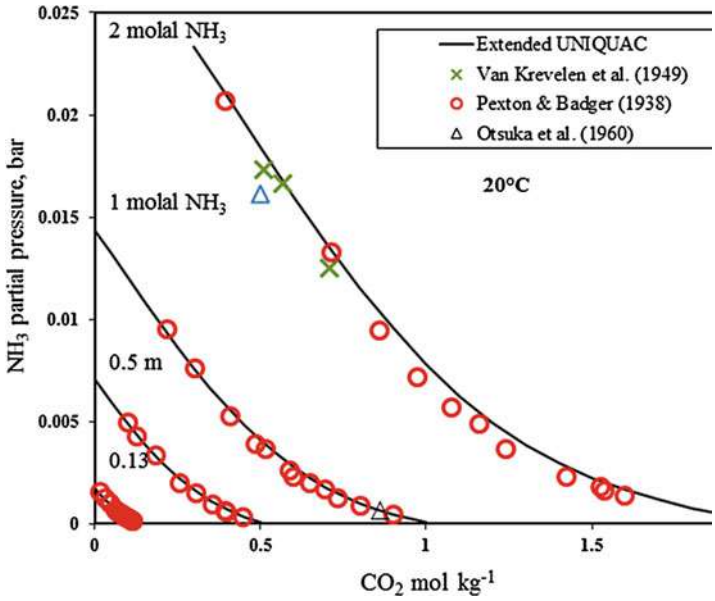

Fig. 16 NH_3 partial pressure versus CO_2 loading

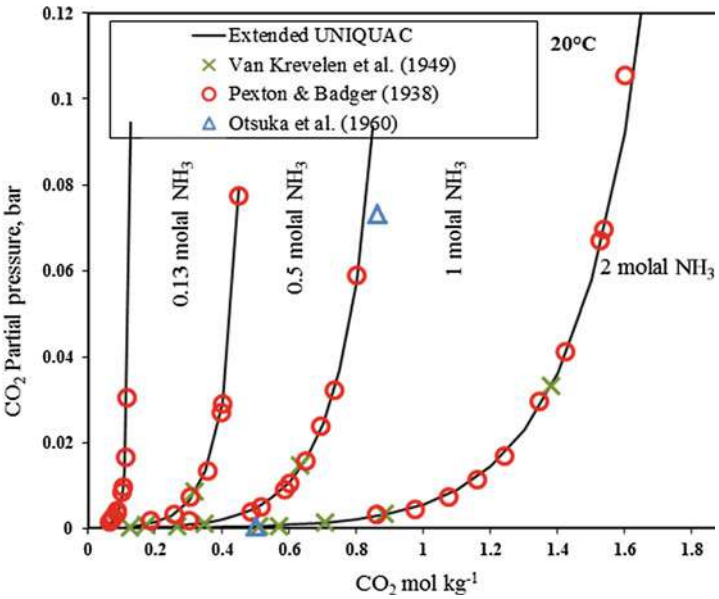

Fig. 17 CO_2 partial pressure versus CO_2 loading

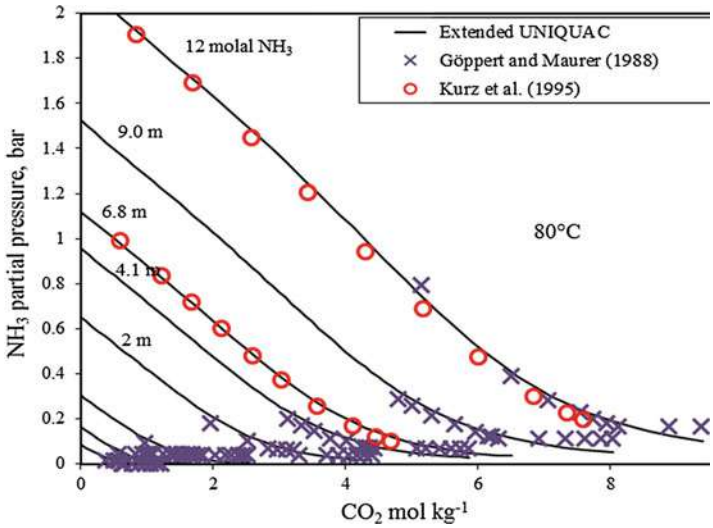

Fig. 18 NH_3 partial pressure versus CO_2 loading

CO_2 loading while CO_2 partial pressure exhibits an adverse changing tendency. When the solution CO_2 loading reaches 1 mol of CO_2 per mole of NH_3, the partial pressure of NH_3 almost vanishes while the partial pressure of CO_2 increases rapidly. It implies that NH_4HCO_3 might be the eventual product of these complicated chemical reactions.

To get a better understanding of vapor–liquid equilibrium at a higher temperature, the experimental results tested at the temperature of 80 °C under ambient pressure are shown in Figs. 18 and 19. The difference between the vapor liquid of lower temperature and that of higher temperature is the magnitude of partial pressure. Obviously, with the increase of temperature, both partial pressure of ammonia and that of carbon dioxide increase. Moreover, the partial pressure of carbon dioxide has been even increased 50–100 times that of deserved at the temperature of 20 °C. It implies that the temperature of 80 °C does facilitate the regeneration process of carbon dioxide.

Solid–Liquid Equilibrium

Solid–liquid equilibrium is less concerned; however, the data of solid–liquid equilibrium is rather important and helpful for the design and operation of aqueous ammonia-based CO_2 capture process. It allows us to determine the appropriate operational conditions to adjust the products. Figure 20 presents the correlation between CO_2 loading and temperature. It can be easily observed that when the loading exceeds 0.6 mole of CO_2 per mole of NH_3, the major product in the solution is ammonium bicarbonate. With the increase of temperature, the possibility to form ammonium carbamate sharply decreases.

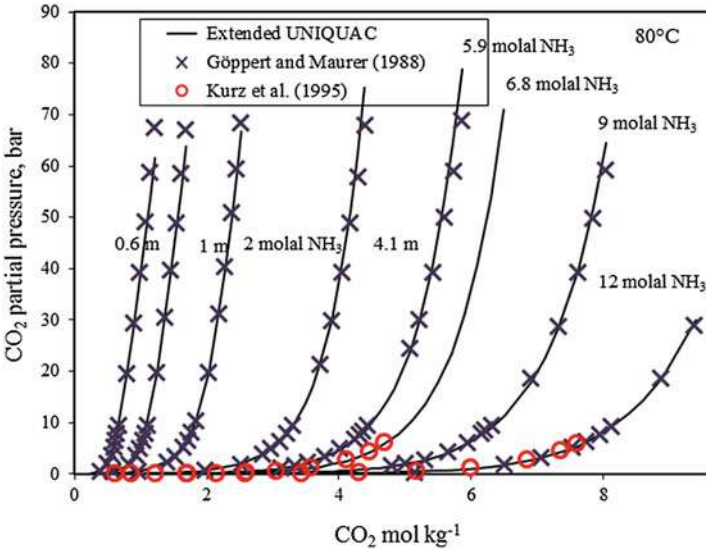

Fig. 19 CO_2 partial pressure versus CO_2 loading

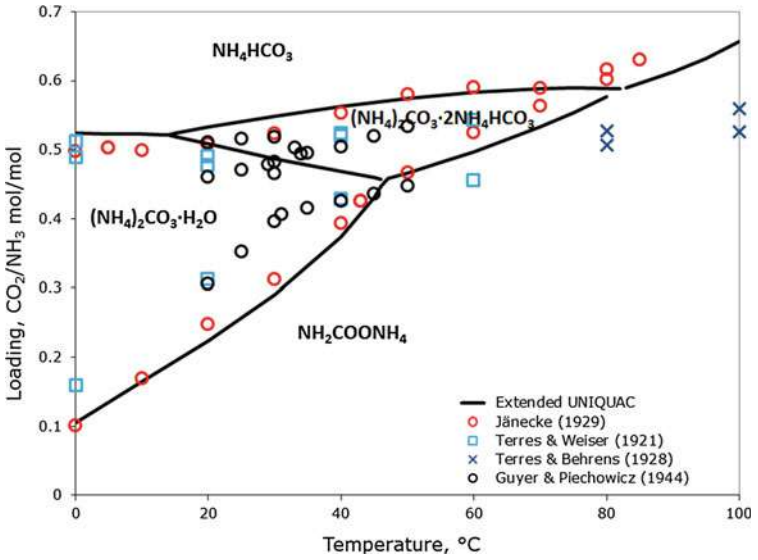

Fig. 20 The correlation between CO_2 loading and temperature

Effect of Reaction Parameters on Absorption Efficiency

During the process of CO_2 absorption into aqueous ammonia, a certain number of controlled conditions have significant impact on CO_2 absorption performance by aqueous ammonia. The concentration of aqueous ammonia, concentration of CO_2 in

the mixed gas, aqueous ammonia flow rate, flue gas flow rate, reaction temperature, controlled pressure, and reactors are discussed to the most extent.

Ammonia concentration

The relationship between aqueous ammonia concentration and CO_2 absorption efficiency is depicted in Fig. 21. It can be easily deserved that, with the increment of aqueous ammonia concentration, the CO_2 absorption efficiency gradually rises. However, for all cases published in the former literature, whenever the aqueous ammonia concentration reaches some specific value for the detailed experimental condition, the CO_2 absorption efficiency cannot be enhanced any further.

The maximum CO_2 removal efficiency can reach 99 %, and the absorption capacity is up to 1.20 kg CO_2/kg NH_3. Under the consistent experimental conditions, the maximum CO_2 removal efficiency is 94 %, and the absorption capacity is 0.40 kg CO_2/kg NH_3 (Bai 1997; Chen 2002).

CO_2 concentration

The effects of CO_2 concentration on its absorption efficiency are similar to that of ammonia concentration. It is easy to understand because increasing CO_2 concentration does good to enhance the mass transfer in gas-film side and promote CO_2 absorption efficiency only when the molar ratio of NH_3–CO_2 excesses its equivalent ratio (Ahn et al. 2011; Chen 2006). The published research results are given in Fig. 22.

Liquid and gas flow rates

The effects of aqueous ammonia (liquid) and flue gas flow rates on CO_2 absorption efficiency are illustrated in Figs. 23 and 24, respectively.

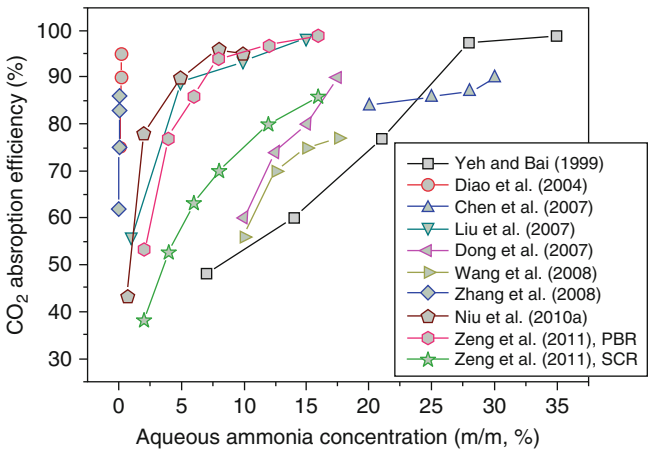

Fig. 21 Relationship between aqueous ammonia concentration and CO_2 absorption efficiency (1 bar, 35 °C, various gas–liquid ratios, various reactors)

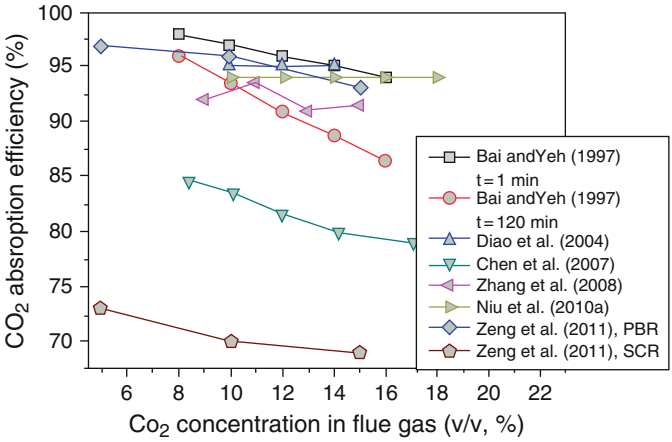

Fig. 22 Relationship between CO_2 concentration and CO_2 absorption efficiency (1 bar, 35 °C, various gas–liquid ratios, various concentrations of absorbent, various reactors)

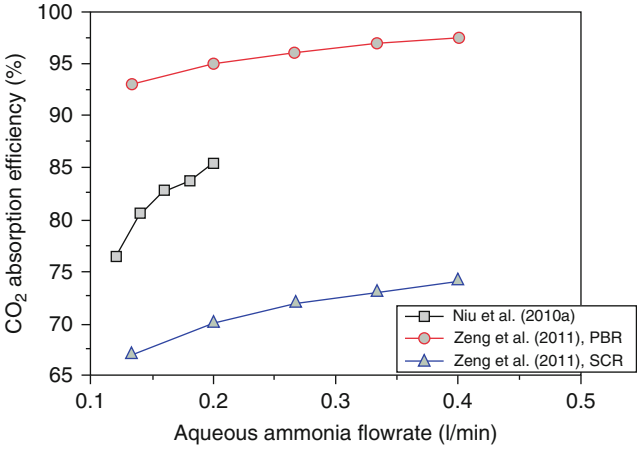

Fig. 23 Effect of aqueous ammonia (1 bar, 35 °C, various reactors)

It can be concluded from Figs. 23 and 24 that with the increment of aqueous ammonia flow rate, the CO_2 absorption efficiency can be improved, but only to a slight extent. However, the effect of flue gas flow rate is more influential than that of aqueous ammonia flow rate. With the increment of flue gas flow rate, the absorption efficiency is reduced sharply. On the whole, the absorption efficiency could be improved when the liquid–gas ratio is increased by either increasing the flow rate (volume) of aqueous ammonia or decreasing flue gas flow rate.

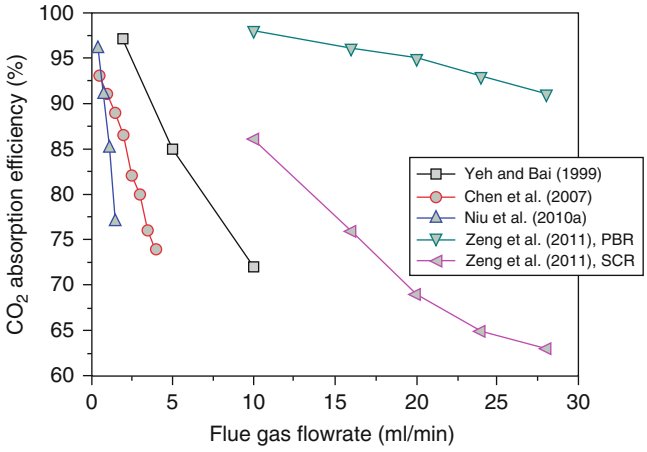

Fig. 24 Effect of flue gas (1 bar, 35 °C, various reactors)

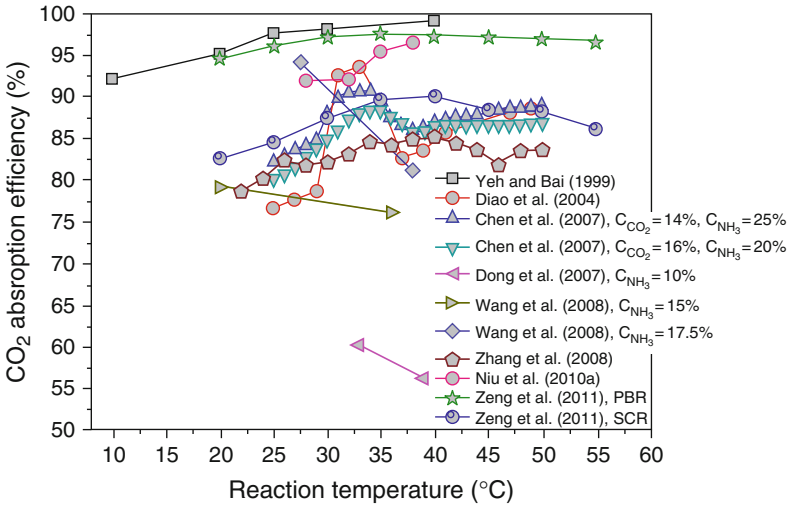

Fig. 25 Relationship between reaction temperature and CO_2 absorption efficiency

Reaction temperature

The effect of reaction temperature on CO_2 absorption efficiency is illustrated in Fig. 25.

Due to the reversibility of ammonia CO_2 reaction, the effect of temperature on the CO_2 absorption efficiency by ammonia is relatively complex with a non-monotonic relationship.

It is related to the reactor structure and other operating conditions. The previous work suggested that the CO_2 absorption reactions are dominant at room

temperature (Shale et al. 1971) while the CO_2 regeneration reactions occur in the temperature range of XX–60 °C (Pelkie et al. 1992). This relationship is also partially reflected by the experimental data. It is observed that most experimental data presented the optimal critical temperature. The absorption efficiency increased as the temperature increased when it was lower than the critical temperature, which indicated that the forward reaction was dominant. When the temperature exceeded the critical temperature, an opposite trend was presented. Note that very few experimental data showed that the absorption efficiency increased as temperature increased in high-temperature range. In addition, some experimental data indicated that absorption efficiencies monotonously decreased with increasing temperature.

Overall, the optimal reaction temperature could only be determined on the basis of a comprehensive consideration of absorption reactor, reaction conditions, and even regeneration energy consumption. According to the experimental results showed in Fig. 25, the optimal reaction temperature should be controlled in the range of 30–40 °C in order to obtain a relatively high absorption efficiency.

Improvement of Aqueous Ammonia

The most concerned inherent problems for aqueous ammonia are its high vitality and low absorption rate. The thermal regeneration method makes the slipperiness of aqueous ammonia become more severe and then leads to much heavier secondary pollution problems. Furthermore, it is essential to find a solution to enhance the reaction rate of aqueous ammonia.

Previous studies show that adding functional chemical additives into aqueous ammonia solution can considerably enhance the reaction rate and reduce the slipperiness of ammonia. Both organic additives, e.g., MEA, DEA, TEA, MDEA, AMP, PZ, AMP, AMPD, AEPD, and THAM, and inorganic additives, which refer to salt of strong acid and weak base such as $Na_3PO_4 \cdot 12H_2O$ and $Na_2B_4O_7 \cdot 10H_2O$ (Amitava 2011; Zhang et al. 2011; Fisher et al. 2005; Jassim and Rochelle 2006), have been studied.

Related experiment suggested that adding 1–3 % (w/w) AMP into ammonia could enhance the CO_2 absorption and control the slip of ammonia in the absorption process. However, it is found that the enhanced effects of 5 % AMP are not as significant as that of 3 % AMP. This demonstrates that when the additive AMP concentration is increased to a certain critical value, continuing addition of AMP is not much effective (Zhu et al. 2011; Teramoto et al. 2003). In essence, research showed that the major effect of organic additives was most of them could effectively reduce the surface tension of the aqueous ammonia and then promote the reaction between ammonia and CO_2 (Cheng et al. 2006; Matsumiya et al. 2005). Other organic additives to improve absorption performance are usually considered to have stronger affinity and faster reaction rate with CO_2 than ammonia (He et al. 2004; Mimura et al. 1998). For instance, when piperazine (PZ) reacts with CO_2 by the zwitterionic mechanism (Caplow 1968; Danckwerts 1979; Yan et al. 2008; Kang et al. 2002), its second-order reaction rate constant is much larger than that of ammonia by an order of magnitude (Puxty et al. 2010; Bougie et al. 2009; Shuster 2010; Kvamsdal and Rochelle 2008), suggesting that it can effectively improve the absorption reaction

process. Additionally, some additives can reduce the loss of ammonia by vaporization and slightly improve the CO_2 absorption efficiency. It was attributed to the interactions between ammonia and additives or absorbents and CO_2 via hydrogen bonding (You et al. 2008; Kvamsdal et al. 2010).

Unlike the mechanism of action of organic additives, inorganic additives indirectly promote the forward reaction through increasing the OH^- concentration or pH value in the solution by their hydrolysis and eventually promote the CO_2 absorption reaction.

However, the inorganic salt additive will reduce the solubility of CO_2 in the solvent, resulting in decreased absorption efficiency (Zhang et al. 2011); You et al. 2008; Eide-Haugmo et al. 2009; Chapel et al. 1999). Therefore, the enhanced effect of absorption efficiency depends on the additive load.

2. Ionic liquids (ILs)

Ionic liquid is regarded as a potential green alternative for the existing CO_2 absorbents, due to its unique characteristics, i.e., wide liquid range, thermal stability, negligible vapor pressure, tunable physicochemical character, and high CO_2 solubility. Blanchard et al. (1999; Schnell 2004) firstly reported that CO_2 is highly soluble in ionic liquid of 1-butyl-3-methylimidazolium hexafluorophosphate ($[C_4mim][PF_6]$). After that, considerable effort has been focused on seeking a sort of suitable ionic liquids as the alternatives for traditional absorbents. High viscosity and expensive material cost are major drawbacks for ionic liquid.

In general, ionic liquids are a category of compounds which are entirely composed of positive-charge ions and negative-charge ions. They tend to be liquid over a wide range of temperature, with a liquid range from −90 °C to 300 °C. It is estimated that the number of ionic liquids can even reach 10^{18}.

Some Key Physical Parameters

- Density
  Densities of ionic liquids are commonly between 0.80 and 2.10 g/cm^3. It has been demonstrated that densities of ionic liquids increase with an increase of the molecular weight of anion when the cation moiety is same. However, densities of ionic liquids decrease with an increase in the length of the alkyl chain in the cation when the anion is fixed.
- Viscosity
  Viscosities of ionic liquids range from 7 to about 1800 mPa s at ambient conditions. Obviously, this property brings trouble to the application of ionic liquids. In this context, a small number of investigations have ever been carried out. The studies lead to the following conclusions.
  1. For ILs with the same anion, the viscosity increases with increasing of the alkyl chain length (Seddon et al. 2002; Haslegrave et al. 1992). Moreover, the more asymmetrical cations have lower viscosity.

2. For ILs with the same cation, the chlorinated and fluorinated anions have higher viscosities than other anions, e.g., [I] > [Cl] > [PF_6] > [BF_4] ~[NO_3] > [Tf_2N]. In general, the effect of cation on viscosity is not that evident as changing the nature of anion (Endresand El Abedin 2006; McMahon and Harrop 1995).

- Heat capacity
  Deserved from a review by Paulechka (2010; Crognale 1999), specific heat capacities of 17 kinds of imidazolium-based ionic liquids are ranging from 1.29 to 1.93 J K^{-1} g^{-1} at the temperature of 298 K and under ambient pressure. Smaller specific heat capacities of ionic liquids relative to that of pure water provide the possibility to reduce the regeneration energy. During the past decade, the data of heat capacity for more than 100 aprotic ionic liquids were reported. However, these data are too less to satisfy the researchers' needs.
- Vapor pressure
  Vapor pressure is nearly negligible even when the environmental temperature is rather high. It might be mainly attributed to their chemical and thermal stability. The characteristic of ionic liquids leads to less consumption of the absorbent and much insignificant environmental hazard. However, ionic liquids can be designed to be volatile while required. Earle et al. (2006; Bacon and Demas 1987) reported that [$C_n$mim][Tf_2N] could be distilled without decomposition at the temperature of 300 °C and 0.1 mbar.
- Toxicity
  Imidazolium-based ionic liquids have been testified to possess a wide range of toxicities for some specified bioassays. Toxicity of ionic liquid correlates directly with the length of the *N*-alkyl substituent in the methyl imidazolium cation. It has been observed an increasing toxicity trend when the alkyl chain length substituent in imidazolium ionic liquids increases. On the other hand, minimal effects on toxicity are observed varying the anion of the methyl imidazolium salts. To avoid the potential contamination of the environment, it is important to minimize the opportunities of exposing ionic liquids to the aquatic media. The treatment and recycle apparatuses must be secured to install and operate normally.

Structure of Ionic Liquids

Figure 26 shows the structure of commonly used cations and anions. It can be easily deserved that the structure of ionic liquid is rather complex. Generally speaking, imidazolium-based ionic liquid is the most often employed category to capture CO_2 due to its high solubility.

Progress in the CO_2 Capture with Ionic Liquids

During the past decade, research into CO_2 capture by ionic liquid-based absorbents can be classified into the following directions, which can be further understood as four classes of ionic liquids with various structures.

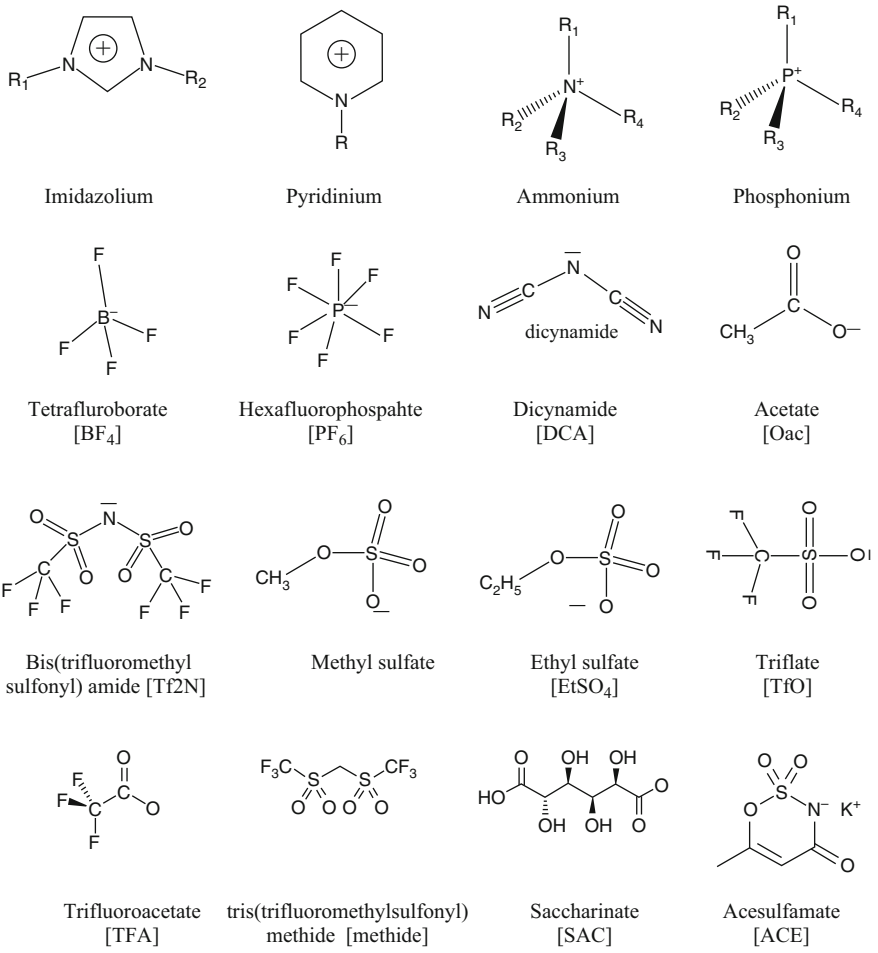

Fig. 26 Structure of commonly used cations and anions

- CO_2 capture with conventional ionic liquids

At the beginning of the study, most researchers focused on the CO_2 solubility of room-temperature ionic liquids due to their easy accessibility. However, with more understandings in this field, people noticed that the conventional ionic liquids absorb and separate CO_2 efficiently only by a mechanism of physical absorption. The absorption rate and capacity are therefore severely limited by this mechanism, e.g., the solubility of CO_2 in $[C_4mim][PF_6]$ is 2.65 mol kg^{-1} at 319 K and 5.73 MPa. In the previous studies, it is found that the anion dominates the interactions with the CO_2, with the cation playing a secondary role. Replacing the acidic hydrogen on the C_2 carbon of the [bmim] cation with a methyl group leads to a reduction in the

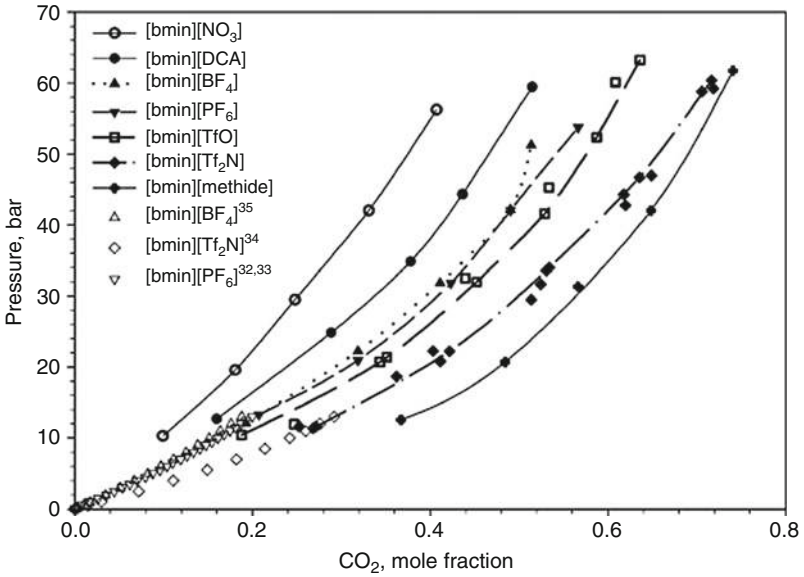

Fig. 27 Anion effect on the solubility of imidazolium-based ionic liquids at 25 °C

experimental enthalpy of absorption by about 1–3 kJ/mol. Figure 27 shows the correlation between pressure and CO_2 mole fraction. It can be seen that the solubility of CO_2 in [bmim] cation-based ILs at 25 °C increases in the following order: $[NO_3] < [DCA] < [BF_4] < [PF_6] < [TfO] < [Tf_2N] <$ [methide].

Some major findings in the field of conventional ionic liquids are summarized as follows (Table 8):

- CO_2 capture with functionalized ionic liquids

As discussed above, the dissolution of CO_2 in the conventional ionic liquid is through physical absorption mechanism, and the CO_2 absorption capacity can be further improved by functionalization of ionic liquid with a suitable moiety, such as the amino group and the other functional groups. Overall, two techniques are usually utilized by functionalizing the anion with alkaline group-NH_2 and attaching the functional group to the anion.

Bates et al. (2002; Thitakamol et al. 2007) firstly synthesized [NH_2p-bim][BF_4] consisting of an imidazolium ion to which a primary amine moiety is covalently bonded and gave the proposed reaction mechanism between FIL and CO_2, similar to the reaction between traditional organic amine and CO_2. The reaction mechanism between CO_2 and [NH_2p-bim][BF_4] is presented in Fig. 28. Experimental results show that the ultimate CO_2 absorption capacity of [NH_2p-bim][BF_4] can reach 0.5 mol CO_2 per mol IL and CO_2 can be regenerated by heating IL to 80 ~ 100 °C. There was no obvious loss of efficiency when the ionic liquid was recycled for five

cycles. After that, more attempts have been performed and superior results are obtained. A brief summary of the related work is presented in Table 9 (Fig. 29).

- CO_2 capture with supported ionic liquids membranes

It is well known that the ionic liquid has a relatively better performance in terms of thermal/chemical stability and essentially negligible volatility. Meanwhile, membrane can enhance the contact between gas and absorbents and further to cope with the limitations caused by ionic liquid. Above all, a certain number of researchers have carried out some work to explore the prospects of supported ionic liquid membranes involving CILs or FILs or both in CO_2 capture. Previous studies show that supported ionic liquids may prove a better choice in CO_2 separation from flue gases. Although several drawbacks, such as the thick membrane and inapplicability in separating CO_2 from the flue gases at high pressures, still hinder the application of supported IL membrane, it is already regarded as a potential technology for CO_2 capture. More researches will focus on the role of anion/cation in optimization of molar volume of constituent ILs and the structure of the support materials to develop more stable, more permeable, but thinner membranes (Table 10).

- CO_2 capture with polymerized ionic liquids

There is an inherent drawback for SILM. Once the pressure drop surpasses the liquid stabilizing forces within the matrix, the liquid may leach through membrane pores which may dramatically affect the mass transfer process. To avoid this phenomenon, Tang et al. (2005a; Mogul 1999) firstly proposed transforming ILs into polymeric form which could apparently increase the CO_2 sorption capacity compared with conventional ILs. Experimental results showed that both CO_2 sorption capacity and sorption rate of the polymers of tetraalkylammonium-based ILs are superior to those conventional ILs, e.g., CO_2 sorption capacity of poly (p-vinylbenzyl) trimethylammonium tetrafluoroborate (P[VBTMA][BF_4]) is 7.6 times that of [C_4mim][BF_4]. The selectivity of polymers is also testified to be rather satisfying. When the experimental conditions are set as 78.97 kPa and 22 °C, Tang et al. (2005b; Soosaiprakasam and Veawab 2008) found that it could selectively absorb CO_2 from N_2/CO_2 mixed gas without any absorption toward N_2 or O_2. Hu et al. (2006; Lenard et al. 1990) reported that the CO_2-selective membranes with thermal, chemical, and mechanical stability could be prepared by grafting polyethylene glycol (PEG) onto ionic polymers, such as P[VBTMA][BF_4]. Bara et al. (Mimura et al. 1998) found the solubility, permeability, and diffusion of CO_2 in both types of poly-CIL increased dramatically, and the sorption/desorption was completely reversible, which made these poly-ILs very promising as sorbent and membrane materials for CO_2 separation.

Tang et al. (Yan et al. 2008; Kang et al. 2002; Shuster 2010; Kvamsdal and Rochelle 2008; Kvamsdal et al. 2010) studied the CO_2 solubility in an ammonium-type ionic and other types of polymers and probed the structure effects on the CO_2 sorption. They showed the CO_2 sorption capacities of the PILs with different cations

Long alkyl substituents on the cation and cross-linking decreased the CO_2 sorption capacity.

Bara et al. (Mimura et al. 1998; Eide-Haugmo et al. 2009) tethered oligo(ethylene glycol) or nitrile-terminated alkyl substituents to CIL monomers, and these polymer membranes were found to exhibit 50 % greater CO_2/N_2 and CO_2/CH_4 separation factors than those with comparable length *N*-alkyl substituents but with similar CO_2 permeability. The OEG-functionalized poly-CIL exhibited several times higher permeability than those with CnCN functional groups. They mixed CIL and poly-CIL as a composite gas separation membrane to absorb CO_2 and showed that by incorporating an appropriate amount of CIL and introducing free ion pairs into the polymer membrane, the CO_2 permeability and CO_2/N_2 selectivity increased up to 300–600 % and with 25–33 %, respectively, relative to the analogous poly-CIL membrane lacking any free ion pairs.

- CO_2 capture with mixture solvent of ionic liquids and molecular solvents

The viscosities of ionic liquids or their mixtures are usually much thicker than common amines, especially the viscosities of FILs. Furthermore, the reaction rate of ionic liquid is relatively lower than that of the most concerned commercial amine-based absorbents. In this context, some researcher proposed forming novel absorbents through mixing ionic liquids with molecular solvents. Generally speaking,

Table 10 A brief summary of supported ionic liquids membranes studies

Ionic liquid + membrane	Performance	References
Supported ionic liquids membranes based with conventional IL		
[emim][Tf_2N] [emim][CF_3SO_3] [emim][dca] [thtdp][Cl] PES	The performance of the tested RTIL-membranes is competitive or superior to existing membrane materials with their ideal-selectivity versus permeability ratios being above the Robeson upper bound for polymers	Scovazzo et al. (2004) (Polderman et al. 1955)
[C_4min][Tf_2N] Al_2O_3	An ionic liquid-based separation in a membrane separator with a 12-μm ionic liquid film with the same thermodynamic and transport characteristics as [C_4min][Tf_2N] is $27/metric ton of CO_2 removed, a cost 18 % lower than Simbeck's estimate for amine scrubbing	Baltus et al. (2005) (Yazvikova et al. 1975)
[C_4mim][PF_6] TiO_2/SiC	The CO_2 removal efficiency is over 80 % at 0.1 MPa, 40 °C	Moriya et al. (2007) (Davis and Rochelle 2009)
[C_4min][BF_4] PVDF	The selectivity of CO_2/CH_4 and H_2S/CH_4 was found to be 25–45 and 130–260	Park et al. (Rooney et al. 1998)

researchers have mixed water/methanol, alkanolamines, superbase, or other organic solvents into various ionic liquids to create an absorbent of better overall performance.

ILs Plus Amines

The primary purpose of this idea is to merge the eco-friendly features of ILs with the high reaction rate of amines. Another highlight for this idea is the economic performance in terms of both capital cost and operational cost. When amines of appropriate portions are introduced into ionic liquids, both the lower material price and lower pump energy consumption caused by relatively less viscosity of absorbents are favorable.

Camper et al. (2008) have demonstrated that RTILs and alkanolamines can be mixed in a proficient and effective manner for CO_2 gas capture, which exceeds those amine functionalized TSILs.

Zhang et al. (2010b, c) blended tetramethylammonium glycinate ([N_{1111}][Gly]), tetraethylammonium glycinate ([N_{2222}][Gly]), tetramethylammonium lysinate ([N_{1111}][Lys]), and tetraethylammonium lysinate ([N_{2222}][Lys]) with MDEA to form absorbents for CO_2 separation. Experiments show that addition of amino acid IL into MDEA could evidently improve the CO_2 absorption performance of MDEA. Moreover, the regeneration performances of IL + MDEA aqueous blends varied with the cations: ([N_{1111}] [Gly]) > ([N_{1111}][Lys]) > ([N_{2222}] [Gly]) > ([N_{2222}] [Lys]). The ultimate CO_2 regeneration efficiency of aqueous blend of 15 % ([N_{1111}] [Gly]) + 15 % MDEA even reached 98 %.

Based on the experimental research into the proposed absorbents such as amines-IL-H_2O, IL-H_2O, and amines-H_2O at temperature ranging from 303.15 to 343.15 K with different IL mass fractions, Zhao et al. (2010) concluded that the absorbent of amines-IL-H_2O shows the best performance on CO_2 capture. In the successive study, Zhao et al. (2011a) investigated the solubilities of CO, H_2, N_2, O_2, and CO_2 in IL,

[MDEA][Cl] when the pressure varies from 1.22 to 8.62 MPa and the temperature changes from 313.15 to 333.15 K. Experiments showed that the solubility of CO_2 was further superior to the other gases. Zhao et al. (2011b) also found that the absorption capacity of MCHP (MDEA-[MDEA][Cl]-H_2O-PZ) at 303.15 K and 1.50 MPa was approximately 0.1584 g of CO_2 per gram of MCHP. When the ionic liquid was replaced by [MDEA][PF_6], the absorption capacity of MCHP was 0.15 g of CO_2 per gram solvent of MCHP (MDEA-[MDEA][PF_6]-H_2O-PZ).

Ahmady et al. (2011) obtained the data for CO_2 loading in mixture of 4.0 mol/L aqueous MDEA and three types of imidazolium-based ionic liquids, [bmim][BF_4], [bmim][Ac], and [bmim][DCA], at temperature ranging from 303 to 333 K and CO_2 partial pressure ranging from 100 to 700 kPa. It is concluded that the CO_2 loading in mixtures increased with the rising of CO_2 partial pressure while decreased with an increase of temperature or ILs concentration increases.

Lu et al. (2012) investigated a mixed absorbent composed of MEA and [Bmim]BF_4 with the optimum mole ratio of MEA to [Bmim]BF_4 7:3. Experimental results showed that the absorption capacity of the mixed absorbent was significantly higher than pure MEA aqueous, approaching 0.6XX mol of CO_2 per mol of MEA.

In order to discover the influence of temperature, solution composition, and pressure on CO_2 absorption in aqueous solutions of MDEA and [N_{1111}][Gly], Gao et al. (2013) carried out the equilibrium absorption under a wide range of pressure (0–300 kPa) at three temperatures in a dual-vessel absorption equilibrium system. It was derived that with the increase of ILs or MDEA concentration, the solution density grows slightly, while the viscosity rises dramatically.

Baj et al. (2013) investigated the impact of blends of MEA and eight kinds of ILs. The presence of water was having a determinant effect on the volume of CO_2 that can be absorbed. The addition of water to [BMIM][OAc] decreased the amount of absorbed CO_2. Thus, CO_2 absorption capacity was not linearly dependent on the mass fraction of the water/ILs/MEA system. However, the absorption rate was increased with an addition of water; it was due to the lowering of viscosity.

ILs plus superbase or other organic solvents

Recently, a new class of solvent called binding organic liquids (BOLs) or switchable solvents has been discovered which can be formed and used in the presence of water. If water is in significant quantities, undesirable bicarbonate salts may be formed; however, these salts can be broken down more efficiently than in MEA systems due to the anticipated lower specific heat of CO_2 BOLs than water.

Jessop et al. (2005a) designed DBU, which is the first CO_2 BOL. Absorption capacities of CO_2 BOL are 2–3 times higher than those of aqueous alkanolamines. And then Wang et al. combined bicyclic amidine (DBU) with hydroxyl modified IL as a superbase to trap the proton produced during sorption process of CO_2, which proved to be an effective way in achieving an equimolar of sorption.

Zhang et al. (Oyenekan and Rochelle 2006) mixed IL 1-butyl-3-methylimidazolium chloride ([C4mim][Cl]) with chitin or chitosan as a mixed solvent to capture CO_2. Chitin has two hydroxyl groups in the cellulose-like polymeric structure, whereas chitosan has an additional amine group. For the chitosan/IL mixture, the measured absorption capacity exceeds the theoretical capacity due to the physical

absorption of CO_2 in these liquids. Physical absorption is also observed for the chitin/IL mixture. Although this approach cannot provide as high absorption capacities as pure FIL, it really has the advantage of bringing a fully recyclable, less corrosive, and nonvolatile CO_2 absorbent.

In summary, the viscosity of this kind of solvent is lower than that of pure ILs and easier to regenerate than the traditional alkanolamines. So it maybe another potential option to CO_2 capture in the future.

Future research should be focused on the following issues:

1. Understanding the mechanism of the CO_2 capture with ILs combing molecular simulation and experimental characteristics and revealing the relationships between structures of IL and the performance of CO_2 capture;
2. Developing the new ILs with low cost, low viscosity, and high absorption capacity with high selectivity, which will reduce the absorption rate and decrease the energy demand for desorption. The CO_2 desorption process is also crucial with respect to the energy consumption required by industries;
3. Studying the transport phenomena which will be very important for the suitable design and operation of industrial unit, especially at low pressure and high temperature (like flue gas from coal-fired power plants) used for CO_2 capture with ionic liquids.

Though there are lots of problems in using ILs to capture CO_2, we believe all the problems will be resolved one by one with in-depth investigation, and then it is possible to use ILs to capture CO_2 on large scales in the future.

3. Mixed amines

A single absorbent to satisfy all the requirements for a CO_2 separation process seems hard to find. Some researchers try to combine the advantages of several amines (Polderman et al. 1955). The new types of mixed amines are expected to have high CO_2 absorption capacity, high CO_2 loading, and low regeneration energy consumption. Generally speaking, monoethanolamine and diethanolamine have the advantage of high absorption rate, while triethanolamine has the advantage of low energy consumption. Based on the analysis above, mixed amines have become a new research direction nowadays. Although sterically hindered amines seem to be rather expensive, they have also become a research object because of high absorption capacity and absorption rate. For example, the mixed absorbents developed by MHI which are called KS-1/KS-2 and KS-3 employ sterically hindered amines as a component of the absorbent. The KS serial absorbent has already been verified to be better than the standard, single MEA solution. The energy consumption is reported to be reduced by 40 % compared to that of a MEA process. Zhejiang University developed MEA/MDEA and MDEA/PZ mixed amine absorbents, and the test result shows that they can decrease regeneration energy consumption by over 5–10 %.

Piperazine (PZ) is a cyclic diamine which has been studied as an advanced solvent for CO_2 capture. Because of its rapid formation of carbamate with CO_2, piperazine is used to be a promoter in blends for CO_2 capture with small concentrations. It is established that 8 m PZ (40 wt% PZ) has superior performance than conventional solvent 30 wt% MEA for CO_2 capture. Under process conditions, 8 m PZ has twice absorption rate and higher cyclic CO_2 capacity than 30 wt% MEA (Rochelle et al. 2011). Freeman has demonstrated that PZ is more stable at high temperature up to 150 °C and less prone to oxidation than MEA (Freeman and Rochelle 2011). The expected energy required for PZ system is 220 kwh/t CO_2 with optimized process design, 10–20 % less than MEA (Freeman et al. 2010). However, PZ has limited solubility window where solid precipitation occurs at both low and high CO_2 loading. It is a proper way to solve the problem by using PZ in blends with other highly performing amines. In this context, PZ blends with MEA, hexamethylenediamine (HMDA), diaminobutane (DAB), bis(aminoethyl)ether (BAE), aminoethylpiperazine (AEP), and 2-amino 2-methyl-propanol (AMP) have been investigated (IPCC 2005). Most of them have better solubility window than 8 m PZ, and the absorption rate in concentrated PZ blends is 1.5–2 times higher than 30 wt% MEA. However, the effect for degradation rate is different in various PZ blends. Combination of AMP and PZ catalyzes the degradation of each other, but for MDEA and PZ blends, the degradation rates are slower than their individual ones.

4. Phase transitional solvent

Phase transitional absorbent has attracted more and more attentions due to its great potential in reducing energy penalty for CO_2 capture. Rather than considering liquid–liquid phase separation and precipitation as drawbacks, some researchers regard it as a good property to reduce cost for CO_2 capture (Zhang et al. 2011).

French Institute of Petroleum (IFP) has developed DMXTM solvents in which the CO_2 captured concentrates in one of the two phases, and only a portion of the total flow rate has to be sent to the stripper. The DMXTM process proposed by Raynal can remarkably reduce the heat duty of reboiler to 2.3 GJ/t CO_2 (Raynal et al. 2011). Tan investigated kinetics and thermodynamic of the lipophilic amine blend of DPA and DMCA and found the cyclic loading of this solvent can reach up to 0.7 mol CO_2/mol amine (Tan 2010). Zhang did research on thermomorphic phase transitional solvents (TBS) and found a new ternary blended solvent DMCA + MCA + AMP which has successfully met the desired phase change temperatures, remained a high net CO_2 loading (>3.5 mol/kg), and exhibited a remarkable chemical stability against degradation. Moreover, the energy consumption of TBS process in which agitation, nucleation, and phase split are employed is only less than 2.0 GJ/t CO_2 (Zhang et al. 2013). Hu investigated a phase transitional absorption which was composed of 80 % solvent B and 20 % activated agent A. After absorption, the two liquid phases were separated and only 20 % of the absorbent was forwarded to regeneration (Hu 2009). Xu found 2 M 1,4-butanediamine (BDA) blended with 4 M 2-(diethylamino)-ethanol (DEEA) has 48 % higher cyclic capacity and 46 % higher

cyclic loading than 5 M MEA. Moreover, the separation mechanism of the phase transitional solvent was found due to the limited solubility of DEEA in the reaction products of BDA with CO_2 and the fast reaction rate of BDA with CO_2 (Zhang et al. 2013). Brennecke proposed phase change ionic liquids to remove CO_2 from flue gas (Dame UON). They discovered solid ionic materials with high CO_2 uptake would form a liquid upon reacting with CO_2. In the regeneration step, the heat of fusion of the salt would supply part of the heat needed to desorb the CO_2 from the absorbent, and the heat of regeneration would be significantly reduced.

Phase transitional absorbent is a novel concept for CO_2 capture which has great potential in reducing energy penalty. However, the new technology still meet challenges such as viscosity of rich solvent, pressure drop, and liquid holdup which means the design and modification of convention absorption column are required, and further investigations should be done for industrialized application.

Absorber

Packed Tower

A packed tower is a common choice in the traditional chemical absorption process to remove CO_2. The technology of the packed tower is mature, and it has already developed a huge market although there are still some problems. Low speed in mixing and mass transfer would lead to the big size of equipment and huge investment. The direct contact of gas and liquid would lead to such problems as entraining, channeling, bubbling, and overflowing. Hence, strengthening the mass transfer in reaction equipment and solving the operation problems in the contact of gas and liquid are the key points to reduce the tower size as well as the investment.

1. Packing

Packing is used to increase the gas–liquid contact time and surface area during CO_2 absorption and desorption process. Mainly, there are two kinds of packing, random packing and structured packing. In recent years, the performance of various packings are widely reported, and properties of structured and random packing like surface area and void fraction are compared in the review paper by Tan et al. (2012), as listed in Table 11. Structured packings are favored for they can provide a much higher overall mass transfer coefficient and lower pressure drops than random packings. Recent studies show that the development of new packing and the improvement of inner attachment structure inside of the packed columns would strengthen mass transfer so as to reduce the size of equipment. The new packing can lower the system resistance and strengthen the mass transfer capacity. As a result, the performance of the equipment will be improved. Figure 30 shows the typical structure of a packed tower and some new packing.

2. Liquid distributors

Generally, fluid distribution in packed columns is not uniform, especially in the liquid phase. Maldistribution of fluids is always responsible for a significant reduction in the transfer efficiency. Normally, liquid distribution depends on the

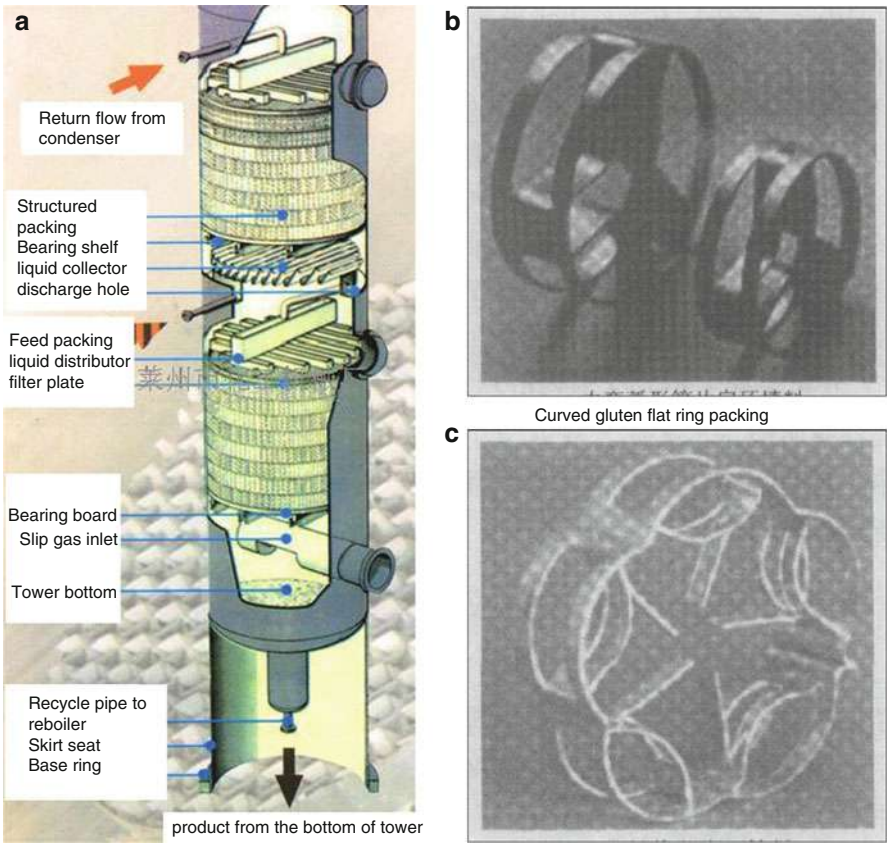

Fig. 30 Packed tower and some packing (Weiyang 2005)

distributors and the packing that is adopted in the column. Thus, liquid distributors are significantly meaningful to the packing column of high mass transfer efficiency. Liquid distributors are complex and expensive elements which are aimed to uniformly distribute the liquid over the packing. Their main parameters are the drip point density and their structure with regard to the underlying packing (Bozzano et al. 2014). The use of well-designed distributors coupling with the packing is a key point to achieve a best performance of the packing column. However, the study of liquid distributors and particularly their interactions with the beneath packing column are still a relatively unexplored area. In principle, the design of the liquid distributor should fulfill the following requirements (Spekuljak and Monella 1994): (1) the largest number of liquid distribution points in the column cross-section; (2) operating flexibility, without sacrificing the other requirements; (3) to be mechanically robust and easy to install into and remove from the column shell; (4) to minimize the distributor height; and (5) easy to clean and maintain.

Hollow Fiber Contactor

Many researchers hope to find a new CO_2 absorption equipment to reduce the equipment size. A hollow fiber contactor is one type of new absorption equipment widely studied now (Yan et al. 2007).

In a hydrophobic hollow fiber contactor (Fig. 31), gas and the absorbent solution flow in different sides of the hollow fiber. Gas and liquid contact indirectly, and absorbent entraining, channeling, bubbling, and overflowing can be avoided. At the same time, a hollow fiber's large surface area (1,000–3,000 m^2/m^3) can reduce the volume of the equipment effectively. Studies show that using hollow fiber contactor can reduce the size of an absorption and regeneration tower by 63 % compared with a packed tower.

However, membrane contactors also have some disadvantages. First, the presence of membrane adds extra mass transfer resistance, which will result in a reduction in the overall mass transfer rate. But this negative impact can be potentially eliminated by the advantage of large interfacial mass transfer area. The main challenge for membrane contactor is the issue of membrane wetting, which leads to the deterioration of CO_2 absorption flux in long-term operation and limits its large-scale commercial application. In order to solve this problem, a number of studies have been conducted, including the selection of membrane materials and mechanism of membrane wetting and prevention of membrane wetting.

Super-Gravity Rotating Bed

To solve the size problem of the common packed tower, Ramshaw (Ramshaw and Mallinson 1981) put forward the concept of a super-gravity rotating bed. High-speed rotation of the central axis can cause centrifugal super gravity, which can strengthen the transfer, mixing, and reaction process. Studies show that the mass transfer rate of such a super-gravity rotating bed is 10–1,000 times that of common packed tower. Therefore, the volume of the reactor can be greatly reduced.

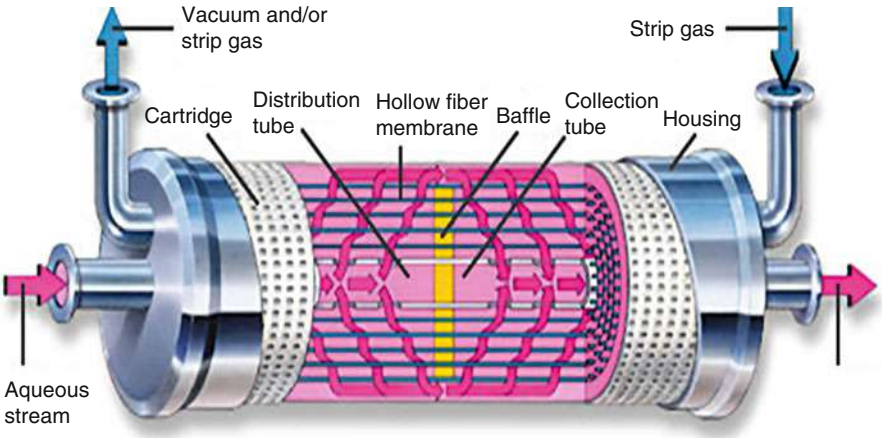

Fig. 31 Illustration of typical hollow fiber contactor (Yan et al. 2009)

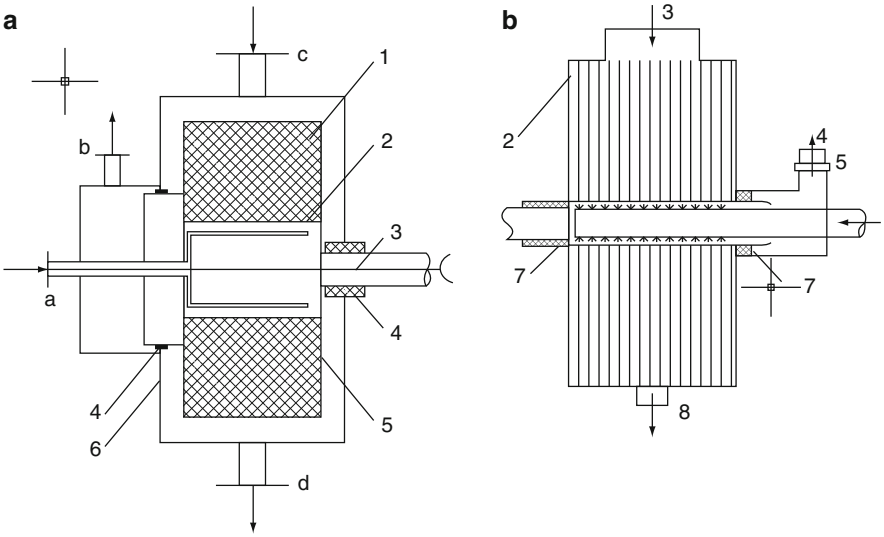

Fig. 32 Two kinds of rotating bed for CO_2 capture. (**a**) Structure of a wire packing rotating bed (*1*, packing; *2*, rotor; *3*, shaft; *4*, seal; *5*, liquid distributor; *6*, shell; *a*, liquid inlet; *b*, gas outlet; *c*, gas inlet; *d*, liquid outlet). (**b**) Structure of a disk packing rotating bed (*1*, shaft; *2*, concentric ring wave disk packing; *3*, gas inlet; *4*, gas outlet; *5*, separator of gas and liquid; *6*, spray tube; *7*, filler; *8*, liquid outlet with seal) (Chen 2002)

Some researchers have studied the CO_2 removal process of rotating beds and obtained the effect on CO_2 absorption characteristics of related operation and design parameters. Chen Minggong (2006) proposes the rotating disk super-gravity bed which has some improvements to traditional rotating packing beds, as shown in Fig. 17. Recently, studies of super-gravity rotating beds are mainly carried out in the chemical industry. The knowledge of inside flow fluid structure with high gas flow, mass transfer strengthening of flue gas decarbonization, and the adaptability of real gases are lacking (Fig. 32).

Integration and Optimization of the Process

As one of early chemical absorption processes, amine-based CO_2 scrubbing process was proposed by Bottoms in 1930. Based on its rationality and formerly applied occasions, during the following 70 years after this invention, few researchers tried to modify this process. However, when people realize the correlation between climate change and CO_2 emissions, things are changed. The energy consumption of this process is deemed to be unacceptable, especially to those occasions of high gas flow rate and lower CO_2 partial pressure, e.g., coal-fired power plants.

In this context, a sharp increase of patents related to process modification appeared in the past decade. It is widely considered that integration and optimization

of the process is one of the most effective ways to further reduce the energy consumption for chemical absorption method. In general, integration and optimization of the process can be understood or interpreted as two distinct meanings. One understanding refers to process modification and heat integration toward various components inside of carbon capture plant itself, while the other recognition is the integration between carbon capture plants with the other system. According to the components for integration, modifications to amine scrubbing process can be classified into two categories, integration with other system and optimization of itself.

Process Optimization by Coupling with Other System

- Integration of steam cycle and the boiler
  For amine scrubbing, thermal energy is needed for amine regeneration, electricity consumption for CO_2 compression, and cooling necessities for refrigeration. An important consideration to select steam quality for the stripper is the steam pressure. It is widely accepted that the reboiler temperature should not exceed 122 °C, or else degradation of MEA and corrosion of the equipment will be intolerable. In general, the temperature difference between the high-temperature side and low-temperature side ranges from 10 °C to to 15 °C in the reboiler, which means that the steam conditions of the saturation temperature amounts to 132–137 °C. Saturation pressure at this temperature is 2.8–3.4 bar. This thermal energy can be supplied from either an auxiliary boiler or from a power plant steam extraction. Finding the optimum way to extract this steam becomes essential in order to get the less power plant energy penalty. One potential form of the simplified CO_2 capture steam extraction system is shown in Fig. 33. Two evident characteristics for this process are that the steam is extracted from IP/LP crossover pipe for amine solvent regeneration and a throttling regulating valve in the LP turbine inlet should be installed to make the pressure stable. Although the operating requirements of CO_2 capture system can be achieved, the efficiency of LP section will reduce to some extent.

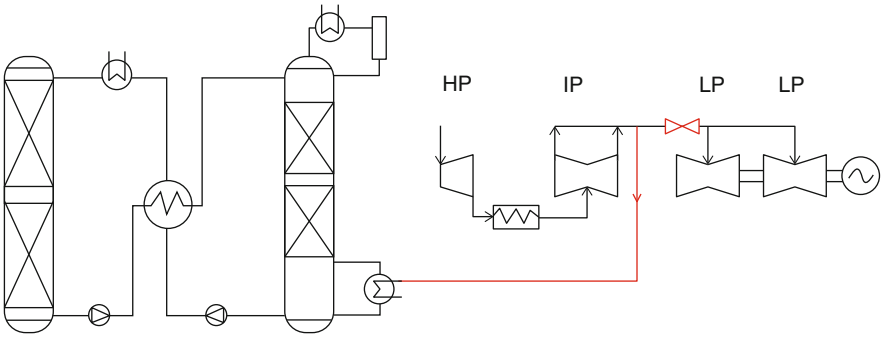

Fig. 33 Coupling between the steam cycle and the stripper's boiler

In addition to the process given in Fig. 33, there are a large number of variants of coupling between the amine scrubbing system and power plants, e.g., extracting steam from other parts of the steam cycle, integrating the condensate system of amine scrubbing with a power plant.

- Integration of flue gas and amine scrubbing
  Flue gas after removing SOx and NOx is usually of high temperature. In order to obtain a relatively stronger thermodynamic driving force, flue gas needs to be cooled before it is sent to the CO_2 absorber. Usually a pretreatment column is set to cool down the flue gas to the required temperature. However, it is not wise to waste this part of heat in the flue gas. Due to this reason, some researchers proposed adding a heat exchanger to utilize the heat of flue gas. A potential form to utilize the heat from flue gas is illustrated in Fig. 34. A heat exchanger is set up to replace the pretreatment column. The waste heat of flue gas can be used to raise the temperature of the rich solution.
- Integration of DeSOx and amine scrubbing
  In addition to the waste heat in the flue gas, remaining contaminants should also be concerned. In the one hand, remaining components, which refer to SOx, NOx, and particle matters, may affect the performance of carbon capture system, such as CO_2 removal efficiency and treatment of heat-stable salts. In the other hand, it is possible to integrate the desulfurization and carbon capture into one tower so as to reduce the capital cost of the equipment and save the space for power plants.

  Reddy et al. (2007) propose using a two-stage quench scrubber in place of the standard flue gas pretreatment column. Their modification refers to pretreatment systems where an alkali wash is utilized to remove SOx/NOx components in the flue gas. Hakka and Ouimet (2007) use a similar approach as indicated above for the sequential removal of SO_2 and CO_2 from a gas stream (Fig. 35), thus avoiding the generation of heat-stable salts. The cooled gas stream then passes through a

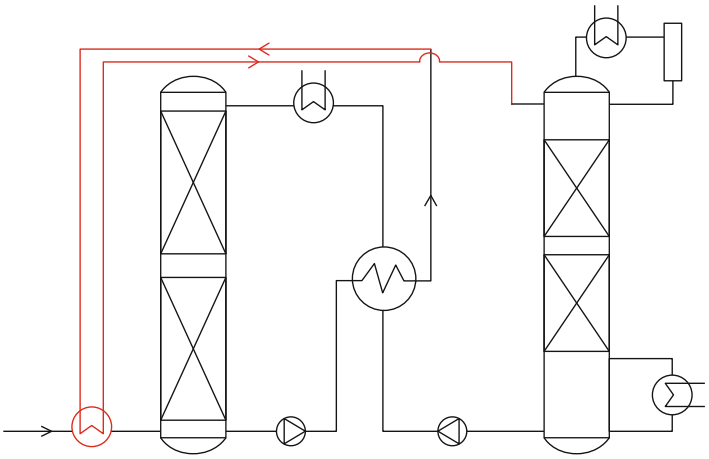

Fig. 34 Utilization of flue gas heat

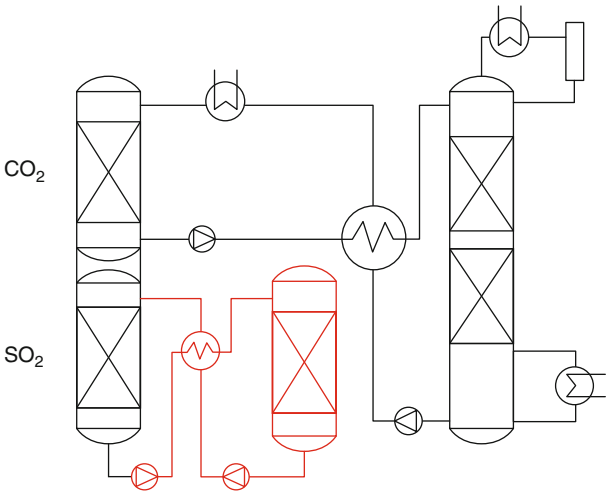

Fig. 35 Integration of DeSOx and amine scrubbing

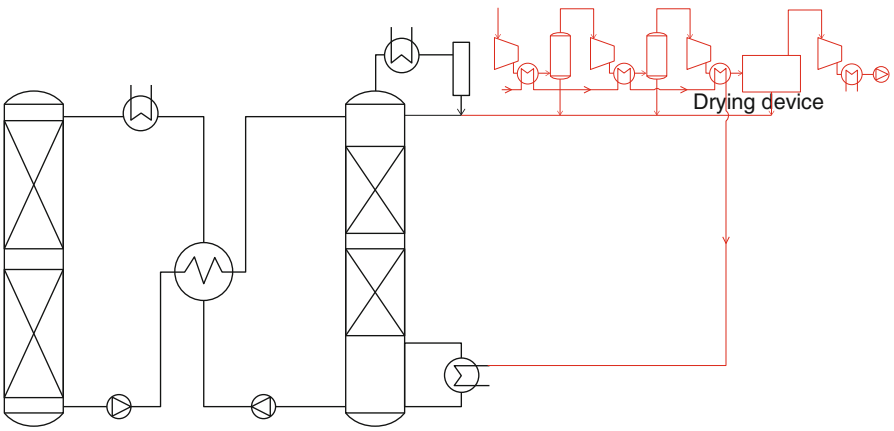

Fig. 36 Integration of compressors and amine scrubbing

SO_2 scrubbing section, followed by a CO_2 scrubbing section. Both the SO_2 and CO_2 scrubbing sections use sorbents that can be regenerated. Shaw (2009) also suggests a similar method for integrating the SO_2 and CO_2 capture processes.

- Integration of Compressors and amine scrubbing
  Once CO_2 is captured from flue gas, it will be sent to the transportation system or storage tanks after compression and dehydration. During the CO_2 compression, a large number of heat would be generated. One potential form is shown in Fig. 36. The heat of compression is utilized by heat transfer with fluids, and the working fluids are sent to the reboiler. Vapor recompression in the overhead of the stripper can be also regarded as a variant of this method.

Process Optimization by Modifications of Reactors and the Original Process

Process optimization illustrated in this section refers to the modifications toward the process itself. It is intended to seek a balance between kinetics and thermodynamics in the aspect of reactors. It also attempts to manage and improve the heat transfer between the process flow components. Yann et al. (2014) classified these modifications into three classes and 20 subclasses. Three major classes are absorption enhancement, heat integration, and heat pumps. This classification is partially based on the component inside of the process. The drawback for this method is that it brings trouble to understand the widely accepted and discussed modification concepts.

Process optimization is introduced concept by concept in this chapter. Once you figure out the nature of each concept, its derivations and compounds with other concepts will be easy for you to understand and manipulate. Until now, the most discussed concepts include interstage temperature control (particularly intercooling), split flow, vapor recompression, multi-pressure stripping, and heat integration.

- Interstage temperature control (intercooling and inter-heating)

It is a known fact that the chemical reaction between CO_2 and absorbent is usually exothermic and spontaneous. The exothermic effect can result in an increase in the temperature of the solvent pumped into the absorber. This will limit the driving force for absorption and hence lower the absorption capacity of the solvent system. In the aspect of thermodynamics, CO_2 absorption reactions favor lower temperatures, while higher temperatures facilitate reaction kinetics. The higher temperature will lead to the reduction of viscosities and the increase of diffusion coefficients, therefore obtaining higher mass transfer coefficients. These two effects always fight with each other in an adiabatically operated absorber.

Intercooling is to withdraw a fraction of the solvent in the lower section of the absorber, to cool down the solvent and send it back to the adjacent area of the absorber. The simplified process is shown in Fig. 37. The reason to do this is that at the lower section of the absorber the mass transfer driving force of solvent becomes weaker with the increase of CO_2 loading and temperature. To decrease the temperature of solvent is obviously beneficial to enhance the mass transfer driving force. The modification of inter-heating is similar to that of intercooling. The modification is usually installed at the top section of the absorber. At that section, reaction rate is the most concerned thing. To increase the temperature in this section facilitates to improve the kinetics performance of solvent.

Experimental validation of Knudsen et al. (2011) shows no clear effect of intercooling modification for MEA and a reduction of boiler duty of 7 % for activated AMP. The multiple intercooled column (Sanpasertparnich et al. 2011) leads to approximately 20 % reduction of the reboiler duty. The effect of inter-heating has not been validated by experimental studies.

There are a certain number of variants of interstage temperature control. Interstage temperature control can be also applied to the regenerator. Aroonwilas et al. (2007) proposed a process to adjust the temperature distribution in the absorber

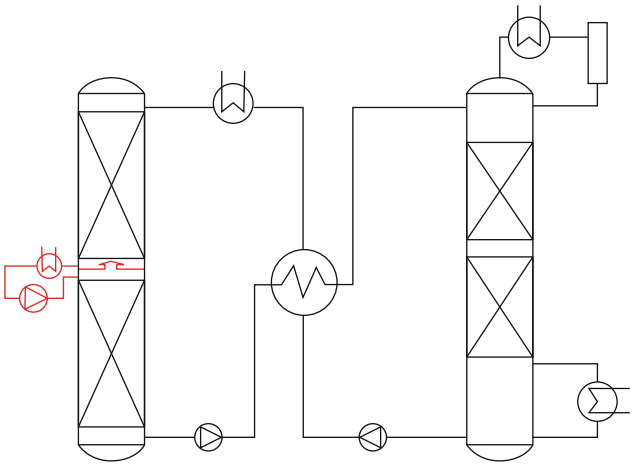

Fig. 37 Schematic of interstage temperature control process

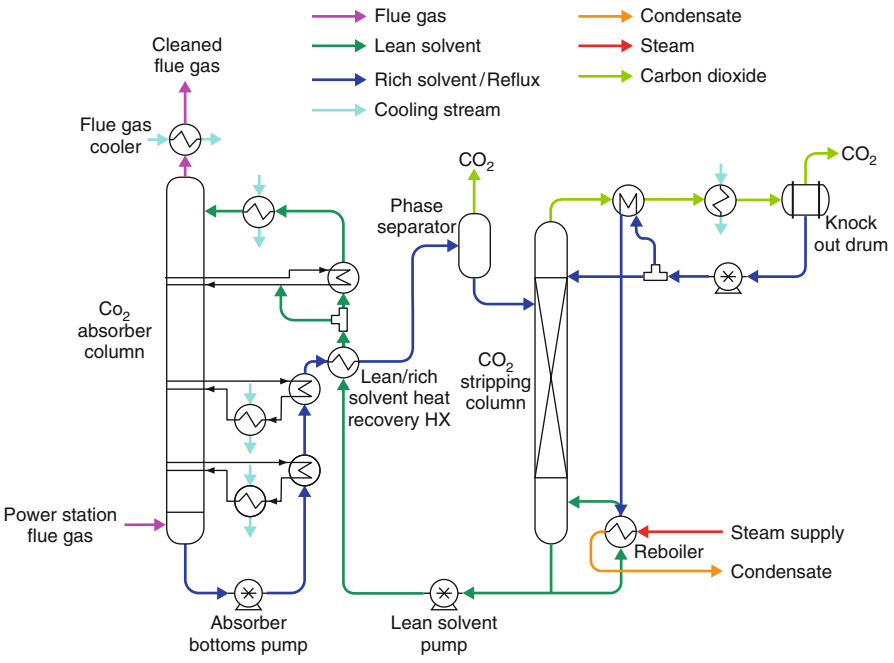

Fig. 38 Example of interstage temperature control process proposed by Aroonwilas

which is outlined in Fig. 38. The patent uses heating in the top section of the absorber to enhance the kinetically limited mass transfer in this section. Interstage cooling is then used to provide thermodynamically driven mass transfer in the lower stages of the absorber by maintaining a higher loading of CO_2 in the solvent. This process is

similar to concepts published by Leites et al. (2003). Aroonwilas and Veawab (2007) also suggest the incorporation of some heat recovery. Part of the condensate removed from the CO_2 leaving the stripper is used to cool the vapor upstream of the separator. The heated condensate is then used as feed for the reboiler.

- Split-flow process

There is no identical definition for split-flow process. A basic principle of this method is that either the flow in a pipe or the flow in the reactors should be split or divided into two or more parts. The splitting may occur at any position of the typical process, and the only purpose is to save energy or reduce the cost.

In 1934, the concept of split-flow process was firstly put forward by Shoeld, which is considered as one of the first methods proposed for addressing temperature problems in the absorber. During this process, both the absorber and stripper are split into two or more stages. Compared with the typical base process, partially used/regenerated solvents are introduced to recycle between the middle stages of absorber and those of stripper. The whole process is outlined in Fig. 39.

Shoeld declared that a 50 % reduction in steam usage within the stripping column could be achieved compared to processes using a single-stage absorber and stripper. The results were based on the comparison of a typical set of operating data for single-stage and split-flow systems using a sodium phenolate solution to capture the acid gas. However, Shoeld did not point out the applicable specific pressures.

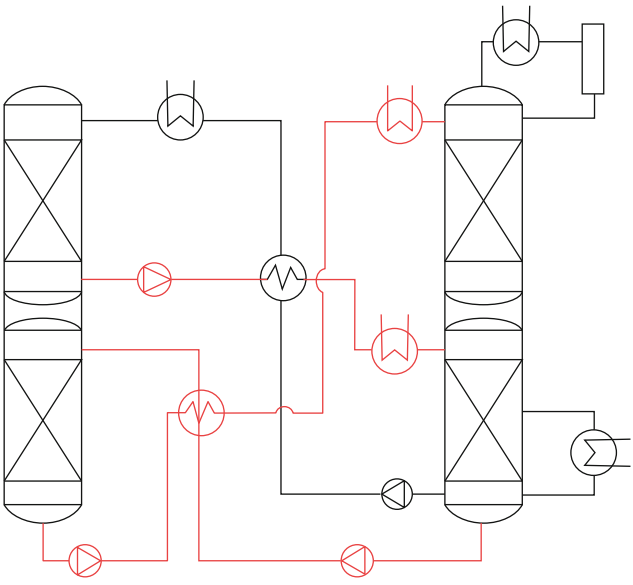

Fig. 39 Schematic of split-flow process proposed by Shoeld

Although the split-flow process was testified to be rather effective and feasible, researchers also noticed the drawbacks for this method. Towler et al. (1997) presented a comprehensive overview of the shortcomings of the standard split-flow process. They demonstrated that variation in the solvent concentration within the split loop might lead to thermodynamic inefficiencies.

Generally speaking, it is easier to strip solvents that are more concentrated in the active component. Towler et al. investigated split-flow process using TSWEET® and HYSIM®. Results show that the condensation mostly appears in the first few trays below the inlet of the rich solvent stream. Meanwhile, the chemical solvent in the upper section of the stripping column is generally dilute. Condensate steam at the overhead condenser returns to the stripping column as reflux to cool the exiting vapor stream, decrease the condenser duty, and maintain the water balance of the system. Moreover, the reflux further dilutes the solvent in the upper section of the stripper. It implies that solvent withdrawn from the stripper midsection will be much more dilute than solvent extracted from the stripper bottom section. Hence, to achieve the specified carrying capacity, the solvent flow rate needs to be increased which will bring more energy consumption.

In order to overcome the drawbacks of the standard split-flow process, Towler et al. suggested adding a second reboiler on the side draw from the stripping column, allowing the concentration of the solvent in this stream to match that leaving from the bottom of the column. Returning the reflux stream to the lowest point possible in the stripper (i.e., the reboiler) avoids dilution of the solvent in the stripping column while maintaining the water balance of the system. On the basis of their modeling results, Towler et al. claim that their improved split-flow process reduces the energy requirement of the stripping column by 70 % over that of the standard split-flow process (Fig. 40).

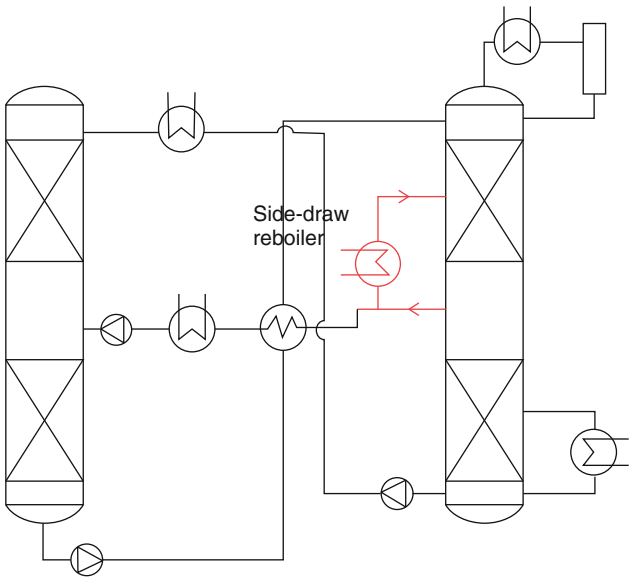

Fig. 40 Schematic of split-flow process with side-draw reboiler

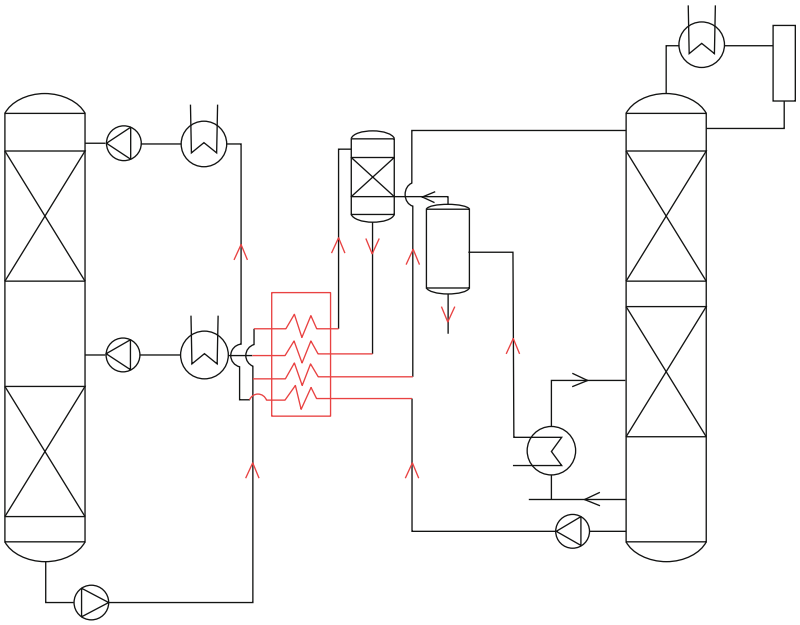

Fig. 41 Schematic of split-flow process with rich solution splitting

Reddy et al. (2004) pointed out similar problems of the standard split-flow process, and they brought forward a totally different method to overcome these problems (Fig. 41). They split the rich solvent into two parts. One portion of the rich solvent passing through cross-heat exchanger is fed to a conventional stripping column which produces a lean solvent. The lean solvent is then recycled to the top portion of the absorber. The other portion of the rich solvent stream is fed to a second stripping column. Heating from the lean/rich heat exchange is used to provide the energy needed to regenerate a semi-lean amine in this column. In addition, further stripping is achieved by adding steam flashed from the condensate from the conventional stripping column reboiler. This semi-lean amine is recycled to the absorber midsection. Interstage cooling between the two sections of the absorber is also recommended.

Mak (2006) proposed a more complex transformation of split-flow process in patent No.CA2605649 (Fig. 42). The components include both two separate stripping columns and a single two-stage stripping column, which are used to produce both lean and ultra-lean regenerated absorption solvents. Frankly speaking, this process is similar with the process proposed by Reddy. However, there are two evident differences between them. One difference is that in Mak's patent, one portion of the CO_2-rich solvent is sent to the stripper without heating. The other difference is that the stripper for Mak's process is a two-stage stripper.

As described by Mak, utilizing this process can effectively reduce the regenerator reboiler and condenser duties even if stripping is performed at higher temperatures than standard. It also declares that the reduction of amine recirculation rate can be

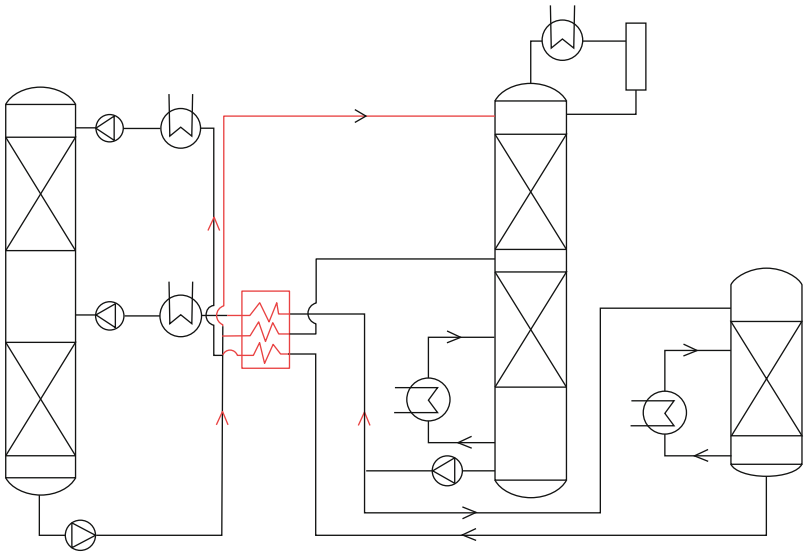

Fig. 42 Schematic of split-flow process proposed by Mak

achieved with the dual absorption and regeneration. It can be easily understood that once the circulation rate has been reduced, the pump energy required to operate the system will be much lower. Moreover, the lower circulation rate also leads to the minimizing of equipment size and savings in capital costs.

Eisenberg and Johnson (1979, Fig. 9) invented a simplified split-flow process with the idea of splitting the rich stream and using an unheated portion in the top section of the stripping column (Fig. 43). It is claimed that the overall energy requirement of the system can be reduced by maximizing the recovery of heat from the hot lean absorbent, as well as from the stripping vapors in the stripping column. However, there is a potential problem for this system. The problem is that the lean loading recycled to the absorber column may be slightly higher than that of standard process, which is caused by the relatively lower ratio of steam to liquid at the bottom of the column.

- Vapor recompression

Heat of steam vapor in the overhead separator of the stripper is generally wasted. The vapor recompression process is therefore put forward to address this problem. In this method, steam is extracted from one part of the stripping column, recompressed and either condensed with the heat of condensation providing part of the reboiler duty, or reintroduced into the column to provide additional stripping steam.

Woodhouse (2008) put forwarded a possible form to integrate vapor recompression method with CO_2 capture processes. In the system proposed by

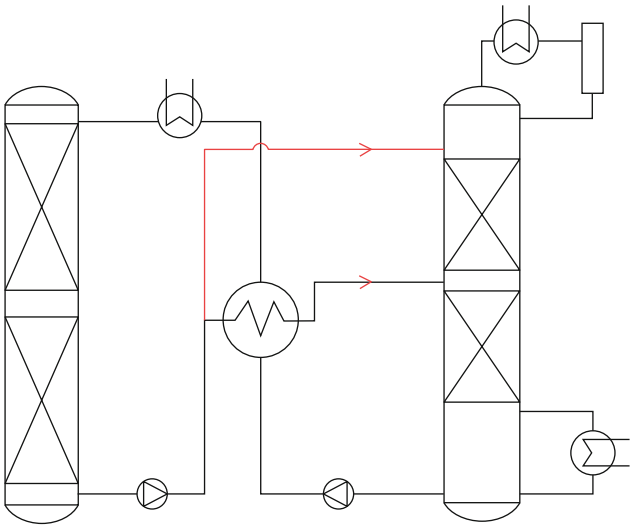

Fig. 43 Schematic of split-flow process proposed by Eisenberg and Johnson

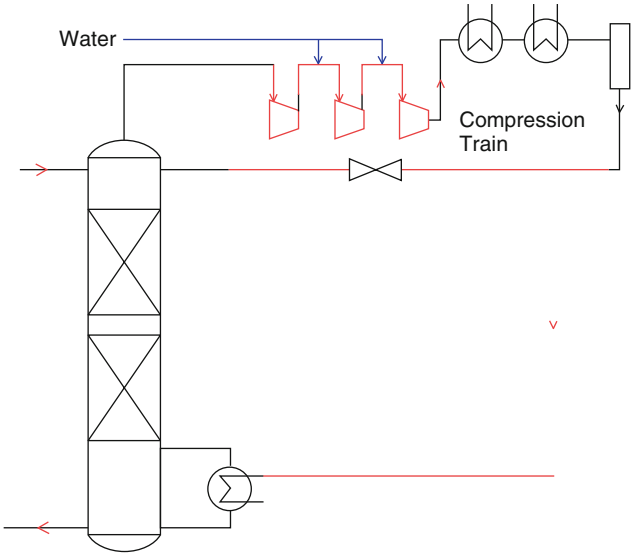

Fig. 44 Schematic of vapor recompression process proposed by Woodhouse

Woodhouse (Fig. 44), stripper overhead vapors are compressed to 2–5 times the operating pressure of the stripping column before being separated in a multistage compressor. An important feature of this system is that additional water is injected between compression stages to cool and saturate the vapor stream. The hot

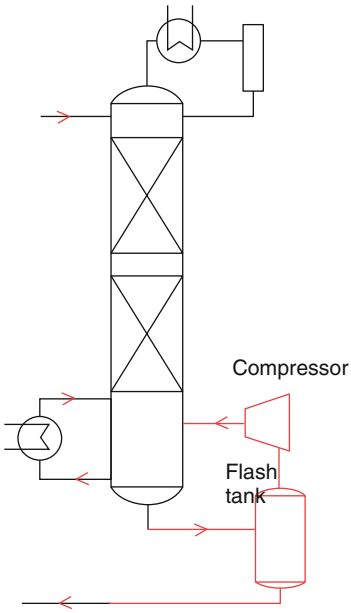

Fig. 45 Schematic of vapor recompression process proposed by Reddy

compressed vapor is then used to provide heat for other processes. It is considered as a potential substitute for the stripping column reboiler. According to his simulation results, this modification may lead to a reduction of 24 % of the duty for the stripping column reboiler. It should be pointed out that this process is rather similar to the concepts proposed by Jassim and Rochelle (Rochelle et al. 2006). The evident difference is that there is additional water injection between the compression stages used in this patent. However, the issue of water balance should be further studied due to the introduction of additional water.

Reddy et al. (Reddy 2007) showed the other transformation of process integrated with vapor recompression (Fig. 45). In this process, the hot lean stream leaves the stripping column and then is sent to a flash drum where the vapors are released due to the descending pressure. After that, the vapors (mainly steam) are compressed and reinjected back into the column to enhance the mass transfer of stripping process. Compared with Woodhouse's idea, there is no water loss or water makeup in this process, which makes it much easier to be accepted. According to Reddy et al.'s model, the net energy requirement of the system can be decreased although the compressing the flashed vapors requires additional electric power. Other benefits bringing forward by this modification include the reduction of the cooling water consumption and shrinking of the size of the stripping (Fig. 46).

It can be easily found that Woodhouse added the compressor at the overhead of the stripper and Reddy installed the compressor at the bottom of the stripper. In this context, Oyenekan and Rochelle (2006) set the compressors at the midsection of the stripper, which exhibits a form of the multi-pressure (or multiflash) stripper (Oyenekan

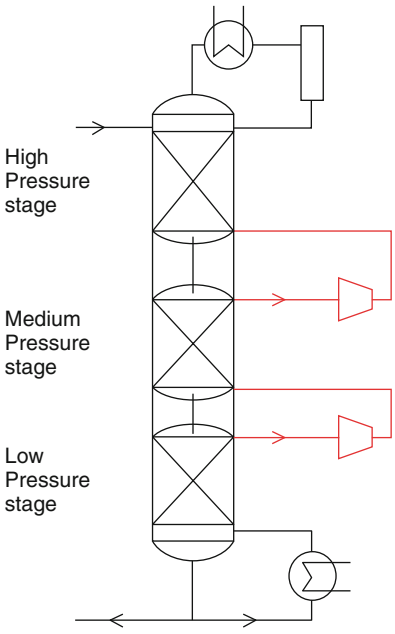

Fig. 46 Schematic of vapor recompression process proposed by Oyenekan and Rochelle

and Rochelle 2007). The feature of this process is that the stripper is divided into separate stages and the controlled operating pressure of each stage is gradually increasing from the bottom to the top of the stripper. The vapor from a lower pressure stage is compressed and subsequently used as stripping medium in a higher pressure stage. Multi-pressure stripping provides the possibility to recover the latent heat of water so as to decrease reboiler duties. Another benefit of this process is that the pressure at the top of the stripper is relatively higher than the standard stripper which is helpful for the final CO_2 compression to sequestration pressures. Oyenekan and Rochelle (2007) report that the reboiler duty is reduced by 20–27 % (depending on rich CO_2 partial pressure). Moreover, they claim an 8 % saving in equivalent work for the multi-pressure stripper compared to the "base case" (30%MEA).

- Matrix stripping

Matrix stripping virtually can be regarded as a transformation of vapor recompression process. As a further extension of the multi-pressure stripper, Rochelle and Oyenekan (Rochelle et al. 2006) call it matrix stripping. A number of strippers operating at different pressures in a matrix pattern are included in this process which is outlined in Fig. 47.

In this configuration, the rich solvent from the absorber is split into three streams and then enters the top of each stripping column, respectively. The flow direction of the regenerated solvent is from the stripper of higher pressure subsequently to the stripper of lower pressure. The vapor venting out from the top of each column is cooled and sent

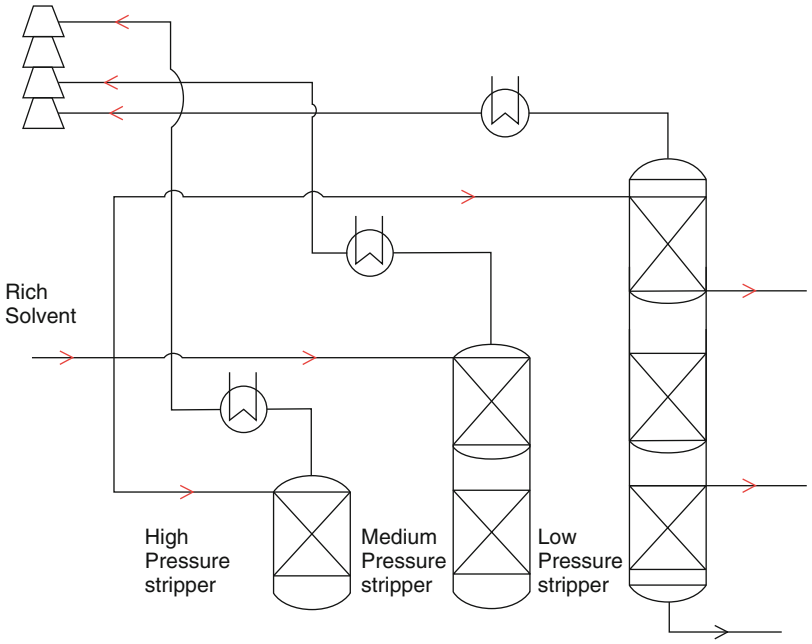

Fig. 47 Schematic of matrix stripping process

to the corresponding stage of the compression train. The multi-pressure stripper addresses the problem of utilization of the latent heat of the water vapor. It is claimed by simulation results that reductions in stripping energy requirements of 15–30 % can be achieved.

- Heat integration

It is well known that in a standard chemical absorption process, there are a number of heat exchangers to cool or heat the working fluids. To reduce the energy consumption, some researchers attempt to recover part of the wasted heat during the process. Kamijo et al. (Kamijo 2006) proposed recovering the waste heat of hot flue gas in the upper stream. The schematic of his idea is shown in Fig. 48. This configuration claims a 6.77 % reduction in reboiler heat duty, with a slight increase in condenser duty (~1 %).

The flue gas cooling stage is separated into two aspects: (1) indirect heating of the fluid from the stripper and (2) use of a heat pump to provide heat for the reboiler. Heat released from the CO_2 compression stage can also be used to supplement the heat pump. This patent claims that most or all of the energy needed for desorption can be obtained from the flue gas cooling stage/heat pump. In addition, as the stripper energy comes from the heat pump, integration with the power plant steam cycle is not required.

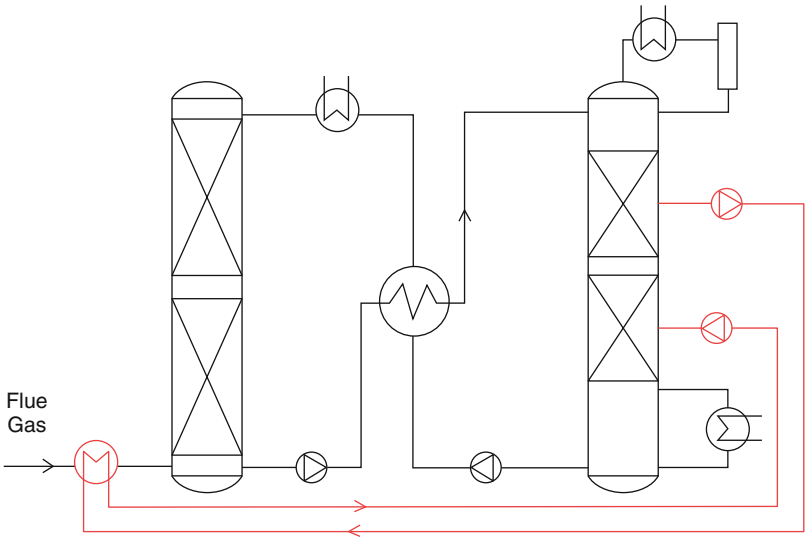

Fig. 48 Schematic of heat integration process proposed by Kamijo

Environmental and Economic Issues

Water Issue

Introduction

Carbon capture technologies could increase the water demand on thermoelectric power plants. It is important to estimate and explore the possible effects CO_2 mitigation will have on water demands. Current carbon capture technologies under development for coal-based power generation require large amounts of water. This analysis assumes that aggressive carbon mitigation policies will be put in place in the near future that would require all new and existing PC (pulverized coal) plants with scrubbers and IGCC (integrated gasification and carbon capture) plants to utilize carbon capture technologies by 2030. The water requirements, at full load, for PC and IGCC plants with and without carbon capture derived from the detailed performance study and used in this analysis are shown in Fig. 49. All additional cooling systems required for the retrofits and all new PC and IGCC capture ready plants are assumed to be recirculating systems based on current regulations and concerns with once-through systems.

It is astonishing that water needs may hinder the application of CCS (carbon capture and storage) technologies. As an Australian report states, coal-fired power plants incorporating carbon capture and storage could be one-quarter to one-third more water intensive. However, the addition of CO_2 capture and compression even

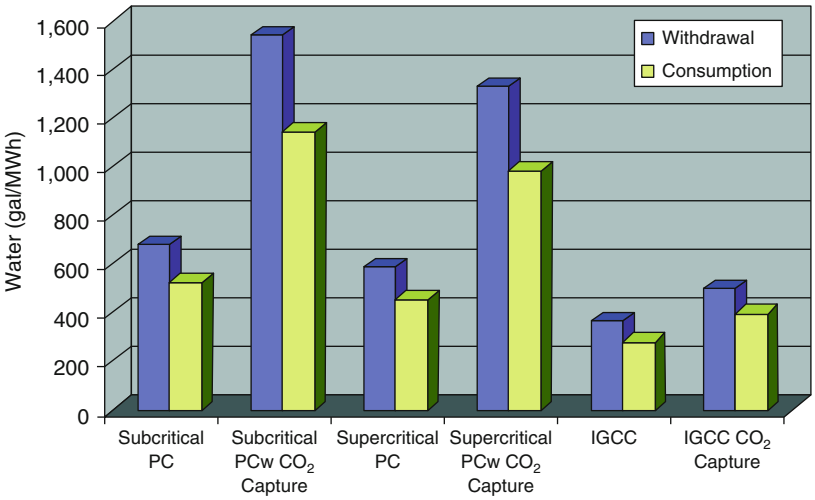

Fig. 49 Water requirements at full load for PC and IGCC plants with and without carbon capture (Shuster 2010)

increases water consumption by 50–90 %, which is indicated in the latest NETL (National Energy Technology Library) report. Whichever the value is in absolute numbers, it seems to be rather unacceptable as the basic water requirement for coal-fired plants is huge. Especially, it is unacceptable for places which are short of water, such as the Western USA and Western China.

Water Balance Strategy for Power Plants with CO_2 Capture

When considering a mode of operation which requires no makeup water, a subset of interrelated factors affecting the water balance should be assessed, such as:

- Flue gas temperature, absorber inlet and outlet: Due to the increased degradation of the amine by an increase in temperature, it is recommended to precool the flue gas to a temperature below at least 80 °C.
- Temperature profile within the absorption section of the absorber: As the CO_2 is absorbed into the solvent, the temperature of the downflowing solvent will increase due to the exothermic absorption reaction, and, thus, some water will inevitably be vaporized. Toward the top part of the column, the colder solvent will recover parts of the water vapor via condensation, and the temperature at the top section will determine the extent of this recovery. The resulting temperature profile along the column shows a pronounced bulge, the size and position of which depend on various factors including solvent flow rate and gas inlet CO_2 content (Kvamsdal and Rochelle 2008). For the optimal design case described later, the peak temperature occurs at the top of the column. The driving force of

mass transfer decreases with an increasing temperature in contrast to the reaction rate which increases. Consequently, the temperature bulge results in less favorable driving forces, although the kinetics becomes faster. If the former dominates, it may be of interest to provide methods that increase the thermodynamic driving forces by reducing the temperature bulge, which can be done by removing heat either within the absorber by intercooling or, prior to the absorber, by means of precooling.

- Absorber inlet lean amine temperature specification: The solvent temperature at the top of the absorption section will influence the absorber outlet gas temperature, thereby determining the amount of condensed water in the absorber section, though this effect is reasonably small.
- Washing sections in the top of the absorber and desorber: The main purpose of the washing section is to reduce the loss and emission of amine into the atmosphere. Thus, the process water fed to the top of the washing section must be almost free of amine.

In addition, the temperature of the cleaned flue gas before being released into the atmosphere (and thus its water content) is largely dependent on the temperature of the large recycling of water around the lower water wash section. These factors imply the establishment of a fine balance in order to keep the net water buildup or loss to a minimum, that is, close to zero on average. On this basis, a control strategy including the following steps was proposed (Fig. 50):

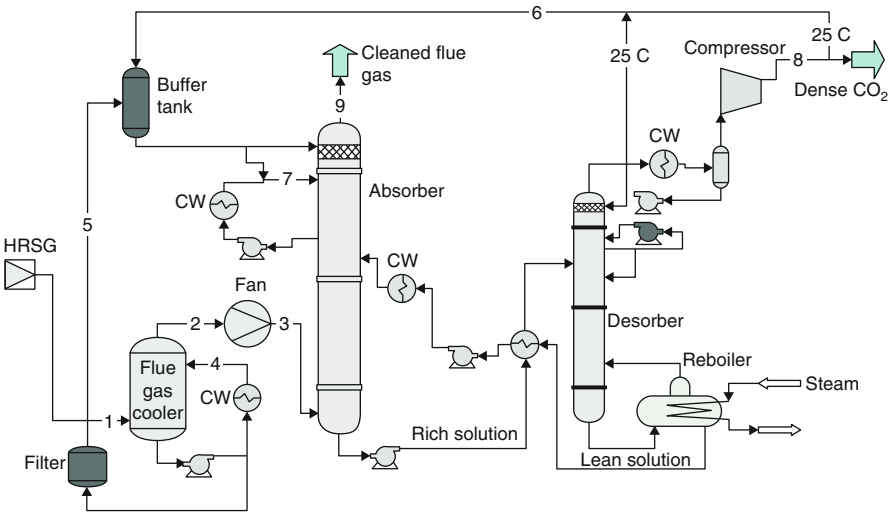

Fig. 50 The absorption system with a water-balancing strategy (indicated with *bold* streams) (Kvamsdal et al. 2010)

1. Precooling the flue gas prior to the absorption column
   - By reducing the temperature of the flue gas slightly below its dew point, some excess water will be produced in the direct contact precooler (DCC). This water is filtered and routed to a buffer tank (stream 5 in Fig. 50), which serves as the makeup water source for the water wash section of the upper part of the absorber, while also securing a proper water balancing during the transient conditions of the plant. The amount of excess water produced will be a trade-off between the cost of the cooling water requirement due to an increase in the size of the fresh cooling water recycling (stream 4 of Fig. 50) and possibly of the precooler and the possibility of a lower desorber reboiler duty and live steam demand, which is discussed later.
2. Water recycling
   - As the content of the amine in the water separated from the compression section and retrieved from the desorber condenser is almost negligible, these water sources (stream 6 of Fig. 50) can be utilized in the water wash section in the upper part of the absorber. Therefore, a bleed stream from the desorber reflux stream can be recycled to the absorber water wash section. The rest can be used in the desorber water wash section, in conjunction with a locally cooled water recycling circuit.
3. Gas cooling upon leaving the absorption column
   A temperature adjustment in the water wash section is required in order for the cleaned flue gas to leave the column at a desired humidity level, which corresponds to the amount of inlet water. Possible solutions could be:
   - Temperature measurement at the top of the absorber and adjustment of the cooling duty in the lower water wash section (stream 7 of Fig. 50) to approach the dew point (i.e., the dew point of the flue gas accounted for the CO_2 removal). This is accomplished by controlling the temperature of the cooler outlet in the lower water wash circulation. The advantage of doing it in this manner is that the temperature is easily measured and the accuracy becomes higher than with other online measurements. The drawback of this solution is that the inlet gas dew point varies as the flue gas concentration changes.
   - Online measurement of moisture in both the flue gas from the HRSG (heat recovery steam generator) unit and the cleaned flue gas effluent. An adjustment is then made by controlling the temperature in the water of the cooler outlet of the lower water wash circulation. One drawback of doing it this way may be obtaining incomplete measurements of the moisture if the samples are not properly heated since accurate online moisture measurements are generally difficult to achieve.

Environmental Effect

Environmental Assessment of the Alkanolamines

Amine-based processes have been used commercially for removal of acid gas impurities from process gas streams, and they are currently the most popular way

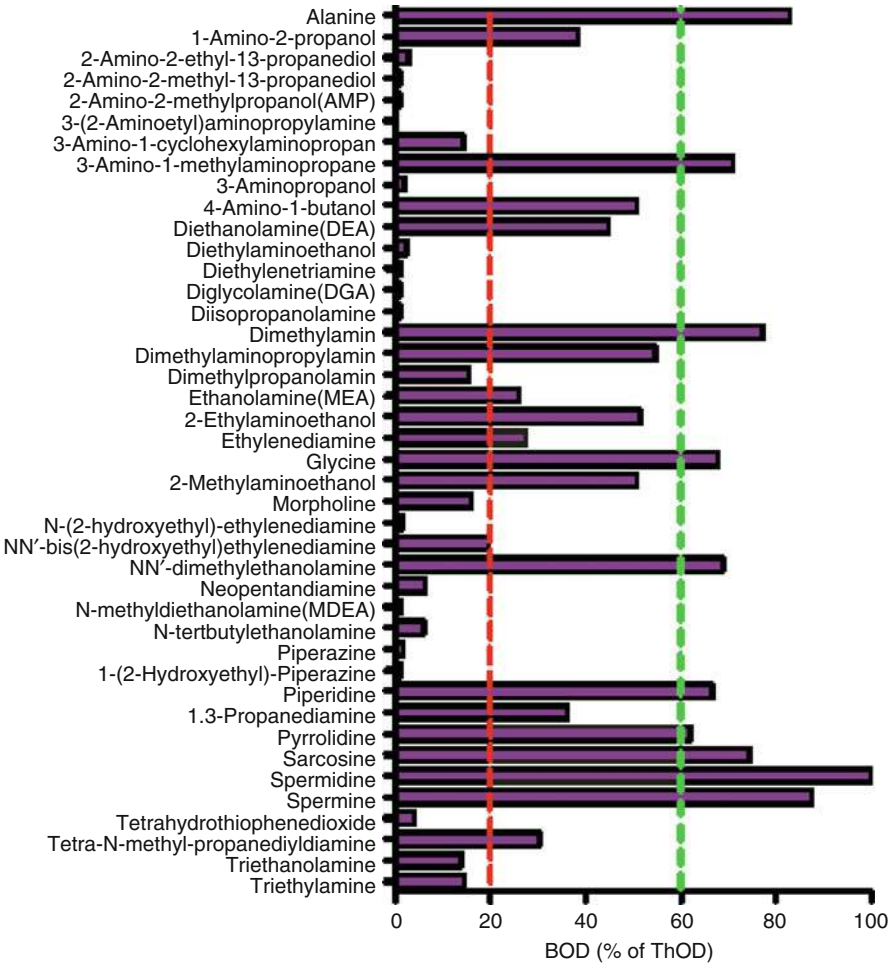

Fig. 51 The biodegradability of all the chemicals tested, results shown as percent degraded with regard to the theoretical oxygen demand (ThOD). The *red line* shows the lowest acceptable value for a chemical to be released in the marine environment, while the *green line* is the lower limit for a chemical to be released independent of the ecotoxicity (Eide-Haugmo et al. 2009)

to remove CO_2 in industry. For natural gas sweetening operations, typically alkanolamines like monoethanolamine (MEA), diethanolamine (DEA), and *N*-methyldiethanolamine (MDEA), as well as mixtures of alkanolamines, are used. Capture by absorption relies on large-scale use of chemicals, and emissions of the solvent may occur through the cleaned exhaust gas as degraded solvent and as accidental spills. It is thus important that the chemicals used have low or no environmental effect. Figures 51 and 52 show chemical test and ecotoxicity testing results of different absorbents based on EC-50.

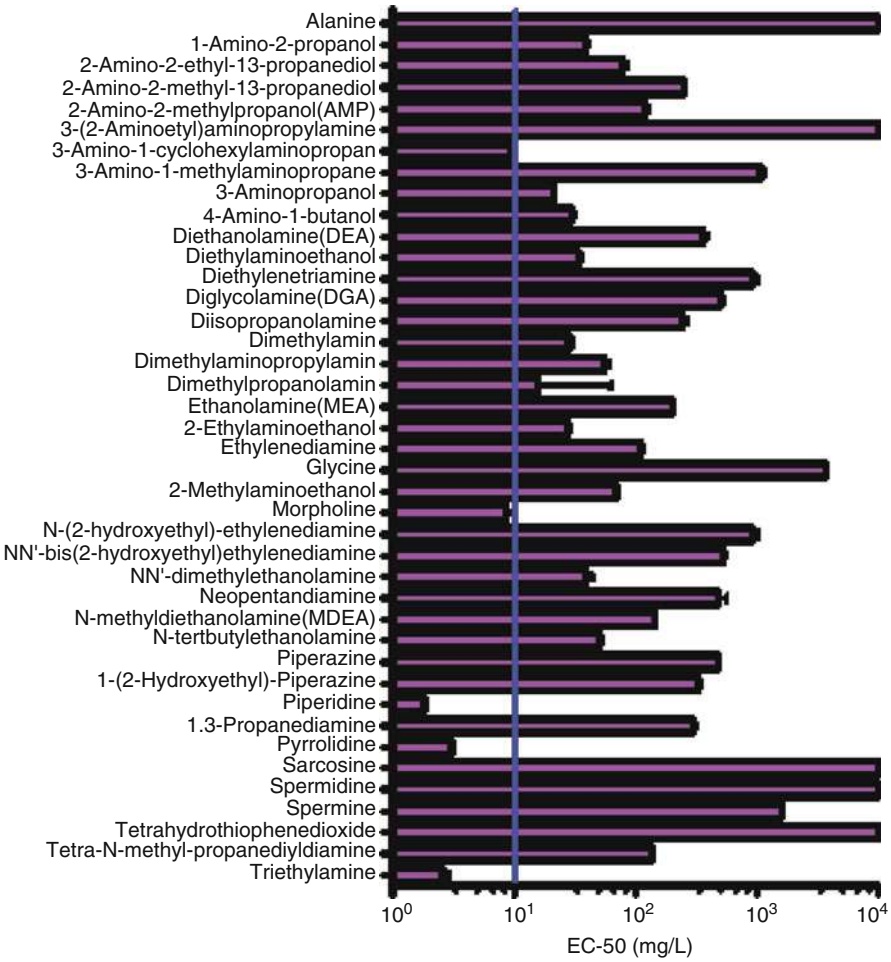

Fig. 52 Results of the ecotoxicity testing, shown as concentration where compounds inhibited algal growth by 50 % (EC-50). The blue line shows the lowest acceptable value (10 mg/L) for a chemical to be released in the marine environment (Eide-Haugmo et al. 2009)

Emission and Its Impact on the CO_2 Capture Process

Pollutant emissions potentially harming human health and the environment essentially stem from two sources in CO_2 capture processes: point of discharge and fugitive emissions. The emissions from the point of discharge are intentional, predictable, and quantifiable based on plant operating conditions. Such emissions are the treated gas released from the absorber top and the waste of process solution released from solution reclamation or other purification units. Fugitive emissions are unintentional releases from process equipment and piping during plant operation. Details of these emissions are given below.

Point Discharge of Treated Gas

A CO_2 capture unit releases the treated gas from the absorber top to the atmosphere on a continuous basis. The treated gas is basically composed of the flue gas with a reduced CO_2 content and vapors of process solution. The flue gas entering the CO_2 capture unit contains a great number of substances. Most of these substances, by themselves, have significant impacts on human health and the environment, and they are currently controlled under the environmental laws and regulations. Most gaseous components, including CO, HCl, HF, NO*x*, and SO*x*, are toxic. From MSDS (material safety data sheets), the organic compounds resulting in detrimental carcinogenic damage include benzo(a) anthracene, benzo(a)pyrene, benzo(b) fluoranthene, benzo(k)fluoranthene, chrysene, naphthalene, acetaldehyde, benzene, benzyl chloride, bis(2-ethylhexyl)phthalate, chlorobenzene, chloroform, 2,4-dinitrotoluene, dimethyl sulfate, ethyl benzene, ethyl chloride, ethylene dichloride, ethylene dibromide, formaldehyde, isophorone, methyl bromide, methyl chloride, methyl hydrazine, methyl tert-butyl ether, methylene chloride, tetrachloroethylene, styrene, and vinyl acetate. In addition, trace metals, such as arsenic, beryllium, cadmium, chromium, cobalt, lead, and nickel, are toxic and also carcinogenic.

Despite their adverse impacts, flue gas substances are not considered to be contributors to any environmental impacts caused by the CO_2 capture unit integrated into a power plant. This is because these flue gas substances are intrinsically and originally produced from the coal combustion regardless of the installation of a CO_2 capture unit. Vapors of process solution are, however, considered to be the actual emissions resulting from the CO_2 capture unit.

The emission of process solution vapors greatly depends on the operating conditions of the absorber top and the thermodynamic properties (i.e., vapor pressure) of the chemicals contained in the process solution. As an example, the vapor pressure of MEA is a function of absorber temperature (at the top) and chemical concentration (i.e., it increases with increasing MEA concentration and temperature). Any substance with high vapor pressure tends to vaporize and leave the top of the absorber very easily with the treated gas. A water wash and/or a well-designed mist eliminator are commonly installed at the top section of the absorber to reduce such entrainment and volatility loss.

According to the vapor pressures, for each chemical, besides water vapor, vapors of certain absorption solvents and degradation products can be released from the absorber top, but the release of corrosion inhibitors is considered negligible due to the extremely low partial pressure of the compounds. The primary amine MEA tends to cause greater solvent volatility loss than other alkanolamines but still less than methanol. On average, the entrainment can lead to the emission of up to 8.5 mg amine/Nm^3 of treated gas (Veldman 1989), and the total solvent loss is about up to 1.6 kg solvent/t CO_2 for gas-fired flue gas (Chapel et al. 1999). The entrained vapors of absorption solvents should cause low toxicity to human health and the environment due to their diluted concentrations in the atmosphere. The level of exposure depends on many factors, including environmental, geographic, and atmospheric conditions, which can affect the distribution and dispersion of pollutants from the

source of discharge into the air. The US laws regulate MEA by OSHA (Occupational Safety Health Administration) and DEA by NESHAP (National Emission Standards for Hazardous Air Pollutants), while the Canadian laws control DEA as "need to be declared" in NRPI. The other solvents are not enforced by any laws yet.

The degradation products, including formic acid, 1-propanamine, 2-butanamine, acetone, ammonia, butanone, and ethoxyethene, also have a tendency to vaporize and entrain with the treated gas, since their vapor pressures are higher than the vapor pressure of water at 20 °C. It was found that 2-butanamine, ammonia, and ethylamine are fairly toxic and can affect human health through skin burns and irritation. From its MSDS, 2-butanamine is also reported to be very harmful to aquatic organisms. However, 2-butanamine, ammonia, and ethoxyethene are currently not regulated under any laws, while the rest are enforced by US laws. Formic acid and butanone are controlled under Canadian laws.

According to general practice for gas-treating processes, a side stream of process solution must be purified to remove suspended solids, degradation products, and other process contaminants so that the concentration of active absorption solvents can be maintained. The solution purification is carried out through continuous adsorption, using mechanical and activated carbon filtration, and periodic thermal reclaiming. The filtration removes solid contaminants and large molecules of degradation products. As such, it results in routine disposal of wastes in the form of filter sludge/filter waste products, filter bag, cartridge, suspended solids, and used activated carbon. The thermal reclaiming is in operation to remove heat-stable salts, nonvolatile organics, and suspended solids via a side stream of 0.5–2 % of the process solution (Kohl and Nielsen 1997). The reclaiming operation will be performed when the content of heat-stable salt anions in the process reaches 1.2 wt% of the solution (CCR Technologies Inc.) or when the degradation product exceeds 10 wt% of active alkanolamine solvents (Kohl and Nielsen 1997). This generates a reclaimer waste comprising mostly heat-stable salts and solid precipitates and also small amounts of absorption solvents, corrosion inhibitor, and other additives. As an example, approximately 0.003 m^3 of reclaimer waste/t of CO_2 captured was produced in a commercial FG Econamine process (Chapel et al. 1999). Examples of reclaimer waste samples and their concentrations obtained from the IMC Chemical Facility in Trona, CA, in 1998 are summarized (Strazisar et al. 2003; Schnell 2004).

Among the chemicals present in the reclaimer wastes, heavy-metal corrosion inhibitors make the process waste toxic to humans and the environment. According to the US Environmental Protection Agency (EPA), corrosion inhibitors containing vanadium, antimony, and cyanide compounds are considered hazardous substances, and they are priority/toxic pollutants under the CAA (Clean Air Act) and also considered hazardous wastes under RCRA (Resource Conservation and Recovery Act). In Canada, uses of toxic substances, including several inorganic heavy metals, are controlled under CEPA (Canadian Environmental Protection Act). Many countries and regions around the world are introducing a series of controlling regulations to provide guidelines on the use and discharge of these toxic substances, especially inorganic salts and salts of heavy metals. In Europe, for example, the European

Union (EU) has charged the Paris Commission (PARCOM) with providing a framework for legislation (Haslegrave et al. 1992; McMahon and Harrop 1995). Other highlighted regulations include the Emergency Planning and Community Right to Know Act of 1986, regulations adopted by the US Occupational Safety and Health Administration (OSHA) in 1993, and adoption of the Chemical Hazard Assessment and Risk Management (CHARM) model in the UK and other European countries (Singh and Bockris 1996). Because of the adopted regulations, the use of toxic corrosion inhibitors makes disposal of the industrial waste difficult and costly (Kohl and Nielsen 1997; Singh and Bockris 1996). Restriction on the use of other heavy-metal inhibitors can be anticipated in the near future. Arsenic is a good example of the corrosion inhibitors; it was used effectively in gas-treating plants but is now banned from industrial applications due to its high toxicity and impacts on the environment.

Some degradation products, especially heat-stable salts and cations, are being regulated under laws and regulations. Their impacts are mostly irritation and burns. However, there are no regulations to control the emissions of such degradation products with high toxicity as 1H-imidazole, 2-butanamine, and 2-methylpropanenitrile.

The process wastes are generally disposed of by incineration and landfilling. Incineration involves the supply of energy and the phase change of wastes either from solid to liquid or gas or from liquid to gas. As a result, burning the process wastes produces ashes of both degradation products and additives together with vapors of amine solvents. Some of these products are harmful to humans and the environment, as described previously. To reduce the release of trace metals, a posttreatment of incineration (i.e., wet scrubber) should be used. In contrast to incineration, placing the process wastes in landfills does not result in a phase change of wastes, thus minimizing the emission of vapors of any toxic substances. Nevertheless, the process wastes should be neutralized prior to disposal in landfills.

Fugitive Emissions

Fugitive emissions also contribute to environmental impacts in addition to the above point-source emissions. During plant operation, the process fluids can be unintentionally released from the CO_2 capture unit mainly through leaks, which are usually a consequence of deterioration of process equipment and pipes, corrosion, impact damage, and vibration. Such emissions are unpredictable, random, and intermittent and can occur everywhere on the site, such as at pumps, valves, flanges, connectors, pressure relief devices, sampling connections, open-ended lines, instruments, vents, drains, and meters. According to the European Sealing Association (ESA) (2005), for any commercial plant, valves, especially control valves, contribute to the greatest extent to leakage losses (50–60 %), followed by relief valves (15 %), tanks (10 %), pumps (10 %), and flanges (5 %).

Apart from leakage losses, working and breathing losses also account for some fugitive emissions. Working loss occurs when the storage tanks of absorption solution are being filled. The quantity of solution vapor released from the tanks depends on temperature, vapor pressure of the solution, and pumping rate. Breathing

losses are caused by thermal expansion of the solution vapor in the tanks as a result of temperature increase during daytime. Regardless of their sources, fugitive emissions release certain amounts of process fluids and materials, including untreated flue gas, treated gas, absorption solvents, corrosion inhibitors, degradation products, and chemical additives, whose impacts to humans and the environment were previously discussed. The importance of fugitive emission has been recognized in environmental laws and regulations.

Accidental Release

Accidental release is a large release, spill, or discharge of process fluids as a result of accidents and emergency operations. The quantities of such releases are much larger than those of the fugitive emissions. According to the American Petroleum Institute (API) (2001), accidental release can be caused by failures of process equipment due to physical erosion, wear and tear, corrosion, malfunctions of process controls and instrumentation that lead to overpressure, overheating, and liquid overflow, as well as improper operations that lead to foaming, pluggings, or blockage of process equipment and piping.

Management of Pollutant Releases and Their Impacts

Although the impacts of a CO_2 capture unit integrated to the power plant are not severe, an environmental management system (EMS) should be practiced to control pollution, minimize waste production, ensure progress toward an environmental goal, and provide safety plans for normal plant operation and accidents. The EMS requires a commitment from top management to establish a corporate environmental management policy and educate employees on the policy (Crognale 1999). Proper operation, monitoring, and maintenance of process equipment, piping, and instrument and control systems play a key role in reducing emissions of hazardous substances from process points of discharge, fugitive sources, and accidental events. Pipeline and tube bundles in the heating elements should be regularly monitored, due to deterioration by corrosion. Trays or packings in both absorber and regenerator should be kept clean from sludge deposit. The amounts of heat-stable salts or any particulates in the process solution must be kept low to avoid foaming problems, which are a primary cause of entrainment at the absorber top. Repair, replacement, and modification of the existing equipment must be done promptly when the damage is identified. Several publications provide guidelines for amine plant operations. Bacon and Demas (1987) recommended tests on lean and rich amine solution loadings, total heat-stable salts, anion and cation assay, soluble iron content of solutions, degradation products, and foaming tendency (Bacon and Demas 1987). Pauley (1991) suggested that the amine solution should be sampled and tested regularly for organic acids, heat-stable salts, amine concentration, soluble metal content, iron sulfide content, liquid hydrocarbon content, and water content (Pauley 1991). Nielsen et al. (1995) provided a set of maximum concentrations of heat-stable salts that should be kept to prevent severe corrosion (e.g., 250 ppm for oxalate; 500 ppm for formate, glycolate, malonate, sulfite, and sulfate; 1,000 ppm for succinate; and 10,000 ppm for thiosulfate) (Nielsen and Lewis 1995). The

Table 12 Equipment modifications for control of equipment leak (European Sealing Association (ESA), 2005) (Thitakamol et al. 2007)

Equipment	Modification
Valves	Sealless design
	Avoid using valves with rising stem (gate valves and globe valves)
	Install the rupture disks before the safety valve to damp small pressure fluctuation
Pump seals	Sealless design
	Closed-vent system
	Dual mechanical seal with barrier fluid maintained at a higher pressure than the pumped fluid
Flanges and connectors	Weld together
	Correct selection and installation of the gasket and regular maintenance
	Minimize the number of flanged connection
Pressure relief devices	Closed-vent system
	Rupture disk assembly
Open-ended lines	Blind, cap, plug, or second valve

recommendations for leakage reduction from these process components are summarized in Table 12.

Standard plans for the worst and the most likely emergency scenarios should also be developed to effectively and immediately mitigate accidental release. Such plans must at least provide proper procedures for handling the release and cleanup of hazardous pollutants and must be distributed to and well understood by both plant employees and local authorities, such as local police, fire fighters, and hospitals.

Economical Factors of Chemical Absorption Systems

Economic considerations of chemical absorption systems are another key factor to affect the application of the capture technology. All the commercial technology seems hard to satisfy the requirement of power plants due to the problem of high cost. Figure 53a–c, respectively, shows different CO_2 capture technology on COE (cost of electricity), thermal efficiency, and CO_2 capture cost (NETL Report 2008).

It is easily derived from the above charts that these technologies are still rather expensive to be applied. More research needs to be performed to cut the energy consumption and capital cost so as to meet the economical requirements.

Above all, although chemical absorption is considered to be the most mature technology nowadays for CO_2 capturing, there is still a long way to go to put it into practice in large-scale power plants. Chemical solvent scrubbing processes are expected to improve between now and 2020. Improvements will be made by a combination of design optimization in a competitive market and technology developments, such as new solvents. Combustion power generation processes

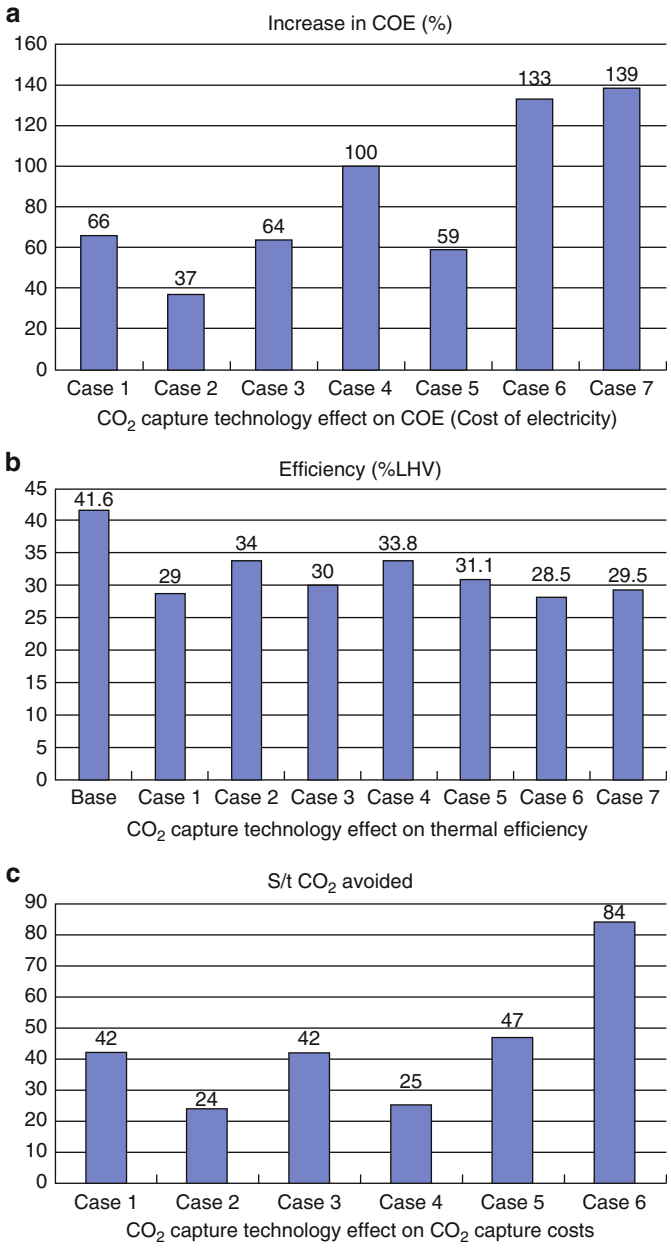

Fig. 53 CO_2 capture technology economy. *Base* refers to the standard pulverized coal power plant; *Case 1* refers to conventional MEA scrubbing technology; *Case 2* refers to aqueous ammonia scrubbing technology; *Case 3* refers to oxy-fuel combustion technology; *Case 4* refers to IGCC technology; *Case 5* refers to membrane separation technology; *Case 6* refers to pressure swing adsorption technology; *Case 7* refers to temperature swing adsorption technology

are also expected to improve, and these improvements will contribute to an overall improvement in the economics of power plants with post-combustion CO_2 capture.

Industry Application and Future Direction

Industry Application

Introduction

To assess the potential of CCS as an option for reducing global CO_2 emissions, the current global geographical relationship between large stationary CO_2 emission sources and their proximity to potential storage sites has been examined. Globally, emissions of CO_2 from fossil fuel use in the year 2000 total about 23.5 Gt CO_2. Of this, close to 60 % was attributed to large (>0.1 Mt CO_2/year) stationary emission sources. Table 13 lists the profile by process or industrial activity of worldwide large stationary CO_2 sources with emissions of more than 0.1 Mt CO_2/year.

The most promising near-term strategy for mitigating CO_2 emissions from these facilities is the post-combustion capture of CO_2 using chemical absorption with subsequent geologic sequestration. While MEA absorption of CO_2 from coal-derived flue gases on the scale proposed above is technologically feasible, MEA absorption is an energy-intensive process and especially requires large quantities of low-pressure steam. It is the magnitude of the cost of providing this supplemental energy that is currently inhibiting the deployment of CO_2 capture with MEA absorption as means of combating global warming. Hence, all governments are rather cautious to make a plan of CO_2 mitigation. Table 14 lists some CCS projects for power plants, which are related to chemical absorption. Table 15

Table 13 Profile by process or industrial activity of worldwide large stationary CO_2 sources with emissions of more than 0.1 Mt CO_2/year (Source: IPCC special report on carbon dioxide capture and storage 2005)

gives a list of worldwide large-scale power plant CCS projects based on chemical absorption.

Typical CO_2 Capture Projects

CCS Projects in the USA

Although CCS experiences a number of challenges and several projects are canceled due to the instability of policies, America is still one of the most developed countries in the CCS field. Chemical absorption is widely accepted in the demo plants nowadays. Alstom has a total of four demonstration projects operating or completing, which are respectively based on chilled ammonia, advanced amine, and oxy-combustion. Powerspan also develops some post-combustion CO_2 capture pilot plants. The major projects are listed in Table 14.

- SECARB Plant Barry CCS Project

The capture facility (Fig. 54), located at Alabama Power Company's Plant Barry, is equivalent to 25 megawatts (MW) and utilizes post-combustion amine capture

Fig. 54 SECARB Plant Barry CCS project

technology licensed by Mitsubishi Heavy Industries America (MHIA). CO_2 captured at the plant is transported 12 miles via dedicated pipeline for underground storage in a deep, saline geologic formation within the Citronelle Dome. **This project is one of the first and the largest fully integrated commercial prototype coal-fired carbon capture and storage projects in the USA.** The CO_2 capture rate of this plant is over 500 tons per day with a removal efficiency of more than 90 %. According to the operation history, the steam consumption is 0.98 t of steam per ton of carbon dioxide.

Europe

CCS development in Europe is rather optimistic due to the wide broadcast of CCS knowledge and public acceptance in CCS technologies. The UK, Norway, Italy, Germany, and the Netherlands are among the promoting countries in the world. A typical CCS project in the UK is presented below.

- Ferrybridge CCS Pilot Plant

The Doosan Babcock, SSE (Scottish and Southern Energy), and Vattenfall consortium successfully completed a 2–year test program on the post-combustion carbon capture (PCC) pilot plant at SSE's Ferrybridge Power Station in December 2013. The 100 ton CO_2/day (15MWt, 5MWe equivalent) CCPilot100+ PCC pilot plant (Fig. 55), using Doosan Babcock's PCC technology, was the first of its size to be integrated into a live power plant in the UK. 90 % CO_2 capture was successfully demonstrated at 100 ton CO_2 capture per day on MEA and up to 120 ton CO_2

Fig. 55 Ferrybridge CCS Pilot100+

capture per day on RS-2TM. The MEA baseline regeneration energy was 3.5 GJ/ton CO_2, which is in agreement with MEA performance results from other pilot plants.

CCS Projects in China

More than ten large-scale demo plants have been put into operation in China since 2007. Meanwhile, a certain number of CCS projects are on schedule.

- Huaneng Gaobeidian CCS Pilot Plant

As the first post-combustion carbon capture pilot plant in Beijing of China, Huaneng Gaobeidian Power Plant got the most concern in 2008. The pilot plant was put into operation in June 2008. Amine-based scrubbing technology is chosen to capture CO_2 from coal-fired flue gas stream. The CO_2 capture rate for the pilot plant is greater than 85 %, and the CO_2 capture capacity is over 3,000 tons per annum. The captured CO_2 is further purified to food grade and is reused in the beverage industry in the Beijing area. Huang et al. (2010) declared that the solvent is composed by MEA of 18–22 wt%, antioxidant of 0.15–0.25 wt%, inhibitor of 0.08–0.15 wt%, and water of 78–82 wt%. According to the operational experiences, the consumptive cost recovery for 1 t of CO_2 (99.7 %, 30 °C, 40 kPa) is about 25.3 US$. In order to capture CO_2, the COE will increase by 0.02 US$/kW • h, which increases the electricity purchase price by 29 %. At 2010, Huaneng group erected another 120 kt/a CO_2 capture demonstration project at Huaneng Shanghai Shidongkou Power Plant, which is the largest CO_2 post-combustion capture project in China at that time (Fig. 56).

CCS Projects in Canada

Canada government and industry give a great support to CCS project, and several large-scale CCS projects have been erected in recent years in which the largest one is Boundary Dam CCS project.

Boundary Dam CCS Project

The Boundary Dam Integrated Carbon Capture and Storage Project (Stéphenne 2013) is the world's first and largest commercial-scale CCS project of its kind, which is located in Saskatchewan, Canada. The project was fully put into operation on October of 2014. It transforms the aging Unit 3 at Boundary Dam Power Station into a reliable, long-term producer of 110 MW of base-load electricity with a CO_2 capture rate over 90 % and a CO_2 capture capacity exceeding one million metric tons of CO_2 per year. The resulting captured CO_2 emissions are compressed and transported through pipelines to Cenovus Energy who uses the CO_2 for enhanced oil recovery activities in the Weyburn oil field. Meanwhile, all the sulfur dioxide (SO_2) present in the flue gas is recovered and used for production of sulfuric acid which is subsequently sold as a valuable by-product to offset a part of the operational costs.

Fig. 56 Huaneng Gaobeidian CCS pilot plant

The carbon capture technology which is supplied by Shell Cansolv uses regenerable amines to capture both SO_2 and CO_2. Figure 57 presents the schematic of Cansolv process for the Boundary Dam Project. In order to decrease the steam requirement of carbon capture process, Cansolv employs both selective heat integration and innovative combined SO_2/CO_2 capture system. With this approach, the capture plant steam requirement is significantly reduced.

Future Directions

Introduction

Post-combustion capture involves the removal of CO_2 from the flue gas produced by combustion. Existing power plants use air, which is almost four-fifths nitrogen, for combustion and generate a flue gas that is at atmospheric pressure and typically has a CO_2 concentration of less than 15vol %. Thus, the thermodynamic driving force for CO_2 capture from flue gas is low (CO_2 partial pressure is typically less than 15 kPa creating a technical challenge for the development of cost-effective advanced capture processes. In spite of this difficulty, post-combustion carbon capture has the greatest near-term potential for reducing GHG emissions, because it can be retrofitted to existing units that generate two-thirds of the CO_2 emissions in the power sector. Figure 58 indicates that as innovative CO_2 capture and

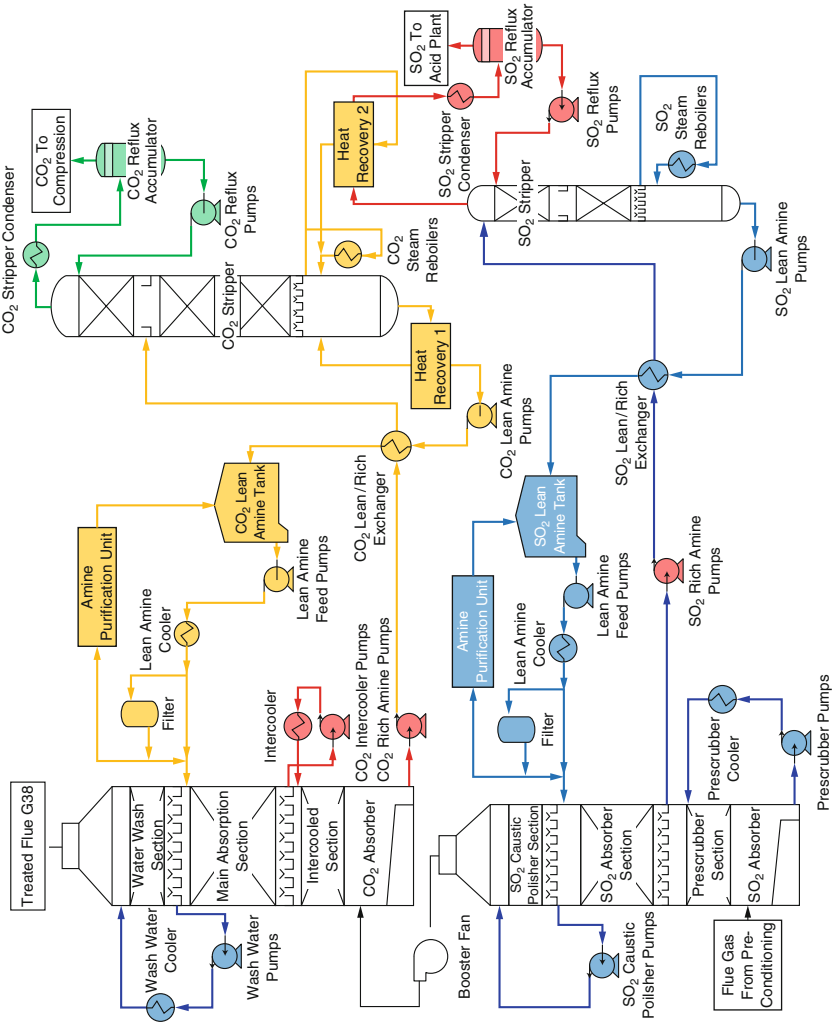

Fig. 57 Process lineup of the Boundary Dam CCS project

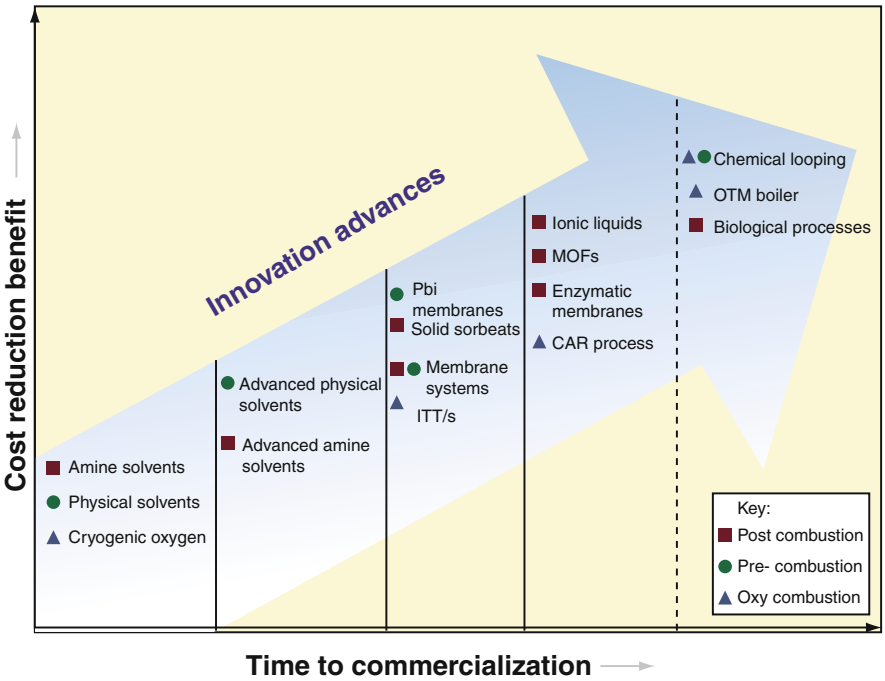

Fig. 58 Innovative CO_2 capture technologies – cost reduction benefits versus time to commercialization (Figueroa et al. 2008)

Table 16 Pros and cons of current CO_2 separation technologies

CO_2 capture technology	Pros	Cons
Amine scrubbing	Applicable to CO_2 partial pressures	Process consumes considerable energy
	Recovery rates of up to 95 % and product purity >99 vol.% can be achieved	Solvent degradation and equipment corrosion occur in the presence of O_2
		Concentrations of SO *x* and NO *x* in the gas stream combine with the amine to form irregenerable, heat-stable salts
		Rectisol™ refrigeration costs can be high
Ammonia process	Lower heat of regeneration than MEA	Ammonium bicarbonate decomposes at 140_F (use Kelvin), so temperature in the absorber must be lower than 140_F (use Kelvin)

(*continued*)

Table 16 (continued)

CO_2 capture technology	Pros	Cons
	Higher net CO_2 transfer capacity than MEA	Ammonia is more volatile than MEA and often provides an ammonia slip into the exit gas
	Stripping steam not required	Ammonia is consumed through the irreversible formation of ammonium sulfates and nitrates as well as removal of HCl and HF
	Offers multi-pollutant control	
Membrane technology	No regeneration energy is required	Membranes can be plugged by impurities in the gas stream
	Simple modular system	Preventing membrane wetting is a major challenge
	No waste streams	Technology has not been proven industrially

Table 17 Future directions of chemical absorption technologies for CO_2 capture

Technology for CO_2 capture	Future direction
Amine scrubbing	Absorbent studies
	1. Set an evaluation criterion for the selection of amines
	2. Mixed amines
	3. Ionic liquid
	4. New solvents
	Absorber column studies
	1. New packings
	2. High-efficiency reactors
	Process integration and optimization
	1. Heat integration
	2. Water balance
Ammonia process	Optimization of regeneration process
	Slippery control of ammonia
	Selection of additives for ammonia solution
Membrane technologies	Plugging mechanism of membrane and control measures
	Wetting mechanism of membrane and control measures
	Selection and pretreatment of membrane
	Optimization of process

separation technologies advance, significant cost reduction benefits can potentially be realized once they are commercialized. Obviously, as a method of post-combustion capture, chemical absorption is the most likely technology in the upcoming years. Table 16 shows the pros and cons of current CO_2 separation technologies.

Future Directions of Chemical Absorption Technologies for CO_2 Capture

To predict the future directions of chemical absorption technologies is a hard task. Every technology occupies its own advantages and disadvantages. The predictable truth is that the improvement of the chemical absorption technologies is the future work. Whatever the novel technology turns out, the technology should occupy the basic elements such as absorbent, absorber, and cyclic process. Hence, the future direction must have great improvement on the related problems. Some potential directions for the existing technologies are analyzed in Table 17.

CO_2 Capture Using Solid Sorbents

Yao Shi, Qing Liu, and Yi He

Contents

Abstract

Global warming and climate change due to the emission of greenhouse gases, especially CO_2, has become a widespread concern in the recent years. Capturing CO_2 is one of the major approaches to tackle this issue. Among the currently available CO_2 capture technologies, adsorption processes using solid sorbents capable of capturing CO_2 have shown many advantages. In

the past few years, many groups have been engaged in the development of new solid sorbents for CO_2 capture with superior performance and desirable economics. The main purpose of this chapter is to provide a bridge between detailed technical reports and broad resource and economic assessments on CO_2 capture using solid sorbents. The fundamental aspects of solid sorbents for CO_2 capture are firstly discussed, which include both the selection and the evaluation of sorbents. The following characteristics of solid sorbents are covered: the equilibrium adsorption capacity, selectivity, adsorption/desorption kinetics, multicycle durability, mechanical properties, hydrothermal and chemical stability, and energy consumption of regeneration. Typical families of solid sorbents such as activated carbonaceous materials, polymeric materials, zeolites, silica, metal–organic frameworks (MOFs), and alkali-metal carbonate loaded with or without functionality for the adsorption of CO_2 are then reviewed, respectively. In addition, a brief review on technical challenges and pilot plant developments are presented. Finally, a few recommendations are provided for further research efforts on CO_2 capture with solid sorbents.

Introduction

Growing concerns for global warming and climate change in recent years have motivated research activities toward developing more efficient and improved processes for carbon dioxide (CO_2) capture and sequestration (CCS) from large point sources, such as coal-fired power plants, natural gas processing plants, and cement plants (Samanta et al. 2012). The development of efficient technologies for the capture and sequestration of carbon dioxide produced by existing point sources will prove vital in controlling the environmental impact of anthropogenic emissions. In order for these technologies to be economically viable, CCS systems must curb the energy penalty associated with CO_2 capture and sorbent regeneration and operate effectively in realistic conditions. The search for materials that fulfill the criteria of an efficient CO_2 sorbent has been proceeding with urgency (Sumida et al. 2012).

Processes based on aqueous amine absorbents represent the currently available and practically applied technology for CO_2 capture. They include an energy penalty of roughly 30 % on top of the power generation of the plant (Rochelle 2009). An alternative approach to reduce the energy penalty is by using solid sorbents as they have comparatively lower heat capacities. This chapter is devoted to the fundamentals of the solid adsorbents for CO_2 capture and the present status and prospect of their applications. The adsorption of CO_2 can be classified as physical adsorption (adsorption enthalpy $<$20–40 KJ/mol), chemical adsorption (adsorption enthalpy $>$20–40 KJ/mol), or both. These two types of adsorption differ from each other in many ways. The major difference is briefly discussed as follows.

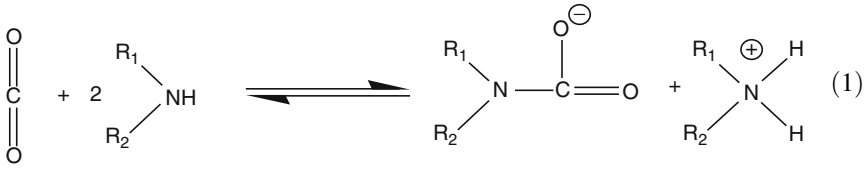
The solid adsorbents for CO_2 capture can be various solid materials, including porous carbonaceous materials, zeolites, alumina, silica, and metal–organic frameworks (MOFs). For physisorption, the mechanism of CO_2 capture can be explained with the selective adsorption of CO_2, which is caused by van der Waals interaction between the CO_2 and adsorbent, as well as by pole–ion and pole–pole interactions between the quadruple of CO_2 and the ionic and polar sites of the sorbent surface (Samanta et al. 2012).

Most of the conventional physisorbents suffer from poor selectivity for CO_2 and low CO_2 adsorption capacities, especially at a relatively low CO_2 partial pressure. In order to increase CO_2 adsorption capacity and to keep high selectivity for CO_2, chemical modifications are often performed on the surface of the porous materials by incorporating basic groups which are capable of interacting efficiently with acidic CO_2. Amine is one of the commonly used functional groups for this purpose. Amine-based adsorbents can be classified into three classes (Li et al. 2010; Jones 2011):

- **Class 1**: This class of supported sorbents is prepared by physically loading monomeric or polymeric amine species onto or into the micro-/mesoporous support (impregnation).
- **Class 2**: The amine, mainly amine-containing silane, is covalently tethered to a solid support. This is accomplished by binding amines to oxides via the use of silane chemistry or via preparation of polymeric supports with amine-containing side chains. This provides covalently tethered amine sorbents which possess the potential to be completely regenerable through multicycle adsorption/desorption processes.
- **Class 3**: These adsorbents are based on porous supports upon which amino-polymers are polymerized in situ. This class of sorbents can be considered a hybrid of the first two classes (Li et al. 2010).

The structures of commonly used amines for sorbent functionalization were given in Table 1.

CO_2 adsorption using amine-functionalized sorbents involves chemical reaction. Therefore, it is essential to know how the nature of amine influences the adsorption capacity and the rate of adsorption. The zwitterion mechanism originally proposed by Caplow (1968) is often used to explain the reaction of primary/secondary amines and CO_2. The mechanism involves two steps: (1) formation of zwitterion and (2) deprotonation of zwitterion. The overall reaction can be written as:



where $R_2 = H$ for the primary amine.

Table 1 Structure of widely used amines for sorbent functionalization (Samanta et al. 2012)

Name	Structure	Name	Structure
Amines		Silanes	
Monoethanolamine (MEA)		3-aminopropyltrimethoxysilane (APTS)	Diethanolamine (DEA)		3-aminopropyltriethoxysilane (APTES)	Triethanolamine (TEA)		N-[3-(trimethoxysilyl)propyl]-ethylenediamine (AEAPTS)	Polyethyleneimine (PEI)	 (R=H for linear, R=H or CH_2 for branched)	N-[3-(trimethoxysilyl)propyl]-diethylenetriamine (DAEAPTS)	Diethylenetriamine (DETA)		Ethylhydroxyl-aminopropyl-trimethoxysilane (EHAPTS)	Tetraethylenepentamine (TEPA)		Diethylhydroxyl-aminopropyl-trimethoxysilane (DEHAPTS)			Cyclic	
Tetraethylenepentamine-acrylonitrile (TEPAN)		Aziridine	
Pentaethylenehexamine (PEHA)		1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)	2-Amino-2-methyl-1,3-propanediol (AMPD)		1,5-diazabicyclo [4.3.0]non-5-ene (DBN)	
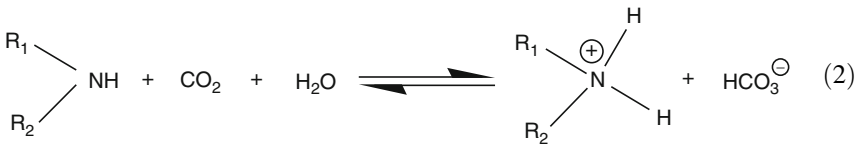
2-(2-Aminoethylamino)ethanol (AEAE)		N-methyltetrahydropyrimidine (MTHP)	

If we consider the amine as a base, the equilibrium CO_2 adsorption capacities of primary/secondary amines are restricted by the overall stoichiometry to 0.5 mol (mol of amine)$^{-1}$.

The important reaction between CO_2 and the sterically hindered primary or secondary amine would be the formation of bicarbonate, as shown by reaction 2, similar to the case of tertiary amines. The stoichiometry for this reaction allows a CO_2 loading of up to 1 mol (mol of amine)$^{-1}$ for hindered primary or secondary amine.



(2)

The reaction of CO_2 with moderately hindered amines includes the formation of a carbamate, as in the case of no hindered amines (reaction 1), the stoichiometry of which allows a CO_2 loading of up to 0.5 mol (mol of amine)$^{-1}$. Instead, the reaction produces protonated amine and bicarbonate ion in the presence of moisture, leading to a higher capacity for CO_2 up to 1.0 mol (mol of amine)$^{-1}$. The mechanism of this reaction is suggested to be base-catalyzed hydration of CO_2, as given previously in reaction 2 (Donaldson and Nguyen 1980). Generally, the formation of bicarbonate allows a high equilibrium capacity, but the kinetics is very slow. The primary and secondary amines can react directly with CO_2, while tertiary amines cannot directly react with CO_2. They lack the free proton needed in the deprotonation step.

Fundamentals of CO_2 Adsorption Using Solid Sorbents

Criteria for Selecting Sorbents

The selection of solid sorbents for CO_2 capture largely depends on the scenario where a solid sorbent is used. Capturing CO_2 from a flue gas stream and a biogas stream demands significant different criteria as these streams have dissimilar characteristics in composition, temperature, etc. The selection of sorbents for CO_2 capture must satisfy important criteria to be both economical and operational, as well. Here, we listed few most important criteria as below (Samanta et al. 2012; Yong et al. 2002; Sayari et al. 2011):

- **Adsorption capacity for CO_2**: The equilibrium adsorption capacity of a sorbent material is of great importance to the capital cost of a CO_2 capture system, as it dictates the amount of adsorbent to be used in an adsorption column and its size. Working capacity, which is an effective capacity in an adsorption/desorption cycle, is preferred to be used in place of equilibrium capacity in practice. To enhance the competitiveness of solid sorbents with existing monoethanolamine (MEA) scrubbing system, the CO_2 working capacity should be in the range of 3–4 mmol/g of sorbent (Gray et al. 2008). Because the study of CO_2 adsorbents is in its early stage, most of the CO_2 capture capacity reported in this review are lower than this criterion.
- **Selectivity for CO_2**: The selectivity, which is defined by the ratio of the CO_2 capacity to that of another component, has a direct influence to the purity of CO_2 captured. The purity of CO_2 has impacts on transportation and sequestration. It plays a vital role in the economics in CO_2 sequestration. Desired sorbent materials should exhibit high CO_2 selectivity over other bulk gas components. In addition, it is important that solid sorbents also show high capacity for CO_2 in the existence of significant amounts of water vapor.
- **Adsorption/desorption kinetics**: Fast adsorption/desorption kinetics for CO_2 under the operating conditions is extremely essential. The cycle time of a CO_2

Table 2 Physical parameters of gases relevant to carbon dioxide capture processes (Sumida et al. 2012; Li et al. 2009)

Molecule	Kinetic diameter (Å)	Polarizability (10^{-25} cm^{-3})	Dipole moment (10^{-19} esu^{-1} cm^{-1})	Quadrupole moment (10^{-27} esu^{-1} cm^{-1})
H_2	2.89	8.04	0	6.62
N_2	3.64	17.4	0	15.2
O_2	3.46	15.8	0	3.9
CO	3.76	19.5	1.10	
NO	3.49	17.0	1.59	
H_2O	2.65	14.5	18.5	
H_2S	3.60	37.8	9.78	
CO_2	3.30	29.1	0	43
NO_2		30.2	0	

adsorption system is controlled by the kinetics of adsorption and desorption. Fast kinetics yields a sharp CO_2 breakthrough curve, while slow kinetics provides a distended breakthrough curve. The overall kinetics of CO_2 adsorption onto a functionalized solid sorbent is influenced by the intrinsic reaction kinetics of CO_2 with the functional group present, as well as the mass transfer or diffusional resistance of the gas phase through the sorbent structures. The structures of porous support functionalized also can be tailored. The faster an adsorbent can adsorb CO_2 and be desorbed, the less of it will be needed to capture a given volume.

- **Mechanical strength of sorbent particles**: During multicycle between the adsorption and desorption steps, the sorbent must ensure microstructure and morphological stability and retain the CO_2 adsorption capacity. It is crucial to have microstructure and morphological stability of tailored regenerable sorbents in multicycle operation to maintain high kinetics. Operating conditions, such as high volumetric flow rate, vibration, and temperature, should not give rise to appreciable disintegration of the sorbent particles. This could also happen via abrasion or crushing. Therefore, adequate mechanical strength of sorbent particles is critical to minimize the sorbent makeup rate, as well as to keep CO_2 capture process cost-effective.
- **Chemical stability/tolerance to impurities**: Solid sorbents for CO_2 capture – in particular, amine-functionalized sorbents – should be stable in an oxidizing environment and be resistant to common gas contaminants. It is likely that contaminants such as SO_x, NO_x, and heavy metals should be removed, as they unfavorably affect the CO_2 adsorption process of the sorbent materials. Table 2 lists physical parameters of gases relevant to CO_2 capture processes.
- **Regeneration of sorbents**: The heat of adsorption, which is a measure of the energy required for regeneration, should be substantially low. The sorbent should be regenerable through a suitable pathway while maintaining efficient CO_2 adsorption capacity during repeated adsorption/desorption cycles.

Table 3 List of adsorption isotherm models

Isotherm	Form	Parameter meaning	References
Langmuir	$q_e = \frac{q_m}{1/K_L + C_e}$	q_e amount of CO_2 adsorbed at equilibrium (mmol/g); q_m maximum adsorption capacity of CO_2 (mmol/g); C_e CO_2 concentration at equilibrium (vol%); K_L Langmuir isotherm constant (1/vol.%)	(Crini et al. 2007)
Freundlich	$q_e = K_F C_e^{1/n}$	K_F Freundlich isotherm constant ((mmol/g)/(vol%)$^{1/n}$); n Freundlich constant	(Crini et al. 2007)
Langmuir–Freundlich	$q_e = \frac{q_m (K_L C_e)^n}{1 + (K_L C_e)^n}$		(Nestle and Kimmich 1996)
Temkin	$q_e = B\ln(K_T C_e)$	K_T Temkin equilibrium binding constant (mmol/g); B heat of adsorption constant	(Monazam et al. 2013)

Additionally, the ease of regeneration of the CO_2 sorbent will also help to reduce the cost of capture.

- **Sorbent costs**: These represent perhaps the most subtle characteristics. A cost of \$5/kg sorbent leads to a very good scenario, while a cost of \$15/kg sorbent is not economical. Therefore, to be more economical, the cost of the CO_2 adsorption sorbent should be in the range of approximately \$10/kg.

The attributes mentioned above are desirable for an ideal adsorbent. However, rarely will a single adsorbent be optimal in all these attributes. Therefore, useful adsorbents will be those that effectively and economically capture CO_2.

Thermodynamics of CO_2 Adsorption

The equilibrium adsorption isotherm is essential for the design of adsorption systems, which is usually described by an isotherm equation characterized by certain parameters whose values express the surface properties and affinity of the sorbent. The adsorption isotherms, in fact, describe the equilibrium relationships between adsorbent and adsorbate and the ratio between the amount adsorbed and that left in the reactant at a fixed temperature at equilibrium. Several commonly used adsorption models, such as Langmuir, Langmuir–Freundlich, Freundlich, and Temkin isotherms, were applied to evaluate feasibility of CO_2–adsorbent interaction (Table 3).

Isosteric heat of adsorption (Q) (adsorption enthalpy, $\triangle H$) is commonly defined as the enthalpy change of adsorption. Values of Q for the adsorption of CO_2 onto adsorbent were calculated from adsorption data obtained at different temperatures using the Clausius–Clapeyron equation:

Table 4 Kinetic adsorption models

Kinetic model	Equation	Differential form	References
Pseudo-first order	$q_t = q_e\left(1 - e^{-k_1 t}\right)$	$\frac{\partial q_t}{\partial t} = k_1(q_e - q_t)$	(Serna-Guerrero and Sayari 2010)
Pseudo-second order	$q_t = \frac{q_e}{\frac{1}{k_2 q_e} + t}$	$\frac{\partial q_t}{\partial t} = k_2(q_e - q_t)^2$	(Ho and McKay 1999)
Avrami's fractional order	$q_t = q_e\left(1 - e^{-(k_A t)^{n_A}}\right)$	$\frac{\partial q_t}{\partial t} = k_A^{n_A} t^{n_A - 1}(q_e - q_t)$	(Serna-Guerrero and Sayari 2010)
Sayari's fractional order	$q_t = q_e - \frac{1}{\left[\frac{(n-1)k_n t^m}{m} + \frac{1}{q_e^{n-1}}\right]^{\frac{1}{n-1}}}$	$\frac{\partial q_t}{\partial t} = k_n t^{m-1}(q_e - q_t)^n$	(Heydari-Gorji and Sayari 2011)

$$\left[\frac{\partial(\ln P)}{\partial(1/T)}\right]_q = -\frac{Q}{R} \tag{3}$$

where P is CO_2 partial pressure (Pa), T is the absolute temperature (K), and R denotes the universal gas constant, 8.3145 J/mol · K.

Kinetics of CO_2 Adsorption

CO_2 adsorption/desorption kinetics are critical characteristics for the performance of sorbents (Zhao et al. 2013). The kinetics determined the amount of the time required for one adsorption/desorption cycle. They are closely related to the size of adsorption/desorption columns, as well.

The kinetics can be described with various models, which are available in literatures. Because of the complexity involved in the prediction of kinetic parameters, a typical approach consists of fitting experimental data to a series of established models and selecting the one that provides the best fit. In recent years, however, several researchers attempted to rationalize some of the most popular kinetic models, making it possible to deduce information regarding the adsorbent–adsorbate interactions. Table 4 shows the list of equations associated with the kinetic models explored in this work, where t is the time elapsed from the beginning of the adsorption process, q_t is the amount adsorbed at a given point in time, and q_e represents the amount adsorbed at equilibrium.

To investigate the kinetics of CO_2 adsorption onto adsorbent, the following four models are often considered:

(i) Pseudo-first-order kinetic model: The Lagergren's pseudo-first-order model was the first adsorption rate equation described for sorption of liquid/solid system and one of the most commonly used adsorption rate models. It is represented by Eq. 1:

$$\frac{\partial q_t}{\partial t} = k_1(q_e - q_t) \tag{4}$$

where q_e and q_t are the adsorption capacity at equilibrium and at time t, respectively, and k_1 is the pseudo-first-order adsorption rate constant. For the boundary conditions $q_t = 0$ at $t = 0$ and $q_t = q_e$ at $t = \infty$, the integrated form of the Eq. 1 becomes

$$q_t = q_e\left(1 - e^{-k_1 t}\right) \tag{5}$$

(ii) Pseudo-second-order kinetic model: This model was put forward by Ho et al. (Ho and McKay 1999). It assumes that the adsorption capacity is proportional to the number of active sites occupied on the sorbent. It has been applied for analyzing chemisorption kinetics from liquid solutions (Ho and McKay 1999). This model is expressed by Eq. 3:

$$\frac{\partial q_t}{\partial t} = k_2(q_e - q_t)^2 \tag{6}$$

where k_2 is the pseudo-second-order adsorption rate constant. The integrated form for the abovementioned boundary conditions is

$$q_t = \frac{q_e}{\dfrac{1}{k_2 q_e} + t} \tag{7}$$

(iii) Avrami's fractional-order kinetic model: This model was recently developed based on Avrami's kinetic model to simulate phase transition and crystal growth of materials (Lopes et al. 2003). It has been applied to describe the adsorption of CO_2 on amine-functionalized adsorbents (Serna-Guerrero and Sayari 2010). The general form of the model is as follows:

$$\frac{\partial q_t}{\partial t} = k_A^{n_A} t^{n_A - 1}(q_e - q_t) \tag{8}$$

where k_A is the Avrami kinetic constant and n_A is the Avrami exponent. The Avrami exponent, n_A, is a fractionary number, which reflects mechanism changes that may take place during the adsorption process (de Menezes et al. 2012). The n_A is the dimensionality of growth of adsorption sites: $n_A = 2$ for one-dimensional growth, $n_A = 3$ for two-dimensional growth, and $n_A = 4$ for three-dimensional growth (Benedict and Coppens 2009). For a homogeneous adsorption in which the probability of the adsorption to occur is equal for any region for a given time interval, $n_A = 1$ (Avrami 1939, 1941). An Avrami exponent of exactly 2 indicates perfect one-dimensional growth from adsorption sites which form continuously and at a constant rate (Benedict and Coppens 2009). The integrated form for the abovementioned boundary conditions is

$$q_t = q_e\left(1 - e^{-(k_A t)^{n_A}}\right) \tag{9}$$

(iv) Fractional-order kinetic model: Heydari-Gorji and Sayari (2011) recently proposed this general semiempirical kinetic equation to describe the adsorption rate of CO_2 on amine-functionalized PE-MCM-41 adsorbents. In this mode, the adsorption rate is assumed to be proportional to the nth power of the driving force and mth power of the adsorption time. This kinetic model is represented by Eq. 7 as follows:

$$\frac{\partial q_t}{\partial t} = k_n t^{m-1}(q_e - q_t)^n \tag{10}$$

where k_n, m, and n are the constants for the fractional-order kinetic model. Since the fractional-order kinetic model represents the complexity of the reaction mechanism that may involve more than one reaction pathway (Lopes et al. 2003; Cestari et al. 2006), the parameter k_n could be an overall parameter that may couple various adsorption-related factors (Zhao et al. 2013). Integrating Eq. 7 for the abovementioned boundary conditions gives

$$q_t = q_e - \frac{1}{\left[\frac{(n-1)k_n t^m}{m} + \frac{1}{q_e^{n-1}}\right]^{\frac{1}{n-1}}} \tag{11}$$

The temperature dependence of the kinetic constant k_A may be described by the Arrhenius equation:

$$k_A = Ae^{-(E_a/RT)} \tag{12}$$

where A is the Arrhenius pre-exponential factor, E_a is the activation energy, R is the universal ideal gas constant, and T is the absolute temperature.

Typical Processes for CO_2 Capture

Based on how adsorbents are regenerated after each adsorption cycle in a CO_2 capture process, processes for CO_2 capture can be classified as temperature swing adsorption (TSA), pressure swing adsorption (PSA), vacuum swing adsorption (VSA), or a combination of these three basic processes. In all of these processes, the solid adsorbents will be packed into a large column, and CO_2 will be desorbed by increasing the temperature (for TSA) or reducing the pressure (for PSA and VSA) of the bed.

Among the three typical processes, TSA is particularly promising as it can use low-grade heat from the power plant as a source of energy for regeneration (Merel et al. 2008; Berger and Bhown 2011). In a TSA cycle (Fig. 1, left), the saturated adsorbent is heated from ambient temperature to the optimal desorption temperature of the adsorbent. As the temperature is increased, CO_2 desorbs from the adsorbent. Then the increased gas pressure drives the desorbed gases from the

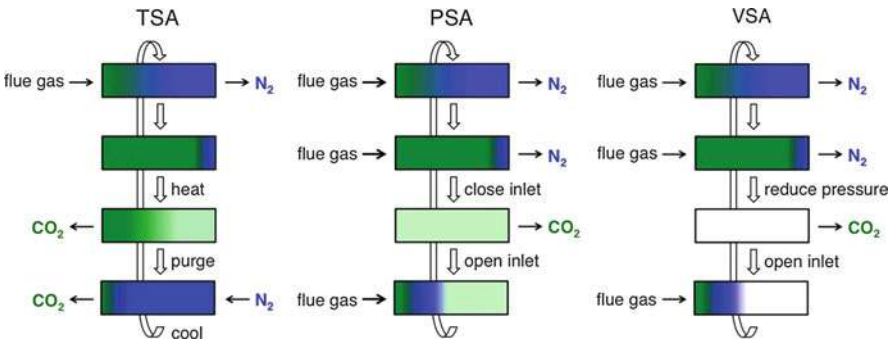


Fig. 1 Schematic diagrams of idealized TSA, PSA, and VSA processes for regenerating solid adsorbent in a fixed-bed column (Sumida et al. 2012)

column. Once equilibrium is reached at the maximum desorption temperature and no more adsorbed gas elutes from the column, a purge is used to push off any desorbed gases that fill the void spaces of the bed until the purity of eluted gas falls below a desired level. Finally, the bed is cooled and prepared for the next adsorption cycle.

For a PSA (Fig. 1, center) or VSA (Fig. 1, right) regeneration process, the column pressure is lowered after adsorption in order to desorb the adsorbed gas. For PSA, the inlet gas is pressurized by compression during adsorption and flowed through the column until saturation. Once the inlet valve is closed, the column pressure decreases toward ambient pressure. The pressure drop desorbs significant quantities of CO_2 from the adsorbent. Similarly, VSA lowers the pressure of the column to subatmospheric pressure after adsorption at a higher pressure. The vacuum applied to the column removes the CO_2 from the pores.

Since post-combustion flue gas is released near ambient pressure, compressing or applying a vacuum to such a large volume of gas is difficult; therefore, TSA might represent the most viable process. For pre-combustion capture, a PSA cycle is expected to be most appropriate because the gas stream is inherently pressurized after the conversion reactions (Mason et al. 2011; Herm et al. 2011).

The possibility of optimizing the parameters in each of these regeneration cycles and of combining multiple processes presents the option of tailoring the regeneration process to match the properties of a given adsorbent (Ishibashi et al. 1996; Mulgundmath and Tezel 2010). Primarily, regeneration strategies must be designed to minimize the total cost of capturing CO_2; therefore, there will be a trade-off between maximizing the working capacity and minimizing the energy required for regeneration (Berger and Bhown 2011; Rubin et al. 2007; House et al. 2009). Detailed analysis of the energy and economic optimization issues in CO_2 capture is crucial in directing the optimization of real-world CO_2 capture processes.

Typical Solid Sorbents for CO_2 Capture

Activated Carbon-Based Sorbents

Inorganic carbon is available in various forms, such as porous activated carbons (ACs), carbon nanotubes (CNTs), graphenes, etc. Adsorption behaviors of CO_2 on commercial and synthesized activated carbon-based sorbents have been widely studied experimentally and theoretically by a number of research groups from low to very high pressure. The structural properties and adsorption capacities are summarized in Table 5. As shown in Table 5, by incorporating certain functional groups into its porous surface, the CO_2 adsorption capacity of carbonaceous materials could be significantly enhanced.

ACs are widely used as adsorbents in various industrial fields (water treatment, gas purification) due to wide availability and the low cost of raw materials. ACs are low-cost materials with fast adsorption kinetics and require low regeneration energy. However, the predominance of ACs still fails to offset the drawbacks of physical adsorption processes. The CO_2 adsorption capacity using ACs decreases as the temperature increases (see Fig. 2) (Berlier and Frere 1996; Do and Wang 1998). At low partial pressures of CO_2, ACs exhibit lower adsorption capacity and selectivity than zeolites due to their unfavorable adsorption isotherms (Chue et al. 1995). The presence of water vapor may negatively affect the CO_2 capacity of ACs because of competitive adsorption between CO_2 and water vapor (Wang et al. 2008a). Additionally, other components or contaminants also have a detrimental impact on the CO_2 adsorption process.

Przepiorski et al. (2004) found significant improvement of CO_2 adsorption with commercial AC treated with ammonia at high temperatures (>473 K). The sorbent treated with ammonia at 673 K showed the adsorption capacity of 1.73 mmol/g. This improvement was ascribed to the introduction of nitrogen-containing groups to carbon structure. Pevida and his group (Pevida et al. 2008) made a conclusion that the CO_2 adsorption capacity is not directly related to the total nitrogen content of sorbents but rather to specific nitrogen functionalities that are responsible for increasing the CO_2–adsorbent affinity. Alesi et al. (2010) studied CO_2 adsorption and regeneration conditions of tertiary amidine derivatives supported on AC from 302 to 323 K. It was found that CO_2 adsorption on the amidine-modified AC only occurred in the existence of moisture. Adsorption of water vapor on the hydrophilic AC support limits the CO_2 capture capacities.

Maroto-Valer et al. (2005; Tang et al. 2004; Zhang et al. 2004; Zhong et al. 2004) found that anthracite coal with 2 h of activation at 1163 K achieved a CO_2 adsorption capacity of 1.49 mmol/g (Maroto-Valer et al. 2005). The feasibility of a high-surface-area sorbent from low-cost anthracites was also investigated (Zhong et al. 2004; Maroto-Valer et al. 2005). The adsorption capacity of polyethylenimine (PEI)-impregnated deashed anthracite sorbent was ~2.13 mmol/g at 348 K (Zhong et al. 2004). In another study, they observed a decrease in adsorption capacity of activated anthracites impregnated with PEI with increasing adsorption temperature (Maroto-Valer et al. 2005).

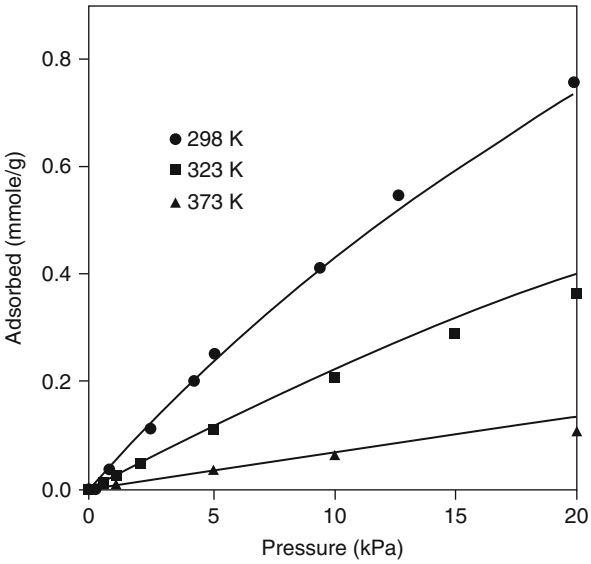

Fig. 2 Isotherm for adsorption of CO_2 on activated carbon (Do and Wang 1998)

Carbon-enriched fly ash concentrates treated with various amines were developed by Gray et al. (2004), Maroto-Valer et al. (2008; Zhang et al. 2004), and Arenillas et al. (2005). A typical comparison of CO_2 adsorption capacities of activated fly ash carbon and its alkanolamine-modified counterparts at various temperatures was reported by Maroto-Valer and others (Maroto-Valer et al. 2008). It was found that activation by steam before impregnation could successfully increase the pore volume and surface area, consequently resulting in the increase of CO_2 capture capacity (Zhang et al. 2004; Maroto-Valer et al. 2008). The impregnation with PEI could significantly enhance the adsorption capacity of this class of sorbents up to 2.13 mmol/g at 348 K, which is much higher than that without impregnation (0.22 mmol/g at 348 K) (Zhang et al. 2004). Arenillas et al. (2005) achieved the CO_2 adsorption capacity of ~1.02 mmol/g at 348 K using activated fly ash-derived sorbents impregnated with PEI (Zhang et al. 2004; Arenillas et al. 2005). Fly ash impregnated with PEI and its blend with poly (ethylene glycol) (PEG) was also investigated. The addition of PEG into the PEI-loaded sorbents improves the CO_2 adsorption capacity and kinetics, which could be attributed to the bicarbonate formation reaction in the presence of PEG (attracts more water).

CNT can act as a suitable candidate for CO_2 capture by choosing the appropriate pore size and optimum conditions (Huang et al. 2007; Razavi et al. 2011). Considerable experimental research and theoretical modeling efforts are being devoted to investigate the adsorption of CO_2 on CNTs. Cinke et al. (2003) reported CO_2 adsorption on purified single-walled carbon nanotubes (SWCNTs) in the temperature range from 273 to 473 K (see Fig. 3). The CO_2 adsorption capacity of SWCNTs was twice that of AC. Lu et al. (2008) reported CO_2 capture by CNT and its modification. After functionalization, CNT showed a significant enhancement in

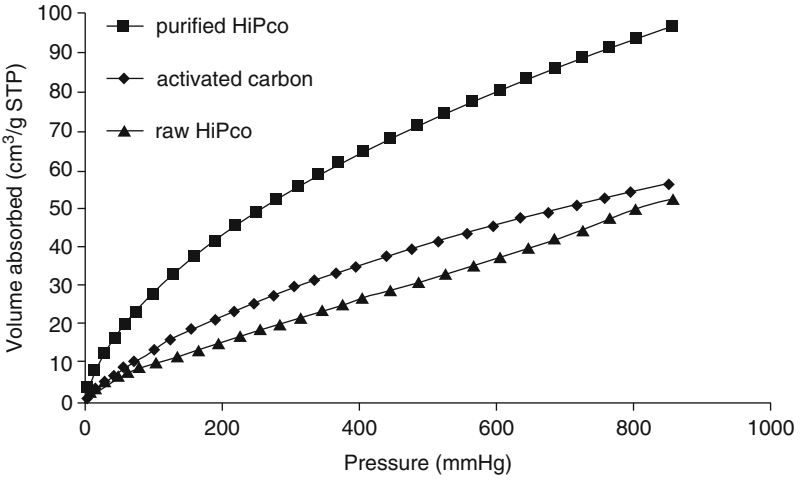

Fig. 3 Comparison of CO_2 adsorption capacities of high-pressure CO conversion (HiPco) single-walled nanotubes (SWNTs) and activated carbon (AC) at 308 K (Cinke et al. 2003)

CO_2 adsorption capacity. CNTs modified by APTES were also tested for their CO_2 adsorption potential at various temperatures by Su et al. (2009). The CO_2 adsorption capacities of CNTs and CNTs (APTS) increased with water content, and decreased with temperature, indicating the exothermic nature of adsorption process. The CO_2 adsorption capacity of CNT (APTS) was ~2.59 mmol/g at 293 K. The potential application of CNT as the support for amine-impregnated sorbents has been studied by Fifield et al. (2004). In order to increase the affinity of the carbon structure, pyrene methyl picolinimide (PMP) was introduced as anchors. Dillon et al. (2008) synthesized and characterized PEI-functionalized SWNTs. A maximum adsorption of 2.1 mmol/g was reported for PEI (25000)-SWNT at 300 K. Hsu et al. (2010) proposed that a combination of thermal and vacuum desorption of CNT (APTES) at 393 K could reduce the regeneration time. The adsorption capacities and physicochemical properties were preserved after 20 cycles of adsorption/regeneration.

Industrial-grade multi-walled carbon nanotubes (IG-MWCNTs) impregnated with tetraethylenepentamine (TEPA) were systematically investigated for CO_2 capture by Liu et al. (2014a, b). TEPA-impregnated IG-MWCNTs were shown to have high CO_2 adsorption capacity comparable to that of TEPA-impregnated P-MWCNTs (Ye et al. 2012). The adsorption capacity of IG-MWCNT-based adsorbents was in the range of 2.145–3.088 mmol/g, depending on adsorption temperatures. The isosteric heat of adsorption for CO_2 decreased with the increase in CO_2 loading (Fig. 4). The high heat of adsorption in the lower loading region was due to the reaction of CO_2 with the active sites of TEPA. The process of IG-MWCNTs-50 adsorption of CO_2 was partly physical and partly chemical adsorption. The adsorption/desorption kinetics of CO_2 on TEPA-impregnated

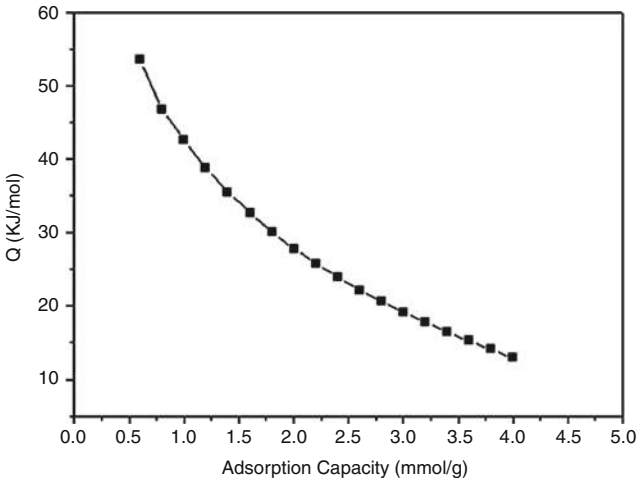

Fig. 4 Isosteric heats of adsorption of CO_2 for IG-MWCNTs-50 in a binary mixture of CO_2 and N_2 (Liu et al. 2014a)

IG-MWCNTs was investigated to obtain insight into the underlying mechanisms on the fixed bed. Avrami's fractional-order kinetic model provided the best fitting for the adsorption behavior of CO_2. In order to find the optimal regeneration method, three desorption methods were evaluated for the regeneration of solid sorbents. The activation energy E_a of CO_2 adsorption/desorption was calculated to evaluate the performance of the adsorbent. The effect of gas contaminants on the adsorption behavior of adsorbents for CO_2 was also studied. H_2O and NO had a minimal impact on CO_2 adsorption capacity, while the effect of SO_2 on CO_2 adsorption was influenced by adsorption temperature and SO_2 concentration.

Skoulidas et al. (2006) carried out simulations to analyze the adsorption and transport diffusion of CO_2 and N_2 in SWCNTs at room temperature. They reported that transport diffusivities for CO_2 in nanotubes with diameters ranging from $\sim$1 to $\sim$5 nm are approximately independent of pressure. The observed diffusion mechanism is not Knudsen-like diffusion. Based on Monte Carlo simulations, Huang et al. (2007) showed that CO_2 adsorption in the range of 4–9 mmol/g is an increasing function of the diameter of the CNTs. Additionally, CNTs demonstrated a higher selectivity toward CO_2 than other sorbents, such as ACs, zeolite 13X, and MOFs. Razavi et al. (2011) also concluded that CNTs exhibited a higher selectivity of CO_2 over N_2, compared to other carbon-based materials, for the separation of CO_2/N_2 mixture.

In summary, the impregnation of amines for carbonaceous materials is found to be effective to enhance CO_2 adsorption capacity. However, the impregnation also caused a significant decrease of the surface areas and pore volume. Although the exact mechanism of these changes is still not well understood, it is believed that the size and molecular structure of amines play an important role.

Polymer-Based Sorbents

Polymeric amine sorbents have been used for years to capture CO_2 in closed environments, such as aircraft, submarine, and space shuttles, under the concentrations of CO_2 <1 % (Satyapal et al. 2001). However, the cost of these sorbents is too high for large-scale applications in the industry. Table 6 shows the CO_2 adsorption capacity of polymer-based solid sorbents (Choi et al. 2009).

Satyapal et al. reported on a proprietary adsorbent HSC+ (consisting of PEI bonded to a high-surface-area, solid polymethylmethacrylate (PMMA) polymeric support coated with PEG). PEG was used to enhance the cyclic capacity of the sorbent. CO_2 adsorption capacity of the HSC+ sorbent was ~0.91 mmol/g at ambient pressure and 313 K, and the heat of adsorption was estimated to be -94 ± 8 kJ/mol. A variety of ethanolamines and their mixtures were impregnated with PMMA beads with high surface areas by Filburn et al. (2005). The results showed the advantage of secondary amines over other amine types in adsorbing low levels of CO_2, using a PSA process (Filburn et al. 2005). In their further studies, MEA, modified TEPA (TEPAN), and a mixture of ethyleneimine (E-100), reaction-modified ethyleneimine with acrylonitrile (E-100AN), etc. were used to functionalize PMMA (Lee et al. 2008a). TEPAN- and E-100AN-functionalized PMMA revealed remarkably higher cyclic CO_2 capacities and reproducibility.

Gray et al. immobilized Michael addition reaction products of ethylenediamine and TEPA with acrylonitrile within the pores of PMMA beads. The average CO_2 adsorption capacities of the sorbent were in the range of 3.4–6.6 mmol/g over four adsorption/desorption cycles. Furthermore, DBU was immobilized in PMMA beads in order to achieve the higher CO_2 capture capacity (Gray et al. 2008). With a DBU loading of 29 wt%, the modified sorbent showed an adsorption capacity of 3.43 mmol/g at room temperature under 10 % CO_2 and 2 % H_2O in He gas. However, the CO_2 capacity decreased significantly to 2.34 mmol/g as the temperature increased to 338 K, which is contrary to that observed for amine-impregnated mesoporous inorganic sorbents. Besides PMMA, other supports such as silicon dioxide (CARiACT) and polystyrene (macronet) were also compared (Gray et al. 2009). The CARiACT- and PMMA-supported PEI sorbents showed CO_2 capture capacities of 2.5–3.5 mmol/g under humid conditions and stability in the temperature range of 298–378 K for ten cycles.

Li et al. (2008a, b) reported the development of fibrous sorbents for CO_2 capture by coating PEI onto commercial glass fiber matrix with high surface area, using epoxy resin (EP) (Li et al. 2008a) and epichlorohydrin (ECH) (Li et al. 2008b) as a cross-linking agent. The CO_2 adsorption capacities were 6.30 mmol/g for PEI cross-linked with EP-coated fiber and 4.12 mmol/g for PEI cross-linked with ECH-coated fiber at 303 K, 1 atm and under humid conditions. Both modified fibrous adsorbents could be completely regenerated at 293 K. However, these modified glass fibrous adsorbents were most efficient at room temperature. At a higher temperature of 323 K, the adsorption capacity decreases drastically. In addition, Yang et al. (2010) synthesized an amine-containing fibrous adsorbent (PAN-AF) by grafting copolymerization of allylamine onto polyacrylonitrile

Table 6 CO_2 adsorption capacity of polymer-based sorbents

Sorbent	Pore size (nm)	Pore volume (cm^3/g)	BET surface area (m^2/g)	Temperature T (K)	Pressure p (atm)	Capacity (mmol/g)	References

(PAN) fiber. The CO_2 adsorption capacity of 6.22 mmol/g with a grafting degree of 60.0 wt% was reported. Regeneration of PAN-AF is suggested to be carried out by heating PAN-AF in boiled water.

Zeolite-Based Sorbents

Zeolites are widely used in the field of gas separation and purification. Conventional zeolites are based on silicate frameworks wherein substitution of some of the Si with Al (or other metals) results in a negative charge on the framework or with cations (usually Na or other alkaline or alkaline-earth metals) within the pore structure. These cations can be exchanged to the adsorption characteristics or fine-tune the pore size. Owing to their defined crystalline structures, these sorbents have uniform pore sizes in the range of 0.5–1.2 nm, which is a property that allows them to separate molecules via the molecular sieving effect. Separation of gases by the zeolite adsorbents can also occur through the mechanism of selective adsorption of those molecules that have a relatively large energetic dipole and quadruple. The gases that have high quadrupole moment, such as CO_2 (Table 2) (Coriani et al. 2000), interact strongly with the electric field created by the structural cations of zeolites, and this favors their adsorption. Separation of gases in zeolites depends on the following factors: structure and composition of the framework, cationic form, purity, size and shape of the molecules, and molecular polarity. The typical physical properties of the zeolites are summarized in Table 7.

Zeolites have demonstrated promising results for the separation of CO_2 from gas streams. There is plenty of published literature concerning CO_2 adsorption over different types of zeolites, such as zeolites A, X, and Y, and other natural zeolites, such as chabazites, clintopiles, ferrierites, mordenites, etc. Table 7 lists the various zeolites for application of CO_2 separation from gas mixtures.

Earlier, a study of adsorption of CO_2 on various synthetic zeolites (4A, 5A, and 13X) and natural zeolites (mordenite, ferrierite, clinoptilolite, and chabazite) showed 13X and chabazite, among the synthetic and natural zeolites, respectively, to be better adsorbents for CO_2 separation from N_2 (Inui et al. 1988). The work by Siriwardane et al. (2003) indicated that natural zeolite with the highest surface area and highest sodium content showed the highest CO_2 adsorption capacity and highest rates of adsorption. A wide-ranging screening study of ~13 synthetic zeolites, including 5A, 13X, NaY, ZSM-5, and HiSiV-3000 (based on ZSM-5 structure with a silica-to-alumina ratio (Si/Al >1000), was conducted by Harlick and Tezel (2004) for the capture of CO_2 from flue gas. Adsorption capacities of the adsorbents increased in the following order (in the pressure range of ~0–2 atm):13X (Si/Al = 2:2) > NaY (Si/Al = 5:1) > H-ZSM-5-30 (Si/Al = 30)> HiSiv3000 > HY-5 (Si/Al = 5) (Fig. 5). It might be on account of a low Si/Al ratio with cations (sodium) in the structure that show strong interactions with CO_2. Zukal et al. (2010) investigated CO_2 adsorption on six high-silica zeolites (SiO_2/Al_2O_3 > 60): TNU-9, IM-5, SSZ-74, ferrierite, ZSM-5, and ZSM-11. TNU-9 and IM-5 were found to have the highest CO_2 adsorption capacity, attaining 2.61 and 2.42 mmol/g at the pressure of 100 kPa, respectively.

Table 7 CO_2 adsorption capacity of zeolites

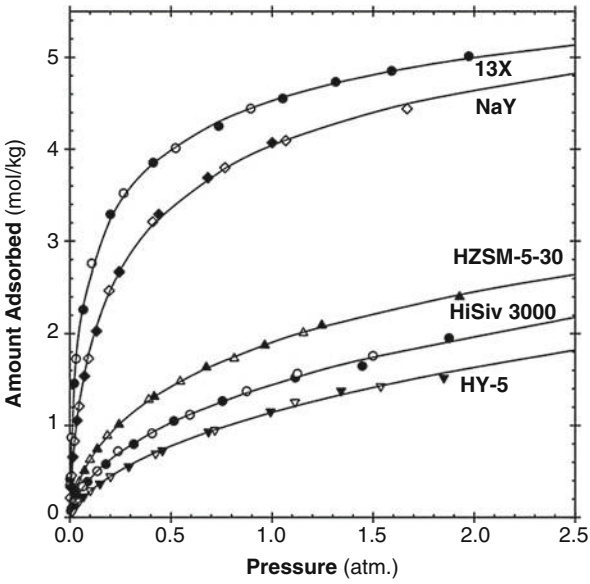

Fig. 5 Comparison of CO_2 adsorption isotherms for fresh zeolites at 295 K (Harlick and Tezel 2004). The *filled* symbols were obtained by regenerating the fresh adsorbent at 200 °C for 12 h followed by the adsorption study. The *open* symbols were obtained as a repeat of 200 °C regeneration for 12 h followed by adsorption without changing the adsorbent sample

To enhance the adsorption capacity of CO_2, the modification of zeolites via the introduction of electropositive and polyvalent cations was concentrated. Khelifa et al. (2004) concluded that NaX (Si/Al = 1.21) zeolite exchanged with Ni^{2+} and Cr^{3+} showed a decrease in CO_2 adsorption capacity, compared to that of the parent NaX zeolite, due to a weak CO_2–sorbent interaction. NaX and NaY and those resulting from ions exchanged with Cs, since it is the most electropositive metal of the periodic table, were tested regarding the adsorption of CO_2 by Diaz et al. (2008). Cs-treated zeolites performed better and were more active for adsorption at higher temperatures (373 K). Zhang et al. (2008a) prepared chabazite (CHA) zeolites (Si/Al < 2.5) and exchanged them with alkali cations (e.g., Li, Na, and K) and alkaline-earth cations (e.g., Mg, Ca, Ba) to evaluate their potential for CO_2 capture from flue gas by VSA below 393 K. From the adsorption isotherm, it was found that the NaX zeolite shows superior performance at relatively low temperatures, while NaCHA and CaCHA hold comparative advantages for high temperature (>273 K) CO_2 separation. According to the research of the selectivity of ion-exchanged ZSM-5 zeolites by Katoh et al. (2000), M-ZSM-5 (M = Li, Na, K, Rb, and Cs) might be attributed to the fact that almost all CO_2 molecules strongly adsorbed on the cation sites, while N_2 interacted with the wall of the H-ZMS-5.

There is a detrimental effect of water vapor on CO_2 adsorption for zeolite, due to its preferential adsorption from the gas mixture (Brandani and Ruthven 2004; Li et al. 2008c). Trace amounts of water vapor could significantly decrease the CO_2 adsorption capacity, because it gets competitively adsorbed on the zeolite surface and blocks the access for CO_2 (Brandani and Ruthven 2004). It was demonstrated by another study that the adsorption of CO_2 is considerably inhibited by H_2O as CO_2 and water vapor adsorption on zeolite 13X (Li et al. 2008c).

Zeolites with large surface area and pore volume present a potential option for CO_2 adsorption. However, CO_2 adsorption capacity on zeolites decreases significantly as the temperature increases. The capacity will also be very low in the existence of moisture. Therefore, a few researches (Table 7) synthesized aminated zeolites as alternative sorbents.

Zeolite 13X was modified with MEA by Jadhav et al. (2007) by impregnation method. Compared with unmodified zeolite, a higher capacity at 293 K was obtained with MEA loading of 50 wt%, despite reduced pore volume and lower surface area resulted from impregnation. The chemical interaction between CO_2 and amine probably played a significant role in adsorption of CO_2 at 293 K. Similarly, Su et al. (2010) dispersed TEPA into commercially available Y-type zeolite (Si/Al = 60). They obtained a CO_2 adsorption capacity of 4.27 mmol/g at 333 K in the presence of 15 % CO2 and 7 % water vapor in gas stream. In another study, Fisher et al. (2009) employed β-zeolite as a solid support for TEPA impregnation and compared it with TEPA-impregnated silica and alumina. The TEPA-modified β-zeolite exhibited a CO_2 adsorption capacity up to 2.08 mmol/g at 303 K under the 10 % CO_2/90 % argon flow, outperforming TEPA/SiO_2 and TEPA/Al_2O_3 sorbents. TEPA/β-zeolite maintains its CO_2 capture capacity for more than 10 adsorption/regeneration cycles. Their study suggests that the higher capacity of TEPA/β-zeolite can be related to zeolite's high surface area.

Silica-Based Sorbents

Impregnated Silica-Supported Sorbents

The first amine-impregnated silica used to capture CO_2 was reported by Song and others (Xu et al. 2002), and they used wet impregnation of hydrothermally synthesized MCM-41 with PEI to create an adsorbent in terms of a "molecular basket" (Xu et al. 2002, 2003, 2005a, b). In their further study, Xu et al. (2003) reported the highest CO_2 adsorption capacity of 3.02 mmol/g with MCM-41-PEI at a PEI loading of 75 wt% under a pure CO_2 atmosphere and at 348 K. As expected, increased PEI loadings led to higher adsorption of CO_2. Compared with the chemical adsorption for higher PEI loadings, the physical adsorption on the unmodified pore wall of MCM-41 (and the capillary condensation in the mesopore) is negligible. Additionally, a synergetic effect of MCM-41 and PEI for CO_2 adsorption was hypothesized (Xu et al. 2003). When the mesoporous pores were loaded with ~50 wt% PEI, the highest synergetic adsorption gain was obtained. MCM-41 impregnated with PEI exhibited an increase in adsorption capacity with increasing temperature, in comparison to ACs and zeolites. Xu et al. (2003) assumed that low adsorption rate caused by kinetic limitations results in the low adsorption capacity at low temperature. Therefore, the overall process is kinetically controlled.

Song and his groups also studied a series of performance and stability using a MCM-41-PEI sorbent to capture CO_2 from simulated flue gas, flue gas from a natural gas-fired boiler, and simulated humid flue gas using a packed-bed

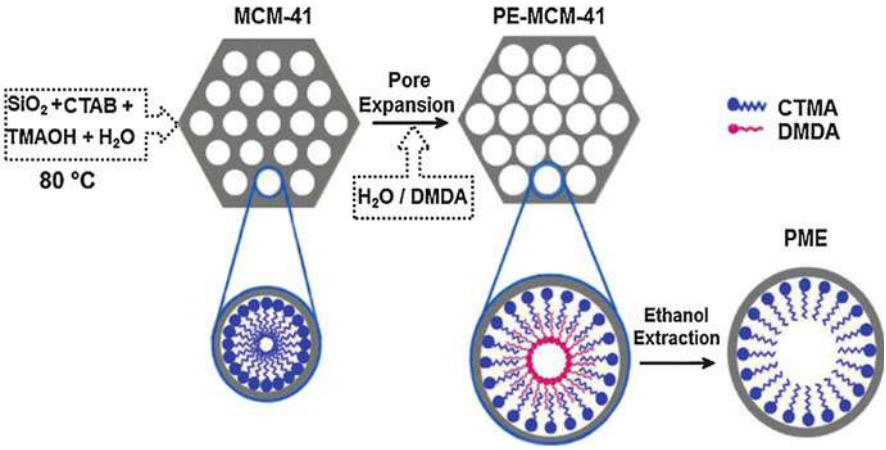

Fig. 6 Schematic representation of the synthesis of PME (Heydari-Gorji and Sayari 2011)

adsorption column (Xu et al. 2005a, b). The adsorbent showed a separation selectivity of ~180 for CO_2/O_2 and >1000 for CO_2/N_2. The adsorbent was stable at 348 K after ten cycles of adsorption/desorption process, while it was not stable when the operation temperature was >373 K. The observation of NO_x to be adsorbed simultaneously with CO_2 indicates the need for preremoval of NO_x from flue gas (Xu et al. 2005a, b). In addition, the CO_2 adsorption capacity was enhanced when the moisture concentration is lower than that of the CO_2, which could be due to the formation of bicarbonate ion (reaction 2) during the chemical interaction between PEI and CO_2 in the presence of moisture.

To enhance the CO_2 adsorption capacity of MCM-41-PEI, PEI supported on pore-expanded (PE) MCM-41 was studied by Heydari-Gorji et al. (2011). The adsorption capacity exhibits as high as 4.68 mmol/g at 348 K for 55 wt% PEI loading due to the well-dispersed PEI inside the PE-MCM-41 pores (Heydari-Gorji and Sayari 2011) (Fig. 6). As an alternative strategy to further improve efficiency for CO_2 adsorption, Yue et al. (2008a) impregnated TEPA into as-prepared MCM-41 that had been prepared with the ionic surfactant cetyltrimethylammonium bromide (CTAB). The as-prepared MCM-41 impregnated with 50 wt% TEPA exhibited a CO_2 adsorption capacity of 4.16 mmol/g in 5 % CO_2, probably owing to better amine distribution using ionic surfactant templates (Yue et al. 2008a). The type, amount, and distribution of the surfactant in the pores of MCM-41 all have significant influences on adsorption process. However, their studies showed that the adsorbent required only 1.5 min to reach the adsorption halftime but 140 min to reach close to equilibrium adsorption capacities.

SBA-15-supported sorbent loaded with 50 wt% PEI was developed by Ma et al. (2009). The CO_2 adsorption capacity of 3.18 mmol/g was obtained at 348 K under a CO_2 partial pressure of 15 kPa. The CO_2 adsorption capacity was ~50 % higher than that of their previously reported MCM-41-PEI sorbent, probably due to the higher pore diameter and pore volume of SBA-15. This allows the PEI-modified

sample prepared from SBA-15 to have a higher surface area for the same PEI loading. The significant role of the distribution of the amine groups impregnated in the porous materials has been confirmed by Zhu and his group (Yue et al. 2006). As-prepared mesoporous SBA-15 occluded with an organic template (Pluronic P123) was used to impregnate TEPA. The CO_2 adsorption capacity of the modified SBA-15 with a TEPA loading of 50 wt% was higher than that of the calcined SBA-15. The presence of the template enhanced the accessibility of CO_2 to TEPA because of a better dispersion and distribution of amines. Furthermore, Yue et al. (2008b) also synthesized as-prepared SBA-15-supported sorbents through dispersing amine blends of TEPA and DEA. The hydroxyl group in DEA is found to significantly improve the CO_2 adsorption. Hydroxyl group facilitates the formation of the carbamate zwitterion; therefore, equilibrium CO_2 loadings of amine can reach 2 mol CO_2 (mol amine)$^{-1}$.

Ahn and coworkers (Son et al. 2008) synthesized a series of PEI-loaded (50 wt%) ordered mesoporous silica supports, namely, MCM-41, MCM-48, SBA-15, SBA-16, and KIT-6, to evaluate their CO_2 adsorption performance. All impregnated sorbents showed substantially higher CO_2 sorption capacities and stability, as well as faster adsorption kinetics, than that of pure PEI. The CO_2 adsorption capacities were in the following order: KIT-6 ($d_p = 6.5$) > SBA-15 ($d_p = 5.5$) ≈ SBA-16 ($d_p = 4.1$) > MCM-48 ($d_p = 3.1$) > MCM-41 ($d_p = 2.1$), where d_p is the average pore diameter (nm). The adsorption performance was proposed to be influenced by the pore diameter and pore arrangement of mesoporous silica materials. Bulky PEI is assumed to be introduced to the pore easily as the pore size in the support increases. Goeppert et al. (2010) studied nanostructured fumed silica impregnated with various organoamines, namely, PEI, MEA, DEA, TEPA, and PEHA, as well as 2-amino-2-methyl-1-3-propanediol (AMPD), 2-(2-amino-ethylamino)ethanol (AEAE), etc. Simple amines such as MEA, DEA, AEAE, etc. are not suitable for impregnation, due to amine leaching problems at higher temperature.

As shown in Table 8, amine-impregnated silica sorbents can effectively adsorb CO_2 with relatively higher working capacity. The modification of pore size of silica support can further enhance the adsorption capacity. The adsorption capacity of amine-impregnated silica sorbents is not sensitive to the presence of moisture (in many cases, moisture helps to obtain higher capacity). However, the durability and regeneration kinetics of the amine-impregnated solid sorbents have not been tested adequately. Their desorption kinetics is still slow. In addition, considerable loss of amines is a major drawback for impregnated amine-functionalized sorbents.

Grafted Silica-Supported Sorbents

The synthesis and characterization of amine-grafted mesoporous silica sorbents (Class 2 category) for CO_2 capture were reported by many groups. In this case, amine, mainly aminosilane, is covalently tethered to the silica support (Choi et al. 2009). Three methods have been used for the grafting of amine onto a silica support: post-synthesis grafting, direct synthesis by co-condensation, and anionic template synthesis with the help of the interaction between the cation head in

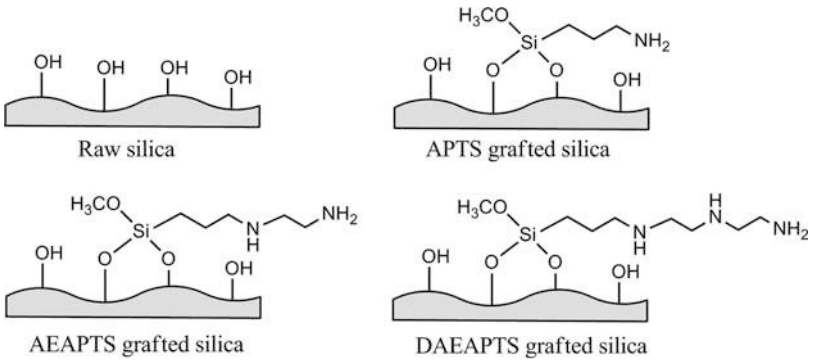

Fig. 7 Modified hexagonal mesoporous silica (*HMS*) materials (Chaffee et al. 2002)

aminosilane and anionic surfactants (Chew et al. 2010). The mesoporous nature of the silica permits high diffusivity of organic amine into the pore structure and, following functionalization, easy diffusion for CO_2 to enter and leave the pores. A wide variety of aminosilanes (see Table 8) have been grafted onto the surface of porous silica for the investigation of the impact of amine type and loadings on the CO_2 adsorption capacity.

Leal et al. (1995) first investigated the chemisorption of CO_2 onto APTES-grafted surface of silica gel. However, the CO_2 adsorption capacity of this sorbent was far below the requirement for industrial application of the sorbents. Afterward, a series of aminopropyl-grafted hexagonal mesoporous silica (HMS) compounds was prepared and characterized by Chaffee's group to enhance CO_2 adsorption. The grafted HMS materials, as shown in Fig. 7, were developed by Delaney et al. (Chaffee et al. 2002) using 3-aminopropyl-trimethoxysilane (APTS), aminoethyl-aminopropyl-trimethoxysilane (AEAPTS), and N-[3-(trimethoxysilyl) propyl) diethylenetriamine (DAEAPTS), ethylhydroxyl-aminopropyl-trimethoxysilane (EHAPTS), and diethylhydroxyl-aminopropyl-trimethoxysilane (DEHAPTS) (see Table 8). The modified silica supports showed high surface area with varied concentrations of surface-bound amine and hydroxyl functional groups. The modified HMS sorbents were also shown to reversibly adsorb significantly more CO_2 than modified silica gel, as reported by Leal et al. (1995). The ratio of CO_2 molecules adsorbed per available N atom was ~0.5 for HMS-APTS, HMS-AEAPTS, and HMS-DEAPTS, which is consistent with the carbamate formation mechanism, as presented by reaction 1. For HMS-DEHAPTS, the ratio was ~1. Because tertiary amines cannot form stable carbamates, it was proposed that the hydroxyl groups may serve to stabilize carbamate-type zwitterions.

Based on a systematic investigation on CO_2 adsorption on different mesoporous silica substrates and their amine-functionalized hybrid product, Knowles et al. (2005, 2006; Chaffee 2005) also pointed out that the extent of surface functionalization is found to be dependent on substrate morphology (e.g., available surface area, pore geometry, and pore volume), diffusion of reagents to the surface, as well as the silanol concentration on the substrate surface. The higher nitrogen

content of the tether caused a higher CO_2 adsorption capacity. The CO_2 adsorption performance of hybrid materials exhibited highest CO_2 capacity of ~1.66 mmol/g at 293 K in dry 90 % CO_2/10 % argon mixture, and good adsorption kinetics, reaching equilibrium within 4 min.

Hiyoshi et al. (2004, 2005) revealed the potential application of aminosilane-modified mesoporous silica for the separation of CO_2 from gas streams in the presence of moisture. In their subsequent research (Hiyoshi et al. 2005), DAEAPTS-SBA-15 showed enhanced CO_2 adsorption capacity after SBA-15 was treated with boiling water for 2 h, followed by the grafting of aminosilanes. The CO_2 adsorption capacity reached 1.58 and 1.80 mmol/g in the absence and presence of moisture, respectively. The efficiencies of the aminosilanes at identical amine surface density were in the following order: APTES > AEAPTS > DAEAPTS. Gray and coworkers (Gray et al. 2005; Chang et al. 2003; Khatri et al. 2005, 2006) also prepared a series of amine-grafted SBA-15 sorbents for CO_2 adsorption. Enhanced CO_2 adsorption capacity was observed in the presence of H_2O because of the formation of carbonate and bicarbonate (Chang et al. 2003) confirmed by Khatri et al. (2006). Khatri et al. (2006) and Zheng et al. (2004) studied the thermal stability of several grafted SBA-15 and found these to be stable up to 523 K. Furthermore, the SO_2 adsorption on APTES-SBA-15 led to a sharply decrease of CO_2 adsorption capacity, indicating the necessity of SO_2 removal before amine-based CO_2 adsorption (Khatri et al. 2006).

Sayari and coworkers (Harlick and Sayari 2006, 2007; Sayari et al. 2005; Serna-Guerrero et al. 2008, 2010a, b, c; Belmabkhout et al. 2010; Belmabkhout and Sayari 2010; Sayari and Belmabkhout 2010) developed pore-expanded MCM-41 mesoporous silica (PE-MCM-41) grafted with amine. The DAEAPTS-grafted PE-MCM-41 support with aminosilane loading of 5.98 mmol (N)/g showed an adsorption capacity of 2.05 mmol/g at 298 K and 1.0 atm for a dry 5 % CO_2 in N_2 feed mixture (Harlick and Sayari 2006). The amine surface density of the sorbent had a strong impact on the adsorption capacity. However, the existence of moisture did not significantly improve the performance of the amine-impregnated PE-MCM-41 sorbents. Subsequently, Harlick and Sayari (2007) found that, compared with dry grafting procedure, wet grafting via the co-addition of water at 358 K showed an increase in the total amine content, resulting in a 90 % overall improvement. The sorbent exhibited good stability over 100 cycles with an average working adsorption capacity of 2.28 mmol/g for pure CO_2 through regeneration under a vacuum at 343 K (Serna-Guerrero et al. 2010a), while the temperature swing regeneration process was suitable only at >393 K (Serna-Guerrero et al. 2010b). In addition to thermal stability, it also showed extremely high selectivity for CO_2 over N_2 and O_2 (Serna-Guerrero et al. 2010b, c; Belmabkhout et al. 2010; Belmabkhout and Sayari 2010). It was also confirmed by Belmabkhout and Sayari (2010) that SO_2 has an adverse effect for CO_2 capture (Khatri et al. 2006). In addition, this group noted that their sorbent underwent over 700 cycles without any loss of capacity when adsorption and regeneration was carried out using a humid gas with ~7.5 % relative humidity at 343 K. Furthermore, experimental data of CO_2 uptake as a function of time at temperatures between 298 and 373 K were fit to a series of kinetic models, namely, Lagergren's pseudo-first- and pseudo-second-order and

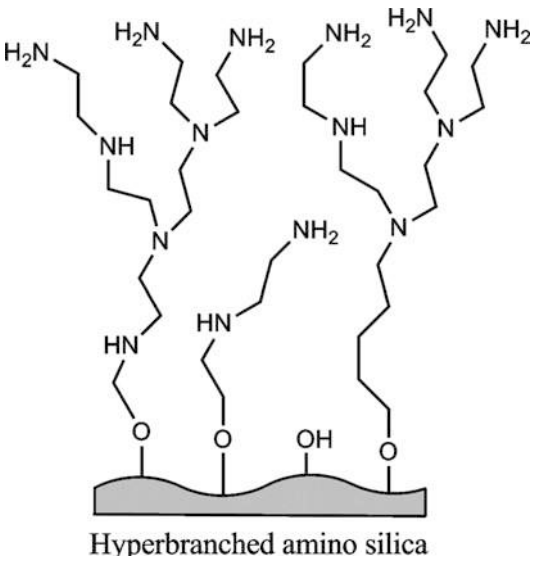

Fig. 8 Hyperbranched amino silica (Drese et al. 2009)

Avrami's kinetic models. The adsorption kinetics of CO_2 on amine-functionalized PE-MCM-41 was successfully described using Avrami's kinetic model with a reaction kinetic order of 1.4, which has been associated with the occurrence of multiple adsorption pathways (Serna-Guerrero and Sayari 2010).

Jones and his coworkers developed a covalently tethered hyperbranched aminosilica (HAS) sorbent (Fig. 8) with high amine content capable of capturing CO_2 reversibly from flue gas. They also compared it with other covalently supported solid sorbents (Hicks et al. 2008; Drese et al. 2009). HAS was synthesized via a one-step surface polymerization reaction of aziridine monomer inside SBA-15 pores (Drese et al. 2009). The HAS sorbent had an amine loading of 7.0 mmol N/g and CO_2 adsorption capacity of 3.08 mmol/g when tested in a packed-bed reactor under a flow of 10 % CO_2/90 % argon saturated with water at 298 K. It was stable over 12 cycles with regeneration temperature at 403 K. In another study, Drese et al. (2009) proposed modification of the HAS synthesis conditions, such as the aziridine-to-silica ratio and the solvent to further tune the sorbent's composition, adsorbent capacity, and kinetics. They found that higher amine loadings contributed to a better adsorption capacity.

The comparison of three APTES-grafted mesoporous silica materials, namely, MCM-41 ($d_p = 3.3$), SBA-12 ($d_p = 3.8$), and SBA-15 ($d_p = 7.1$), was made by Zelenak et al. (2008). The sorbent capacity was consistent with the order of pore size and amine surface density, similar to that observed in the amine-impregnated mesoporous silica sorbents. Kim et al. (2008) developed and tested a series of amine-functionalized mesoporous silica sorbents via anionic surfactant-mediated synthesis method for CO_2 adsorption at room temperature. As expected, higher amine loading on the mesoporous structure was the governing factor to achieve high CO_2 adsorption.

Table 8 lists the CO_2 adsorption capacity of various amine-grafted adsorbents. Although the functionalization of mesoporous silicas with amine functional groups significantly enhances the CO_2 adsorption capacity of silica substrate, the reported equilibrium CO_2 adsorption capacities are not as high as those reported with amine-impregnated mesoporous silicas. Moreover, the low thermal stability of mesoporous silicas, in the presence of water vapor at elevated temperature, is still one of the major concerns.

Metal–Organic Frameworks

MOFs are network solids composed of metal ion or metal cluster vertices and organic linkers. The ability to freely incorporate and vary organic linkers in MOFs translates to abundant options to control pore shape, pore size, and the chemical potential of the adsorbing surfaces and, consequently, their capacity, selectivity, and kinetics. MOFs have two important features: (i) their syntheses can be modular, and (ii) the solids are crystalline. Because the bonding (coordinate covalent) is weaker than those in metal oxides, solvated pores are not sure to necessarily exist if the solvent is removed. Indeed, these compounds can be classified into three generations due to this fact: first generation, those that collapse irreversibly and are not porous; second generation, those that retain their structures and show reversible gas sorption isotherms; third generation, a category where the material behaves more like a sponge and changes structure reversibly with guest sorption (Kitagawa et al. 2004).

Many of the MOFs show large CO_2 adsorption capacities at pressures at and above 1 bar, due to their high surface areas. However, the adsorption capacities at lower CO_2 pressures are often not directly reported, and these have been carefully estimated for CO_2 (0.15 bar) and N_2 (0.75 bar) and are listed in Table 9. Table 9 also lists the calculated selectivity values for CO_2 over N_2 at 298 K for selected MOFs, using the molar ratio of the CO_2 uptake at 0.15 bar and the N_2 uptake at 0.75 bar. The direct measurement of multicomponent isotherms, which has not been performed for CO_2/N_2 mixtures, is necessary in order to evaluate the accuracy of selectivity factors predicted from single-component isotherms and ideal adsorbed solution theory (IAST).

Surface Functionalization of MOFs

It is essential to tune the affinity of the framework functionalities toward CO_2 for optimization of the adsorptive properties. The various kinds of functionalities to enhance CO_2 capture performance are discussed in the following sections, including amines, strongly polarizing organic functionalities, and exposed metal cation sites.

- **Pores Functionalized by Nitrogen Bases**. MOFs functionalized with basic nitrogen-containing organic groups have been widely investigated for the CO_2 adsorption. The dispersion and electrostatic forces due to the interaction between

the quadrupole moment of CO_2 and localized dipoles generated by heteroatom incorporation are typically responsible for the enhanced CO_2 adsorption performance. In some cases, acid–base-type interactions of the lone pair of nitrogen with CO_2 have also been observed. The degree to which nitrogen incorporation improves CO_2 adsorption depends significantly on the properties of the functional group. Three major classes of nitrogen-functionalized MOFs have been synthesized: heterocycle (i.e., pyridine) derivatives (Stylianou et al. 2011; An and Rosi 2010; An et al. 2010), aromatic amine (i.e., aniline) derivatives (Millward and Yaghi 2005; Zhao et al. 2009a; Arstad et al. 2008a; Stavitski et al. 2011; Couck et al. 2009), and alkylamine (i.e., ethylenediamine) bearing frameworks (McDonald et al. 2011; Demessence et al. 2009; Hwang et al. 2008).

- **Other Strongly Polarizing Organic Functional Groups**. In addition to the nitrogen-based functionalities, organic linkers with heteroatom functional groups (other than amines) have also been examined on the CO_2 adsorption behavior (Phan et al. 2010; Banerjee et al. 2008, 2009; Deng et al. 2010). These functional groups contain hydroxy, nitro, cyano, thio, and halide groups, and the degree to which CO_2 adsorption capacity is improved in these cases depends primary upon the extent of ligand functionalization and the polarizing strength of the functional group. Generally, strongly polarizing groups will influence CO_2 adsorption favorably.
- **Exposed Metal Cation Sites**. The generation of structure types bearing exposed metal cation sites on the pore surface is another way that has been used to enhance the affinity and selectivity of MOFs toward CO_2 (Mason et al. 2011; Chui et al. 1999; Bordiga et al. 2007; Vishnyakov et al. 2003; Caskey et al. 2008; Bloch et al. 2010). $Cu_3(BTC)_2$ (HKUST-1) is one of the most studied materials featuring such binding sites (Chui et al. 1999). It shows a cubic, twisted boracite topology constructed from dinuclear Cu^{2+} paddlewheel units and triangular 1,3,5-benzenetricarboxylate linkers. The as-synthesized form of the framework has bound solvent molecules on the axial coordination sites of each Cu^{2+} metal center, which can be subsequently removed in vacuo at elevated temperatures to create open binding sites for guest molecules. The open metal cation sites serve as charge-dense binding sites for CO_2, which is adsorbed more strongly at these sites due to its greater quadrupole moment and polarizability.

Application for MOFs in Harsh Environment

Understanding the effects of the contaminants (water vapor, SO_2, NO_x, et al.) is critical to properly evaluate MOFs in a realistic CO_2 capture process. Here, we discuss a number of researches that have aimed to study the performance of MOFs under more realistic conditions.

- **Stability to Water Vapor**. Although partial dehydration of the effluent may be possible, it is costly and most likely not feasible on a large scale to dry the gas completely prior to adsorbing CO_2 (Granite and Pennline 2002; Lee and Sircar 2008). In evaluating MOFs for applications in CO_2 capture processes, it is significant to consider not only the stability of the framework to water vapor but also the effect of water vapor on the adsorption of CO_2.

Regarding water stability, the metal–ligand bond is typically the weakest point of a MOF, and hydrolysis can cause the displacement of bound ligands and collapse of the framework structure (Low et al. 2009). This was first observed in MOF-5, which is water sensitive and begins to lose crystallinity when exposed to small amounts of water vapor.

It was found that the basic zinc acetate clusters characteristic of most zinc carboxylate MOFs, such as MOF-177 and the IRMOF series, are most susceptible to hydrolysis (Cychosz and Matzger 2010). The trinuclear chromium clusters found in many of the MIL series of frameworks are the most stable, while the copper-paddlewheel carboxylate clusters found in HKUST-1 exhibit intermediate stability.

One way to increase the water stability of MOFs is to use azolate-based linkers rather than the typical carboxylate linkers (Demessence et al. 2009). The azolate linkers can bind metals with a similar geometry to carboxylate ligands, but their greater basicity typically results in stronger M–N bonds and greater thermal and chemical stability. The relative M–N bond strengths can be predicted based on the pK_a values associated with the deprotonation of the free ligand. Therefore, stability typically decreases with the pK_a: pyrazole ($pK_a = 14.4$) linkers exhibit the greatest stability, imidazole ($pK_a = 10.0$) and triazole ($pK_a = 9.3$) are intermediate, and tetrazole ($pK_a = 4.6$) linkers are the most labile (Fig. 9).

An alternative strategy for increasing the metal–ligand bond strength in MOFs is through the use of trior tetravalent metal cations (Low et al. 2009). Generally, frameworks containing Cr^{3+}, Al^{3+}, Fe^{3+}, and Zr^{4+} cations exhibit a high degree of stability in water. Specifically, MIL-53 (M(OH)(BDC), M = Cr^{3+}, Fe^{3+}, Al^{3+}) is a flexible framework that expands or contracts based on the absence or presence of water (Serre et al. 2002; Whitfield et al. 2005; Loiseau et al. 2004). The overall framework scaffold remains intact upon repeated exposure to water, due to the reversibility of the structural transition. MIL-100 and MIL-101 are rigid trivalent frameworks built from trinuclear metallic clusters that have shown a high stability in both boiling water and steam. On the contrary, the zirconium(IV)-based UiO-66, which contains extremely robust $Zr_6O_4(OH)_4(CO_2)_{12}$ cluster units (Fig. 10), exhibits their high solubility in water (Cavka et al. 2008).

There have been several researches of MOF stability in liquid water, but few regarding different levels of humidity. HKUST-1 was initially focused on understanding the effect of water on CO_2 capture in MOFs. The effect of water coordination on the CO_2 adsorption performance of HKUST-1 was tested (Yazaydin et al. 2009a). Near 5 mmol/g of CO_2 was adsorbed for the dehydrated form, compared with less than 1 mmol/g at 1 bar in the fully hydrated form. This is in agreement with a similar research, which found that HKUST-1 shows a decrease in CO_2 uptake to about 75 % of its original value and a concurrent loss of some crystallinity after exposure to 30 % relative humidity (Liu et al. 2010). In a similar study, CO_2 adsorption isotherms were measured at different water loadings for HKUST-1 and Ni_2(dobdc) (Liu et al. 2010). Both MOFs retained some adsorption capacity for CO_2 at low water loadings but exhibited essentially no capacity above 70 % relative humidity. Significantly, water adsorption caused a much faster decrease in CO_2 adsorption for zeolites 5A and NaX than for either MOF.

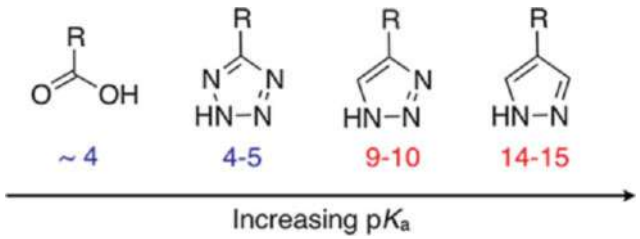

Fig. 9 The general trend of increasing pK_a for ligands built from carboxylic acids, tetrazoles, triazoles, and pyrazoles. The metal–ligand bond is expected to be stronger as the pK_a increases (Sumida et al. 2012)

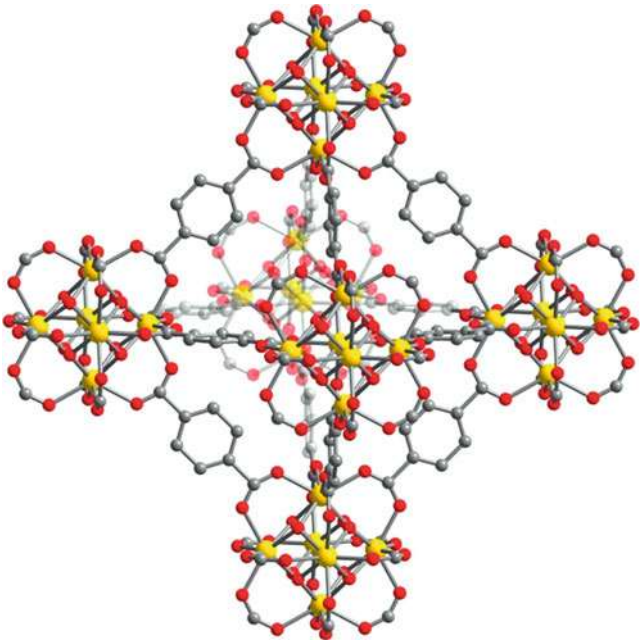

Fig. 10 A portion of the crystal structure of the high-stability metal–organic framework UiO-66 (Cavka et al. 2008). *Yellow*, *gray*, and *red spheres* represent Zr, C, and O atoms, respectively. H atoms are omitted for clarity

In order to evaluate their CO_2/N_2 separation performance, the effects of water vapor on the performance of the M_2(dobdc) (M = Zn, Ni, Co, and Mg) series of MOFs were studied (Fig. 11) (Kizzie et al. 2011). Although Mg_2(dobdc) has the highest reported adsorption capacity for CO_2 at low pressures, it performed the worst out of the series with a recovery of only 16 % of its initial capacity after regeneration. Ni_2(dobdc) and Co_2(dobdc) performed far better with recoveries of

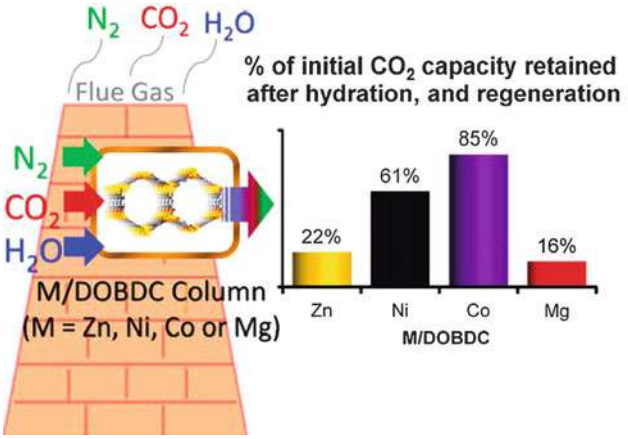

Fig. 11 Comparison of the flow-through CO_2 capacities, as determined from breakthrough experiments using a 5:1 N_2/CO_2 mixture, for pristine M_2(dobdc) and regenerated M_2(dobdc) after exposure to 70 % RH (Kizzie et al. 2011)

61 % and 85 % of their initial CO_2 capacity, respectively. This is in consistent with a similar study that found Ni_2(dobdc) could maintain its CO_2 capacity after steam conditioning and long-term storage, while Mg_2(dobdc) suffers a significant loss in capacity (Liu et al. 2011).

Some flexible MOFs exhibit promising CO_2 adsorption properties in the existence of water vapor (Cheng et al. 2009). In one report, water induced structural changes in MIL-53 that promoted a higher selectivity for CO_2 over CH_4 (Llewellyn et al. 2006). The breakthrough CO_2 adsorption of the flexible framework NH_2-MIL-53(Al) in the presence of 5 % water vapor was also investigated (Stavitski et al. 2011). Interestingly, CO_2 is selectively retained by the framework even in the presence of water.

While the abovementioned experiments are crucial for the initial assessment of MOFs for CO_2 capture, multicomponent adsorption isotherms are of high priority for evaluating and understanding the performance under conditions likely to be encountered in an actual capture system (Keskin et al. 2010).

- **Other Minor Components**. The exact amount of each species present in actual gas varies based on the specific configuration of a given plant. Particularly, in order to research the influence of flue gas contaminants, MIL-101(Cr) was selected as the focal point by Liu (Liu et al. 2013). CO_2 adsorption capacity of MIL-101(Cr) was able to maintain a high level of performance in trace gas-contaminated environments as well as after multiple cycles of adsorption and mild-condition regeneration. The addition of H_2O, SO_2, and NO to a 10 vol. % CO_2/N_2 feed flow was found to have only a minor effect on adsorption capacity. Under feed flow conditions of 10 vol.% CO_2, 100 ppm SO_2, 100 ppm NO, and 10 % RH, MIL-101(Cr) preserved greater than 95 % of its adsorption capacity after 5 cycles of adsorption/desorption.

Regenerable Alkali-Metal Carbonate-Based Sorbents

Due to the low operating temperature (<473 K), chemical adsorption of CO_2 with a dry regenerable alkali-metal carbonate-based solid sorbent (M_2CO_3, where M = K, Na, Li) is being considered for a period of time for CO_2 capture. In the adsorption process (carbonation, reaction 9), CO_2 and H_2O react with the carbonate sorbent in the range of 333–383 K and form alkali-metal bicarbonate. Heat treatment of the bicarbonate in the range from 373 to 473 K regenerates alkali-metal carbonate, releasing the CO_2 (decarbonation; reaction 10). The maximum theoretical capacity of Na_2CO_3 is 9.43 mmol/g.

Carbonation:

$$M_2CO_3 + H_2O + CO_2 = 2MHCO_3 \tag{13}$$

$\triangle H = -135$ kJ/mol, M = Na; $\triangle H = -141$ kJ/mol, M = K

Decarbonation:

$$2MHCO_3 = M_2CO_3 + H_2O + CO_2 \tag{14}$$

Hayashi et al. (1998) developed a TSA and a regeneration cyclic process for CO_2 capture using K_2CO_3 supported on AC. K_2CO_3 performs the best out of the three carbonates, as shown in Fig. 12. It has a wide carbonation temperature range where the sorbent efficiency is 100 %. In addition, there was an optimum loading of K_2CO_3 on AC support. Above the optimum loading, excess K_2CO_3 blocks micropores of AC, restricting CO_2 diffusion to the active reaction sites, leading to the reduction of working adsorption capacity and adsorption kinetics.

Seo et al. (2007; Lee et al. 2008b) investigated the effect of water vapor pretreatment on Na_2CO_3-based sorbent system in a bubbling fluidized-bed reactor

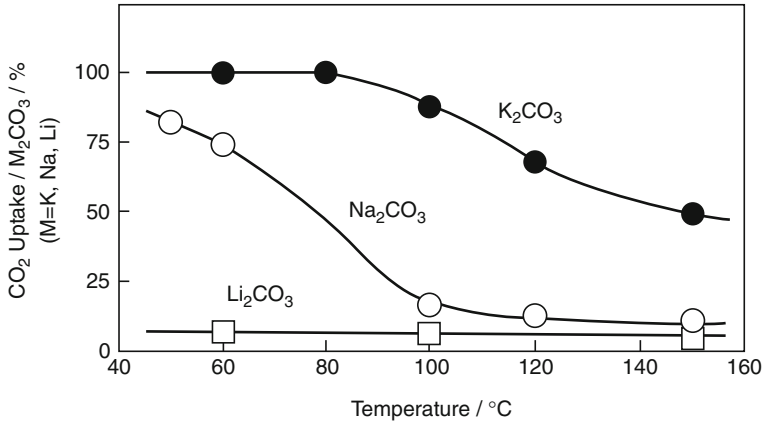

Fig. 12 Effect of temperature on the efficiency of CO_2 capture by alkali-metal carbonates. Feed gas composition: 13.8 % CO_2, 10 % H_2O, and balance He (Hayashi et al. 1998)

and found that, out of six types of spray-dried sorbent systems, three samples had better CO_2 adsorption capacity than MEA. Okunev et al. (2000, 2003; Sharonov et al. 2004) studied the impact of a porous support matrix on the CO_2 adsorption of K_2CO_3. Both hydrophilic (silica gel, alumina, vermiculite) and hydrophobic (AC) materials were used for support. The porous alumina/K_2CO_3 sorbent system possesses the highest dynamic capacity initially, but it decreases immediately after the first cycle. A completely reversible regeneration was observed in the case of an AC-impregnated sorbent system. The sorbent system dynamic capacity decreases in the following sequence: alumina > AC > vermiculite > silica gel.

To identify the best sorbent support system, some researchers (Lee et al. 2006a; Lee and Kim 2007) have prepared several K_2CO_3-based sorbents by impregnating it on various supports, such as AC, TiO_2, Al_2O_3, MgO, SiO_2, and zeolites. CO_2 adsorption capacities of K_2CO_3/AC, K_2CO_3/TiO_2, K_2CO_3/MgO, and K_2CO_3/Al_2O_3 (with an active phase loading of ~30 wt%) were ~2.0, 1.9, 2.7, and 1.9 mmol/g, respectively. However, the CO_2 adsorption capacities of K_2CO_3/Al_2O_3 and K_2CO_3/MgO decreased after regeneration at ≤473 K , because of the formation of $KAl(CO_3)_2(OH)_2$, $K_2Mg(CO_3)_2$, and $K_2Mg(CO_3)_2 \cdot 4(H_2O)$ phases during carbonation, which were not completely converted to the original K_2CO_3 phase. However, in the case of K_2CO_3/AC and K_2CO_3/TiO_2 sorbent systems, regeneration was not a problem in the temperature range of 403–423 K. "KZrI30" (30 wt% K_2CO_3/ZrO_2 sorbent system) was developed in 2009. The CO_2 adsorption capacity of the sorbent was ~96 % of the theoretical value in the presence of 1 % CO_2 and 9 % H_2O at 323 K, and it almost remained the same in multicycle operation (Lee et al. 2009). It is reported that the enhanced CO_2 capture capacity can be obtained by converting the entire $K_2CO_3 \cdot 1.5H_2O$ phase to the $KHCO_3$ phase if the sorbents are fully activated with excess water (Lee et al. 2006b). Lee et al. (2011) reported a new regenerable modified Al_2O_3 support for K_2CO_3 sorbent for CO_2 adsorption below 473 K. The CO_2 adsorption capacity of the 48 wt% K_2CO_3-loaded sorbent was ~2.9 mmol/g and did not decrease over five cycles.

Zhao et al. (2009b, c) found that K_2CO_3 with hexagonal crystals has superior carbonation kinetics over monoclinic K_2CO_3, because of the crystal structure similarities between K_2CO_3 (hexagonal) and $KHCO_3$. Table 10 summarizes the literature data on alkali carbonate sorbents for CO_2 capture.

In summary, the high CO_2 capture capacity of Na_2CO_3 (9.43 mmol/g) and K_2CO_3 (7.23 mmol/g) and favorable carbonation/regeneration temperature between 333 K and 473 K suggest that they are potentially excellent adsorbents for CO_2 capture. Moreover, they have the additional advantage of being relatively inexpensive. However, to be commercially viable, the long-term stability and persistence performance of these sorbents under real flue gas conditions of post-combustion applications have yet to be established.

The above discussion clearly indicates that several chemisorbents, such as amine-functionalized sorbent (both impregnated and grafted), have shown promise to meet the desired working capacity target in simulated flue gas conditions. Mostly, chemisorbents are found to have higher CO_2 selectivity. Amine-functionalized polymer-based sorbents showed very high adsorption capacity, but

Table 10 Alkali carbonate sorbents for CO_2 capture

Active phase	Support	Temperature of operation (K)	wt% active phase	Gas composition	Capacity (mmol/g)	References
K_2CO_3	AC, activated coke, and silica	Ads.: 373 Reg.: 423	~35 wt% in AC	Simulated flue gas and actual flue gas in slipstream	~2.1 (Ads. efficiency ~80 %)	(Hayashi et al. 1998)
